The European Journal of Endocrinology Prize Lecture

The European Journal of Endocrinology Prize is awarded to a candidate who has contributed significantly to the advancement of knowledge in the field of endocrinology through publication. This year's recipient is Professor Filip K. Knop who will receive his prize and deliver his lecture as part of the ECE 2018 Opening Ceremony on Saturday 19 May 2018. Further information on the prize can be found at https://www.ese-hormones.org/grants-and-awards/awards/.

Filip K. Knop, MD PhD, is a consultant endocrinologist, professor of endocrinology and head of Clinical Metabolic Physiology at Steno Diabetes Center Copenhagen, University of Copenhagen, Denmark. Prof. Knop has been involved in diabetes research since his fellowship at The Distinguished Gifford Laboratories for Diabetes Research, University of Texas, Southwestern Medical Center in Dallas in 1999 where he was supervised by Professor Christopher B. Newgard. Filip K. Knop's research, for which he has received a number of grants and honours (e.g. named 'Rising star' by the European Association for the Study of Diabetes), centres on the pathophysiology of type 2 diabetes, obesity, regulation of appetite and food intake, and the therapeutic role of incretins. He is particularly interested in the integrative role of the gut and the liver in human (patho)physiology and has authored >250 scientific publications. He serves as a referee for several international journals including The Lancet, British Medical Journal, Diabetes and Diabetologia and he is a member of numerous professional societies and committees.

The European Journal of Endocrinology Prize Lecture

EJE1

A gut feeling about glucagon

Filip Knop
Denmark.

Hyperglucagonaemia (in the fasting as well as in the postprandial state) is considered a core pathophysiological component of diabetes and to contribute substantially to the hyperglycaemic state of diabetes. Hyperglucagonaemia is usually viewed upon as a consequence of pancreatic alpha cell insensitivity to the glucagon-suppressive effects of glucose and insulin. Since we observed that the well-known hyperglucagonaemic response to oral glucose in patients with type 2 diabetes is exchanged by normal suppression of plasma glucagon levels following isoglycaemic intravenous glucose administration in these patients, we have been focusing on the gut and gut-derived factors as potential mediators of diabetic hyperglucagonaemia. In a series of clinical experiments we have elucidated the role of gut-derived factors in diabetic hyperglucagonaemia and shown that glucose-dependent insulinotropic polypeptide promotes hyperglucagonaemia and that glucagon, hitherto considered a pancreas-specific hormone, may also be secreted from extrapancreatic tissues - most likely from proglucagon-producing enteroendocrine cells. Furthermore, our observation that fasting hyperglucagonaemia is unrelated to the diabetic state, but strongly correlates with obesity, liver fat content and circulating amino acids, has made us question the common 'pancreacentric' and 'gluco-centric' understanding of hyperglucagonaemia and led to the hypothesis that steatosis-induced hepatic glucagon resistance (and reduced amino acid turnover) and compensatory glucagon secretion mediated by increased circulating amino acids constitute a complete endocrine feedback system: The liver-alpha cell axis. This presentation summarises the physiological regulation of glucagon secretion in humans and considers new findings suggesting that the liver and the gut play key roles in determining fasting and postabsorptive circulating glucagon levels.

The Geoffrey Harris Prize Lecture

The prestigious Geoffrey Harris Prize is awarded to an established researcher in the field of neuroendocrinology and is the first of its kind in Europe. This year's recipient is Professor Christos S. Mantzoros, who will receive his prize and deliver his lecture as part of the ECE 2018 Opening Ceremony on Saturday 19 May 2018. Further information on the prize can be found at https://www.ese-hormones.org/grants-and-awards/awards/.

Christos S. Mantzoros, MD, DSc, PhD h.c. mult. is Professor of Medicine at Harvard Medical School and Boston University School of Medicine. He currently also serves as the Chief of Endocrinology, Diabetes and Metabolism at the Boston VA Healthcare System and the Director of the Human Nutrition Unit of the Division of Endocrinology Diabetes and Metabolism at Beth Israel Deaconess Medical Center. Dr. Mantzoros is also the director for the VA Boston Healthcare System fellowship program with Boston University Medical Center (BUMC). He has served as a board member, an advisor, or head of the scientific advisory boards of non-profit foundations as well as government and private entities. He also serves as the Editor-in-Chief of the journal Metabolism and is on the editorial board of several scientific journals worldwide. His research has resulted in more than 600 publications in Medline, more than 150 publications under the collaborative Look Ahead Research Group, more than 200 chapters and reviews and has received more than 49,000 citations and an H index of 114 with an i10 index of 421 (Google Scholar).

The Geoffrey Harris Prize Lecture

GH1

Geoffrey Harris Award
Christos Mantzoros
USA.

My research focuses on the interplay of brain and adipose tissue and the elucidation of the physiology, diagnostic, and therapeutic utility of adipokines and myokines. We defined the central role these compounds play in normal physiology and pathophysiology of several diseases in humans, with the notion that such investigations will eventually lead to new treatments for metabolic and cardiovascular disease. We have also studied in-depth the role of leptin in the brain, defining the neuroendocrine and functional brain deficits in hypoleptinemia and how these, as well as deficits in fertility and bone physiology, can be corrected by the administration of leptin, which in turn acts centrally to effect these changes. This work, in addition to his work on leptin in lipodystrophy, contributed greatly to the FDA approval of leptin in the United States and Japan, with other approvals forthcoming. Additionally, we have worked on the development of INT131, a selective PPARγ modulator, which increases levels of adiponectin. This compound was recently approved by the FDA for phase III clinical trials. In light of adiponectin's role in neuroendocrinology and metabolism, this drug is another useful translational tool that will undoubtedly lead to much-needed therapeutic applications. Extending our previous work in the field of neuroendocrinology, we are currently investigating the effect of liraglutide, a GLP-1 agonist, and lorcaserin, a serotonin 5HT-2c receptor agonist on appetite regulation and energy homeostasis. Results from these on-going studies show that liraglutide decreases attention to high fat or high calorie foods through actions in the brain, and we identified GLP-1 receptors in human brains for the first time. These exciting results will set the foundation for decoding the pathophysiological- neuroendocrine mechanisms involved in obesity and energy homeostasis, support the establishment of effective therapies for obesity, and help to identify the individuals who will benefit from them.

European Hormone Medal Lecture

The European Hormone Medal is awarded to an international scientist who has made significant contributions to the field of basic or clinical endocrinology. This year's recipient is Professor Ilpo Huhtaniemi who will receive his prize and give his lecture as part of the European Congress of Endocrinology (ECE), beginning on the 19 May 2018. Further information on the prize can be found at https://www.ese-hormones.org/grants-and-awards/awards/.

Ilpo Huhtaniemi, MD, PhD, is Emeritus Professor of Reproductive Endocrinology at Imperial College London, and Professor of Physiology at University of Turku, Finland. His research interests include clinical and basic reproductive endocrinology, in particular the function of gonadotrophins and male reproduction, as well as male contraception, hormone-dependent cancer, and the endocrinology of ageing. He has authored about 700 peer-reviewed research articles and reviews. He was Chief Editor of Molecular and Cellular Endocrinology in 1999–2017. He is recipient of several awards, including the fellowship of The Academy of Medical Sciences (UK), and Doctor Honoris Causa at the Medical University Lodz, Poland and University of Szeged, Hungary. He has held several positions of trust in international scientific organizations, e.g. Past President of International Society of Andrology and Member of the Executive Committees of EFES and ESE.

European Hormone Medal Lecture

EHM1

Unraveling Secrets of the Hypothalamic-Pituitary-Gonadal Axis

Ilpo Huhtaniemi
UK/Finland.

As in all fields of the life sciences, enormous development has taken place in my special field of interest, i.e. reproductive endocrinology, during the nearly 50 years' time that I have been involved in basic and clinical research. My research has focused to large extent on functions of the hypothalamic-pituitary-gonadal axis and more specifically on physiology and pathophysiology of gonadotrophin function. My research career in not unlike the human life-span, because my first studies concerned fetal endocrinology, demonstrating testosterone production in human fetal testis and its regulation by hCG. I thereafter focused on function of gonadotrophin receptors and their role on normal and pathological gonadal function. More recently, I have become interested in endocrinology of the aging male. One earlier study that I was pleased to be involved in was the discovery of the first inactivating mutation of FSH receptor in humans. We subsequently continued on the line of unraveling the molecular mechanisms involved in mutations of gonadotrophin and their receptor genes by producing several genetically modified mouse models (transgenic and knockout) for disturbances of gonadotrophin function. These studies unraveled novel functional features of gonadotrophins in the regulation of gametogenesis, as tumor promoters, in extragonadal functions, and concerning molecular aspects of their actions. Finally, my participation in the European Male Ageing Study (EMAS) has widened understanding of the physiology and pathophysiology of male aging – an appropriate way to round up the career for an aging reproductive scientist. In this lecture I will review some of our findings along the hypothalamic-pituitary-gonadal axis that have furthered our knowledge about this fascinating regulatory cascade, in addition to providing me with some intellectual satisfaction of discovery.

DOI: 10.1530/endoabs.56.EHM1

Clinical Endocrinology Trust Lecture

The Clinical Endocrinology Trust (CET) Award is given for clinical research that addresses aspects of endocrinology at the forefront of clinical practice. This year's recipient is Professor Philippe Chanson who will receive his prize and give his lecture as part of the European Congress of Endocrinology (ECE), beginning on the 19 May 2018. The award is sponsored by the Clinical Endocrinology Trust and further information can be found at https://www.ese-hormones.org/grants-and-awards/awards/.

Philippe Chanson is Professor of Endocrinology at University Paris-Sud and Head of the Department of Endocrinology and Reproductive Diseases at Bicêtre's Hospital (Assistance Publique-Hôpitaux de Paris), where he coordinates a National Center for Rare Pituitary Diseases. He also leads the Bicêtre HCP for Endo-ERN. He is a member of several scientific societies including Endocrine Society, European Society of Endocrinology, European Neuroendocrine Association (ENEA), Pituitary Society, Growth Research Society and French Society of Endocrinology. He participates actively to numerous Consensus Groups organized by these Societies. He is the General Secretary of the « French Pituitary Club » and past Treasurer of ENEA.
His main interest is in Neuroendocrinology: pituitary adenomas including acromegaly, Cushing's disease; and Reproduction (gonadotropic function and disorders) which are his main clinical research themes. He conducts his basic research in INSERM U 1185 on effects of GH on kidney and on pituitary tumorigenesis. He has served the Boards of Clin Endocrinol, J Clin Endocrinol Metab, Endocrine, J Endocr Soc and is now in the Editorial Board of Pituitary. He is the author or co-author of more than 260 original peer-reviewed contributions and many invited reviews or book chapters.

Clinical Endocrinology Trust Lecture

CET1

Growth Hormone: not too much… not too less..!

Philippe Chanson
France.

Growth hormone (GH) and insulin-like growth factor-I (IGF-I) have important metabolic actions. GH/IGF-I excess and GH deficiency are each associated with 'opposing' comorbidities that often mirror one another. Cardiac and vascular comorbidity demonstrates that 'too much' may be as bad as 'too little'. An association between acromegaly and increased cardiac mortality has long been claimed. This was based on epidemiological studies of patients treated a long time ago, when the current therapeutic tools were not available and radiotherapy was widely used. Recent epidemiological studies and data from acromegaly registries show no excess mortality and that cardiovascular disease is not the leading cause of death. This is thanks to effective treatment of acromegaly and aggressive management of comorbidities (diabetes, hypertension, lipid disorders). Observations resemble those in the background general population. In contrast, the clinical features of hypopituitarism with GH deficiency are more like those of the metabolic syndrome. This may explain why patients have an increased cardiovascular and cerebrovascular risk. GH treatment improves cardiovascular risk factors and is associated with a decreased incidence of cardiovascular (but not cerebrovascular) events in some studies. It also seems to be associated with a reduction in all-cause mortality in both sexes, but particularly in males, who attain the level of the general population. Thus, according to our homeostatic model, the GH/IGF-I axis follows the general rule that in medio stat virtus or 'virtue stands in the middle'!

DOI: 10.1530/endoabs.56.CET1

Plenary Lectures

Contraception: Past and future

PL1

Contraception: past, present, and future

Philippe Bouchard
France.

50 years after the approval in the USA of the first oral contraceptive, it is quite remarkable that this considerable medical advance, may be the greatest medical discovery in the last century, the combined pill, which replaced condoms and unreliable natural methods, is still a matter of controversy. Recently, fear for hormones is more and more common in women in relation with the pill scares observed in UK and in France, and in relation with the media noise on Endocrine disruptors. However, it must be remembered that 40% of all pregnancies are still undesired, thus leading to a large number of pregnancy terminations, and also in the maternal consequence of unintended pregnancies. The pill is still a method of choice, safe and efficient, provided women are selected with exclusion of high risk individuals of some methods. Contraception is not only important for individual and couples but play an important role in population dynamics. Further long acting contraception methods such as implants or IUS, and OCs are now available, while new estrogens are also on the market or near commercialization such as Estetrol containing pills. Implants and vaginal rings, are safe and well tolerated, and IUS and IUDs are more and more user friendly. The most recent and remarkable developments are the progress in Emergency contraception using Ulipristal Acetate, a very efficient and risk free method. Finally, the recent discovery of beneficial effects of progestins in particular on brain function are now clear and provides a new advantage. Finally, while the pill is less used in women, the last progress come from the development of male contraception methods. Following the failure of the development of methods by the Pharma industry, new methods supported by NIH, using DMAU, dimethylandrolone undecanoate oral pill, Nestorone-testosterone gel, NES implants, are in development and preliminary results show a remarkable tolerance and a good efficacy. These methods produce a very high rate of extreme oligospermia, and are very promising for a near availability on the market. In addition, research into the development of non-hormonal contraception for men is progressing in several laboratories. The non-hormonal approach aims at inducing reversible infertility without interfering with hormones secreted by the hypothalamus, pituitary gland, and testis. New research target spermiogenesis, differentiation, maturation of sperm, or factors inhibiting sperm motility. Antagonists to the testis-specific Bromo Domain Protein, or to the retinoic acid receptors, involved in meiosis, proved effective in inhibiting spermatogenesis. Adjudin or H2-gamendazole, two modified lonidamine derivatives, cause premature spermiation and infertility. Eppin (epididymal protease inhibitor) secreted by Sertoli cells is also a potential target. Anti-Eppin antibodies inhibit human spermatozoa motility. Blocking CatSper (cationic channel of sperm), a novel and complex ion channel mediating $Ca2^{+}$ entry in sperm flagellum, or the sperm-specific glyceraldehyde-3-phosphate dehydrogenase (GAPDS) result in reduced sperm motility. New formulations designed to deliver specifically such antagonists are also under early testing. Contraception is a treasure, all the methods available should eradicate the need for abortions, and the most recent methods are safe and user friendly. Research in particular on methods impacting on oocyte fertilization should continue. Novel technologies include research on nanoparticles, microarray patch, drug-eluting fibers, as well as improved long-acting reversible contraceptives including new intra uterine systems, novel design of vaginal rings, and microchip technology. Research on genomics and proteomics is needed to define new targets for future development. Continuing funding is absolutely needed. Unmet needs in family planning remain a significant challenge worldwide. As a result, women continue to bear the burden of more than 85 million unplanned pregnancies and 48 million abortions each year. Novel male contraceptives could play a meaningful role in averting unintended pregnancies especially in settings where novel methods can attract new contraceptive users.

DOI: 10.1530/endoabs.56.PL1

Bone regulates the Brain

PL2

Bone Regulates the Brain to Control Appetite

Stavroula Kousteni
USA.

The discovery of the multiple endocrine functions of bone on the control of energy metabolism raised the question of whether several bone-derived hormones may exist that contribute to the regulation of metabolic functions such glucose tolerance, insulin sensitivity and energy expenditure, or whether they elicit a yet unanticipated endocrine function.. In response to this question a known hormone with a previously unidentified action was found to mediate a new metabolic function of bone: appetite. We have found Lipocalin 2 (LCN2), a previously thought adipokine, as an osteoblast-enriched secreted protein regulating food intake. Inactivation of Lcn2 specifically in osteoblasts (Lcn2osb-/- mice) increases blood glucose levels fat mass and body weight, decreases serum insulin and leads to glucose intolerance and insulin resistance. These effects result mainly from a 23.7% increase in food intake which is first detected at 3 weeks of age and remains elevated thereafter. In contrast, inactivation of Lcn2 in adipocytes has no effect on any of metabolic parameters. LCN2 is secreted by osteoblasts, crosses the blood brain barrier (BBB), binds to the melanocortin 4 receptor (MC4R) in the paraventricular and ventromedial neurons of the hypothalamus and activates the MC4R-dependent anorexigenic pathway. In addition, LCN2 has a physiological role in the regulation of feeding. LCN2 serum levels in fasted and refed wild type mice increased 3-fold after refeeding. This was to be due to a 1.6 fold increase in Lcn2 expression by osteoblast osteoblasts since Lcn2 expression by adipocytes was not altered. Intraperitoneal administration of recombinant LCN2 to fasted Lcn2-/- mice immediately after refeeding suppressed food intake within 1 hour and decreased body weight gain within 2 hours as efficiently as in WT mice. These observations identify Lcn2 as an osteoblast-derived anorexigenic hormone and regulation of appetite as a novel endocrine function of bone.

DOI: 10.1530/endoabs.56.PL2

The wonder world of GnRH neurons

PL3

The wonder world of GnRH neurons - cracking the pulse generator

Allan Herbison
New Zealand.

The gonadotropin-releasing hormone (GnRH) neurons are key cells regulating fertility in all mammals including humans. They release GnRH in an episodic manner to drive the pulsatile secretion of luteinizing hormone (LH) and follicle-stimulating hormone critical for gonadal function. Remarkably, the GnRH neurons are not born in the brain but arise from the nose and migrate into the brain during early embryogenesis. This unique origin engenders a variety of unusual and unique properties in the GnRH neuron. Foremost is their scattered location throughout the basal forebrain from where they send projections to the median eminence at the base of the brain to release GnRH into the pituitary portal system. Again, remarkably, this projection is not an axon but a blended process called a 'dendron' with unique properties of both dendrites and axons. Decades of study have focused upon defining the special characteristics of the GnRH neuron that may underlie their ability to generate pulsatile GnRH secretion. By and large, this has been unsuccessful. The discovery in 2003 of key role for kisspeptin in human fertility and pulsatile gonadotrophin secretion provided an important clue suggesting that an external neuronal input to the GnRH neuron may be critical for pulsatility. Since that time, studies in genetically-manipulated mouse models have addressed the role of kisspeptin neurons in pulse generation using a range of cellular approaches combined with the latest optogenetic techniques enabling high precision investigations *in vivo*. Together, these studies have identified the GnRH pulse generator as being a population of kisspeptin neurons located in the hypothalamic arcuate nucleus that exhibit synchronized episodes of activity which activate the GnRH neuron dendron to evoke pulsatile LH secretion. This represents an unusual and unexpected mechanism of generating pulsatile hormone secretion and opens up new possibilities for the manipulation of fertility in the clinic.

DOI: 10.1530/endoabs.56.PL3

The Retina as a Window for Exploring the Brain in Diabetes

PL4

The Retina as a Window for Exploring the Brain in Diabetes

Rafael Simó
Spain.

Evidence is accumulating that type 2 diabetes (T2D) is associated with cognitive impairment and dementia. In fact, numerous epidemiological studies have demonstrated that T2D patients have a significantly higher risk of developing neurodegenerative diseases and, in particular, Alzheimer's disease (AD). In clinical practice there are no reported phenotypic indicators or specific examinations to identify T2D patients at risk of developing AD. This gap should be urgently bridged given the rise in the global prevalence of T2D with cognitive

impairment and in anticipation of improved treatments for the prodromal stages of AD. Diabetic retinopathy (DR) is one of the most frequent diabetic complications and the leading cause of visual impairment and preventable blindness. Although traditionally DR has been considered a microvascular disease, there is emerging evidence that neurodegeneration is an early pathogenic event. In fact, the American Diabetes Association has recently defined DR as a highly specific neurovascular complication. Since the retina is ontogenically a brain-derived tissue and it has been suggested that it may provide an easily accessible and non-invasive way of examining the pathology of the brain. Therefore, it could be postulated that in patients developing neurodegeneration of the brain there is a co-occurring neurodegenerative process in the retina ('the eye as a window of the brain'). In this regard, we have recently suggested that retinal sensitivity assessed by microperimetry could be a useful biomarker for identifying patients with T2D who are at risk of developing AD. This nested case-control pilot study will be commneted on. We have recently found by proteomic analysis of human retinas from diabetic patients several genuine pathways triggered in the brain of neurodegenerative diseases. These findings suggest that the study of neurodegeneration in the diabetic retina could be useful to further understand the neurodegenerative processes that occur in the brain of persons with diabetes.

DOI: 10.1530/endoabs.56.PL4

The link between insulin and fatty liver

PL5

The link between insulin and fatty liver

Gerald Shulman
USA.

Ectopic lipid deposition in liver and skeletal muscle plays a major role in the pathogenesis of insulin resistance and type 2 diabetes (T2D). Furthermore, nonalcoholic fatty liver disease (NAFLD) is a major predisposing factor for nonalcoholic steatohepatitis (NASH) and hepatocellular cancer and is an independent risk factor of cardiovascular disease. Understanding the cellular and molecular mechanisms by which ectopic lipid promotes insulin resistance in liver and identifying the key lipid mediators in this process is therefore of great interest. Recent studies have identified diacylglycerols, as a molecular trigger for lipid-induced hepatic insulin resistance through activation of PKC-epsilon (PKCe) resulting in phosphorylation of insulin receptor Thr1160 and inhibition of insulin receptor kinase activity. In addition, alterations in hepatic acetyl-CoA, an allosteric activator of pyruvate carboxylase, have been shown to mediate insulin suppression of hepatic gluconeogenesis as well as promote increased rates of hepatic gluconeogenesis in patients with poorly controlled T2D. In support of these mechanisms recent studies have demonstrated the potential utility and safety of liver-targeted hepatic mitochondrial uncoupling as a novel therapeutic approach to treat NAFLD, NASH and T2D in rodent and non-human primates and reverse hepatic insulin resistance and diabetes by decreasing hepatic DAG-PKCe activity and reducing hepatic acetyl-CoA content.

DOI: 10.1530/endoabs.56.PL5

Does therapy for thyroid dysfunction decrease mortality?

PL6

Does therapy for thyroid dysfunction decrease mortality?

Laszlo Hegedüs
Denmark.

Background
Meta-analyses have questioned whether mortality is increased in hyper- and hypothyroid individuals, and if so the magnitude. This is mainly due to inadequate size of study populations, differences in study design and participant characteristics, lack of control for confounders and whether the participants are treated.
Materials
Using record-linkage data from nationwide Danish health registers, and after adjustment for preexisting morbidity, a 22–42% excess mortality was demonstrated in hyperthyroidism, higher in Graves' disease than in toxic nodular goiter. In hypothyroidism the excess mortality was 23%. In both phenotypes there was an increased risk of being diagnosed with a number of morbidities, especially cardiovascular diseases. For both hyper- and hypothyroid individuals there was an increased risk - 51 and 140%, respectively - of being diagnosed with psychiatric diseases (psychosis, depression and anxiety). Both hyper- and hypothyroidism was associated with an increased risk - 88 and 89%, respectively - of receiving disability pension. The above studies lacked adequate thyroid function variables and data on therapy. In a register-based Danish cohort of ca. 235.000 individuals offering such data, and followed for a median of 7 yr., increased mortality (23%) in untreated but not in treated hyperthyroid patients was demonstrated. Hazard ratio for mortality was around 1.12 for every 6 months of decreased TSH, whether individuals were treated or not. In the same cohort, untreated hypothyroid individuals had an excess mortality of 46%, which was at large uninfluenced by age (below or above 65 yr.) and severity (mild or overt) of hypothyroidism. Mortality was increased by 5% for every 6 months of increased TSH.
Conclusions
Mortality is increased in both hyper- and hypothyroidism. Cumulative periods of abnormal TSH increases mortality in both treated and untreated individuals, suggesting that not lack of therapy but lack of maintaining euthyroidism may drive excess mortality.

Metabolic control of longevity

PL7

Anti-obesity effect in mice and monkeys of partial inhibition of PI3Kα

Manuel Serrano
Spain.

Partial inhibition of PI3K is one of the best-validated and evolutionary conserved manipulations to extend longevity. PI3K is a master regulator of anabolism and the best validated beneficial effects of reduced PI3K are related to metabolism and include increased energy expenditure, reduced nutrient storage, and protection from obesity. We have found that a dual chemical inhibitor of the α and δ PI3K isoforms (CNIO-PI3Ki) reduces obesity in mice and monkeys, without evident toxic effects after long-term treatment. Similar effects have been observed with the pan-PI3K inhibitor GDC-0941.The doses used only achieved a mild inhibition of PI3K activity and therfore did not result in significant hyperglycemic peaks. More recently, we have found that the selective PI3Kα inhibitor BYL-719 (also known as alpelisib) also has anti-obesity activity. This is in contrast to the selective PI3Kδ inhibitor GS-9820 (also known as acalisib), which had no effect. However, the dose of BYL-719 required to reduce obesity was 10-times higher than the equivalent dose of CNIO-PI3Ki, which could suggest that simultaneous inhibition of PI3K α and δ is more effective than single inhibition of the α isoform. In summary, we conclude that inhibition of PI3Kα is sufficient to reduce anabolism, increase energy expenditure and reduce obesity, and suggest that concomitant PI3Kδ inhibition could play an auxiliary role.

Predicting events in autoimmune thyroid disease

S1.1

The THEA score in familial thyroid dysfunction. Predictive factors of autoimmune thyroid disease

Grigorios Effraimidis
Denmark.

AutoImmune Thyroid Disease (AITD) is, nowadays, generally considered to be a complex multifactorial entity, in which the interplay between genetic and environmental factors results in the expression of the disease. Genetic predisposition plays a major role in the pathogenesis of AITD, as siblings and other family members of AITD patients are at increased risk for AITD. Then, how can we, as physicians, answer the question of our AITD patients 'will my children also get the disease?'. A predictive score for the development of overt hypothyroidism or hyperthyroidism within 5 years was composed, based on the findings from a prospective observational study of the 'Amsterdam AITD cohort'. The score is called the Thyroid Events Amsterdam or THEA score. The cohort consisted of healthy first- or second- degree female relatives of patients with AITD who were observed for 5 years. Thyroid function tests, family history and exposure to some environmental insults at study entrance were put in a model for the calculation of the score. The numerical THEA score predicts events by weighing the three independent risk factors: TSH, TPOAb and family background. The higher the THEA score, the higher the risk of developing overt thyroid dysfunction within a period of 5 years. During the presentation, I aim to give a description of the development of the THEA score, its clinical applicability, a brief report of the recent clinical studies regarding the factors which influence the development of AITD and, finally, what the future holds in the field of the prediction of developing AITD.

IgG4 related thyroid autoimmune disease

Luca Chiovato
Italy.

IgG4-related disease (IgG4-RD) is a fibro-inflammatory, immune-mediated, systemic disease usually presenting with tumefactive lesions and a subacute onset mimicking malignancy. A subset of autoimmune thyroid pathologic conditions can be incorporated in the spectrum of IgG4-RD. In some cases of Hashimoto's Thyroiditis (HT) a rich IgG4-positive plasma cell infiltration has been described, and a marked storiform fibrosis is typical of the fibrotic variant of HT (FVHT) and of Riedel's Thyroiditis (RT). In addition, the serum levels of IgG4 have been demonstrated to correlate with activity and severity of Graves' orbitopathy (GO). Finally, IgG4-RD should be considered in the differential diagnosis of Graves' like orbitopathy. The pathogenesis of IgG4-related thyroid diseases is poorly understood, but an autoimmune process resulting from genetic and environmental factors is hypothesized to play a pivotal role. Whether or not IgG4 have a direct pathogenic effect still remains to be ascertained, because infiltrating IgG4-positive plasma cells might only represent an epiphenomenon. The diagnostic criteria for specific IgG4-related thyroid diseases rely on histology. Thus, tissue biopsy is mandatory for a correct clinical assessment. Lympho-plasmacytic infiltrate, storiform fibrosis and obliterative phlebitis are the histologic hallmarks that confirm the clinical suspicion. The measurement of serum IgG4 levels may contribute to the diagnostic workup, and specific cut-offs have been propose in thyroid IgG4-RD. However, IgG4 serum negative patients do exist. Thus, the presence of high levels IgG4 in serum is not necessary to diagnose thyroid IgG4-RD. On the other hand, monitoring serum IgG4 levels can demonstrate treatment response or disease activity. Management options are both medical and surgical, depending on which condition has been diagnosed. Generally, glucocorticoids are the first line therapy and allow reducing the progression of the disease, while surgical management has been performed only in rare cases.

S1.3

New scores for the prediction of Graves' disease

Miloš Žarković
Serbia.

After treatment, hyperthyroidism will relapse in approximately half of the Graves' diseases patients, and clinically relevant orbitopathy will develop in about 25% of the diseased. Therefore, predicting who will relapse or develop orbitopathy is both clinically important and contributes to understanding of the pathophysiology of the disease. To predict the risk of recurrence of hyperthyroidism, before the start of antithyroid drug therapy, GREAT (based on clinical markers) and GREAT+ (based on clinical and genetic markers) scores were proposed. GREAT score is based on age, free thyroxin (fT4) concentration, thyrotropin-binding inhibitor immunoglobulin (TBII) concentration, and goitre size (according to the World Health Organization). GREAT+ score also includes HLA polymorphisms (DQB1-02, DQA1-05, DRB1-03) and PTPN22 C/T polymorphism. Higher score was correlated with the greater risk of hyperthyroidism relapse. Recurrence of hyperthyroidism occurred in 16% of the patients with the GREAT score 0–1, 44% when GREAT score is 2–3, and in 68% of the patients with the GREAT score 4–6. GREAT+ score further improved classification. Only 4% of subjects with GREAT+ score 0-2, had hyperthyroidism relapse, while 84% with GREAT+ score 7–10 relapsed. Independent, external validation of the GREAT score proved good validity of this score to predict disease relapse. To predict development or progression of Graves' orbitopathy in patients with Graves' hyperthyroidism PREDIGO score has been recently proposed. This score is based on clinical activity score (0 vs. $>$ 0), TBII concentration, duration of hyperthyroid symptoms before therapy, and smoking. This score has very good negative predictive value (0.91). Predictive scores allow choosing appropriate therapy for the patients (drugs, surgery, radioactive iodine), thus enabling to prevent or minimize adverse effects of the chosen therapy.

Hyponatremia and mortality: moving beyond associations

Ewout Hoorn
The Netherlands.

Acute hyponatremia can cause death if cerebral edema is not treated promptly. Conversely, if chronic hyponatremia is corrected too rapidly, osmotic demyelination may ensue, which also potentially is lethal. However, these severe complications of hyponatremia are relatively uncommon and often preventable. More commonly, hyponatremia predicts mortality in patients with advanced heart failure or liver cirrhosis. In these conditions, it generally is assumed that hyponatremia reflects the severity of the underlying disease rather than contributing directly to mortality. The same assumption holds for the recently reported associations between hyponatremia and mortality in patients with pulmonary embolism, pulmonary hypertension, pneumonia, and myocardial infarction. However, recent data suggest that chronic and mild hyponatremia in the general population also are associated with mortality. In addition, hyponatremia has been associated with mortality in long-term hemodialysis patients without residual function in whom the underlying disease cannot be responsible for hyponatremia. These new data raise the question of whether hyponatremia by itself can contribute to mortality or it remains a surrogate marker for other unknown risk factors. In this presentation I will review hyponatremia and mortality and explore the possibility that hyponatremia perturbs normal physiology in the absence of cerebral edema or osmotic demyelination.

Hereditary diabetes insipidus

Jonas Rutishauser
Switzerland.

Background
Families with inherited forms of diabetes insipidus (DI) have been described since the mid 19th century. Depending on the involved gene, the disorder is transmitted in autosomal dominant, autosomal recessive, or X-linked fashion.

Nephrogenic DI
Patients typically have a severe phenotype manifesting shortly after birth. They are most often males with X-linked disease due to variations in the vasopressin V2 receptor (AVPR2) gene. Rarely, variations in the aquaporin-2 (AQP2) gene underlie autosomal recessive or dominant transmission. Mutant proteins are functionally deficient and mostly retained in intracellular compartments.
Neurogenic DI
Symptoms of autosomal dominant familial neurohypophyseal DI (ADFNDI) start subtly months to years after birth, gradually increasing in severity. ADFNDI is caused by variations in the vasopressin (AVP) gene. Mutant proteins form amyloid-like aggregations and are retained in the endoplasmic reticulum. Rarely, autosomal-recessive neurohypophyseal DI results from AVP variations causing impaired binding to the AVPR2.
Diagnosis and treatment
Clinical testing by water deprivation (with or without infusion of hypertonic saline) is feasible but should be performed with caution, particularly in nephrogenic DI, since children may rapidly become severely dehydrated. Measurement of circulating copeptin levels during the test procedure facilitates differential diagnosis, and MRI of the hypothalamic/pituitary region may show abnormal findings. Direct genetic testing is indicated if a DI pedigree is present, or in patients with early-onset idiopathic DI even in the absence of a family history. Treatment strategies in hereditary DI follow those in non-hereditary disease. Pharmacological chaperones to promote rescue and membrane insertion of intracellularly retained AVPR2 molecules are not yet in clinical routine.
Conclusion
A family history of DI should prompt the correct diagnosis, but de novo mutations have been described as well. Mutational analysis is preferable over functional testing, particularly in children and in hereditary nephrogenic DI, where dehydration may become severe.

Going hedonic – the role of FGF21 in the preference for sweet and alcohol

Niels Grarup
Denmark.

Human health is influenced by diet composition as well as total energy consumption; however, the circuits that control hunger and food-seeking in general are better understood than the interoceptive mechanisms that lead to consumption of specific nutrients, though the latter may impact both total energy intake and the health quality of food choices. Thus, a better understanding of the biological basis of palatable nutrient appetite is needed to improve diet quality and human health in modern food environments. However, food preferences are partly heritable. Genome-wide association studies have correlated genetic variants at the FGF21 locus with relatively increased carbohydrate and decreased protein and fat intake. FGF21 is a liver-derived hormone that exerts a range of metabolic effects in rodents and non-human primates in both physiological and pharmacological contexts. We recently found that carriers of a genetic variant in FGF21 had higher intake of candy and sweet food. Recent work furthermore clarifies the role of FGF21 in relation to alcohol intake in human genetic studies, human physiological studies and rodent mechanistic investigations. Similarly, recent genetic studies of the UK Biobank clarify the long-term impact of naturally occurring FGF21 variants on obesity and cardiovascular health. Further studies will seek to elucidate other genetic and hormonal factors involved in regulation of 'the sweet tooth' and other hedonic behavioural habits.

Bile Acid & Microbiota
(*Endorsed by Endocrine Connections*)

S3.1

Crosstalk between bile acids and the gut microbiota – influence on host metabolism

Annika Wahlstrom
Sweden.

Bile acids are endocrine molecules that in addition to facilitating the absorption of fat-soluble nutrients regulate numerous metabolic processes, including glucose, lipid, and energy homeostasis. The actions of bile acids are mediated through specific bile acid-activated nuclear and membrane bound receptors such as farnesoid X receptor (FXR) and G protein-coupled receptor 5 (TGR5). Bile acid signaling is modified by interactions with gut bacteria which metabolize primary bile acids into secondary bile acids and thereby changes their affinity for their receptors. FXR and TGR5 have become major targets for studies of metabolic diseases and it is clear that the microbiota can modulate signaling through both FXR and TGR5 via modifications of bile acids. Conversely, bile acids can modulate gut microbial composition both directly and indirectly through activation of their receptors. To study the influence of microbiota and bile acid interactions on host metabolism we use germ-free mice that can be colonized with specific communities of bacteria. These mice are important tools but the interpretation and translation of results from mouse models must be done carefully since mice and humans have substantial differences in bile acid composition. The major primary bile acid in germ-free mice, TβMCA, is absent in adult humans and this bile acid function as an FXR antagonist. It has been shown that mice treated with antibiotics or Tempol have increased levels of TβMCA and are protected against diet- induced obesity and it was suggested that intestinal-specific inhibition of FXR was responsible for the beneficial effects. It has also been shown that a glycine-conjugated form of βMCA (GβMCA) improved metabolic phenotypes in obesity mouse models. On the other hand, it has also been shown that intestinal-specific activation of FXR with fexaramine protects against the development of obesity and was associated with increased thermogenesis and browning of adipose tissue. Furthermore, it has been suggested that some of the beneficial effects following bariatric surgery may be mediated by changes in gut microbiota, bile acid profile and FXR activation. Thus, targeting the interplay between microbiota, bile acids and FXR and/or TGR5 signaling seems to evolve as a promising avenue for the treatment of metabolic diseases but much more research is needed especially in humans.

S3.2

Subclinical hypothyroidism is 'not' a disease (Contra)

Laura Gathercole
UK.

Thyroid diseases are common disorders. Globally, hypothyroidism is still frequently caused by iodine deficiency. In iodine sufficient areas, the most common cause of hypothyroidism is thyroid autoimmunity. Subclinical hypothyroidism is defined as elevated thyroid-stimulating hormone (TSH) levels with free thyroxine (fT4) estimates within the reference range. It is a common disorder that increases with age affecting up to 20% of the elderly, with a higher prevalence in women. Some prospective data have shown increased risks of coronary heart disease, heart failure, and cardiovascular mortality among affected adults, while others have not. Conflicting results have further been found on the association between subclinical hypothyroidism and cognitive impairment, depression and the risk of fractures. Overt hypothyroidism must be treated with levothyroxine. It is less clear if subclinical hypothyroidism requires replacement therapy. Screening for thyroid disease is not recommended by guidelines, but case finding based on specific criteria form general practice among endocrinologists. Since the condition is solely based on a laboratory diagnosis, there are many difficult factors to be aware of, including definition of the reference ranges for TSH and T4, both of which depend on laboratory and population factors; how measurements and interpretations of the laboratory tests for thyroid related hormones may be complicated by confounders due to medications, oral contraceptives, other diseases, non-thyroidal illness, and interference, and the difficulty of laboratory measurements to correct for these changes. Furthermore, the few randomized clinical trials have shown no beneficial effect from T4 treatment. Thus, due to current lack of evidence regarding the optimal treatment strategy in individuals with subclinical hypothyroidism, the best management of such persons is inclusion in trials, or to follow serum TSH values, which often normalize spontaneously. If TSH levels exceed 10 mIU/l, substitution might be considered, but even then, there is no direct evidence justifying treatment.

S3.3

Bile acids and metabolic effects of bariatric surgery

Glenn Gerhard
USA.

Bariatric surgery, also known as metabolic surgery, has been shown through multiple clinical trials to result in superior efficacy and sustainability of weight loss and remission of diabetes after surgery in patients with extreme obesity

compared with intensive medical and lifestyle interventions. Although the metabolic effects of bariatric surgery have been observed for over 50 years, the primary molecular mechanisms underlying these effects are not well understood. A number of theories for the improvements in dysglycemia have been proposed, although accumulating evidence from both clinical observations and animal models supports a mechanistic role for alterations in bile acid levels. Bile acids have long been recognized as important mediators in the intestinal absorption of lipids but they also serve as ligands for the nuclear receptor farnesoid X receptor (FXR) and the cell surface receptor G protein–coupled bile acid receptor 1 (TGR5) which can have multiple and complex metabolic effects. The mechanisms by which post-bariatric changes in bile acids may affect glucose metabolism include regulating levels of fibroblast growth factor 19 (FGF19), glucagon-like peptide 1 (GLP-1), organ-specific effects, inflammation, and alterations in the gut microbiome. Due to their multiple and pleiotropic effects, the definitive role of bile acids in bariatric surgery is not yet known and will likely require randomized controlled clinical trials with specific bile acids and/or bile acid receptor modulators.

Environmental effects on endocrine functions

S4.1

Developmental exposures to endocrine disrupting chemicals (EDCs) reprogram the epigenome to increase risk for hormone-dependent cancers and other diseases of adilthood

Cheryl Walker
USA.

While organisms have evolved to maintain the fidelity of their genome, the epigenome, in contrast, is inherently plastic, with extensive remodeling required during normal development. This epigenomic plasticity plays a role in preparing the developing organism for its adult environment. The epigenome is able to sense environmental cues, providing an opportunity for adaptive changes during development that can provide a later-life survival advantage. However, epigenomic plasticity also carries a liability. Adverse environmental exposures can disrupt the developing epigenome, and this developmental reprogramming can have life-long consequences, increasing risk for many diseases. Our work has revealed vulnerabilities in the epigenetic machinery targeted by environmental exposures, specifically endocrine disrupting chemicals (EDCs) that activate nuclear hormone receptors (NHRs). EDCs initiate non-genomic NHR signaling, activating kinases that disrupt the epigenetic machinery of developing cells by phosphorylating and altering the activity of the 'readers, writers, and erasers' of the epigenome. For example, the EDC bisphenol A (BPA) engages NHRs to activate PI3K/AKT signaling, phosphorylating the histone methyltransferase MLL to increase the active H3K4 histone mark at reprogrammed genes. This developmental reprogramming persists into adulthood, long after the initial environmental exposure occurred, resulting in changes in gene expression that increase disease risk. Interestingly, the impact of epigenetic reprogramming may be silent until challenged with another, later life exposure. For example, altered gene expression associated with an increase in active H3K4me1 or H3K4me3 marks may not occur until the promoters of reprogrammed genes are engaged by transcription factors, as is the case for hormone-responsive genes that become hyper-responsive to estrogen or testosterone. Alternatively, reprogramming of specific transcription factors, such as the transcription factor EGR-1 (which is activated by high-fat diet), can drive an exaggerated transcriptional response to high-fat diet in EGR-1 target genes. Thus, while epigenetic alterations induced by environmental exposures persist into adult life, their effect on gene expression may be conditional on later life events, which then reveal the impact of developmental reprogramming and promote adult onset disease.

Iodine deficiency in pregnancy and development of offspring

Malgorzata Trofimiuk-Muldner
Poland.

Iodine as the main component of thyroid hormones is an essential micronutrient for proper neurodevelopment. According to the WHO, its deficiency is the most common cause of preventable brain damage worldwide. Although most severe forms of iodine malnutrition have almost been eliminated, mild-to-moderate iodine deficiency is still very common, affecting approximately two billions people worldwide. Due to increased iodine requirements during gestation, iodine deficiency in pregnant women may be an issue even in populations considered iodine sufficient. Iodine deficiency is linked to the spectrum of health consequences defined as iodine deficiency disorders. Fetuses and young children are particularly vulnerable to deleterious effects of iodine malnutrition. It has been demonstrated in animal models that even mild iodine deficiency during gestation affects the brain cortex cytoarchitecture, glial development and myelinization in offspring, resulting in impaired learning capacity and behavioural changes. In humans consequences of severe iodine malnutrition, endemic cretinism included, have been well described. Prophylaxis with iodised oil in areas of severe iodine deficiency was proved to be effective in placebo-controlled randomised trials and resulted in a reduction of abortion, prematurity and stillbirth rates, as well as in decreased frequency of myxedematous cretinism. An evidence on the negative impact of mild-to-moderate iodine deficiency during pregnancy on children neurodevelopment is conflicting. Low iodine status in early pregnancy has been linked with lower verbal IQ and reading scores in the offspring (ALSPAC cohort), child language delay, behaviour problems, and reduced fine motor skills (Norwegian cohort) or lower spelling scores (Australian data). However, the association between children cognition and urinary iodine concentration during gestation has not been confirmed in a Dutch birth cohort, probably due to a low frequency of iodine deficiency in this group. The recently published results of randomised, placebo-controlled trial did not prove that iodine supplementation of mildly iodine deficient pregnant women influenced the neurocognitive development of their children.

S4.3

Environmental contaminants and endocrine disruption: the story of obesogens

Ana Catarina Sousa
Portugal.

According to the World Health Organization, obesity is one of the most important public health challenges of the 21st Century. There is no doubt that excessive calories intake and lack of exercise, are important factors, and that genetics plays a critical role. However, because genes in the population do not change fast enough, other causes must be involved. The involvement of other causes in the etiology of obesity is further strengthened by the fact that obesity is increasing sharply in young children, including babies for whom changes in exercise and eating patterns are unlikely to have occurred in the past decades. Furthermore, increases in body weight have also been reported in laboratory, domestic and wild animals. Such evidences strengthen the hypothesis that environmental factors are at play. In 2006, a new theory on the role of environmental contaminants in the etiology of obesity was proposed by Dr. Bruce Blumberg. This theory, known as the 'obesogen effect' postulates that environmental chemicals are able to promote obesity by increasing the number of fat cells and/or the storage of fat into the existing adipocytes. It was originally proposed for tributyltin (TBT), a potent endocrine disrupting chemical responsible for sex changes in marine gastropods. This endocrine disruptor was responsible *in vitro* and in experimental animals for the induction of adipogenesis; furthermore, prenatal exposure to TBT in mice was associated with adiposity later in life and in future generations. Since the obesogen theory was proposed, compelling evidences from *in vitro*, *in vivo* an epidemiological studies arose in the scientific literature and today several chemicals are considered as obesogens. This presentation will provide an overview of the implications of obesogens in metabolic disorders, while explaining the major classes of obesogenic compounds to which we are continuously exposed. Preventive measures to reduce exposure to these toxic chemicals will be described and the future perspectives in this exciting emerging field will be discussed.

The role of sperm epigenome in fertility and inheritance

S5.1

The quality control of the male germline transcriptome

Noora Kotaja
Finland.

Accurate posttranscriptional regulation of gene expression is essential for the production of good quality spermatozoa. Active cell type-specific transcription, exceptionally diverse transcriptome, and finally, near-to-complete transcriptional

silencing during the late steps of spermatogenesis create a high demand for effective RNA regulatory mechanisms. Furthermore, RNAs packed inside spermatozoa can mediate epigenetic inheritance of father's acquired disorders, therefore having important implications on offspring health. Male germ cells are characterized by intriguing cytoplasmic ribonucleoprotein granules (germ granules) that participate in RNA regulation during spermatogenesis. By molecular characterization of germ granules in mice, we have revealed their central role in germline-specific RNA regulation. We have shown that in addition to the PIWI-interacting RNA (piRNA) pathway, germ granules in haploid male germ cells accumulate the components of the nonsense mediated mRNA decay (NMD) pathway. The NMD acts mainly by promoting the degradation of mRNAs undergoing premature translation termination, but it can also regulate the stability of a variety of other kind of substrates. Using germ cell-specific knockout mouse models, we have shown that the NMD-targeted RNA degradation is required for normal spermatogenesis, and has a critical role in the control of male germ cell's transcriptome. Altogether our results emphasize the significance of germ granule-associated RNA quality control mechanisms in the maintenance of male fertility.

Mechanisms of epigenetic inheritance through sperm: lessons we have learnt from model organisms

Tanya Vavouri
Greece.

Our lifestyle habits and environmental exposures are typically considered to affect only our health (with the exception of pregnant mothers). Nevertheless, there is epidemiological evidence from human studies that adverse health consequences can also be observed in offspring and grand offspring (e.g. Roseboom *et al*., Molecular and Cellular Endocrinology, 2001). The mechanisms of trans- or inter-generational epigenetic inheritance are currently not known. We, and others, have therefore turned to animal models to try to understand the mechanisms involved. During my talk I will present two animals models of inter- or trans-generational epigenetic inheritance and what we have learnt from them about how information is transmitted through the germline (Ost *et al*., Cell, 2014; Klosin *et al*, Science 2017).

Pharmacogenetics in type 2 diabetes: precision medicine or discovery tool?

Jose Florez
USA.

In recent years technological and analytical advances have led to an explosion in the discovery of genetic loci associated with type 2 diabetes. However, their ability to improve prediction of disease outcomes beyond standard clinical risk factors has been limited. On the other hand, genetic effects on drug response may be stronger than those commonly seen for disease incidence. Pharmacogenetic findings may help to uncover new drug targets, illuminate pathophysiology, clarify disease heterogeneity, aid in the fine-mapping of genetic associations, and contribute to personalized or precision treatment. In diabetes, precedent for the successful application of pharmacogenetic concepts exists in monogenic forms of the disease, such as maturity onset diabetes of the young or neonatal diabetes. Whether similar insights will be produced for the common form of type 2 diabetes remains to be seen. With recent advances in genetic approaches, the successive application of candidate gene studies, large-scale genotyping studies and genome-wide association studies has started to generate suggestive results that may lead to changes in clinical practice. However, many potential barriers to the translation of pharmacogenetic discoveries to the clinical management of diabetes still remain. In this presentation, we will offer a contemporary overview of the field in its current state, identify potential obstacles, and highlight future directions.

S6.2

Genetics can help to improve precision medicine in diabetes

Leif Groop
Sweden.

Diabetes is presently classified into two main forms, type 1 (T1D) and type 2 diabetes (T2D), but especially T2D is highly heterogeneous. A refined classification could represent an important step towards precision medicine in diabetes. We have carried out a data-driven cluster analysis in 15,000 'T2D-patients' aged 18 years or older from four different cohorts in Sweden and Finland using six variables (age at diagnosis, GAD-antibodies, BMI, HbA1c, HOMA2-B and HOMA2-IR) (Ahlqvist A *et al*. Lancet D&E, 2018). We thereby identified five replicable clusters of diabetes patients, three more severe forms and two milder forms with different patient characteristics and risk of diabetic complications. Cluster 1 included patients with severe autoimmune diabetes (SAID) and cluster 2 similarly insulin-deficient patients (SIDD) with poor metabolic control and high risk of diabetic retinopathy. Individuals in the most insulin-resistant cluster 3 (SIRD) had a 4-5-fold increased risk of diabetic kidney disease and hepatosteatosis compared to other clusters. The obesity-related cluster 4 (MOD) and age-related cluster 5 (MARD) showed a rather benign course of the disease. A criticism of cluster analyses is that they are rather subjective. To address this criticism we used genetics. One could think that cluster 2 included patients with misdiagnosed T1D, but this cluster did not show any association with T1D-associated HLA types. Cluster 3 showed association with SNPs associated with hepatosteatosis, whereas only clusters 4 and 5 showed clear association with established T2D SNPs. Till date we used a panel of 170 SNPs but are now performing GWAS with the hope to identify cluster-specific gene scores. In conclusion, we have been able to stratify patients into five subgroups predicting disease progression and development of diabetic complications more precisely than the current classification and we have used genetics to validate this clustering.

Precision Nutrition in Obesity: gene-diet interactions

Jose Ordovas
USA/Spain.

Background

Obesity, resulting from complex interactions between genetic and non-genetic factors, is one the most pressing health challenges in our society. Current treatments for losing weight based mainly on diet and exercise are mostly unsuccessful in the long term. Therefore, as an alternative to the current strategy of one-size-fits-all, a more individualized approach is proposed in which genotype data are used to personalize treatment and to optimize the results.

Objective
To inform about the state of the art research related to the influence of genetic variation in the modulation of the association between diet on obesity and weight-related measures.
Results
Most of the published research use observational studies to identify gene by diet interactions modulating obesity risk. Far fewer are randomized clinical intervention trials assessing short-term weight-loss or its long-term maintenance in relation to specific genotypes. The results of the studies undertaken to date show significant progress in identifying polymorphisms in genes related to obesity, the greatest body of literature being reported for the FTO gene. The results on gene-diet interactions in determining obesity phenotypes are very heterogeneous, with few exceptions such as the APOA2 locus with saturated fat and BMI. An important recommendation is to standardize the methodology for undertaking these studies. Furthermore, such lack of replication suggests undetected higher-level interactions and experimental caveats. One of the potential interactive factors is chronobiology. It has been shown that genetic variation in Clock-related genes is associated with obesity and with the response to dietary interventions aimed to lose weight. Moving forward, the integration of different high-throughput 'omic' techniques (i.e., genomics, epigenomics, and metabolomics) will provide the mechanistic basis to well-validated gene-diet interactions and add credibility to this area of nutrition research.
Conclusions
Despite substantial progress, the current evidence level of applying genotype data to obesity treatment is in its early stages. Nevertheless, prospects are promising.

Expanding the spectrum of thyroid hormone use (*Endorsed by the European Journal of Endocrinology*)

S7.1

Triac: hormone, metabolite and drug.
Theo Visser
Rotterdam, Netherlands.

The prohormone thyroxine (T4) is the major product secreted by the thyroid gland, while most actions of thyroid hormone (TH) are initiated by binding of the active hormone 3,3′,5-triiodothyronine (T3) to nuclear receptors. The biological activity of TH is thus determined by the intracellular T3 concentration in target tissues, which depends on 1) the circulating concentrations of T4 and T3, 2) the activity of deiodinases catalyzing the conversion of T4 to T3 or to receptor-inactive metabolites, and 3) the activity of transporters which facilitate the cellular uptake and/or efflux of T4 and T3. As in many animals, administration of T4 or T3 induces the metamorphosis of the invertebrate amphioxus. However, T3 is incapable of stimulating the TH receptor in amphioxus in vitro, in contrast to the potent stimulation by 3,3′,5-triiodothyro-acetic acid (Triac)1. Furthermore, a deiodinase has been characterized in amphioxus, which is inactive towards iodothyronines but effectively deiodinates Triac2. Together, these findings suggest that Triac is the active TH in amphioxus. Early studies of the metabolism of T3 in humans and animals have indicated the formation of Triac but the exact nature of this process has not been established3. The first step in the conversion of T3 to Triac is likely catalyzed by one or more aminotransferases, resulting in the formation of 3,3′,5-triiodothyropyruvic acid. The latter may then be oxidized to Triac, but it is unclear what enzyme, if any, is involved in this oxidation. Recent studies in our lab have resulted in better insights in the pathway by which T3 is converted to Triac. Triac has been used for TSH-suppressive therapy in patients with thyroid cancer or patients with thyroid hormone resistance, based on a greater central than peripheral activity of Triac. It is now also tested as a therapy for patients with severe X-linked psychomotor retardation (Allan-Herndon-Dudley syndrome, AHDS) caused by mutations in the TH transporter MCT8. MCT8 is essential for TH transport into and inside the brain, and TH deficiency in the developing brain results in severe neurological deficits. Supported by *in vitro* and animal experiments, Triac does not require functional MCT8 for transport into brain cells, and would thus be effective in restoring thyromimetic activity in the brain of AHDS patients3.

Tetrac as an antiangiogenic agent in cancer
Kathrin Alexandra Schmohl
Germany.

In 2005, Bergh *et al*. first described a cell surface receptor for thyroid hormones (TH) T3 and T4 on integrin αvβ3 that is expressed on tumour cells and dividing endothelial cells. The deaminated T4 derivative tetraiodothyroacetic acid (tetrac) is a specific inhibitor of integrin-mediated TH action. Building on Paul Davis' pioneer studies, we are investigating the effects of TH and tetrac on mesenchymal stem cells (MSCs), important progenitor cells of the tumour's fibrovascular network, in the context of tumour angiogenesis. We were the first to show that recruitment and invasion of MSCs into tumours is significantly enhanced by TH stimulation and blocked by tetrac. In addition, we demonstrated that tetrac reverses the differentiation of MSCs towards a cancer-associated fibroblast-like and pro-angiogenic phenotype that occurs under tumour cell-conditioned medium and TH stimulation. Moreover, tetrac inhibited TH-stimulated endothelial cell tube formation, as did supernatant from MSCs stimulated with tumour cell-conditioned medium and TH in the presence of tetrac. Further, we established a reporter gene system by transfecting MSCs with the sodium iodide symporter (NIS) under control of the promoter for the vascular endothelial growth factor (VEGF), a critical angiogenesis mediator, leading to enhanced NIS-mediated iodide uptake activity after stimulation with tumour cell-conditioned medium and TH that was blocked by tetrac. In an orthotopic hepatocellular carcinoma xenograft mouse model, tumoural radioiodide uptake, measured by iodide-124 PET, demonstrated successful tumoural recruitment of MSCs followed by VEGF promoter-driven NIS expression. In hyperthyroid animals, tumoural radioiodide uptake was strongly enhanced compared to euthyroid and hypothyroid mice, while treatment with tetrac markedly reduced uptake, confirming inhibition of TH-mediated stimulation of VEGF by tetrac. Our data suggest that tetrac blocks the pro-angiogenic signalling of TH in MSCs via integrin αvβ3, providing further evidence of the anti-angiogenic activity of tetrac in the context of tumour stroma formation.

Thyroid hormones, metabolites, and analogs: Potential therapies for non-alcoholic fatty liver disease and other metabolic conditions
Paul Yen
Singapore.

Thyroid hormones (THs) are known to regulate both lipid, glucose, and cholesterol metabolism. These effects have led to biochemical and molecular studies on the roles that they and their metabolites have on these processes. Additionally, TH analogs have been developed to improve metabolic conditions such as hypertriglyceridemia hypercholesterolemia, and obesity while minimizing side effects such as tachycardia and osteoporosis that occur in hyperthyroidism. Typically, these analogs have preferential binding to the TH receptor beta isoform or preferential uptake by the liver. It now has been appreciated that THs also may have beneficial effects for the treatment of non-alcoholic fatty liver disease (NAFLD). We and others observed that TH and TH analogs decreased hepatosteatosis in animal and cell culture models of NAFLD by stimulating autophagy and b-oxidation of fatty acids. Additionally, we found that intrahepatic triiodothyronine (T3) levels were decreased and serum T3 levels were normal in an animal model of NAFLD. These findings suggested that there may be 'liver-specific hypothyroidism' in NAFLD so serum TH levels alone may not be sufficient to determine the TH status within the liver in this condition. We also have shown that the TH metabolite, diiodothyronine (T2), decreased hepatosteatosis in rats fed high fat diet by stimulating autophagy and acylcarnitine flux. We recently completed a pilot clinical study showing that low dose levothyroxine supplementation was able to decrease hepatosteatosis in euthyroid adult Asian men with diabetes. Taken together, these findings suggest that TH supplementation or the employment of TH metabolites and analogs may have therapeutic promise for the treatment of NAFLD and other metabolic conditions.

Bone fragility – from bench to clinic

S8.1

Clinical spectrum of new monogenic forms of osteoporosis

Outi Mäkitie
Finland.

Genetic factors play an important role in osteoporosis. Several monogenic forms of osteoporosis have been recognized. The most common of these is osteogenesis imperfecta (OI) in which dominantly inherited mutations in the genes encoding type I collagen (COL1A1 and COL1A2) are responsible for approximately 90% of the cases. Several rare autosomal recessive forms of OI have also been described. In these the defects lie in proteins involved in posttranslational modification of type I collagen. Recent discoveries have further elucidated the genetic determinants of early-onset skeletal fragility and several forms not related to type I collagen have been identified. The discovery of LRP5 mutations in osteoporosis-pseudoglioma syndrome and in early-onset osteoporosis first indicated that the WNT signaling pathway plays an important role in bone mass accrual. Several other studies thereafter, including our discovery of WNT1 mutations in early-onset osteoporosis, have further highlighted the pathway's significance in various disorders of low and high bone mass and provide evidence for the potential of WNT targeted therapies in osteoporosis treatment. The X-chromosomal osteoporosis caused by PLS3 gene mutations is another example of novel monogenic forms of osteoporosis that can be used to study cellular mechanisms leading to bone fragility. PLS3 osteoporosis affects mainly males and leads to severe progressive spinal osteoporosis; even females carrying the mutation may develop symptomatic osteoporosis. Our studies in patients with PLS3 deletions suggest that PLS3 plays a significant role in bone mineralization but the pathogenetic mechanisms are not fully understood. Several other monogenic forms of osteoporosis are under investigation. These highlight the complexity of molecular mechanisms governing normal

Hypophosphatasia – diagnosis and treatment

Lothar Seefried
Germany.

Hypophosphatasia (HPP) is a rare inborn metabolic disorder due to ALPL gene (1p36.12) mutations leading to deficient activity of the Tissue Non-Specific Alkaline Phosphatase (TNSALP), a homodimeric cell surface phosphohydrolase expressed in multiple tissues. Autosomal recessive or dominant inheritance of more than 300 different loss-of-function mutations cause accumulation of TNSALP substrates, including inorganic pyrophosphate (PPi), a potent inhibitor of mineralization, Pyridoxal 5-phosphate, the major circulating form of Vitamin B6 and Phosphoethanolamine (PEA). The clinical spectrum of disease manifestations both in terms of severity and organ involvement is remarkably broad, ranging from stillbirth and perinatal/infantile life-threatening symptoms, including chest and lung hypoplasia and pyridoxine-dependent seizures over premature loss of deciduous teeth and rachitic bone deformities in early childhood to unspecific musculoskeletal issues with rheumatoid/inflammatory pain, muscular weakness and fatigue along with compromised physical performance and recurrent, sometimes poorly healing fractures and bone marrow lesions. Beyond assessment family and individual medical history and clinical examination, diagnostic workup includes laboratory evaluation with Alkaline Phosphatase activity below age/sex adjusted normal range, elevated substrate levels (PLP in serum/plasma and urinary PEA) and eventually genetic testing for ALPL-Gene mutations, even though is to be considered that available evidence does not support the idea of a reproducible or meaningful genotype-phenotype correlation. Treatment is always multidisciplinary, including different medical specialties depending on prevailing organ manifestations and has to be tailored to individual needs. Following multinational approval of Asfotase alfa, a recombinant bone anchoring human alkaline phosphatase, enzyme replacement therapy (ERT) is available in Europe to treat bone manifestations of the disease in patients with childhood onset HPP. Study data on ERT clearly shows significantly improved survival of treated children as compared to a historical cohort. Further treatment modalities in addition and for less severely affected patients include analgesic medication with NSAIDs, supportive care with physiotherapy and phosphate reduced diet or phosphate binders and interventions to improve bone health including moderate Vitamin D supplementation and osteoanabolic treatment on an individual per-case decision, while avoiding bisphosphonates which appear to aggravate HPP-associated bone manifestation.

Klinefelter syndrome – a challenge for endocrinologists

Eberhard Nieschlag
Centre of Reproductive Medicine & Andrology, University of Münster, 48149 Münster, Germany.

Klinefelter syndrome (KS) is usually perceived as a disorder causing infertility and androgen deficiency and indeed, KS is the most frequent form of hypogonadism with 1 – 2 cases per 1,000 males and with a 47,XXY karyotype, the most frequent male chromosome disorder. Yet the incidence of the syndrome is probably significantly higher than the diagnosed casas suggest. Although subtle symptoms may be already evident in childhood and puberty, androgen deficiency usually only becomes evident in early adulthood. The manifold comorbidities of the KS should provide clues to the underlying genetic disorder. In the young patient neurological and psychological deficits may become evident e.g. in verbalization and attention, with learning difficulties resulting in professional and socio-economic underachievement. At a later age metabolic disturbances may occur (metabolic syndrome, diabetes type 2, venous thromboembolism, cardiovascular diseases, osteoporosis and fractures, autoimmune diseases, mediastinal tumors and mammary carcinoma). Doctors and hospitals consulted for these comorbidities often fail to recognize the underlying condition. However, the most prominent somatic feature of KS, the very small testes, are not investigated routinely so that this clue to the karyotype as the decisive diagnostic procedure remains overlooked. Although testosterone substitution is usually prescribed when testosterone serum levels become subnormal, optimal modalities and onset of treatment have not been explored by controlled trials. Similarly, although paternity has become possible by TESE and ICSI, the optimal time for testicular biopsy and the possible benefit of any pretreatment remain unclear. Although psychological support has beneficial effects especially in the transition phase, it is only provided in selected centers. Further elucidation of the genetic basis underlying the wide phenotypical heterogeneity in KS should provide new diagnostic and therapeutic approaches, e.g. paternal or maternal origin of the supernumerary X-chromosome, undetected mosaicism, extent of X-chromosome inactivation and polymorphism of the androgen receptor. To coordinate these approaches and to initiate the required research remains a challenge to the endocrinologists.

Does 'healthy obesity' exist in andrology?

Giovanni Corona
Italy.

Introduction
Obesity is a cause of erectile dysfunction (ED) whereas its relationship with male infertility is more conflicting. The term metabolically healthy obesity (HO) has been used to describe an obese phenotype that does not have the burden of any metabolic disorder. The aim of the present study is to analyse the contribution of HO in the pathogenesis of ED and male infertility and to verify the value of HO in predicting major adverse cardiovascular events (MACE).
Methods
An unselected series of 4382 (51.4 ± 13.1 years) men with sexual dysfunction (SD) and 222 (37.3 ± 8.6 years) males of infertile couples were studied. A subset of men with SD ($n = 1687$) was enrolled in a longitudinal study. Several clinical, biochemical and ultrasound parameters were evaluated. HO was defined as the presence of body mass index > 30 kg/m2, HDL > 40 mg/dl and absence of diabetes or hypertension.
Results
Among the patients with SD, 723 (16.5%) were obese and among them 163 (3.7%) were HO and 560 (12.8%) had a complicated obesity (CO). Similarly, among men of infertile couple 55 (24.8%) were obese and among them 18 (8.1%) had HO and 37 (16.7%) CO. After adjustment for confounders, when compared to healthy normal weight individuals, in both samples, either subjects with HO or CO had lower total T levels. Conversely, no difference between HO and CO were observed. In addition, in both samples men with CO but not those with HO reported worse erectile function when compared to healthy normal weight individuals. When PCDU parameters were considered, peak systolic velocity evaluated in flaccid conditions was lower in both HO and CO when compared to normal weight subjects in subjects with sexual dysfunction as well as in those of infertile couples. In addition, men of infertile couples with CO but not those with HO showed higher risk of ultrasound and biochemical (semen IL-8) features of prostatic inflammation when compared to normal weight subjects. Conversely, no differences in seminal parameters among groups were observed. Finally, the longitudinal study, after adjusting for confounders, both HO and CO were independently associated with a higher incidence of MACE (HR = 4.800 [1.265;18.214]; HR = 3.041 [1.078;8.573] 2.469 [1.019;5.981], respectively; both $P < 0.05$), when compared to the rest of the sample.
Conclusions
Our data suggest that healthy obesity induces subclinical ED and prostatic inflammation independent of T levels and it is associated with an increased CV risk.

Whole genome landscape in pancreatic neuroendocrine tumours

Vincenzo Corbo
Italy.

Pancreatic NETs (PanNETs) are characterized by recurrent molecular alterations, including genetic inactivation of MEN1, ATRX/DAXX, and activation of the PI3K/mTOR pathway. The International Cancer Genome Consortium effort on PanNETs provide a first snapshot of how heterogeneous is the combination of genetic alterations that drive this tumour type, yet converging into four pathways whose alteration has been enriched by newly discovered mechanisms. Whole-genome sequencing of 102 primary PanNETs and validation on additional 62 cases defined the genomic events that characterize their pathogenesis. The mutational signatures PanNET harbour include a deficiency in G:C > T:A base excision repair due to inactivation of MUTYH, which encodes a DNA glycosylase involved in base-excision repair. Clinically sporadic PanNETs contain a larger-than-expected proportion of germline mutations, including previously unreported mutations in the DNA repair genes MUTYH, CHEK2 and BRCA2. Together with mutations in MEN1 and VHL, these mutations occur in 17% of patients. Somatic mutations, including point mutations and gene fusions, are commonly found in genes involved in four main pathways: chromatin remodelling, DNA damage repair, activation of mTOR signalling (including previously undescribed EWSR1 gene fusions), and telomere maintenance. In addition, gene expression analyses identified a subgroup of tumours associated with hypoxia and HIF signalling. While calling for further integration of genetic and epigenetic analyses, these data allow reconciling previous findings in a defined frame, and may provide clinical research with markers for patients stratification and to guide targeted therapy decisions.

Novel aspects of Craniopharyngioma

S11.1

Molecular pathogenensis of craniopharyngioma

Carles Gaston-Massuet
UK.

Craniopharyngiomas (CPs) are tumours located in the sellar and parasellar region, thought to have an embryonic origin and/or to arise from pituitary progenitors/stem cells. They have an overall incidence of 1–2 new cases/million population/per year and are subdivided into two histologically different subtypes, adamantinomatous (aCPs) and papillary (pCPs). The clinical manifestations at diagnosis for CPs are: headache, visual disturbances, polyuria/polydipsia, endocrine dysfunction such as growth retardation, puberty disturbances and obesity. The current therapy of choice is complete resection or partial resection with the intention to maintain optic nerve and hypothalamic functions if these areas are affected. Overall surgical survival rates are high (90%), although post-surgical morbidity is present in 100% of the patients, leading endocrine deficiencies and lifelong treatment. Recently, molecular studies have identified that the two CPs subtypes are genetically distinct with aCPs mainly harboring mutations in Wnt signaling effector, β-catenin, and pCPs in the BRAFV600E oncogene. These molecular findings have led to the identification of possible therapeutic treatments for pCPs using BRAF inhibitors, which highlights the importance genetic studies for the identification of future targeted therapies. Transgenic murine models of aCPs have revealed novel therapeutic targets that could be beneficial for aCP treatments and identified pathways important in tumour progression both in humans and murine models. Moreover, we present genetic studies from a large cohort of aCP patients that suggests that the reported mutual genetic exclusivity of CPs subtypes, is in fact more heterogeneously complex than previously thought, and that the underlying genetic drivers for a large proportion of CPs patients remains unknown.

Bariatric surgery as treatment in craniopharyngioma

Daniel S. Olsson
Sweden.

Patients with craniopharyngioma suffer from excess mortality and morbidity, especially patients with childhood onset of the disease. The impaired outcome in

these patients is in part related to hypothalamic obesity, which is mainly caused by hypothalamic damage. The hypothalamic damage seems to result in autonomic nervous system dysfunction as well as leptin and insulin resistance. These factors negatively affect food intake, food satisfaction, metabolism and energy expenditure. In 'common' obesity, bariatric surgery has been shown to be highly effective. Therefore, bariatric surgery has been proposed as a therapeutic option in patients with craniopharyngioma and hypothalamic obesity. Multiple aspects need to be considered in obese patients with craniopharyngioma. For example, will bariatric surgery in patients with hypothalamic obesity lead to similar results to those found in patients with 'common' obesity and, also, will the surgery and/or the weight loss have a significant effect on hormonal replacement therapy? The talk will review the effects of bariatric surgery in patients with craniopharyngioma. Furthermore, the results of the latest collaborative study, between Erasmus University and Gothenburg University will be presented. In this study, eight patients with craniopharyngioma received bariatric surgery and was compared to closely matched patients receiving the same type of surgery for 'common' obesity. The craniopharyngioma patients were followed for 2 years regarding effects on body weight, hormonal replacement therapy and side effects.

DOI: 10.1530/endoabs.56.S11.2

S11.3

The psychosocial, neuroendocrine and cognitive effects of childhood craniopharyngioma

Helen Spoudeas
UK.

Craniopharyngiomas are paradoxically considered 'benign' and hence curable by complete excision. Despite a high survival rate, however, this notion belies a high morbidity and propensity for premature mortality from neuroendocrine disease and treatment complications in those diagnosed in childhood, whose disease differs from that in adulthood. These result from a proximity to, and invasion of, vital ophthalmic, neurometabolic, neurocognitive and neuroendocrine pathways, and the subsequent impact on normal growth, learning and maturation processes in the developing child. Some of these are life threatening, and all are life changing. The devastating effects of hypothalamic injury are poorly understood, whilst endocrine replacement therapy and neurocognitive rehabilitation are not always timely or streamlined into treatment pathways. In 2005, the first UK consensus management guidelines recognised the surgical contribution to hypothalamic injury and advocated conservative debulking strategies and up front radiation to stabilise disease, avoiding further surgical hypothalamic harm or that due to recurrence. Poor cognitive and endocrine outcomes have traditionally been blamed on cranial radiation rather than pre-existing disease (eg.diagnostic delays, recurrence) or treatment (eg.radical excision) variables, with increasing attempts to avoid or refine this in children. Since 2009, the theoretical cognitive advantages afforded by the reduced penumbral scatter of proton beam irradiation has made this the NHS UK standard of care, patients being sent to USA for therapy, without a risk-benefit analysis as compared with photons.We will present neuroendocrine and cognitive outcome data on our cohort of 54 patients treated on a conservative surgical and early radiation strategy over two decades, and compare these with our own historical, radical surgery series (published 1996) by treatment era, and with other published series. Our early longitudinal evidence suggests tumour position, size, recurrence and Paris grade of hypothalamic involvement at diagnosis, as well as the surgical and radiation strategy (early vs late) are greater influencers of outcome than type of radiation (protons vs photons), and a 2-staged surgical and early radiation strategy which stabilises disease, can reduce the neuroendocrine morbidity burden. Infants and children under 3 years at diagnosis are particularly vulnerable to poor outcomes, with greater prevalence of blindness at presentation, diagnostic delays, stroke, recurrent cystic tumours treated with experimental intracystic interferon, and avoidance of radiaition considered too neurotoxic. A considered 2-stage surgical strategy avoiding hypothalamic harm, timely radiation and intensive interval neuroendocrine / cognitive assessment and rehabilitation, are more likely to improve outcomes than radiation type.

S12.2

Bone quality evaluation in Pituitary diseases

Natasha Appelman-Dijkstra
The Netherlands.

The skeleton consists of cortical bone and trabecular (cancellous) bone. Cortical bone, which comprises 80% of the skeleton, is designed to provide rigidly and strength and is predominantly found in the long bones, e.g. at the femur. Cancellous bone has a more flexible design with interconnecting trabecles, and is metabolically more active then cortical bone. The balance between formation and resorption is essential for maintaining a normal bone mass and skeletal integrity. Disruptions in the ratio of bone formation and resorption in favour of resorption will ultimately lead to progressive bone loss and increased bone fragility. In daily clinical practice, Bone Mineral Density (BMD) measurements using DXA remain the corner stone for the diagnosis of osteoporosis. BMD has been shown to be a strong predictor for fractures however there is increasing evidence that factors other than BMD determine bone fragility and thus fracture risk. These underlying secondary risk factors for fractures should be taken into account in the assessment of an individual's fracture risk and are usually present in patients with pituitary diseases. These secondary factors may be identified by medical history and evaluated and confirmed using appropriate laboratory investigations including thyroid, gonadal function. But Cushings disease, Acromegaly or growth hormone deficiency should be considered as well. Besides laboratory examinations, additional radiological evaluation should take place when evaluating these patients. The presence of one or more vertebral fractures has been shown to represent a strong independent predictor for future vertebral and for non-vertebral fractures. Vertebral fractures have been shown to be associated with increased morbidity and mortality. Increased incidence of Vertebral fractures have been reported in patients with Acromegaly and Growth Hormone deficiency where bone mass might even be within the normal range. Therefore other techniques should also be explored to further evaluate fracture risk in patients with pituitary diseases.

S12.3

Parathyroid dysfunctions – bone mass and fractures in primary hyperparathyroidism

Jens Bollerslev
Norway.

Primary Hyperparathyroidism (PHPT) is the most common disease among parathyroid disorders compared to Chronic Hypoparathyroidism, Calcium Sensor disorders (loss or gain of function mutations) or Parathyroid Cancer. The clinical presentation of PHPT has changed dramatically after the increased accessibility to biochemical analyses. The diagnosis is today often made by change in patients without specific symptoms. Operative treatment is always an option and recommended in patient with markedly increased calcium levels or typical symptoms. Bone metabolism in PHPT has been systematically investigated. Bone turnover is increased with a reversible bone loss at the trabecular surface, whereas there seems to be a non-reversible loss at the cortical level. Epidemiological and observational studies have demonstrated increased fracture rate in PHPT, and long term longitudinal studies have revealed a significant bone loss primarily at cortical sites with observation. Thus, diagnostic osteoporosis by DXA or low energy fractures is regarded as treatment indication (operation) even in the mildest cases. The primary treatment of PHPT is surgical removal of the enlarged parathyroid mass, most often being a parathyroid adenoma. Surgery (or anti-resorptive, medical treatment) will decrease bone turnover, filling the enlarged remodeling space and thereby in theory normalize fracture rate. However, only few prospective studies have looked into the benefit of operation versus

conservative observation without intervention in PHPT. Observational data and recent prospective, randomized studies indicate that bone mass might become critical low with prolonged observation. In alignment, there seems to be a treatment effect on fracture rate with surgical treatment. Most patients with PHPT will present with few if any symptoms, high normal or slightly increased calcium levels with only moderately elevated PTH. Differential diagnoses must be ruled out and familiar or syndromic forms identified. An increased awareness on bone mass and fracture rate in patients to be followed without intervention is recommended.

DOI: 10.1530/endoabs.56.S12.3

The colours of fat

S13.1

Brown adipose tissue as an endocrine organ

Francesc Villarroya
Spain.

Brown adipose tissue (BAT), in addition to its role in adaptive thermogenesis, secretes regulatory factors (brown adipokines or 'batokines') that have autocrine, paracrine, and endocrine actions. Local secretion of brown adipokines by brown adipocytes target distinct cell types in the tissue (e.g. vascular cells, sympathetic nerve endings, immune cells) and promote the remodeling of BAT in response to distinct physiological conditions requiring adaptive thermogenesis. Evidence from BAT transplantation in rodents led to hypothesize that brown adipokines may have endocrine actions which may be involved in the systemic healthy effects (mainly prevention of insulin resistance and obesity) of active brown fat. There is evidence that such healthy effects occur also for the human brown adipocyte secretome. Brown adipokines identified to date are polypeptides, lipid molecules or microRNAs. However, a comprehensive knowledge of the secretome from BAT fat is still lacking. The identification and characterization of brown adipokines may help to identify novel tools for treatment of metabolic diseases, due to the expected healthy properties of signaling molecules released by BAT. Moreover, circulating biomarkers of BAT activity are not available at present, and research on brown adipokines may contribute to the identification of such systemic biomarkers that will be particularly useful in clinical research. Recently, a distinct type of adipose tissue has been identified, the so-called 'beige' adipose tissue which contain thermogenic 'beige' adipocytes resembling brown adipocytes. Several experimental data suggest that the extent of induction of 'beige' adipose tissue in response to thermogenic challenges is associated with protection against obesity and hyperglycemia. To date, the secretome of 'beige' adipocytes appears to resemble that from brown adipocytes, but research for potential differential secretion beige-versus-brown adipokines is ongoing.

DOI: 10.1530/endoabs.56.S13.1

S13.2

Adipose tissue browning in mice and men

Florian Kiefer
Austria.

Promotion of brown adipose tissue (BAT) activity or browning of white adipose tissue has shown great potential as anti-obesity strategy in numerous preclinical models. The discovery of active BAT in humans and the recent advances in the understanding of human BAT biology and function have sparked this field of research. Pharmacological stimulation of energy expenditure to counteract obesity has always been an intriguing therapeutic concept; the identification of the specific molecular pathways of brown fat function is an important step towards developing novel agents that harness the termogenic potential of adipocytes. Two distinct strategies are currently being pursued; one is the activation of bone fide BAT, the other is the induction of BAT-like cells or beige adipocytes within white fat depots, a process called browning. Recent evidence suggests that both phenomena can occur in humans. Cold-induced promotion of BAT activity is strongly associated with enhanced thermogenesis and energy expenditure in humans and has positive effects on fat mass and glucose metabolism. Despite these encouraging results, a number of issues deserve additional attention including the distinct characteristics of human versus rodent BAT, the heterogeneity of human BAT depots, or the identification of the adipocyte precursors that can give rise to thermogenic cells in human adipose tissue. In addition, many exogenous and endogenous factors have been identified to regulate a browning program in human and mouse adipocytes. This talk summarizes the cellular and molecular mechanisms of adipocyte browning, its functional relevance for energy metabolism and the therapeutic potential for obesity.

DOI: 10.1530/endoabs.56.S13.2

S13.3

Browning of adipose tissue in humans

Pirjo Nuutila
Finland.

In 2009 three independent research groups confirmed the existence of metabolically active brown adipose tissue in human adults. There is increasing evidence that enhanced BAT function can improve systemic health in humans by utilizing glucose and lipids from the circulation and by increasing metabolic rate. Therefore BAT activation could provide a strategy to combat the increasing epidemic of obesity and type 2 diabetes. The function of BAT is controlled by various endogenous factors, and hormones including the thyroid hormones. In states of disease or abnormal metabolism, such as hyperthyroidism or obesity, the regulatory systems may become impaired. Positron emission tomography (PET) has provided a non-invasive way to investigate BAT function in humans in vivo. BAT glucose uptake increases in lean men up to 10-fold during cold exposure. The potential of this imaging technique has only partly utilized and focused on glucose metabolism only. Although there is growing amount of reports on BAT activation in humans, evidence regarding the browning of WAT is limited. We and others have shown that BAT activity in morbidly obesity increases after bariatric surgery. Chronic cold exposure for 6 weeks at 17°C during 2-hour per day resulted increase in BAT activity and cold-induced thermogenesis in on-obese individuals with low BAT activity in a study of Yoneshiro et al. The stimulation of BAT during the cold is mediated via NE-dependent pathway. Mirabegron, a beta3-adrenergic receptor agonist used for the treatment of overactive bladder was promising in humans in a short but not in a longer intervention. Irisin is one of the promising ones release e.g. by exercise. The fibroblast growth factor-21 (FGF-21) also interacts with the FGF receptors on the brown adipocytes and they have been shown to stimulate glucose oxidation and thermogenic mechanism in the BAT. Studies about effects of exercise to induce browning have given controversial results. This might be partly due altered substrate metabolism towards utilization of more fatty acids, which is more difficult to measure directly in human BAT. Even the changes in outdoor temperature seems to be blunt the exercise induced effects. The physiological role of BAT in adult humans is still largely open. Totally new areas are coming up constantly. Recent studies have suggested a link between BAT volume and total and spine bone mineral density mainly in women. Numerous efforts are ongoing to find drugs for browning. The heat is still on.

Developmental wiring of GnRH neurons

Ulrich Boehm
Germany.

Puberty is a transition period of reproductive development from juvenile stages to adulthood and depends upon activity of gonadotropin-releasing hormone (GnRH) neurons. GnRH neurons are initially activated in utero, but remain quiescent throughout the juvenile period. Premature reactivation of GnRH neurons results in precocious puberty in mice and humans, but the mechanisms underlying developmental control of GnRH neuron activity remain unknown. The neuropeptide kisspeptin, a potent activator of GnRH neurons that is implicated as a critical permissive signal triggering puberty and a major regulator of the adult female hypothalamus-pituitary-gonadal (hpg) axis, is paradoxically produced by neurons in the developing brain well before puberty onset. We have delineated the underlying neural circuitry using conditional genetic transsynaptic tracing in female mouse embryos. We find that kisspeptin-producing neurons in the arcuate nucleus (ARC) already communicate with a specific subset of GnRH neurons in utero. We show that ARC kisspeptin neurons are upstream of GnRH neurons and that GnRH neuron connectivity to ARC kisspeptin neurons does not depend on their spatial position in the brain. Furthermore, we demonstrate that the neural circuits between ARC kisspeptin and GnRH neurons are fully established and operative before birth. Most GnRH neurons express the kisspeptin receptor GPR54 upon circuit formation, suggesting that the signaling system implicated in gatekeeping puberty becomes operative in the embryo. Distinct roles have been

proposed for AVPV and ARC kisspeptin neurons during reproductive maturation and in mediating estrogen feedback on the hpg axis in adult females. However, little is known about kisspeptin neuron connectivity in adult female mice. We analyzed the connectivity of individual kisspeptin neurons with the GnRH neuron population in adult female mice with a single cell resolution. Only subsets of AVPV and ARC kisspeptin neurons are synaptically connected with GnRH neurons demonstrating functional specialization within the two kisspeptin neuron populations.

Neuroendocrinology right from the nose: Genetics and pathophysiology of the olfacto-genital syndrome (Kallmann syndrome)

Jean-Pierre Hardelin
France.

Kallmann syndrome is a developmental disorder that associates anosmia, related to olfactory bulb aplasia, with congenital hypogonadotropic hypogonadism caused by GnRH deficiency, clinically characterized by the absence of spontaneous puberty and infertility. GnRH deficiency results from the incomplete embryonic migration of neuroendocrine GnRH-cells from the nasal epithelium to the hypothalamic region of the brain, as a consequence of the premature interruption of olfactory, vomeronasal and terminal nerve fibres, which normally guide these cells during their migration to the brain. This developmental connection between the central control of reproductive organs and the peripheral olfactory system (both affected in Kallmann syndrome) accounts for the aforementioned olfacto-genital pathological sequence. Kallmann syndrome can be isolated or associated with various non-reproductive non-olfactory additional anomalies, depending on the causal genes. Kallmann syndrome is genetically heterogeneous, with several different modes of transmission: X chromosome-linked recessive, autosomal dominant, autosomal recessive, and presumably oligogenic. The best characterized causal genes include ANOS1 (anosmin 1), FGFR1 (fibroblast growth factor receptor 1, also involved in Hartsfield syndrome), FGF8 (fibroblast growth factor 8), PROKR2 (prokineticin receptor 2), PROK2 (prokineticin 2), FEZF1 (FEZ family zinc finger 1), SOX10 (sex determining region Y-box 10, also involved in Waardenburg syndrome), and CHD7 (chromodomain helicase DNA-binding protein 7, also involved in the CHARGE association). Notably, this list implicates at least two different cell signalling systems (i.e., signallings by FGFs and by prokineticins) in Kallmann syndrome molecular pathogenesis. However, mutations in any of these genes are found in less than 50% of the patients, indicating that other disease genes remain to be discovered. The complex genetics of Kallmann syndrome, including a biased sex ratio (predominance of affected males) and monogenic versus oligogenic modes of transmission, will be discussed.

EYES: New aspects in the study of neuroendocrine diseases

S15.1

Introduction to EYES

Tatjana Isailovic
Serbia.

The ‘European Young Endocrine Scientists’ (EYES) founded in 2011, is a committee under the patronage of the European Society of Endocrinology (ESE). The primary goal of this committee is to increase the mutual exchange of ideas and knowledge between early career endocrinologists across Europe, in both basic and clinical research. EYES enables young endocrinologists from all ESE member societies to actively contribute to all aspects of the society’s activities, enabling them to fully develop into the next generation of endocrinologists. The committee provides a platform for young scientists in endocrinology to make them feel welcome at ESE and to familiarize with the society’s conferences. EYES aims to support annual meetings exclusively for young scientists in different European countries (The Netherlands, Serbia, Italy, Portugal, Russia and Poland in 2018), giving an opportunity to young scientists to present work in progress, to improve presentation skills and to establish a scientific network in all fields of endocrinology. In an attempt to link young endocrinologists all over Europe and to represent our special interests within the ESE, we would like to invite all interested young researchers and clinicians to take part in this exciting project. Check out our ESE EYES web page and Facebook page, visit us at EYES symposium and join our social evening event during ECE 2018.

Epigenetic and metabolic reprogramming of SDH deficient pheochromocytomas and paragangliomas

Judith Favier
France.

SDHA, B, C, and D (SDHx) genes encode the four subunits of succinate dehydrogenase (SDH), a mitochondrial enzyme of the tricarboxylic acid (TCA) cycle that oxidizes succinate into fumarate. They were the first genes encoding a mitochondrial enzyme demonstrated to act as tumor suppressors, an important finding supporting the hypothesis of a direct link between mitochondrial dysfunction and cancer proposed by Otto Warburg in the 1920’s. It is estimated that germline mutations in SDHx genes represent around half of inherited pheochromocytoma and paraganglioma (PPGL), which are referred to as Cluster 1 tumors. In PPGL, SDH loss-of-function results in the accumulation of succinate, which acts as an oncometabolite, by inhibiting 2-oxoglutarate-dependent dioxygenases among which HIF prolyl-hydroxylases drive a pseudohypoxic response and promote angiogenesis and DNA demethylases cause a hypermethylator phenotype. This presentation will show how our team uses genetic and OMICs analyses on the large series of human PPGL gathered by the French COMETE network, combined with experimental studies on Sdhb knockout cells and xenografts to decipher these mechanisms and develop tools to evaluate the response to anti-angiogenic or demethylating therapies. It will also show how we used OMICS analyses combined with whole-exome sequencing to identify new PPGL susceptibility genes within the cluster 1 group of PPGL. Using such an approach, we previously identified the first PPGL case harboring a germline FH gene mutation and now discovered a new mitochondrial tumor suppressor gene encoding an unsuspected carrier. These finding demonstrate the central role of mitochondrial deficiencies in the predisposition to paragangliomas.

Changing practice in the management of thyroid neoplasms

S16.1

New steps in the genomic alterations of thyroid malignancies

Garcilaso Riesco-Eizaguirre
Spain.

Thyroid cancer is the most common endocrine malignancy giving rise to one of the most indolent solid cancers, but also one of the most lethal. In recent years, systematic studies of the cancer genome, most importantly those derived from The Cancer Genome Altas (TCGA), have catalogued aberrations in the DNA, chromatin, and RNA of the genomes of thousands of tumors relative to matched normal cellular genomes and have analyzed their epigenetic and protein consequences. One unexpected observation is that the genome is massively transcribed in non-coding RNA which role is now beginning to be understood. We now know that the alteration of the transcriptome is not restricted to the production of aberrant levels of protein-coding RNAs (less than 2% of the genome) but also refers to the aberrant expression of multiple noncoding members that comprise the human genome, being microRNAs the most studied and, more recently, long non-coding RNAs (lncRNAs). Moreover, the interplay between lncRNAs and microRNAs appears to be a new level of regulation of importance in several malignancies. Cancer genomics is therefore providing new information on cancer development and behavior, as well as new insights into genetic alterations and molecular pathways. From this genomic perspective, we will review the main advances concerning some essential aspects of the molecular pathogenesis of thyroid cancer focusing on the increasing role of non-coding RNAs. This look across these genomic and cellular alterations results in the reshaping of the multistep model of thyroid tumors development and offers new tools and opportunities for further research and clinical development of novel treatment strategies.

S16.2

Composite approach in the evaluation and management of thyroid nodule

Murat Faik Erdoğan
Department of Endocrinology and Metabolism, Ankara University School of Medicine, Ankara, Turkey.

Thyroid nodules are common in the population. Ultrasound would detect nodules, in about 25% of the adult and half of the elderly population(>60 years). Only 5% of these nodules are malignant, and 60–70% of the detected benign nodules, remains similar or decrease in size during the long term follow-up. Few nodules, i.e >1.3 cm, would function autonomously and cause thyrotoxicosis. Rarely, large single nodules or multinodulated glands could cause compressive symptoms, or esthetic problems. Thus the clinician should plan to treat a small subgroup of patients carrying either of the problems described above and could simply follow-up the majority of the patients without any intervention. Ultrasound is the main tool, which physicians themselves, should use for picking up the high risk cases and decide FNAB. After the initial definition of TIRADS by Horvath et al, other thyroid organizations (ATA, AACE/AME) and recently ETA, developed standardized US risk stratification systems for reporting US features. Aim is to reliably define US assessment categories that can be used to communicate the expected risk of thyroid cancer and define those to be referred for FNAB. After the initial evaluation, appropriate surgical or medical interventions should be undertaken if needed. İ.e.; Surgery for the malignant nodules and/or large compressing multinodulated glands. Percutaneous ethanol injection (PEI) for large cystic nodules. Radiofrequency, percuteneous laser ablation (RFA, PLA) or high intensity focused ultrasound (HIFU) for single or limited number of nodule(s) causing esthetic or compressive problems. Radioiodine for autonomously functioning nodules in benign glands. Majority of the nodules would require no management, and it is the physicians responsibility to avoid unwarranted surgical or invasive intervention. Thyroidectomy is still, frequently, unnecessarily performed, and 30–40% of the postsurgical hypothyroid patients is either under or over replaced.

Recent advances in Primary Adrenal Macronodular Hyperplasia

S17.1

Adrenal development and benign tumor formation

Pierre VAL
France.

The adrenal cortex arises from the adrenogonadal primordium, which is also involved in the formation of the gonadal anlagen and is characterized by expression of the nuclear receptor Sf1. After individualisation, the adrenal primordium undergoes a series of developmental events that culminate with establishment of functional zonation, characterised by differentiation of zona glomerulosa and zona fasciculata. In the past 7 years, we have developed a number of mouse models recapitulating alterations of WNT/b-catenin and PKA signalling pathways identified in patients presenting with adrenal cortex tumours. This has allowed us to demonstrate that constitutive WNT/b-catenin pathway activation causes the development of both benign aldosterone producing adenomas and to a lesser extent adrenal cortex carcinomas, whereas constitutive PKA signalling is associated with the development of benign glucocorticoid-producing tumours. Beyond tumourigenesis, these experiments have also shed light on the mechanisms involved in adrenal cortex development and in particular functional adrenal cortex zonation. Indeed, we have shown that this process relies on a subtle equilibrium between WNT pathway activation by WNT4/RSPO3 in zona glomerulosa and PKA activation by ACTH/MC2R in zona fasciculata. These data emphasize the idea that adrenal tumourigenesis and differentiation share common regulators and pathways. This is further exemplified by our latest experiments showing that the histone methyltransferase EZH2, which is overexpressed in adrenal cortex carcinomas, is also a key player in regulating steroidogenic cell differentiation and maintaining adrenal identity as opposed to gonadal identity. These observations could be relevant to the observation that PMAH with ARMC5 mutations abnormally express a number of gonadal markers. Altogether these findings demonstrate the need for studies integrating analysis of patients' data with findings of basic studies on the mechanisms of adrenal development and differentiation.

Genetics of Primary Bilateral Macronodular Adrenal Hyperplasia: when and what to test

Rossella Libé
France.

Primary Bilateral Macronodular Adrenal Hyperplasia (PBMAH) consists of bilateral development of adrenocortical macronodules causing various level of cortisol excess independently of circulating ACTH. It can be diagnosed after investigations of clinical signs of Cushing's syndrome, but nowadays more often after the investigation of an adrenal incidentaloma in patients with sub-clinical Cushing. Indeed, 10 to 15% of adrenal incidentalomas are bilateral, corresponding mostly to PBMAH. Several observations suggest a genetic origin of PBMAH: case reports of familial forms, the bilateral and multifocal nature of the adrenal nodules. Genes involved in the cAMP/protein kinase A (PKA) signaling pathway, (GNAS) or as modifying gene (PDE11A4) have been reported as causing the disease. In rare cases PBMAH is observed in patients with hereditary familial tumor syndromes including adenomatous polyposis coli gene (APC), MEN1 (Menin) and Hereditary Leiomyomatosis and Renal Cell Cancer (fumarate hydratase). However, most PBMAH patients do not present with such syndromic associations. In these more common patients the use of combined pan-genomic approaches led to the identification of a new tumor suppressor gene, ARMC5, as a frequent cause of sporadic or familial PBMAH (25–50% in the different series). This demonstrates that PBMAH is often genetically determined and brought some new perspectives for early diagnosis of the disease. Genetic screening for ARMC5 germline mutation could help better diagnosis and classification of patients with PBMAH. Familial screening would lead to the identification of the relatives of an index case with ARMC5 mutation at risk of Cushing's syndrome development. Prospective follow-up will allow a better analysis of the development of PBMAH in such families. In conclusion, the genetic origin of PBMAH is now demonstrated in a significant proportion of the cases, offering new perspectives for pathophysiology, therapy and genetic screening.

S17.3

Diagnosis and Management of Primary Adrenal Macronodular Hyperplasia

Dimitra Argyro Vassiliadi
Greece.

Macronodular adrenal hyperplasia refers to adrenal enlargement by large nodules that may be related to ACTH-dependent or ACTH-independent pathologies. The term Primary Macronodular Adrenal Hyperplasia (PMAH) was recently introduced to replace the term ACTH-independent macronodular adrenal hyperplasia, since in some cases paracrine ACTH production may contribute to cortisol secretion, and also to encompass cases of unilateral macronodular hyperplasia. PMAH is a heterogeneous disease comprising different entities. The diagnostic approach depends on the clinical context. PMAH is rarely detected as part of the evaluation for ACTH-independent Cushing's syndrome. It is more often detected incidentally; in this setting imaging and hormonal characterisation are required. According to the recent ESE and ENS@T guidelines imaging characterisation should be done separately for each lesion since occasionally co-occurrence of different entities, such as adenoma, pheochromocytoma, cyst, myelolipoma or even adrenocortical carcinoma, may be encountered. The most common hormonal alteration is autonomous cortisol secretion (ACS). ACS follows a continuum and is best assessed using the 1-mg overnight dexamethasone suppression test. According to recent guidelines values of $\leq$50 nmol/l (1.8 μg/dl) exclude 'ACS', values of $>$140 nmol/l (5 μg/dl) confirm 'ACS' and values between 51 and 140 nmol/l (1.9–5.0 μg/dl) indicate 'possible ACS'. Additional tests including ACTH levels, midnight cortisol or 24-hr urinary free cortisol may aid in establishing the degree of cortisol excess. In addition, serum 17-hydroxyprogesterone should be measured to exclude congenital adrenal hyperplasia, keeping in mind that increased levels may also represent secretion of steroid precursors from the lesion(s). Testing for adrenal insufficiency may be relevant in some cases (i.e. when imaging suggests bilateral infiltrative disease or haemorrhage). In several occasions, aberrant responses due to illegitimate receptor expression are also encountered by relevant testing. Genetic testing may be offered in selected cases based on recent findings that PMAH is genetically determined. The appropriate management of PMAH remains controversial. Bilateral adrenalectomy is a debilitating option, resulting in lifetime steroid dependency. This is why the recent guidelines suggest against bilateral adrenalectomy in patients with no clinical signs of overt Cushing's syndrome. In selected patients unilateral adrenalectomy of the dominant lesion or based on adrenal vein sampling results might be considered. The decision for surgery depends on the degree of hypercortisolism, the presence of co-morbidities, age, general health and patient's preference. In cases where the regulation of cortisol secretion is mediated by aberrant hormone receptors there is some potential for medical therapy.

Borderline testosterone and metabolic outcomes among sexes: clinical relevance

S18.1

Sex hormones, obesity and type 2 diabetes-is there a link?

Alessandra Gambineri
Italy.

The different balance in the sex hormones, androgens and estrogens, is a cardinal aspect of the biology of gender difference and plays a fundamental role in maintaining the physiological state at each age of life. However, the imbalance in sex hormones is involved in some metabolic diseases, particularly type 2 diabetes, with androgens playing an interesting sexually dimorphic role. In particular, the bulk of evidence suggests that hyperandrogenism in women or hypogonadism in men facilitate the appearance of type 2 diabetes mainly via the promotion of metabolically unfavourable changes in body composition. The sexual dimorphism of androgens in the pathophysiology of type 2 diabetes leads to inequalities in both preventive strategies and treatment between women and men. Polycystic ovary syndrome (PCOS) is the most common hyperandrogenic disorder in women with a prevalence in fertile European women of around 6–8%. In these women, hyperandrogenism is associated with chronic anovulation and infertility. The prevalence of insulin resistance, obesity, and the metabolic syndrome in general is also high. In addition, the literature supports the notion that PCOS is associated with an increased susceptibility to develop type 2 diabetes at any age and that androgens are the main link between PCOS and type 2 diabetes. To support this assumption there are only few data that demonstrate that antiandrogenic therapy in women affected by PCOS is able to improve IR, decrease abdominal adiposity and probably prevent metabolic complications such as type 2 diabetes.

DOI: 10.1530/endoabs.56.S18.1

S18.2

Relevant therapies in PCOS

Mirjana Sumarac-Dumanovic
Serbia.

Although there are many phenotypes of polycystic ovarian syndrome (PCOS), we are mainly talking about three phenotypes: metabolic, hyperandrogenic and reproductive phenotype. Obesity and insulin resistance are the major determinants of the metabolic heterogeneity of patients with PCOS. Certain degree of hepatic insulin resistance exists in PCOS irrespective of obesity. In non-obese PCOS preserved insulin sensitivity in peripheral tissues exists. The presence of obesity is of great importance for the treatment of the syndrome. The most important approach should be made to prevent obesity and abdominal adiposity in non-obese women with PCOS. Lifestyle modification, diet and regular physical activity, and anti-obesity drugs, bariatric surgery may be useful in some obese PCOS. It is still dilemma should metabolic complications influence the choice of treatment for PCOS: insulin sensitizer drugs or COCs. Hyperandrogenic phenotype is the most common form of PCOS. Lifestyle changes in the presence of obesity are first line treatment. Pharmacological agents consist of COCs and antiandrogens or combination. In reproductive phenotype, infrequent or absent ovulation is the predominant problem in PCOS women. The main therapeutic issues for women with PCOS and reproductive dysfunction are treatment of infertility or menstrual regulation in PCOS women who do not desire pregnancy. Weight reduction alone may result in spontaneous ovulation in overweight/obese PCOS women. Induction of ovulation can be achieved either by raising endogenous levels of FSH or by giving exogenous FSH by daily injection. The estrogen receptor antagonist, clomiphene citrate, is first choice treatment for induction of ovulation in PCOS, while other antiestrogens are aromatase inhibitors. Metformin has been reported to improve ovulation rates in PCOS women when given alone or together with clomiphene citrate. A low-dose COC may be the most convenient form of treatment for all menstrual irregularities, although cyclical progestogen is an also reasonable alternative.

S18.3

Testosterone, obesity and the metabolic syndrome in males-do we need to replace steroids?

Jean-Marc Kaufman
Department of Endocrinology, Ghent University Hospital, Ghent, Belgium.

Background
In men with obesity and the metabolic syndrome there is an increased prevalence of low serum testosterone. Overweight and moderate obesity is associated mainly with low total testosterone (T) secondary to decreased concentrations of SHBG, which are strongly inversely associated with indices of adiposity and insulin resistance, and preserved free T levels. In more severe obesity and metabolic abnormalities (often with type 2 diabetes) low total T can be accompanied by low free T, usually without appropriate increase of gonadotropins indicating contribution of altered central regulation of gonadal function, of which the underlying mechanisms remain to be fully elucidated. These observations have raised the question whether treatment with T may be needed or beneficial. The main issues involved will be reviewed.
Main points
Are these men hypogonadal? A large proportion of the men with low total T and preserved free T should not be considered as hypogonadal. Those with low free T might be considered hypogonadal if they also present with symptoms of hypogonadism (e.g. sexual dysfunction). Is low T causal in the risk for – or aggravation of obesity and metabolic syndrome? Although the relation between low T and obesity/metabolic syndrome appear to some extent bidirectional, a critical appraisal of the literature indicates that a causal role of T is likely to be only limited with low T rather the consequence than the cause. Is the low T reversible? Weight loss and improved metabolic control can normalize or improve serum T. What are the effects of T therapy on the evolution of obesity and metabolic syndrome? Pharmacologic treatment with T can reduce fat mass and increase lean mass, which may have indirect favorable effects on metabolic control. A critical appraisal of controlled studies learn that these effects remain rather limited and can have at best a marginal effect besides more specific approaches such as based on lifestyle, more specific pharmacologic treatment or bariatric surgery. Is T therapy effective to treat hypogonadism in obese men or men with metabolic syndrome/type 2 diabetes? Yes treatment is effective although possibly less effective than in lean hypogonadal men. How safe is T therapy in these men? Some safety aspects may require special attention (e.g. risk for venous thromboembolism, sleep apnea).
Conclusion
In the present state-of-the-art obesity and metabolic syndrome as such should not be considered as indications for T therapy. Conversely weight loss and improved metabolic control can normalize low T in men with obesity and metabolic syndrome in the absence of other (organic) causes of hypogonadism. In men with obesity and metabolic syndrome and with established hypogonadism (unequivocally low free T and symptoms) T therapy should be considered if measures intended at reducing weight and improving metabolic control fail to normalize or substantially improve serum freeT.

New Aspects of Pituitary Regulation

S19.1

Cytoskeleton, pharmacologic resistance and clinical aggressiveness in pituitary tumours

Giovanna Mantovani
Italy.

Pituitary tumors, are mostly benign, but may cause significant morbidity in affected patients, including visual and neurologic manifestations from mass-effect, or endocrine syndromes caused by hormone hypersecretion. Dopamine (DA) receptor DRD2 and somatostatin (SS) receptors (SSTRs) represent the main targets of pharmacological treatment of pituitary tumors since they mediate inhibitory effects on both hormone secretion and cell proliferation, and their expression is retained by most of these tumors. Although long acting DA and SS analogs are currently used in the treatment of prolactin (PRL)- and growth hormone (GH)-secreting pituitary tumors, respectively, clinical practice indicates a great variability in the frequency and entity of favourable responses. The molecular basis of the pharmacological resistance as well as of clinical aggressiveness are still poorly understood, and several potential molecular mechanisms have been proposed, including defective expression or genetic alterations of DRD2 and SSTRs, or an impaired signal transduction. Recently, cytoskeleton has emerged as novel player implicated in the complex mechanisms of pharmacological resistance of pituitary tumors to DA and SS. In the past 5 years the speaker's group demonstrated that specific cytoskeleton proteins play a key role both in determining tumor clinical aggressiveness and invasion, and in modulating responsiveness to currently used drugs, by regulating receptor localization/signaling. In particular, we demonstrated a role for cytoskeleton protein filamin A (FLNA) in DRD2 and SSTRs receptors expression and signalling in PRL- and GH- secreting tumors, respectively, first revealing a link between FLNA expression and responsiveness of pituitary tumors to pharmacological therapy. Moreover, another cytoskeleton actin binding protein, cofilin, was shown to be a determinant and potential new biomarker for pituitary tumor invasiveness. In this respect, we recently showed that invasiveness of pituitary tumors is promoted by the activation of cofilin, that can be in turn regulated by DRD2. Indeed, DRD2 agonist reduced migration/invasion and increased phosphorylated inactive cofilin in non-functioning pituitary tumoral cells. The talk will provide an overview of the known molecular events involved in SS and DA resistance, focusing on the role played by cytoskeleton by showing both published and unpublished observations.

What fat does with your pituitary

Maria M. Malagon
Spain.

Adipose tissue is a highly active metabolic organ which, together with its classical role as energy storage depot, releases a wide variety of bioactive molecules with signaling properties, the adipokines, that play central roles in the regulation of energy metabolism and homeostasis, immunity and inflammation. Alterations in both adipokine production and lipid metabolism have been proposed to underlie the metabolic and cardiovascular disorders associated to excess body fat accumulation, including insulin resistance, type 2 diabetes, atherosclerosis, dyslipidemia or hypertension. Notably, adipokines and their receptors are also expressed and regulated in other tissues, including the pituitary. We will discuss findings from our group and others on the regulation and molecular mechanisms underlying the action of three major adipokines, leptin, adiponectin, and resistin, on the pituitary cell types as well as their interaction with the major central and peripheral regulators of these cells. Current knowledge, gained from both *in vitro* studies and animal models, including murine and nonhuman-primate species, and human, supports the occurrence of a pituitary-centered local adipokine circuitry which, together with peripheral (i.e. adipose tissue-produced) signaling molecules, may convey metabolic signals to the somatotropic, corticotropic, and reproductive axes. In sum, the pituitary constitutes a relevant site of action for adipokines which likely act as links in the coordinated regulation of metabolism, growth and reproduction.

DOI: 10.1530/endoabs.56.S19.2

S19.3

How cancer treatment effects your pituitary

Frederique Albarel
France.

In recent years, immunotherapy has transformed the treatment in a number of cancers, including melanoma. It is associated with novel autoimmune side effects including endocrinopathies, among which hypophysitis (0.4–20% with Ipilimumab). We carried out a long-term study in endocrinology and dermatology departments of Marseille to characterise ipilimumab-induced hypophysitis in terms of clinical signs, endocrine profile and imaging, at diagnosis and during follow-up. Fifteen patients, treated for malignant melanoma and who presented ipilimumab-induced hypophysitis, were observed between June 2006 and August 2012 in our centre. Symptoms, pituitary function, and pituitary imaging at diagnosis of hypophysitis and during follow-up were recorded. Of 107 patients treated with ipilimumab, 15 (10 mg/kg in 11/15) presented with hypophysitis (14%) at 9.5 ± 9 weeks (mean $\pm$ S.D.) after treatment start, occurring in 66% after the third infusion. The main initial symptoms were headache ($n=13$) and asthenia ($n=11$). All patients but one had at least one hormonal defect: thyrotroph ($n=13$), gonadotroph ($n=12$), or corticotroph ($n=11$) deficiencies. None had diabetes insipidus. Pituitary imaging showed?a moderately enlarged gland in 12 patients. Clinical symptoms improved rapidly on high-dose glucocorticoids ($n=11$) or physiological replacement doses ($n=4$). At the end of follow-up (median 33.6 months, range 7–53.5), corticotroph deficiency remained in 13 patients, 11 recovered thyrotroph and 10 gonadotroph functions. Pituitary imaging remained abnormal in 11 patients. Ipilimumab-induced hypophysitis is a common side effect with frequent hormonal deficiencies at diagnosis. Usually,

hormonal deficiencies improved, except for corticotroph function. Patients receiving these immunomodulatory therapies should be closely monitored especially by systematic baseline hormone measurements after the third infusion and remain? at risk of adrenal insufficiency in the long-term, needing education about adrenal failure risk. We will compare these results with other large international studies, discuss prognostic factors of hypophysitis due to immune check-point inhibitors, possible mechanisms and recommandations about follow-up and treatment.

DOI: 10.1530/endoabs.56.S19.3

All you need to know about lipodystrophy (*Endorsed by Endocrine Connections*)

S20.1

Lipodystrophy as a model for prevalent insulin resistance

David Savage
UK.

All forms of severe lipodystrophy are associated with features of the metabolic syndrome including insulin resistance, T2DM, NAFLD, dyslipidaemia and cardiovascular disease. The question I will address is if this means that what happens in patients with monogenic forms of lipodystrophy is at all relevant to common forms of insulin resistance and the metabolic syndrome.

DOI: 10.1530/endoabs.56.S20.1

S20.2

Acquired forms of lipodystrophy

Giovanni Ceccarini
Italy.

Acquired lipodystrophies (AL) are syndromes characterized by an irreversible loss of subcutaneous adipose tissue and are conventionally distinct in partial (Barraquer-Simons) or generalized forms (Lawrence Syndrome) based on the pattern of adipose tissue disappearance. Alike to congenital forms, AL exhibit metabolic abnormalities that include insulin resistance, diabetes mellitus, hypertliglycerdidemia, reduced leptin levels, hepatomegaly and steatosis. While in most cases of congenital forms of lipodystrophy a genetic alteration can be identified, the pathogenic mechanism responsible for the acquired disease are unknown. Based on the evidence of increased association between AL and autoimmune disorders a reaction against yet-to-be identified white adipose tissue antigens is postulated but the association with autoimmune diseases is variable and any attempt of classification in this context is challenging. Barraquer-Simons syndrome has usually a milder metabolic derangement that may be associated with hypocomplementemia and presence of a 'C3 nefritic factor' auto-antibody, Lawrence syndrome is frequently characterized by the development of severe metabolic complications sometimes difficult to be controlled by standard medical therapies. Other forms of acquired lipodystrophy are iatrogenic. One example being AL secondary to combination anti-retroviral HIV drug treatment. These drugs affect the health of adipose tissue by different mechanisms: generating mitochondrial toxicity, increasing local inflammation, perturbing adipocyte differentiation or impairing hormonal production or signal transduction. Lipodystrophy may also develop after complex treatment related to bone marrow transplant occurring during childhood. Cytotoxic treatments primarily total body irradiation or graft-versus-host disease by taking place during a window of time very sensitive for the commitment of adipose stem cells may affect the normal development of fat mass causing later on lipodystrophy. Bone marrow transplant-induced lipodystrophy is frequently underestimated. Finally, even rarer forms of paraneoplastic, acquired lipodystrophies have been described.

DOI: 10.1530/endoabs.56.S20.2

S20.3

Lipodystrophies, diagnosis and treatment: a step-by-step approach

David Araujo-Vilar
Spain.

Lipodystrophy syndromes are rare heterogeneous disorders characterized by deficiency of adipose tissue, and, frequently associated, but not always, to severe metabolic abnormalities including diabetes mellitus and dyslipidemia. With the exception of HIV-associated lipodystrophy, the other distinct subtypes of lipodystrophy are very infrequent, so they are considered rare diseases. Lipodystrophy is classified as genetic or acquired and by the distribution of fat loss, which can be generalized or partial. In generalized lipodystrophy, adipose tissue is almost absent in patients, whereas in partial lipodystrophy, lipoatrophy affects only specific anatomical sites, and in some cases, lipohypertrophy appears in other sites. Genetic lipodystrophies include Berardinelli-Seip syndrome and Familial Partial Lipodystrophy, but also many different early aging syndromes (progerias) and specific auto-inflammatory syndromes. In this cases, more than 20 genes associated with lipodystrophy have been identified that may assist in diagnosis. Acquired lipodystrophies include, apart HIV-associated lipodystrophy, Lawrence syndrome, Barraquer-Simons syndrome and bone marrow transplant associated lipodystrophy. Because of its rarity and heterogeneity, lipodystrophy may frequently be unrecognized or misdiagnosed, which is concerning because it is progressive and its complications potentially life threatening. Effective management of lipodystrophy includes lifestyle changes and aggressive, evidence-based treatment of comorbidities. Leptin replacement therapy has been found to improve metabolic parameters, mainly in generalized lipodystrophy. In this presentation, it will be described the clinical features of known types of lipodystrophy, an algorithm for differential diagnosis of lipodystrophy subtypes, and suggest specific steps to recognize and diagnose lipodystrophy in the clinical setting.

Fertility in Congenital Adrenal Hyperplasia

Blazej Meczekalski
Poland.

Congenital adrenal hyperplasia (CAH) is defined as several autosomal recessive diseases resulting from mutations of genes for enzymes mediating the biochemical steps of production of mineralocorticoids, glucocorticoids or sex steroids from cholesterol by the adrenal glands. Fertility in women with CAH is essential and underestimated clinical problem. According to current studies patients with classic form of CAH due to 21-hydroxylase deficiency have lower fertility rate that correlate with the severity of mutation. It has complex background which is related to hormonal imbalance, surgery consequences psychological and sexual problems. Menstrual irregularities and anovulation occur frequently in CAH women affecting from 30 to 68% patients. Subfertility problems are milder in patients with nonclassic form of 21-hydroxylase deficiency. Some of these women conceive without treatment. Other women with anovulatory cycles respond to glucocorticoid alone or combined clomiphene citrate. Women with CAH present also higher risk of spontanous abortion than healthy women. Numerous studies reported that glucocorticoid treatment can lower the risk of spontanouse abortion. Males with CAH also may present impaired gonadal function and infertility.CAH patients with fertility problems should be consulted and properly treat.

Bone marrow adipose tissue: starving for attention

William Cawthorn
UK.

Bone marrow adipose tissue (BMAT) accounts for up to 70% of bone marrow volume and over 10% of total adipose mass in lean, healthy humans. BMAT further increases in diverse clinical conditions, including ageing, osteoporosis, obesity/diabetes, glucocorticoid treatment, cancer therapy and, strikingly, during caloric restriction. Many of these conditions are also associated with bone loss and increased fracture risk, and therefore it has been suggested that BMAT might directly impact skeletal remodelling. Recent studies also support a role for bone marrow adipocytes in modulating haematopoiesis, fracture repair and progression of skeletal metastases or myeloid tumours. However, study of BMAT has been relatively limited, and therefore the formation and function of bone marrow adipocytes remains poorly understood. We previously revealed that, during caloric restriction, BMAT contributes to increased circulating levels of adiponectin, a hormone with diverse cardio-metabolic and anti-inflammatory effects. Thus, like white adipose tissue, BMAT is an endocrine organ that can exert systemic effects. My lab is now building on this finding by further investigating the causes and consequences of BMAT formation, in particular during caloric restriction. Our goal is to determine how BMAT impacts metabolic and skeletal health. By combining preclinical models, advanced imaging approaches and clinical sample analyses, our research is beginning to reveal new insights into metabolic and endocrine functions of BMAT; the mechanisms contributing to BMAT formation; and the relationship between BMAT accumulation, bone loss and metabolic health.

Cross-talk between bone marrow and peripheral adipose tissue in man

Peter Arner
Department of Medicine, Karolinska Institutet, Karolinska University Hospital, Stockholm, Sweden.

Previous studies demonstrate unexpectly high human fat cell turnover. About 10% of the total peripheral fat cell pool is renewed every year. In relative terms this turnover is two-fold increased in obesity but reduced in subjects with pernicious adipose morphology (few but large fat cells). High turnover necessitates a renewable source of adipocyte precursors. Two independent studies, using bone marrow transplanted patients as model, demonstrated important contribution of bone marrow precursors to peripheral generation of fat cells. This input occurs throughout the human life span from infancy and onwards. Itis markedly increased among obese subjects where up to 40% of the peripheral fat cells are generated by the bone marrow. Recent studies using advanced FACS sorting and single cell gene expression measures suggest that there is a uniform pool of fat cell precursors in peripheral adipose tissue, indicating that local and bone marrow derived precursors are of the same origin. Thus, cross-talk between bone marrow and peripheral adipose tissue in the generation of fat cells is an important regulatory factor behind formation of human adipose tissue mass and morphology.

Treatment of Pre-Type 2 Diabetes

Riccardo Bonadonna
Italy.

Pre-Type 2 Diabetes has not a commonly shared definition. In this talk, the term will be used to indicate people with impaired fasting glucose and/or impaired glucose tolerance and no evidence of pancreatic beta cell autoimmunity. These people are known to be at increased risk of cardiovascular disease/mortality, yet it it is still unclear whether this abnormal risk can be accounted for by the concomitant presence of well recognized risk indicators/factors, most of which are collected under the umbrella of the Metabolic Syndrome. By the same token, there is no known specific treatment of this increased risk beyond the therapies used for the single known risk factors (therapeutic lifestyle changes, therapies for obesity, dyslipidemia, hypertension, etc.). Type 2 Pre-Diabetes also is a high risk condition for type 2 diabetes. Several clinical trials have documented that primary prevention (and often reversal to normal fasting glucose and normal glucose tolerance) of type 2 diabetes in these people can be achieved by as diverse tools as therapeutic lifestyle changes, or metformin, or acarbose, or pioglitazone, or bariatric surgery etc. In many instances, it is somewhat unclear whether the improvement should be ascribed to the effects of early treatment of diabetes or to a genuine modification of the natural history of the disease. However, beneficial effects may be detected even several years after quitting the preventative intervention. Although therapeutic lifestyle changes should be the mainstay of type 2 diabetes primary prevention, they are not as effectively implemented in standard clinical care as they should, possibly owing to costs and a number of hurdles that both the patient and the health care provider need to overcome. Nevertheless, the agenda of type 2 diabetes worldwide will never meet the challenge of type 2 diabetes pandemics without vast and effective programs of primary prevention.

Ups and downs of hypothalamo-pituitary hormones

S24.1

How Does Pituitary Release its Hormones?

Patrice Mollard
France.

A current challenge in physiology/pathology is translating cell-transduction processes identified *in vitro* into the living organism, especially where cell-cell interaction and dynamics have key functional roles. The pituitary gland, regulating a diverse range of essential physiological functions, exemplifies this challenge: stimulation from the brain is relayed as variable hormone pulses (the hypothalamic-pituitary (HP) system), which are decoded by peripheral organs into differential effects. The stimulatory inputs and intermediary/final secretory output of the HP system have impressive differences in time-scale and the number of cells involved: a few thousand hypothalamic neurons with signalling

frequencies in the millisecond range drive hundreds of thousands of pituitary cells to secrete hormone pulses over a period of hours. These features of the HP system are conserved across a diverse range of mammals. However, how pituitary networks transform hypothalamic inputs into hormone pulses *in vivo* was unknown. Using newly-developed techniques for imaging and manipulating cells *in vivo*, namely in freely-behaving mouse models, we unveiled how the pituitary somatotroph network translates its hypothalamic inputs into GH pulses in the bloodstream.

S24.2

Peripheral activities of growth hormone-releasing hormone (GHRH)

Riccarda Granata
Italy.

Growth hormone-releasing hormone (GHRH) is synthesized in hypothalamic neurons and regulates the secretion of growth hormone (GH) from the pituitary gland. GHRH also displays extra-pituitary activities in a variety of cells and organs expressing both GHRH, GHRH receptor (GHRH-R) and its splice variants (SVs). These include, among others, the retina, pancreas, kidney, skeletal muscle and heart. In the heart, we have demonstrated that GHRH(1-44)NH2 exerts survival and antihypertrophic effects *in vitro* in murine cardiomyocytes and human induced pluripotent stem cell (iPSC)-derived cardiomyocytes, improves heart function and reduces myocardial infarction (MI) in isolated rat hearts. Moreover, we and others have shown that in murine and swine *in vivo* models, agonistic analogs of GHRH, such as MR-409, counteract maladaptive hypertrophy, improve heart function and protect against ischemic injury, suggesting potential therapeutic role in heart failure and regeneration after myocardial infarction. In tumors, GHRH acts as an autocrine/paracrine growth factor and stimulates growth of various cancers. In the last years, many antagonists of GHRH have been synthesized, with potent inhibitory effects on growth of various tumors, including breast, prostate, lung and gastric cancer. Our recent findings indicate that GHRH antagonists MIA602 and MIA690, either alone or in combination with chemotherapics, potently inhibit the growth of human malignant pleural mesothelioma (MPM) cell lines and primary mesothelioma cells *in vitro*, through induction of apoptosis and inhibition of proliferative and survival pathways. Thus, GHRH antagonists may be considered as additional tools for new therapeutic approaches in MPM, for which an effective therapy remains to be established.

S24.3

The role of pituitary hormones (among others) in the generation of metabolic stress responses

Niels Møller
Denmark.

Throughout evolution survival of humanity has relied on the ability to cope with stress, such as fasting, exercise, injury and inflammation. In general these conditions generate a metabolic stress response with release of stress hormones (adrenaline, glucagon, cortisol and growth hormone(GH)) and mobilisation of all major fuel sources - lipids, protein and carbohydrate. In addition bacterial ingredients (eg endotoxin/lipopolysaccharide (LPS)) and cytokines (TNF-alfa, interleukins) have independent metabolic effects including liberation of fat and protein from adipose tissue and muscle and induction of fever('exogenous and endogenous pyrogens'). The exact mechanisms triggering the release of stress hormones are uncertain. An increase in body temperature, whether induced by pyrogens (fever), exercise or heating with hot water, initiates hypersecretion of stress hormones, suggesting that the thermoregulatory unit in the preoptic part of hypothalamus is involved. The metabolic stress response may be divided into a rapid 'fight-or-flight' component, primarily driven by adrenaline and glucagon and a more slow component, driven by cortisol and GH, both being characterised by overall catabolism and increased levels of lactate and ketone body stress metabolites. Infusion studies have shown that: (i) adrenaline, cortisol and GH increase the release of fatty acids and induce insulin resistance (ii) glucagon and cortisol increase protein breakdown and urea formation (iii) all four hormones increase endogenous glucose production and (iv) GH preserves protein by decreasing protein breakdown and urea formation. To test the role of the pituitary gland during metabolic stress we have compared metabolic responses to LPS and TNF-alfa in hypopituitary and control subjects - these studies showed that HP patients had a much lesser increase in lipolysis, protein breakdown and urea formation and that intact pituitary function and appropriate cortisol and GH responses are crucial for a full metabolic stress response.

DOI: 10.1530/endoabs.56.S24.3

Late Breaking

S25.1

Extracellular Vesicles: from waste-containers to new opportunities

Francesc E. Borràs
Spain.

The term Extracellular Vesicles (EVs) encompasses all those vesicular structures (surrounded by a cell membrane) released into the extracellular environment. Virtually all cells are capable of producing EVs through highly conserved mechanisms in evolution. These vesicles serve as a communication channel between different cells of the organism due to their capacity to exchange biomolecules, including proteins, lipids, nucleic acids or carbohydrates. Their membranous packaging gives protection to these molecular messengers, and would provide selectivity to reach possibly distant cells in the organism. Although described in the 80's, the interest in EVs re-emerged in 90's with the description of their ability to present antigens and thus amplify the immune response. Later, the observation that RNA was contained in vesicles pointed to their role as mediators of intercellular communication. Also, as EV composition is dependent on active mechanisms of protein and nucleic acids recruitment, the presence of specific characteristics on the released material spotted on the search for biomarkers of several diseases. Several studies provided evidence that EVs in biological fluids are good source of potential biomarkers for metabolic diseases. Yet, their use as diagnostic and prognostic biomarkers in clinical practice still needs further validation. Importantly, although different isolation methods have been developed for the study of EVs, most of them do not preclude the presence of non-vesicular contaminants. Therefore, it is still necessary to define a consensus technique to overcome the variability of results obtained depending on the technique used. Ideally, this technique must take into account the final objective of the EV preparation (biomarker determination, therapeutic approach, …). An overview of EVs, from their description, methods of isolation and analysis, and application in biomarker discovery will be discussed.

Senescence-associated reprogramming promotes cancer stemness

Clemens A. Schmitt
Germany.

Oncogenic activation and anticancer therapies are known to evoke – especially if apoptotic cell death is no longer available – cellular senescence as another stress-responsive safeguard and ultimate cell-cycle exit program in (pre-)malignant cells. Hence, oncogene-induced senescence (OIS) and therapy-induced senescence (TIS) are considered to operate as important anti-tumor principles. However, we previously reported (Dörr-JR *et al.*, Nature, 2013) that secondary, 'senolytic' elimination of TIS cancer cells improves long-term outcome to therapy, thereby suggesting that lastingly persistent senescent cells might be harmful. Driven by the intriguing overlap of numerous pathway mediators relevant in both stem cell and senescence signaling, we now observed in lymphoma and other cancer types reprogramming of senescent cancer cells into a latent adult tissue stem cell state. Strikingly, these senescent cells exerted their gained stemness upon enforced or spontaneous cell-cycle re-entry out of senescence. As the pivotal underlying mechanism, we identified epigenetic reprogramming into a permissive state for active Wnt signaling, which is maintained in a small but stable fraction of the tumor cells post-senescence. Exploiting a non-stem bulk leukemia model, we found cells incapable of re-initiating the disease to convert into leukemia stem cells via temporarily entering TIS. In this late-breaking presentation, strategies to induce or restore senescence in the first place, and conceptually novel approaches to selectively eliminate these senescent cancer cells subsequently for improved long-term tumor control will be presented and discussed.

LEAP2 is an Endogenous Antagonist of the Ghrelin Receptor

Daniel Kaplan
USA.

Ghrelin, an appetite-stimulatory hormone secreted by the stomach, was discovered as a ligand for the growth hormone secretagogue receptor (GHSR). Through GHSR, ghrelin stimulates growth hormone (GH) secretion, a function that evolved to protect against starvation-induced hypoglycemia. Though the biology mediated by ghrelin has been described in great detail, regulation of ghrelin action is poorly understood. Here, we report the discovery of liver-expressed antimicrobial peptide 2 (LEAP2) as an endogenous antagonist of GHSR. LEAP2 is produced in the liver and small intestine, and its secretion is suppressed by fasting. LEAP2 fully inhibits GHSR activation by ghrelin and blocks the major effects of ghrelin *in vivo*, including food intake, GH release, and maintenance of viable glucose levels during chronic caloric restriction. In contrast, neutralizing antibodies that block endogenous LEAP2 function enhance ghrelin action *in vivo*. Our findings reveal a mechanism for fine tuning ghrelin action in response to changing environmental conditions.

Cortisol: Too much of a Good Thing

S26.1

Genetics of Cushing's disease

Laura C. Hernández Ramírez
USA.

Corticotropinomas represent only a small fraction of all the cases of pituitary adenomas, yet they have the potential for great morbidity and mortality. Presenting clinically as Cushing's disease (CD), corticotropinomas are characterized at the molecular level by resistance to glucocorticoid negative feedback, dysregulation of proteins controlling cell cycle progression, and overexpression of pathways that sustain overactive ACTH production and secretion. Until recently, little was known about the genetic defects underlying most of the cases of CD, and the discovery of somatic gain-of-function USP8 mutations as the most common genetic abnormality in corticotropinomas has represented a breakthrough in the field. Nevertheless, germline causes of CD remain greatly unknown. The vast majority of the patients present sporadically, but CD is part of a growing number of syndromes of isolated pituitary adenoma or multiple endocrine and non-endocrine neoplasia. Although rare, familial forms of CD should be overrepresented among young-onset cases, therefore, pediatric patients represent an excellent opportunity for gene discovery. This talk will review the most recent findings in genetic causes of CD, placed in the context of a large cohort of more than 200 pediatric patients studied at a single center during the last 20 years. The frequency of multiple genetic causes of CD in such setting will be presented, while exploring currently ongoing research projects and discussing new avenues for further investigation. Understanding the genetic defects driving corticotroph tumorigenesis should lead to unraveling novel therapeutic targets. This will hopefully be translated into more efficient strategies for the medical treatment of patients with CD.

S26.2

Hypercortisolism and the brain

Nic van der Wee
The Netherlands.

Background
Alongside various physical symptoms, patients with high levels of cortisol, such as typically found in Cushing's disease, often display a wide variety of neuropsychiatric symptoms such as depression, psychosis, mania and cognitive impairments. This indicates involvement of the central nervous system in hypercortisolism.
Methods
Various neuroimaging approaches can be used to examine the effects of hypercortisolism on the brain. The frequently used structural magnetic resonance imaging (MRI) techniques allow detection of alterations of volume or shape of brain regions or in local grey matter volume. Common functional MRI (fMRI) designs detect changes in task related activity. More novel approaches, such as resting-state fMRI or diffusion tensor imaging (DTI) focus on structural and functional connectivity between brain regions.
Results
Early structural MRI studies in Cushing's disease found indications for bilateral reductions of the volume of the hippocampus and the cerebellum. More recent structural MRI studies also implicate the amygdala and the medial prefrontal cortex, not only in active, but also in remitted hypercortisolism. In addition, specific diffuse alterations of white matter connectivity, suggestive of demyelination were found in both conditions. Furthermore, patients also show disturbed resting state functional connectivity, altered activity during the processing of emotional information and changes in markers of neuronal viability. Data suggests partial reversibility of these functional and structural MRI findings, but longitudinal studies are lacking.
Conclusion
Patients with current or past (endogenous) hypercortisolism show alterations of structure, activity and connectivity of brain circuitry involved in emotion regulation and cognitive processes. Longitudinal studies are lacking and translational approaches are needed to further elucidate the underlying processes.

S26.3

Differentiating Cushing from Pseudo-Cushing

Krystallenia Alexandraki
Greece.

Background
Pseudo-Cushing's syndrome (PCS) constitutes a group of physiological or non-physiological medical conditions that mimic Cushing's syndrome (CS) clinical features along with a mild biochemical hypercortisolaemia which remains under a physiological feedback hormonal control. Physiological conditions such as pregnancy, surgical or emotional stress, severe illness, intense chronic exercise, and non-physiological as chronic alcoholism, obesity, metabolic syndrome, poorly controlled diabetes mellitus, major depression, malnutrition, anorexia nervosa represent a PCS.
Aim of this presentation
The aim of this presentation is to unravel the diagnostic tools that are currently available to differentiate CS from PCS.
Methodology
Differential diagnosis is often challenging since we now frequently see mild cases of CS while symptoms and signs of CS may be present in PCS.
Results
Clinical examination is helpful when signs such as easy bruising without an obvious trauma, facial plethora, proximal myopathy, reddish purple striae (1 cm wide), unexplained osteoporosis or weight gain with decreasing growth in children, suggest hypercortisolism. Biochemical diagnosis in CS includes late-night salivary cortisol (LN-SC), dexamethasone suppression test (DSST), and urinary free cortisol (UFC) as screening tests. However, UFC may be elevated in severe obesity but not in mild or cyclic CS. Dexamethasone suppression-corticotropin-releasing hormone (CRH) test combining the low-dose DSST and the CRH test is based on the fact that dexamethasone suppresses serum cortisol levels in normal individuals as in a small number of those with Cushing's disease (CD), but following CRH administration only patients with CD respond with an increase in ACTH and cortisol secretion. Moreover, desmopressin stimulation test is based on the fact that the vasopressin analogue desmopressin (1-deamino-8D-arginine vasopressin, DDAVP) stimulates ACTH release, representing an aberrant response of neoplastic cells in patients with CD but not in patients with PCS. Finally, LN-SC or midnight serum cortisol demonstrated high diagnostic accuracy in differentiating patients with PCS compared to patients with CS.
Conclusion
Since there is no biochemical suppression or stimulation test and no individual clinical feature that may warrant a 100% diagnostic accuracy for the discrimination of CS from PCS, their combination probably represents the most useful tool for the physicians to challenge this differential diagnosis.

Emerging treatments in osteoporosis

S27.1

Abstract unavailable

S27.2

Novel therapies: PTH-related protein and sclerostin inhibition

Tilman Rachner
Germany.

The treatment of osteoporosis consists of either antiresorptive or anabolic approaches. While there are a number of antiresorptive options available (i.e. bisphosphonates, SERMs and denosumab), teriparatide (PTH 1-34) is currently the only bone anabolic agent approved in the EU. The PTH-related protein (PTHrP) analogue abaloparatide and the sclerostin antibody romosozumab are two anabolic agents that are in the approval process for the treatment of postmenopausal osteoporosis. In the phase 3 ACTIVE trial abaloparatide was compared to placebo and teriparatide for 18 months in postmenopausal women who had already experienced an osteoporotic fracture. Abaloparatide successfully reduced the rate of new vertebral fractures by 86% compared to placebo. Furthermore, abaloparatide achieved greater BMD increases at all measured sites compared to placebo and teriparatide. Based on these results, abaloparatide was FDA approved in April 2017. Romosozumab is a monoclonal antibody that targets the Wnt inhibitor sclerostin. Two phase 3 trials of romosozumab for the treatment of postmenopausal osteoporosis have been completed. The FRAME trial was placebo controlled. After 12 months of romosozumab or placebo, patients were switched to an additional 12 months of denosumab in both groups. The ARCH trial included women that had already experienced a vertebral fracture and compared 12 months of romosozumab to alendronate. After 12 months all patients were switched to open label alendronate. Both trials successfully reached their primary endpoint by reducing vertebral fractures by 75% (FRAME trial) and 48% (ARCH trial) at 24 months, respectively. In the ARCH trial a safety signal for cardiovascular events, not previously seen in other romosozumab trials, was detected with a numerical imbalance between romosozumab (2.5%) and alendronate (1.9%). These results warranted further analyses and have prolonged the approval process for romosozumab.

Sequential and combination therapy for osteoporosis.

Zhanna Belaya
Russia.

Over past years various treatment options for osteoporosis have become available and withdrawn due to side effects or insufficient efficacy. This summary reviews sequential and combination therapy for osteoporosis with the currently approved first line treatments such as potent antiresorbtive (nitrogen-containing bisphosphonates (BP), denosumab (DM)) or anabolic agents (teriparatide, abaloparatide). We assume that all medications are taken with vitamin D and calcium supplements. The differences in mechanisms of action between BP and DM provide explanations in clinical outcome and opportunities in sequential therapy. BP attach to hydroxyapatite preferably on metabolically active bone surfaces, where they are 'ingested' by osteoclasts and promote osteoclast apoptosis. BP can remain in bone tissue for up to 10 years. DM acts by binding to and inhibiting RANKL in circulation, leading to the loss of mature osteoclast formation. DM accesses every bone remodeling unit within circulation and its distribution does not depend on the activity of bone remodeling. In clinical trials, DM given after BP continued to increase bone mineral density (BMD) and produced significantly greater gains in BMD at all measured sites when compared to all BP. Consequently, DM can be given after BP when the treatment goal in BMD gain is not achieved. However, BP also should be given after DM discontinuation to prevent BMD loss. Both VERO and ARCH studies proved that anabolic treatment for osteoporosis is more effective than BP at preventing vertebral fractures in a high risk population (with previous vertebral fractures) in both treatment-naïve or BP treated patients. Consequently, anabolic treatment should be considered either as a first-line treatment in patients with previous vertebral fractures or in case a low-traumatic fracture occurs while on BP treatment. However, the duration of anabolic treatment is limited and requires antiresorbtive medication after discontinuation. The sequential treatment approach in osteoporosis is slightly limited with the result of DATA study, which showed that switching to teriparatide after DM lead to BMD loss and should be considered with caution. According to the DATA study, teriparatide combined with DM gives better BMD gain than both treatments alone. This is the only currently recommended approach using combined treatment in osteoporosis which remains controversial because of the high cost and lack of evidence regarding antifracture benefit.

S28.3

Immunotherapy Related Endocrinopathies

Mark Vanderpump
UK.

Recent advances in immunology have resulted in the development of new classes of immune-modulatory therapy in the management of cancers and an increased overall survival for various cancers. Immune checkpoint direct antibodies block intrinsic down-regulators of immunity, such as cytotoxic T-lymphocyte antigen 4 (CTLA-4) and programmed cell death 1 (PD-1) or its ligand, programmed cell death ligand 1 (PD-L1). As an inevitable consequence of increasing the activity of the immune system, immune checkpoint blockade result in immune-related adverse events (IRAEs). Although any organ can be affected, IRAEs commonly involve endocrine glands. Endocrinopathies described include hypophysitis with or without hypopituitarism, thyroid dysfunction (transient thyrotoxicosis, transient or permanent hypothyroidism, orbitopathy) and rarely adrenalitis and autoimmune insulin-requiring diabetes. The management of hypophysitis, a potentially life-threatening complication, primarily involves replacement of deficient pituitary hormones and consideration of drug discontinuation and/or immunosuppressive glucocorticoid therapy. Hyperthyroidism, most commonly due to a transient thyroiditis than Graves' disease, should be managed conventionally. Primary hypothyroidism, hypoadrenalism and autoimmune diabetes should also be treated with conventional replacement. IRAEs usually develop within the first few weeks to months after treatment initiation but can present after cessation of therapy. Some studies suggest that patients with IRAEs have higher tumour response rates than those without such events, but these findings remain controversial and the development of IRAEs is not required for treatment benefit. There are no clinical or biochemical features which predict those patients who will develop IRAEs. In the absence of clinical trials, management strategies for effectively monitoring or managing specific IRAEs remains variable and are currently based on consensus opinion.

DOI: 10.1530/endoabs.56.S28.3

Thyroid hormone action: regulation and clinical implications

S29.1

Tissue-specific regulation of thyroid hormone action

Balázs Gereben
Hungary.

Thyroid hormone (TH) signalling regulates tissues function in virtually all organs and exerts a striking impact on brain development and function. The major secretory product of the human thyroid gland is thyroxine (T4), a stable pro-hormone. In order to bind the TH receptor TR, T4 needs to get converted to T3 by deiodination. The hypothalamo-pituitary-thyroid (HPT) axis controls circulating TH levels, that show remarkable stability. However, tissue TH action undergoes vigorous changes that is achieved by cell-type specific customization of TH availability by local TH metabolizing deiodinase enzymes and transporters. Region-specific regulation of TH action in the brain is critical to regulate TH-dependent brain function. Importantly, this process is also essential for the generation of T3-mediated negative feedback on hypophysiotropic TRH-synthesizing neurons that are located in the paraventricular nucleus. In the hypothalamus, regulation of region-specific TH action functionally overlaps with central regulation of the HPT axis. Therefore, regulation of hypothalamic TH economy is hallmarked by unique features represented by highly compartmentalised neuro-glial mechanisms. These include TH activation via type 2 deiodinase (D2) in tanycytes, lining the lateral wall and the floor of the third ventricle of the mediobasal hypothalamus; and type 3 deiodinase-mediated TH inactivation that fine tunes TH availability in neurosecretory neurons in a phenotype specific manner. We will discuss recent findings on neuropeptide and ubiquitination mediated regulation of hypothalamic TH metabolism. These studies allow better understanding of hypothalamus-specific TH activation; its impact on the HPT axis; and its hypothalamic and systemic consequences during TH supplementation. Finally, we will discuss the hypothalamic pathogenesis and tissue-specific TH availability during lipopolysaccharide-induced nonthyroidal illness syndrome based on data obtained on our recently generated TH action indicator (THAI) transgenic mouse, allowing the assessment of tissue-specific TH action in the intact context of endogenously expressed regulatory factors of TH economy.

Thyroid hormone economy in human aging

Diana van Heemst
The Netherlands.

Thyroid hormones play an important role in all stages of life, including old age. Several differences have been observed in thyroid function parameters with age, including an increase in circulating thyroid stimulating hormone (TSH) levels gradually increase with age. In order to identify determinants of human longevity, the Leiden Longevity Study (LLS) included 421 families with at least two long-lived Caucasian siblings fulfilling the age criteria (men $\geq$89 years and women $\geq$91 years) without selection on health or demographics. We also included the offspring of these long-lived siblings and partners thereof, serving as a control group. Previously, we found higher TSH secretion and a stronger TSH-fT3 temporal relationship in the offspring compared to controls. Our current research which is performed in the THYRAGE (Resetting the THYRoid axis for prevention of AGE-related diseases and co-morbidities) consortium is devoted at disentangling of the role of thyroid hormone economy in human longevity and age-related diseases, including maintenance and functional decline of the central nervous system, and the musculoskeletal system.

Atypical Genital Development and Hypospadias: a Pediatric Urology perspective from Etiology to Surgery

Nicolas Kalfa
France.

Atypical Genital Development (AGD) is defined as congenital conditions within which the development of chromosomal, gonadal and anatomic sex is atypical. Hypospadias represents one of the aspects of the spectrum of AGD and its less severe for in case of isolated hypospadias. Despite the Consensus Meeting in Chicago in 2005 and an overall accepted classification of ADG, numerous questions remain to be solved. The etiology of AGD and hypospadias is still unclear at the crossroads of genetics, endocrinology and environment. Environmental disrupting chemicals are particularly suspected to participate in the occurrence and the increasing incidence of genital malformations in boys. Controlled prospective studies in patients without any genetic defects on the main candidate genes strongly support the role of environment. Surgical repair of these genital defects is a challenge that aims to provide both a good functional (urinary and sexual) and cosmetic outcome. Technical aspects as well as the age of repair may be of importance. Long-term outcome is still difficult to evaluate due to the heterogeneity of the series, to a wide range of phenotypes and to the evaluation of no-longer used techniques. Prenatal diagnosis of AGD is increasing. Identification of atypical genitalia by prenatal ultrasound remains challenging compared to other defects. Reliable predictive factors to screen the most severe forms of genital malformations are still lacking. What is the clinical spectrum of genital defects diagnosed before birth? What is the rate of associated defects? How to identify predictive factors for severe phenotypes at birth? The late surgery and the no surgery alternatives have recently been proposed. The absence of vital emergency, the absence of the patient's point of view in the early infancy and the questionable value of the parents 'choice lead to new ethical, political and societal questions. But the no surgery option remains a choice. Pros and cons of each attitude remain a hot topic.

Brain structure and function in gender dysphoria

Julie Bakker
Belgium.

The concept of gender identity is uniquely human. Hence we are left with the phenomenon of men and women suffering from Gender Dysphoria (GD) also known as transsexualism to study the origins of gender identity in humans. It has been hypothesized that atypical levels of sex steroids during a perinatal critical period of neuronal sexual differentiation may be involved in the development of GD. In order to test this hypothesis, we investigated brain structure and function in individuals diagnosed with GD using magnetic resonance imaging (MRI). Since GD is often diagnosed in childhood and puberty has been proposed to be an additional organizational period in brain differentiation, we included both prepubertal children and adolescents with GD in our studies. First, we measured brain activation upon exposure to androstadienone, a putative male chemo-signal which evokes sex differences in hypothalamic activation (women $>$ men). We found that hypothalamic responses of both adolescent girls and boys diagnosed

with GD were more similar to their experienced gender than their birth sex, which supports the hypothesis of a sex-atypical brain differentiation in these individuals. At the structural level, we analyzed both regional gray matter (GM) volumes and white matter (WM) microstructure using diffusion tensor imaging. In cis-gender girls, larger GM volumes were observed in the bilateral superior medial frontal and left pre/postcentral cortex, while cis-gender boys had more volume in the bilateral superior-posterior cerebellum and hypothalamus. Within these regions of interest representing sexually dimorphic brain structures, GM volumes of both GD groups deviated from the volumetric characteristics of their birth sex towards those of individuals sharing their gender identity. Furthermore, we found intermediate patterns in WM microstructure in adolescent boys with GD, but only sex-typical ones in adolescent girls with GD. These results on brain structure are thus partially in line with a sex-atypical differentiation of the brain during early development in individuals with GD, but might also suggest that other mechanisms are involved. Indeed, using resting state MRI, we observed GD-specific functional connectivity in the visual network in adolescent girls with GD. The latter is in support of a more recent hypothesis on alterations in brain networks important for own body perception and self-referential processing in individuals with GD.

Special Symposium: Bone & Vitamin D (*Endorsed by Endocrine Connections*)

SS1.1

Free and bound vitamin D and health outcomes.

Inez Schoenmakers
Norwich.

Research into the role of vitamin D in human health has significantly increased. Best known for its role in calcium and bone metabolism, it is now also acknowledged to play a role in non-calcaemic processes, including muscle and immune function. For many of these, randomised controlled trials are underway and mechanisms are only partly understood. The plasma concentration of 25-Hydroxy-vitamin D (25OHD) is considered the best marker of vitamin D status. The free fraction of 25OHD has been proposed as an additional or better measure of tissue availability. Free 25OHD is calculated from total 25OHD, vitamin D binding protein (DBP) and albumin concentrations or directly measured by ELISA. The free hormone theory states that only the free fraction can enter cells. This may however not fully apply to 25OHD since several organs express a megalin-mediated internalisation mechanism for DBP bound metabolites. In healthy people, plasma total and free 25OHD are highly correlated. Specific physiological and pathological conditions are associated with alterations of plasma DBP and the relationship between total and free 25OHD, such as renal disease and pregnancy. The impact of these variations on tissue 25OHD availability is unclear. Compared to total 25OHD, free 25OHD has been reported to be more strongly associated with PTH, BMD and various non-skeletal or calcaemic outcomes (e.g. risk of various types of cancer) in some but not all reports. There is also conflicting evidence regarding racial differences in the total to free 25OHD ratio. These findings may be confounded by methodological issues in one of the DBP assays used, resulting in pronounced differences in DBP concentrations between GC-genotypes. I will review novel research into vitamin D and the current evidence regarding the potential differences between the relationships of free and total 25OHD with health outcomes and the potential role of DBP concentration and genotype.

SS1.2

Vitamin D in critical illness

Karin Amrein
Austria.

Depending on definition and population, vitamin D deficiency (usually 25(OH)D $\leq$20 ng/ml) is present in 30–60% of ICU patients worldwide. Since 2009, observational studies have clearly shown that vitamin D deficiency is linked to excess morbidity and mortality in adults and children including increased organ failure. Preliminary data using metabolomics suggest that several biochemical pathways, which are important for redox regulation and immunomodulation, are affected by vitamin D status. So far, worldwide $<$700 patients have been treated in a very limited number of randomized controlled intervention trials, recently summarized in three different meta-analyses. The largest published study to date, the VITdAL-ICU study (n=475) did not find a difference in the primary outcome length of hospital stay between groups, but there was a significant reduction in mortality in the predefined subgroup of patients with severe vitamin D deficiency. The VIOLET study (USA) and our own VITDALIZE study will together recruit more than 5000 acutely ill patients and answer the question if vitamin D is benefitial in critical illness in the next few years. If the results are positive this would have a huge positive impact on the outcome of critically ill patients worldwide and maybe even change the current inconclusive judgment of the importance of vitamin D for the health of human beings in general.

SS1.3

The effects of Vitamin D deficiency on macrophages function, cholesterol metabolism and cardiometabolic disease

Carlos Bernal-Mizrachi
USA.

Vitamin D has been shown not only to be important for bone and calcium metabolism but also for homeostasis of critical tissues involved in vascular disease. The vitamin D receptor (VDR) and the 1a-hydroxylase enzyme are present in critical cells implicated in the development of vascular disease. Vitamin D influences multiple mechanisms to decrease vascular inflammation: it suppresses the renin-angiotensin system, promotes endothelial nitric oxide release, decreases vascular inflammatory markers and cholesterol deposition, and imbues immune cells with anti-inflammatory properties. Studies in our mouse models of diet-induced insulin resistance show that vitamin D deficiency or conditional deletion of VDR in macrophages promotes insulin resistance, renin-dependent hypertension, and accelerates atherosclerosis. In type 2 diabetes patients, vitamin D deficiency promotes a pro-inflammatory monocyte phenotype with increased adhesion and migration to endothelial cells. Conversely, 25(OH)D or 1,25(OH)2D3 supplementation in culture suppresses this pro-inflammatory monocyte phenotype and reduces cellular cholesterol content by downregulation of ER stress, suggesting that reduced monocyte vitamin D signaling is a critical mechanism for vascular invasion and atherosclerosis. Human observational studies indicate consistent associations between low 25(OH)D levels and increased cardiovascular disease, but the effects of vitamin D supplementation for prevention are conflicting, and study design limitations preclude adequate conclusions.

Guidelines: ESE - ENSAT guidelines on the management of adrenocortical carcinoma in adults

GL1.1

ESE - ENSAT guidelines on the management of adrenocortical carcinoma in adults

Martin Fassnacht
Germany.

In our session we will present for the first time the results of our research and consensus process on the development of clinical practice guideline on adrenocortical carcinoma. A multidisciplinary team of 10 clinical and methodological experts reviewed the entire literature until 31.12.2017 and formulated recommendations on all aspects of the clinical management of adult patients with adrenocortical carcinoma.

Endo-ERN: concrete examples of added value for patient care

ERN1.1

Introduction, structure, and virtual consultation using the EU-ERN CPMS

Alberto Pereira
The Netherlands.

The mission of the European Reference Network on Rare Endocrine Conditions (Endo-ERN) is to reduce and ultimately abolish inaequalities in care for patients with rare endocrine conditions across Europe. Endo-ERN provides equality between paediatric and adult patients, and is supported by the European Society of Endocrinology and the European Society of Paediatric Endocrinology. In order to achieve Endo-ERN's mission and accomplish the concrete objectives the first year was mainly focused on mapping the knowledge base, innovation capacity, and quality of care for each of the main thematic groups, while the second year is now focused on the stepwise execution/ implementation of the planning that was generated in the 1st year. This includes: i) an educational program that fits with the needs of the Endo- ERN members, ii)(in extend of this support) an e-environment that supports all actions of Endo-ERN, iii) Endo-ERN influence on setting guidelines and research agendas, iv) a functional clinical support Operational Helpdesk to democratise access to high-expertise consultations, that also enables linking to registries, and v) a start with an inter-connected diagnostic laboratory network, and setting the standards. The ERN-IT Platform provides the virtual link for the Networks, and includes the public website, the ERN Collaborative Platform, and the Clinical Patient Management system (CPMS). The CPMS has recently been launched to support the cross-border activities of the ERNs enabling virtual consultations by expert boards. To ensure adequate and efficient use of CPMS an operational helpdesks for paediatric and adult endocrinology in Luebeck and Leiden will be instituted. In addition, CPMS will be piloted for a small group of conditions requiring cross-border input and virtual tools for interpreting complex biochemistry. Lastly, CPMS will be linked to EuRRECa (European Registry for Rare Endocrine Conditions) platform.

ERN1.2

Caring for endocrinology across the life span: DSD and Hypogonadotropic hypogonadism

Olaf Hiort
Germany.

The European Reference Network on Rare Endocrine Conditions (Endo-ERN) was founded to improve access to high-quality health care across Europe for patients with rare hormonal disorders. It is meant to encompass all rare endocrine conditions with an equal distribution of paediatric and adult care. The Main Thematic Group (MTG) 'Sex Development and Maturation' is dedicated to the medical conditions involving the reproductive system in both sexes, including the broad ranges of Disorders of Sex Development (DSD) and hypogonadotropic hypogonadism. Medical issues that require special attention range from prenatal therapy in Congenital Adrenal Hyperplasia (CAH) to diagnosis and possibly gender assessment in DSD conditions as well as to hormonal therapies at the time of pubertal development and reproductive assessment in adulthood. The MTG stems from two previous European networks funded by the Cooperation of Science and Technology (COST) in Horizon 2020. The COST Actions GnRHnetwork and DSDnet recently met with the Endo-ERN MTG in order to discuss the most important issues for future care and also scientific progress. In order to provide a solid basis for the future approaches, the need for laboratory comparability across the life-span was emphasized, as well as the compilation of appropriate patient cohorts for clinical trials. Guidelines will help with the enhancement of common and equal management of patients with these rare conditions. Furthermore, through Endo-ERN and the inclusion of relevant patient advocates, this group will be able to pose with relevant stakeholders in the societal discussions on gender issues and overall management of DSD and intersex conditions. Additionally, the MTG can and will link with scientific projects involving basic science, because research on adequate model systems will always provide the basis for further studies on management in humans.

ESE Endo-ERN symposium: Patient and family perspectives, Manuela Brösamle, Endo-ERN ePAG

Manuela Brösamle
Germany.

Introduction
The presentation is based on experiences and opinions of CAH patients represented by German AGS parents and patient initiatives.
Meaning of patient and family perspectives
The aim is to provide an overview about wishes and expectations of German CAH patients. A special view will be given to quality of live and influencing factors of treatment.
Examples of family perspectives
The importance and meaning of patient and family perspectives will be discussed using some concrete examples. The examples relate to both male and female patients.
Conclusion
Factors of influence on patient quality of life. Family perspectives are depending on good medical treatment and education from childhood to adulthood and beyond.
Requirements of good family perspectives
Requirements of good family perspectives are for instance education of the patient and availability of specialized physicians.
Next Steps and To Do's
Finally, the presentation will discuss the endeavours faced and which steps should be prioritized to ensure optimal patient way of life.

A comprehensive map of splicing alterations in small cell lung cancer

Eduardo Eyras
Spain.

Small cell lung cancer (SCLC) is the most aggressive form of lung cancer as it lacks known targets of therapy. 5-year survival is only 5% and patients quickly develop therapy resistance by yet unknown mechanisms. The lack of advances is also related to the fact that SCLC is not part of the ICGC or TCGA cancer genomics projects, and patient material is hard to obtain. SCLC presents frequent amplifications in genes of the MYC family, which are known regulators of splicing factors, but the role of splicing in therapy and resistance is not known yet. We have recently shown that splicing alterations provide new mechanisms of tumor progression [1], and that by analyzing the somatic mutations according to RNA selection processes, new impacts on RNA-processing can be uncovered [2] We have now expanded these efforts to study non-coding variants and RNA-processing alterations in SCLC. We have collected the largest compendium of somatic mutation and RNA-seq data available to date for SCLC samples from multiple sources [3–5]. By integrating this data we have obtained a total of 2.579 splicing altering somatic mutations on 63 samples. Genes with the largest splicing changes included several linked previously with cancer, like LIMS1. Intron retention cases include genes involved in DNA repair, like POLD3; or the NOTCH pathway, like KIT. Among the cryptic junctions showing expression in SCLC we recovered the cases previously reported for RB1 and TP73, plus 86 new ones, including cases in the genes of the Wnt signaling pathway ASPM and CTNND2. This is the largest analysis performed to date of RNA processing alterations in SCLC. The results could lead to the uncovering of novel targets of therapy.

Reprgrammin strategies to obtain functional endocrine units; focus on the adrenal cortex

Leonardo Guasti
UK.

Primary or secondary adrenal insufficiency (AI) results from adrenal failure or impairment of the hypothalamic-pituitary axis, respectively. In both cases, the cortex fails to secrete sufficient amounts of glucocorticoids and adrenal androgens, but in primary AI the clinical consequences of aldosterone deficiency make this a more lethal condition. The most frequent cause of primary AI is autosomal recessive congenital adrenal hyperplasia (CAH), which results from defects in enzymes involved in steroid biosynthesis. Patients with AI need life-long management with exogenous steroids: this can be challenging as no drug suitably mimics the diurnal pattern of cortisol, and objective variables measuring the quality of replacement therapy are lacking. Fine-tuning of replacement therapy leaves only a narrow margin for improvement: under-replacement can result in severe impairment of well-being and incipient crisis, while even subtle, chronic over-replacement has the potential to contribute to excess morbidity including obesity, osteoporosis, hypertension and impaired glucose tolerance. Therefore, better treatment solutions are urgently needed. The ability to generate donor-specific and functional adrenocortical-like cells would facilitate i) the next generation of cell-based treatments for AI; ii) the modelling of adrenal specific diseases and iii) the testing of personalised interventions on cells derived from patients. We have generated human induced steroidogenic cells (hiSCs) using a variety of human cell sources, such as fibroblasts, blood- and urine-derived. reprogramming was achieved threough forced expression of Steroidogenic Factor-1 and activation of protein kinase-A pathway in the presence of luteinizing hormone- releasing hormone. hiSCs have ultrastructural features resembling steroid-secreting cells, express steroidogenic enzymes and secrete steroid hormones in response to both pharmacological and physiological stimuli. hiSCs can successfully engraft into the mouse kidney capsule and can undergo differentiation when injected intra-adrenally. Importantly, the hypocortisolism of hiSCs derived from patients with adrenal insufficiency due to congenital adrenal hyperplasia can be rescued by expressing the wild-type version of the defective disease-causing enzymes. This technology provides an effective tool with many potential applications to study adrenal pathobiology in a personalized manner and opens venues for the development of precision therapies.

3D visualisation of the HPG axis in mice and humans

Paolo Giacobini
France.

Histology has been a golden tool for biological research for decades. Nevertheless, whole organ histology is extremely time and resource consuming and most of the time impossible due to the distortions and lack of algorithms to correctly align thousands of sections. Light sheet-based microscopy is an important, innovative tool that offers nondestructive optical sectioning of selectively stained thick tissues at a spatial resolution between that of micro MRI and confocal microscopy and high-speed scanning capability. Recently developed tissue clearing methods coupled with laser-scanning microscopy made it possible to explore intact organs and to accurately acquire complete histological information about labeled cells/molecules in large tissues, including their spatial density and distribution. Among those techniques, the process called 3D imaging of solvent-cleared organs (3DISCO), has been proved to be a simple and inexpensive method for 3D analysis of immunolabelled transparent organs in embryonic and postnatal animals. Herein, combining 3DISCO with light-sheet laser-scanning ultramicroscopy, we studied the development and 3D organization of the hypothalamic-pituitary-gonadal axis in several mammalian species. Our 3D data demonstrate that with thorough biochemical optimization, we can now detect morphogenetic processes, cell migration and terminal differentiation during embryonic and postnatal development of mice. Moreover, this technique can be adapted to human tissues for volume imaging during fetal development as well as for the analysis of adult post-mortem tissues. The approach thus opens a novel route for high-resolution studies of brain architecture in mammals in physiological and pathological conditions.

Circulating miRNAs in endocrine tumours

Peter Igaz
Hungary.

The discovery of microRNAs (miRNAs) as the endogenous mediators of RNA interference was a major event in contemporary biomedical research. miRNAs were shown to be involved in the regulation of gene expression affecting several basic physiological and pathological processes as parts of the epigenetic machinery. Differential expression of tissue miRNAs were described in several diseases including tumours. In tumours, up- and down-regulated miRNAs can be classified as oncogenes or tumour suppressors, and miRNAs were established as markers of malignancy and prognosis. Novel findings have shown that miRNAs are found in body fluids, as well. miRNAs can be released via passive route (necrosis, inflammation) or by active secretion either in membrane vesicles (exosomes, microvesicles) or in association with macromolecular complexes (Argonaute 2 protein, or high-density lipoprotein). The circulating miRNAs of the blood can be exploited as a form of liquid biopsy, where miRNAs deliver epigenetic gene expression information from various tissues. From a biological point of view, actively secreted miRNAs in exosomes could be the most

interesting. There are several forms of endocrine tumours, where the preoperative diagnosis of malignancy is difficult, such as adrenal tumours. Our research group has been involved in several studies on tissue and circulating miRNA expression in adrenal tumours.Circulating miRNAs can be determined both from unfractionated whole plasm/serum or from extracellular vesicles. The miRNA yield of whole plasm is higher, but actively secreted miRNAs in exosomes could be more specific. In adrenocortical tumours, we could achieve high specificity and sensitivity of exosomal miR-483-5p for the diagnosis of malignancy. Polymerase chain reaction or next generation sequencing are the best for the analysis of plasma miRNAs. The choice of reference gene in PCR studies is a major debated issue. In the session, the theoretical basis, methodological issues and potential applications of this novel field will be discussed.

Adrenal venous sampling vs. imaging for primary aldosteronism: beware of the caveats! (*Endorsed by the European Journal of Endocrinology*)

D1.1

Adrenal venous sampling vs imaging for primary aldosteronism

Per Hellman
Sweden.

In the work-up for primary aldosteronism (PA) adrenal venous sampling (AVS) is a corner stone. Although challenged during recent years by means of being insensitive and invasive, it remains the so far only method for lateralization of PA. Indeed, omission of AVS in young patients with a clear adrenal nodule on a CT scan, and development of noninvasive alternatives using positron emission tomography (PET), may replace AVS in certain subgroups. A review of the curent status of AVS will be presented.

DOI: 10.1530/endoabs.56.D1.1

D1.2

Against – Adrenal venous sampling vs. imaging for primary aldosteronism: beware of the caveats!

Jaap Deinum
The Netherlands.

Primary aldosteronism (PA), the most frequent form of secondary hypertension, has two main causes: unilateral aldosterone-producing adenoma (APA) and bilateral adrenocortical hyperplasia. APA has the potential for cure of PA by adrenalectomy. In order to identify an APA guidelines advocate adrenal vein sampling (AVS), a technically demanding and expensive procedure of limited availability and with a controversy-raising variety in protocols. CT-scanning is a cheaper and simpler alternative to AVS but its concordance with AVS is poor. The supposed superiority of AVS over CT for selecting patients for adrenalectomy is mostly based on retrospective studies in which management was only guided by AVS and clinical follow-up was often poor, leading to a high risk of bias. We therefore performed a more appropriate, pragmatic diagnostic randomised trial, SPARTACUS (Subtyping PA: a Randomized Trial Comparing AVS and Computed Tomography Scan) in which we used clinical outcomes to determine the clinical value of AVS and CT in 200 patients with PA. The main finding is that clinical outcome after 1 year follow-up, defined as the intensity of antihypertensive treatment, is similar regardless if AVS or CT is used to guide management. Blood pressure, assessed by ambulatory blood pressure measurement, was identical in both groups. The other secondary outcomes, biochemical cure, quality of life were not significantly different. AVS-based management was much more expensive. Intriguingly the concordance between CT and AVS in the AVS arm was only 50%, suggesting that both tests are imperfect to predict biochemical cure after adrenalectomy. Before we can support or discard AVS or CT for subtyping of PA we need more studies with better design. In this debate I will explore what scientific questions must be answered and which hurdles are to be taken in order to improve diagnostic management in PA.

Subclinical hypothyroidism is a disease

D3.1

FOR – subclinicl hypothyroidism is a disease

Stefano Mariotti
Italy.

Primary subclinical hypothyroidism (SH) is commonly defined by laboratory parameters (TSH above the commonly accepted reference range of about 0.4–4.0 mU/l with normal FT4). This definition does not implies actual thyroid dysfunction, since individual variations of hypothalamic-pituitary feedback set point due to endogenous (genetic, age/gender, NTIS) or exogenous (e.g. drugs) factors may lead to TSH increase in the absence of thyroid disease. Thus, to answer the question of this debate if SH 'is a disease', the first step is to not consider SH any condition of increased TSH and serum FT4 without a complete clinical evaluation and further laboratory (thyroid autoantibody assay) and instrumental (ultrasound) investigations. Moreover, the term "subclinical" is somewhat misleading, since symptoms of mild or very mild thyroid failure may be absent or non-specific, with many cases of "clinical" primary hypothyroidism (increased TSH, low FT4) very difficult to recognize on clinical grounds, especially in the elderly. The term of 'mild' (or very mild) primary hypothyroidism is therefore more appropriate. Thus, when increased TSH is associated with one known cause of thyroid failure (mostly autoimmune thyroiditis, previous thyroid surgery or radiation), there should be no doubt that mild primary hypothyroidism 'is a (thyroid) disease'. A different question is whether this mild disease needs to be treated with levothyroxine (LT4), as clinical/overt hypothyroidism. Arguments in favour to treat mild primary hypothyroidism include the risk of progression to overt thyroid failure, increased cardiovascular risk (dyslipidemia, increased atherosclerosis and ischemic heart disease, hypertension, decreased endothelial function, decreased systolic and diastolic heart function), potential impairment of neuro-psychological fetal development in pregnant women and mood/cognition disorders. Although several short-term intervention studies provide evidence for improvement of several cardiovascular and cognitive parameters, the main argument against treatment is represented by the lack of convincing evidence from prospective controlled trials. However, epidemiological data suggest that mild hypothyroidism may be 'protective' in the elderly. Nevertheless, several retrospective meta-analyses consistently indicate higher cardiovascular risk in subclinical hypothyroid subjects aged <65 yrs, suggesting the need of prospective controlled trials to ascertain whether and to what extent an early therapeutic intervention may be envisaged in younger subjects with mild thyroid failure. In conclusion, if increased serum TSH is the consequence of a primary thyroid pathology, subclinical (mild) hypothyroidism 'is' a disease. The question of whether and when this mild disease deserves treatment is far to be answered.

AMH as the Primary Marker for Fertility

D4.1

AMH is the primary marker for fertility (Pro)

Didier Dewailly
France.

In women, the anti-Mullerian hormone (AMH) is secreted by the granulosa cells of the growing follicles. Its assay is therefore strongly correlated with the antral follicular count and represents a reliable marker of the ovarian reserve. It also has the advantage of being very reproducible since it has little intra- and inter-cyclic variation. However, it seems to be a good quantitative reflection of the ovarian reserve but not qualitative. This drawback does not make this assay a good predictor of female fertility in the general population. On the other hand, the interest of AMH assay in the context of certain situations at risk or in the management of various pathologies is well established and it can become an indirect marker of female fertility. Indeed, the AMH assay is very useful in screening for situations at risk such as early ovarian insufficiency or polycystic ovary syndrome. Its interest is no longer to prove in assisted reproductive techniques where it is a valuable aid to the choice of techniques, ovarian stimulation protocols and dose of gonadotropins. The AMH assay is also very informative in the follow-up of cancer patients who have required the use of ovario-toxic products or who have undergone mutilating surgeries for the ovaries. In conclusion, although it can not be considered in isolation as a reliable predictor of the chance of pregnancy in women, the AMH assay is one of the essential measures in the management of female fertility.

DOI: 10.1530/endoabs.56.D4.1

D4.2

Debate: AMH as the primary marker for fertility

Joop Laven
The Netherlands.

AMH is a dimeric protein hormone and a member of the TGF-β superfamily. AMH is first expressed in granulosa cells of primary follicles and expression persists in growing follicles up to 6 mm in diameter. In follicle stages beyond 8 mm, AMH expression diminishes and ultimately becomes undetectable once the follicle becomes FSH-dependent1. Its measurement is strongly correlated with antral follicle count and represents a reliable marker of ovarian function. It is reproducible since it has little variation within and between cycles. However AMH assays may display differential results due to pre-analytical proteolysis, conformational changes of the AMH dimer, interfering substances, sample handling, transport and storage conditions, factors underreported in the literature. Finally, there is a urgent need for an international reference standard. Although AMH seems to be a good quantitative reflection of ovarian reserve, it does not assess oocyte quality. This drawback precludes any good prediction of female fertility in any patient population. Although, AMH constitutes a promising marker for age at natural menopause (ANM). As such AMH does not predict the extremes of menopause very well and predicted ages show wide confidence intervals. Hence AMH as a marker for ANM clearly needs improvement before they can be used in the clinical setting. On the contrary AMH assays might become an indirect marker of ovarian function in some women at risk for premature ovarian failure or in the polycystic ovary syndrome. Its interest is no more to be proven in assisted reproductive technology where it is a valuable aid in determining gonadotrophin dosage. AMH is finally very informative in monitoring cancer patients after gonadotoxic drugs or having undergone mutilating ovarian surgeries. In conclusion, although AMH assays are widely used AMH itself is not a reliable predictor of pregnancy in women and therefore it does not predict fertility!

DOI: 10.1530/endoabs.56.D4.2

Pregnant women should be screened for thyroid hormones and antibodies

D5.1

Abstract unavailable.

D5.2

AGAINST: 'Pregnant women should be screened for thyroid hormones and antibodies'

Brigitte Velkeniers & David Unuane
Department of Endocrinology, UZ Brussel, Vrije Universiteit Brussel, Laarbeeklaan, 101 1090 Brussels.

Screening is a process of identifying apparently healthy people at increased risk of a disease or condition. They can then be offered appropriate treatment to reduce the risk arising from the disease or condition.
Thyroid autoimmunity (TAI), defined by the presence of antibodies against thyroperoxidase and thyroglobulin, have been associated with adverse pregnancy outcomes, infertility, and impaired child neurodevelopment. However, associations do not necessarily mean a causal relationship. Other risk factors associated with TAI should be considered, including other organ specific autoimmunity, age, smoking and BMI. Moreover, thyroid autoimmunity can merely reflect an immune dysfunction. TAI is often related to the development of subclinical hypothyroidism during pregnancy, with an inadequate thyroid response to human chorionic gonadotropin. So far, the use of levothyroxine in interventional studies has not provided sufficient evidence to recommend its use in euthyroid TAI pregnant women. It remains unclear whether potential benefits outweigh the possible harm, due to overtreatment during pregnancy. Thyroid hormones (TSH, fT4) are important to sustain pregnancy and neonatal outcome. Clinical thyroid dysfunction (hypothyroidism, hyperthyroidism) should be diagnosed and treated. Subclinical hyperthyroidism has not been associated with adverse pregnancy outcomes. However uncertainty persists with regard to subclinical hypothyroidism. As for TAI, subclinical hypothyroidism has been associated with impaired child neurodevelopment and adverse obstetric outcomes. Intervention studies with levothyroxine in pregnant patients with subclinical hypothyroidism were unable to sustain an improvement in offspring's neuropsychological development. The evidence for intervention with a reduction in adverse obstetric outcomes in this population is weak, with studies lacking adequate power and appropriate design. Also policy on cut-off levels to define TAI and suitable thyroid hormones in pregnancy remains to be determined. Therefore, we recommend against universal screening for TAI and thyroid hormones in pregnant women, but do acknowledge the use of a case finding approach.

Abstract unavailable.

D6.2

Endocrine disruptors: Regulatory vs. Scientific Perspectives (regulatory view point)

Sharon Munn
Italy.

Societal concerns have been growing with respect to the impact of manufactured chemicals in the environment on human health and wildlife and particularly the link to endocrine-related disorders. The European Commission issued a Community Strategy on endocrine disruptors (EDs) in 1999 to identify the causes and consequences of endocrine disruption and to identify appropriate policy action. The implementation of this strategy has led to a greater understanding of endocrine disruption from EU supported research; identification of priority lists of substances for further investigation with respect to their role in endocrine disruption; the validation and acceptance of OECD test guidelines for the identification of EDs; and the introduction of legislative provisions within chemical control-related legislation. Under the authorisation schemes for pesticides (Reg. (EC) 1107/2009) and biocides (Reg. (EU) 528/2012) criteria were required to be set for the identification of endocrine disruptors. These criteria (adopted for biocides in September 2017 and still undergoing the adoption process for pesticides) are based on the WHO/IPCS definition and can be

considered to consist of 3 main elements requiring evidence for i) endocrine activity, ii) an adverse effect, and iii) a biologically plausible link between elements i) and ii). The drafting of guidance on the implementation of the criteria is now underway by the responsible European Agencies, EFSA and ECHA. This guidance is built on the currently available OECD test guidelines relevant to the investigation of a chemical's potential to interfere with oestrogen, androgen or thyroid hormone action. A systematic review of the scientific literature is also required which could uncover evidence for activity on other endocrine pathways. In order to improve the current suite of regulatory test guidelines the EC is funding activities to identify the gaps and propose solutions to fill the gaps through the multi-disciplinary engagement of relevant experts, particularly within the fields of toxicology and endocrinology.

Using diabetes technologies to improve patient self care

Valeria Alcántara-Aragón
Spain.

Diabetes technologies are evolving rapidly. They offer exciting opportunities to improve patient self-care but they may also be challenging for both patients and health-care providers. Thus, the use of technology may empower or burden. To understand and benefit from the use of these technologies we must first go beyond HbA1c, understand what truly matters to our patients, and what technology can provide in this setting. Available data on the use of technology including insulin pumps, continuous glucose monitoring (CGM), flash monitoring, wearables, web and mobile apps, as well as integrated systems will be reviewed. The review of these technologies will focus on how they may improve patient's safety, self-efficacy, comfort and normalization. The use of these technologies is usually not optimal unless there is appropriate therapeutic education by health-care providers, the key aspects to consider in the process will also be evaluated. Clinical trial results from the use of these technologies are necessary, important and will be the basis of the review; however information and experience from true-life conditions are priceless and what makes a true expert. To provide this valuable perspective, the true-life conditions and diabetes technology expert, Adam Brown will also provide his input on how to use these technologies to improve patient self-care.

Acromegaly: Optimal management after surgery

Michal Krsek
Czech Republic.

Acromegaly is a rare condition caused by overproduction of growth hormone (GH). Early diagnosis, optimal treatment and follow-up is essential for prognosis of patients with acromegaly. Surgery is first choice treatment of acromegaly. Cure rates range around 80% (63–100%) in GH secreting microadenomas, however only about 50% (40–72) in macroadenomas. If not curable, surgery has to be followed by other treatment modalities to achieve treatment goals that are according to Endocrine Society guidelines normalization of age adjusted IGF-I serum levels and random GH levels <1 μg/l. Medical tools for GH secreting adenomas include dopaminergic agonists, somatostatin analogues (SSA) and pegvisomant. Radiotherapeutic techniques include stereotactic radiosurgery and fractionated stereotactic radiotherapy. Cabergoline is effective usually in patients with modest hormonal activity only. In monotherapy normalizes IGF-I levels in approximately 30% of patients. However, it could be useful in combination with other drugs. SSA are probably most frequently employed in therapy of residual disease taking the advantage of combination of antisecretory and antitumoral affects. Hormonal normalization rate of 'classical' SSA, lanretoide and octreotide, is approximately 55%, moreover, they lead to significant shrinkage (>20% volume %) of tumorous tissue in approximately 57% of patients. In patients resistant to classical SSA, multiligand SSA pasireotide can be successfully applied and is effective in biochemical control in about 20% of previously resistant patients. Pasireotide is a GH receptor antagonist able to block GH biological action and decrease IGF-I production. It is effective in most patients in normalizing IGF-I levels depending on the dose used. However, it has no antitumoral affect. Radiotherapy is a third-line therapy according to Endocrine Society guideline. Advantage of radiotherapy is its antitumoral effect enabling to withdraw medical therapy in most patients. Proton beam therapy has recently been used for treatment of acromegaly.

Managing delayed puberty

Taneli Raivio
Finland.

Delayed puberty (DP) is traditionally defined as the absence of testicular enlargement by the age of 14 years in boys and absence of breast development by 13 years in girls (1). In both sexes, DP is most frequently caused by constitutional delay of growth and puberty (CDGP), which represents a late variant of the normal timing of puberty (1-3). Other possible causes for DP include permanent hypogonadotropic hypogonadism (HH), functional hypogonadotropic hypogonadism and hypergonadotropic hypogonadism due to gonadal failure. Differential diagnosis of DP can be sometimes challenging, and especially, differentiating between CDGP and partial congenital HH can be notoriously difficult, if not impossible. In our recent analysis of a large patient series from a single academic center, we described the etiology of DP in 174 boys and 70 girls, identified prognostic markers to help the diagnostic procedure, and investigated the relationship between linear growth and different etiologies of DP (3). In this case-based session, we will briefly review the basic concepts of puberty, consider different aspects of the diagnostic procedure in patients with DP in the light of this data, review the treatment options, and discuss the importance of accurate and timely diagnosis.

Osteoporosis in men: management of bone health in the endocrine outpatient clinic

Dirk Vabderschueren
Belgium.

Several wrong conceptions persits with respect to male osteoporosis which unfortunately lead to under- diagnosis as well as under- treatment of this disease. Osteoporosis is still considered a female disorder. However, osteoporosis is not a rare condition especially in elderly and/or hypogonadal men. Moreover, fractures in elderly men are even more strongly associated with mortality than in women. Most of the risk factors for osteoporosis are also similar in men compared to women. These risk factors are easily identified but remain still insufficiently recognized. Dual energy dual energy absorptiometry is also a useful additional tool for the diagnosis of male as well as postmenopausal osteoporosis despites gender differences in bone structure. Reduction of fracture risk as result of antiresorptive as well anabolic anti-osteoporotic therapy is less well established in men than in postmenopausal women. Available data however indicate the outcome of anti-osteoporotic treatment in men at high risk for osteoporosis is not different from women. Therefore, current therapeutic lethargy in men at risk of fractures is not justified. The efficacy of testosterone supplementation with respect to prevention and treatment of osteoporosis however is less well documented in these men. In this lecture a practical approach for management of men with low and borderline low testosterone levels will therefore be presented with specific reference to a recent guideline on this topic of the European academy of andrology.

Medullary thyroid cancer beyond surgery

Ana Luiza Maia
Brazil.

Medullary thyroid carcinoma (MTC) is a rare thyroid C cell malignant tumor that accounts for 3-4% of thyroid gland neoplasias. MTC may occur sporadically or be inherited. Hereditary MTC appears as part of the MEN 2 syndrome. Germ-line mutations of the RET proto-oncogene cause hereditary cancer, whereas somatic

mutations are frequently present in sporadic disease. Currently, early MTC diagnosis followed by total thyroidectomy offers the only possibility of the cure of the disease. Although the majority of MTC patients have a good prognosis, a subgroup of patients develops progressive disease and requires systemic therapy. We will focus on the current therapeutic approaches for patients with advanced disease discussing the advantages and disadvantages of molecular targeted therapies that inhibit RET and other tyrosine kinase receptors involved in tumor angiogenesis. Treatment with tyrosine kinase inhibitors (TKI) increases the progression-free survival but we still needed to answer the question of whether it impacts on overall survival. Hopefully, the cumulative knowledge about molecular profiling of MTC and the TKI-associated side effects will help in choosing the best therapeutic approach to enhance their benefits.

Long-term implications of hypoglycaemia in diabetes Dr Ilhan Satman, Istanbul University, Turkey

Ilhan Satman
Turkey.

Hypoglycaemia is associated with considerable morbidity and even mortality in type 1, and less likely in type 2 diabetes. Generally, hypoglycaemia is accepted as a surrogate marker of poor health as it is likely to be more prevalent in renal and liver failures, which independently increase cardiovascular diasease (CVD) and neurocognitive risks. Hypoglycaemia, have been implicated with a fortunately rare but tragic event, 'dead-in-bed' syndrome. It has been hypothesised that nocturnal hypoglycaemia can lead to the dead-in-bed syndrome via its pro-arrhythmogenic effects. Hypopglycaemia, due to its effects on inflammation and thrombosis can increase CV risk in both types of diabetes. In addition to adverse biological effects, repeated hypoglycaemias has been shown to significantly impair quality of life, and leading to depression in older people with diabetes. Negative psychological effects of hypoglycaemia are particularly deleterious as they can establish a cognitive barrier preventing treatment of future episodes and thus interfering the treatment of hypoglycemia-associated autonomic failure (HAAF). Hypoglycaemia has a significant impact on the risk of fall and related injuries, and dementia or cognitive impairment by various mechanisms. Hypoglycaemia is a major limiting factor for optimising glycaemic control, especially in patients with long-duration type 1, as well as in older patients with type 2 diabetes. Impaired renal and hepatic metabolism with slower counter-regulatory mechanisms, polypharmacy or non-adherence to medications, as well as erratic or poor food intake are the key components of hypoglycaemia in older individuals. Simply relaxing HbA1c goals may reduce the risk but it is not sufficient to protect frail older people against hypoglycaemia. These people may benefit from a switch to regimens including anti-hyperglycaemic drugs that do not induce hypoglycaemia. In conclusion, hypoglycaemia remains a real and continuing problem for people with diabetes. Developing strategies, technologies, and/or therapies designed to prevent and/or minimize the risk of hypoglycaemia is utmost important.

Difficult cases of differentiated thyroid cancer

Emese Mezosi
Hungary.

The incidence of differentiated thyroid cancer (DTC) has increased worldwide which is mainly attributed to the more common detection of early stage DTC. The prognosis of early stage disease is excellent and the present ATA guidelines suggest less radical treatment and follow-up in these cases. TNM staging, risk classification, indication of radioiodine (RAI) treatment, evaluation of therapeutic response and TSH target range have been recently changed. However, 7–10% of DTC cases develop distant metastases and two-thirds of these patients become RAI-refractory. The management of RAI-refractory patients has markedly developed with the availability of new treatment modalities. The presented cases represent the major challenges during the risk classification, follow-up, treatment of choice and emphasize unresolved questions. The patient with papillary thyroid cancer (PTC) is tumor-free after the primary treatment (surgery and RAI) but rising anti-Tg antibody levels are found in the absence of localizable disease – biochemical incomplete response. Anti-Tg antibody positive PTC patient with rising antibody levels and development of lymph node and RAI-refractory pulmonary metastases 9 years after the diagnosis – percutaneous ethanol sclerotherapy (PEI) of lymph node metastasis. The patient tolerated sorafenib treatment only temporarily due to severe side effects. Young PTC patient diagnosed with advanced disease (pT4N1M1), pulmonary metastases and treated with repeated surgeries including gamma-probe guided operation and five RAI therapies. He is followed for 12 years. When can we stop the RAI therapy? A PTC patient with 30-years disease course who underwent five surgeries, five RAI therapies and PEI of recurrent neck lymph node metastases and suspected tongue metastasis and finally PET/CT detected non-RAI avid lymph node mets in the upper mediastinum. A patient suffering from oncocytic follicular cancer, local relapse, cervical lymph node and pulmonary metastases; 17-years disease duration, 3 surgeries, 3 RAI therapies, 2 irradiations and sorafenib therapy since 2012; successful reintroduction of sorafenib treatment after the surgery of metastatic cervical lymph nodes with rapid progression.

Hormone replacement for the travelling patient

Tina Dusek
Croatia.

Millions of people travel across time zones every day for business and for pleasure. Travel-related health issues arise from a variety of factors: infections, prolonged limited mobility during travel, and participation in certain activities, such as diving and high-altitude hiking during travel. Besides that, air travel allows individuals to traverse time zones faster than the internal clock, or circadian rhythm, can adjust. This results in desynchrony between the external light-dark cycle and the endogenous circadian rhythm. Adjusting the hormone replacement during travel in people with endocrine dysfunctions can be challenging. Adjusting strategies vary depending on the medication, the importance of precise timing of medication usage, distance travelled, and duration of the visit. In general, in patients with diabetes, adjustments of insulin doses are unnecessary if patients are crossing fewer than five time zones. Traveling east will shorten one's day, and, in general, may require a reduction in insulin because insulin doses would be administered closer than normal and thus could cause hypoglycemia. Westward travel means a longer day, and so insulin doses may need to be increased. People with adrenal insufficiency should switch the hydrocortisone schedule to the local time. Throughout the time of travelling, hydrocortisone should be used every five to six hours. Estrogen use represents a risk factors for the development of venous thromboembolism during long-distance travel and therefore, in women taking estrogens, prevention of venous thromboembolism during prolonged travel should be considered. Continuous patient education regarding hormone replacement and prevention of possible acute complications are the cornerstones of managing common travel-related problems in patients with endocrine disorders.

Premature ovarian insufficiency: an endocrine perspective

Svetlana Vujovic
Serbia.

Premature ovarian insufficiency (POI) is defined as hypergonadotropic oligo/amenorrhoea with FSH $>$ 40 IU/l, estradiol $<$ 50 pmol/l in women under 40 years of age. Biological aging is faster in this group of women inducing diseases and disturbing quality of life.Infertility in POI represents a special issue. Hypoestrogenism, hypoprogesteronism, hypoandrogenism, decreasing of dehydroepiandrosteron sulfate, growth hormone, and increasing insulin resistance influence all body functions knowing the fact that steroid receptors are present on all blood vessels.Central nervous system changes include depression, lack of concentration, insomnia, anxiety, lower sexual desire and increasing incidence of Alzheimer disease. Cardiovascular changes include blood vessel instability, hypertension, atherosclerotic plaque growth, myocardial infarction, arrhythmias etc. Insulin resistance increases body weight further contributing to

cardiovascular disease. Osteoporosis, joint stiffnes, cartilage and connective tissue changes restricted mobility. Inflammation increase and autoimmune diseases started at that time. Dyspareunia, vulvar atrophy, lower libido ruined sexual life. All these consequences of 'normal aging and physiological menopause process' are not acceptable today having in mind definition of middle age until 60 years of age, according to World Health Organization. The main principle of endocrinology is to reach normal hormone concentrations. In POI estradiol has to be not only sufficient but optimal, according to the age. Adequate replacement of estradiol, progesterone, testosterone (especcialy in the artificial POI), DHEAS and all other hormones is required in POI. Modern endocrinology is responsible for helping women in reaching the optimal quality of life which is impossible without normal gonadal steroids levels.

The effect of gender-affirming therapy on bone in transgender persons

Guy T'Sjoen
Belgium.

Transgender persons on gender-affirming hormonal therapy will have experienced a hormonal reversal that will have had direct and also indirect effects on bone, through body composition changes. Recent evidence suggests that transgender women, even before the start of any hormonal intervention, already have a lower bone mass including a higher frequency of osteoporosis, and a smaller bone size vs. cisgender men. During gender-affirming hormonal treatment, bone mass is maintained or increased in transgender women. In transgender men, bone metabolism seemed to increase during short-term testosterone therapy, but no major changes have been found in bone density. On long-term testosterone therapy, larger cortical bone size was observed in transgender men vs. cisgender women. Fracture data as hard endpoint are not available currently. The follow-up of bone health and osteoporosis prevention in transgender persons is important, especially in transgender women. We advise active assessment of osteoporosis risk factors including the (previous) use of hormonal therapy. Based on this risk profile and the intended therapy, bone densitometry may be indicated. Long-term use of antiandrogens or gonadotropin-releasing hormone agonists alone should be monitored as transgender women may have low bone mass, even prior to treatment. Therapy compliance with the gender affirming hormones is of major concern, especially after gonadectomy. Large-scaled, multicenter, and long-term research is needed to determine a well tolerated dosage of gender-affirming hormonal treatment, avoiding side effects. Data on gender non-binary persons and elderly transgender persons are lacking altogether.

How to integrate PCSK9 inhibitors into hyperlipidemia management

Carmen Georgescu
Romania.

Anti-proprotein convertase subtilisin/kexin type 9 (PCSK9) monoclonal antibodies are a new class of biological drugs that inhibit binding of PCSK9 to the LDL receptor, thus increasing LDL-receptor density and lowering circulating LDL-cholesterol (LDL-C), apo-B100 and Lp(a). Recently released guidelines on management of hyperlipidemia reinforced the attribute of statins as the mainstay of lipid-lowering medication in dyslipidemic at-risk individuals, as every 1.0 mmol/L reduction in LDL-C is associated with a corresponding 20–25% reduction in cardiovascular disease mortality and non-fatal myocardial infarction, in addition to non-LDL-C benefits. Clinical trials demonstrated the advantages of treating extreme risk patients to an LDL-C target $<$55mg/dl by high-intensity statin or add-on non-statin therapies; statin and ezetimibe or, based on outcomes from FOURIER (Further cardiovascular OUtcomes Research with PCSK9 Inhibition in subjects with Elevated Risk) and ODYSEEY clinical program and particularly when $>$25% additional lowering of LDL-C is required, the combination treatment of statin and PCSK9 inhibitors is suggested to accomplish lipid and cardiovascular goals in patients with or without diabetes. PCKS9 inhibitors are capable of further decreasing LDL-C to around 60% when added to maximum statin therapy, which translates for evolocumab into 1% reduction in atheroma volume and atheroma plaque regression in about two-thirds of patients. Therapeutic challenges posed by genetic, familial heterozygous or homozygous hypercholesterolemia might be overcome by adding to maximally tolerated statin therapy non-statin agents including PCSK9 inhibitors, although homozygous receptor negative hypercholesterolemia patients may not respond. As a class effect, PCSK9 inhibitors address dyslipidemia in statin intolerant patients, with evolocumab being slightly more effective compared to ezetimibe in terms of LDL-C reduction and with an overall good tolerability. Adverse effects ($<$2–5%) commonly include nasopharyngitis, muscle-related events, back and leg pain, arthralgia, headache. Conclusion: PCSK9 inhibitors represent a promising non-statin tool in lipid management to be considered in well-defined clinical circumstances.

Controversies in NETs: Is high dose SSA treatment relevant and who needs hemicolectomy?

Gregory Kaltsas
Greece.

Long-acting somatostatin analogs (SSAs) have long been used for symptom control in patients with functional neuroendocrine tumors (NETs) whereas two recent prospective studies (PROMID and CLARINET) have demonstrated their efficacy in controlling tumor growth in patients with gastrointestinal NETs of different tissue origin. For both purposes currently available agents (octreotide LAR 10–30 mg i.m and lanreotide autogel 60–120 mg s.c.) have been used. In case of refractory syndromes dose escalation or shortening the injection interval form 4 to 3 or 2 weeks has been used. There is agreement that dose escalation is justified in patients with refractory carcinoid syndrome for symptom improvement and potentially the prevention of carcinoid heart disease. Long-acting SSAs have also been used in a non-prospective manner at above the upper labeled dosages for obtaining tumor growth control. The efficacy of high dose octreotide-LAR has been reported in 10 studies. Doses studied ranged from a minimum of either 40 mg per month or 30 mg per 3 wk up to a maximum of 120 mg per month and included over 260 patients. Eight studies suggested that increased doses (median 60 mg/day) could be effective at preventing tumor growth without evidence of increased toxicity. A prospective study is currently evaluating whether Lanreotide Autogel 120 mg given twice monthly may exert further tumor control in patients with established progression on 120 mg/monthly. Appendiceal carcinoids are considered to be amongst the most indolent carcinoid tumors with only a minority developing metastatic disease. As the majority of patients are identified incidentally when undergoing an appendicectomy a number of potentially adverse histopathological findings have been employed to identify patients that may require a hemicolectomy to eradicate any residual disease. Although there is relatively lack of good quality data, tumor size and grade seem to be the ones with the highest predictive value.

Erectile dysfunction

Mario Maggi
Italy.

Erectile dysfunction (ED) is a multidimensional disorder characterized by the inability to have successful intercourse with negative consequences in personal self-esteem and in couple relationship. Organic, relational and intrapsychic problems always concur in determining the erectile problem, although in different combination according to the patient characteristics, including age. Fifteen years ago, we have developed and validated a structured interview to identify and quantify the weight of each ED determinant. The organic determinant contributes significantly to ED in all age bands. In young and middle-age patients, intrapsychic disturbances are also important, while they result no longer statistically significant in aged individuals. Relational problems show a major contribution in younger subjects. Recognizing and treating ED is important in all age bands, because they often represent a harbinger of forthcoming cardiovascular (CV) problems. This is particularly relevant in young individuals, where having ED strongly increase CV risk. Several endocrine disorders are underlying the

organic component of ED. Among them are metabolic disturbances, such as diabetes mellitus (T2DM) and obesity, hypogonadism, hyperprolactinemia and, to a lower extent, thyroid diseases. Recognizing the underlying endocrine disorder is of capital relevance because treating it could restore a normal erectile function and improve overall health. For example, treating hypogonadism significantly improve erectile function, as demonstrated by a recent meta-analysis considering RCTs having International Index of Erectile Function (IIEF) as endpoint. However, the improvement in IIEF score was modest upon testosterone replacement therapy (TRT), i.e. 2–3 points, and apparent only in trials involving overt hypogonadism. Hence, there is often the need to associate other types of intervention to fully restore erectile function. Considering that T2DM, obesity and metabolic syndrome (MetS) are the major cause of ED-associated hypogonadism, their treatment is mandatory for sexual health. In fact, lifestyle intervention, including physical activity, improves erectile function and often reverts hypogonadism. In an experimental model of MetS we demonstrated that in the hypothalamus there is clear inflammation associated to a decrease in GnRH expression, secondary hypogonadism and ED. In MetS rabbits, regular physical activity (treadmill) reverted hypothalamic alterations, doubling GnRH expression, restoring normal testosterone levels and erectile function, including cGMP signaling within the penis. Several medications blocking cGMP catabolism in the penis, through the inhibition of phosphodiesterase type 5 (PDE5 inhibitors), are available as a symptomatic aid for improving ED. Although PDE5 inhibitors result very efficient in improving ED (more than 5 IIEF points) they do not resolve the underlying problems.

Vitamin D for everybody?

Stefan Pilz
Austria.

Vitamin D deficiency has a high worldwide prevalence. This is of concern for public health because a poor vitamin D status can lead to musculoskeletal diseases such as rickets and osteomalacia, but vitamin D may also prevent extraskeletal diseases such as respiratory tract infections and reduce premature deaths. Several nutritional guidelines have been revised within the last few years leading to and increase of the recommended dietary reference intakes for vitamin D. Based on a consensus that serum 25-hydroxyvitamin D (25[OH]D) concentrations are used to assess vitamin D status, the recommended target levels for 25(OH)D usually range from $\geq$ 25 to 50 nmol/l (10–20 ng/ml), corresponding to a daily vitamin D intake of 400–800 international units (10–20 μg). General populations clearly fail to meet these recommended dietary vitamin D requirements. In Europe, 25(OH)D concentrations $<$30 and $<$50 nmol/l are present in 13.0% and 40.4% of the general population, respectively. This definitely requires action from public health authorities. Approaches to increase vitamin D status include promotion of a healthier lifestyle, vitamin D supplementation or vitamin D food fortification. The current knowledge on vitamin D safety provides a solid basis to introduce vitamin D food fortification in order to improve public health with this very safe and cost-effective approach. On the other hand, we also have to deal with vitamin D diagnostics and treatment in patient care that is challenging due to inconsistent recommendations and several knowledge gaps regarding clinical effects of vitamin D supplementation.

Your emergency consult about hyponatraemia

Nigel Glynn
UK.

Hyponatraemia is the commonest electrolyte disturbance in hospital patients. It may be observed in up to 30% of cases and it has been clearly associated with an increased morbidity and mortality in a diverse array of clinical scenarios. Despite the frequency of the problem, robust evidence examining its importance and comparing treatment options has traditionally been lacking. However, recent years have seen the publication of high-quality prospective studies evaluating the epidemiology, clinical importance and management of hyponatraemia. Several clinical practice guidelines for the assessment and management of hyponatraemia have been published. However, hyponatraemia is encountered in such a broad spectrum of patients, often with complex comorbidities, that a physician's judgement and individualised management are still required in everyday clinical practice. The commonest cause of hyponatraemia in hospital is the syndrome of inappropriate anti-diuretic hormone secretion (SIADH). However, glucocorticoid deficiency can mimic this syndrome, accounting for up to 4% of cases originally diagnosed as SIADH. Fluid restriction has been the mainstay of treatment for SIADH for many decades. The safety and efficacy of this treatment has not been rigorously examined in prospective trials. Furthermore, it can be practically difficult to implement and maintain in hospital patients. Recently, following the publication of prospective, randomised controlled trials, vasopressin receptor antagonists have been approved for the treatment of SIADH. Clinical experience with these agents is growing worldwide. Severe symptomatic hyponatraemia is particularly challenging. It requires urgent, careful management, with frequent monitoring of serum sodium, to reduce the risk of mortality and avoid permanent neurological injury. This interactive clinical session will discuss cases of hyponatraemia in hospital patients to illustrate complexities in management and suggest approaches to assessment and treatment.

Adrenal Incidentaloma

John Newell-Price
UK.

An adrenal incidentaloma is a mass in the adrenal gland that is found on imaging that has been performed for reasons other than imaging the adrenal. With the increased use of axial imaging increasing numbers of lesions are found that require assessment. Adrenal incidentaloma are found in 4.5% of abdominal and thoracic CT scans. The incidence increases with age, being found in $<$1% of scans in those aged $<$20 y but in around 10% at 70 y. These adrenal masses are encountered by all medical and surgical specialities during radiological investigation. Large retrospective series reveal that the vast majority of adrenal incidentaloma are benign adrenal cortical adenoma, but a wide range of other diagnoses are possible depending on whether there is unilateral or bilateral disease. The two key questions that need to be addressed when assessing an adrenal incidentaloma are: 1) is it benign or malignant? 2) is it functional? These key questions are best addressed by discussion in dedicated adrenal multi-disciplinary team (MDT) meetings attended by specialists expert in assessment of adrenal disease including: adrenal radiologist, adrenal endocrinologist, endocrine / adrenal surgeon, oncologist, clinical chemist, and endocrine nurse specialist. This MTP session will focus on case-based analyses and examples of how to approach this common clinical problem with extensive reference to the European guidelines.

Single-cell technologies in development and disease with a special emphasis on endocrine systems

Karine Rizzoti
London.

Recently developed single cell technologies offer unprecedented investigations of cellular heterogeneity. While significant hurdles remain to be overcome, the field is progressing rapidly. In addition to now commonly performed genome and transcriptome analysis, it appears possible to examine the epigenome, proteome and metabolome at the single cell level. In addition, multi-omics technologies are being developed to profile simultaneously different material sources from the

same cell, enabling for example correlations between genomic mutations and alteration of genes expression. Genome and transcriptome analyses were initially pricey and required wet-lab specialist skills. However, competitive sequencing costs, commercially available kits for material preparation, along with the development of techniques to extract good quality material from clinical samples render these analyses more accessible to both biomedical and clinical researchers. Nevertheless, specialist platforms for microfluidic or droplet technologies are often required, and specialised bioinformatic support is essential for quality control and data analysis. Single cell analyses have already provided significant advances, in particular in the field of cancer, and stem cell research. In contrast with bulk population analysis, examination of genomic material from tumour single cells reveals cellular heterogeneity, allow reconstitution of cellular hierarchies, and sometimes resolution to the cell(s) of origin of the tumour. This maybe the only way to identify rare cell types, and therefore better characterize mechanisms of resistance to treatments, and tumour reoccurrence. In addition, stromal niche cells can be segregated away from tumour cells, and their analysis offer clues to understand how the microenvironment interact with the tumour cells. Furthermore, characterisation of circulating (CTC) and disseminated (DTC) tumour cells can be performed. In stem cell research, characterisation of differentiation pathways is a central question to improve disease modelling and drug screening assays, and ultimately for regenerative medicine. Single cell transcriptome analysis coupled with the development of specific algorithms allows pseudotime analysis of heterogeneous cellular states, and reconstitution of differentiation pathways, with often characterisation of new, previously invisible, intermediate cell states. A special emphasis will be placed to exemplify the advances these technologies have provided in endocrine systems, in both normal and pathological situations. Finally, current challenges and future developments of these techniques will be discussed.

Watch out for noncanonical mechanisms of thyroid hormone action!

Lars Moeller
Germany.

Thyroid hormone (TH) and TH receptors (TRs) α and β act by binding to TH response elements (TREs) in regulatory regions of target genes. This nuclear signaling is established as the canonical or type 1 pathway for TH action. Nevertheless, TRs also rapidly activate intracellular second-messenger signaling pathways independently of gene expression (noncanonical or type 3 TR signaling). To test the physiological relevance of noncanonical TR signaling, we generated knockin mice with a mutation in the TR DNA-binding domain that abrogates binding to DNA and leads to complete loss of canonical TH action. We show that several important physiological TH effects are preserved despite the disruption of DNA binding of TRα and TRβ, most notably heart rate, body temperature, blood glucose, and triglyceride concentration, all of which were regulated by noncanonical TR signaling. Additionally, we confirm that TRE-binding-defective TRβ leads to disruption of the hypothalamic–pituitary–thyroid axis with resistance to TH, while mutation of TRα causes a severe delay in skeletal development, thus demonstrating tissue and TR isoform-specific canonical signaling. These findings provide in vivo evidence that noncanonical TR signaling exerts physiologically important cardiometabolic effects that are distinct from canonical actions. These data challenge the current paradigm that *in vivo* physiological TH action is mediated exclusively via regulation of gene transcription at the nuclear level.

Nursing Management of Congenital Adrenal Hyperplasia (CAH): - Education, Managment and use of Multi-Media Technology

Irene Mitchelhill
Australia.

Introduction
The management of Congenital Adrenal Hyperplasia (CAH) requires specific expertise and understanding in childhood, adolescence and adulthood. Patient education and support is an integral part of this health care process, from the delivery of a diagnosis and explanation by medical staff to the more detailed education provided by nurses in order to help families understand the practical aspects of management.
Background
For parents, the initial diagnosis of CAH is an extremely traumatic time and the grief experienced significantly affects the parental learning process. The appearance of atypical genitalia in a newborn female, or the near death experience of an extremely unwell male infant is a devastating experience for the parents, and the beginning of a long road ahead. Parents need to come to terms with the implications of an autosomal recessive condition, its life-threatening nature, and need for life-long treatment and management. At this time the nurse-patient relationship is crucial in providing emotional support and explanation to support the parents through their grief process. Recognition of specific illness stressors (emotional, cognitive, practical) affecting any learning process needs to be addressed in order to support parental ability to cope and understand. The endocrine nurse role is to provide pschosocial support, education and advocacy. Evaluation and management of the emotional needs of the parents and the clinical needs of the child is an essential component. Providing education initally for parents and child as they grow through adolescence to adulthoodand is ongoing, at the same time continually supporting the parents about their long-term fears for their child's future in adult life.
Conclusion
With CAH primarily a childhood condition, transition to adult care can have its challenges. Health education long term and overall the management plans for CAH should focus on minimising the long-term consequences of over treatment with cortico-steroids in order to suppress the effects of the excess androgen secretion and to ensure a positive wellbeing for adults. Finding the balance is challenging physically and emotionally and can be frustrating for patients. Health Education is now being challenged by public access to information on the internet. Our concern about the validity of such information and its interpretation led to the development of a comprehensive and validated psychococial education program (CAHPEP) for families and patients with CAH, is now a website titled 'CAHPepTalk.com', with translations in Vietmamese, Bahasa-Indonesian and Urdu-Pakistan, with the support of Caring Living As Neighbours (CLAN), APPES & APEG.

Comparison of glucose, peak growth hormone & peak cortisol levels during insulin tolerance testing with two different doses (0.15 vs 0.10 U/kg)

Phillip Yeoh
UK.

The Insulin Tolerance Test (ITT) is the gold standard test to assess growth hormone (GH) and ACTH reserve. This dynamic test induces hypoglycaemia and is commonly performed by endocrine nurses using different insulin doses - commonly 0.15 U or 0.10 U/kg. As part of a quality and safety improvement initiative we conducted a retrospective study to address several questions relating to ITT insulin dose. ITT results ($n = 148$) were retrieved from two large endocrine testing centres. All tests that achieved adequate hypoglycaemia on 1st insulin dose and non-diabetic patients. All patients were given glucose after achieving hypoglycaemia at 30 mins.

Results

- Both insulin doses appear to achieve adequate hypoglycaemia
- Patient glucose levels appear to recover more quickly with the lower dose – thus an important patient safety aspect
- Peak GH levels were similar between insulin doses
- Patients receiving the standard (0.15 U/kg) dose were more likely to exhibit an adequate cortisol response, this might be due to the enhanced stimulus from longer hypoglycaemia although we cannot exclude that this is due to possible patient differences as this is not a truly random sample.

Cooperation between an endocrine nurse, psychologist and physician and their role in the care of depression in patients treated with multi kinase inhibitors due thyroid cancer

Alina Rozanska
Poland.

The treatment with multi kinase inhibitors (MKI) under clinical trials due to advanced thyroid cancer (TC) may postpone moving on the patients with advanced disease to the palliative care stage. However, chronic and escalating somatic symptoms during the treatment may promote the appearance of depressive reactions. It can be expected that a cognitive image of the disease, as a collection of subjective beliefs concerning patient's own illness and treatment, will be an important determinant of mental functioning. The aim of the study was to define a mutual dependence between the intensity of somatic problems, self-image of the illness and depression in patients receiving an experimental treatment of TC.

Material and methods

The study included 32 patients treated with MKI due to TC for at least one year. The study was cross-sectional and it based on different questionnaires: List of Somatic Problems, Beck's Depression Inventory and Short Questionnaire of Diseases Perception (B-IPQ).

Results

Nineteen patients showed severe somatic symptoms (HSS; High Somatic Symptoms), whereas 13 patiens demonstrated none or mild physical symptoms (LSS; Low Somatic Symptoms). The depression intensity was higher in HSS patients than in LSS group. In HSS group a mediating role of self-image relationship to disease somatic symptoms and depression was noticed. The direct effect of somatic symptoms on depression severity was insignificant. While, the belief about a negative impact of physical symptoms on the daily functioning was an important mediator of relations between somatic symptoms and depression in the study group.

Conclusions

The inclusion of interaction aimed at changing the perception of a negative impact of the disease and its treatment on daily life in TC patients can reduce the risk of deterioration in depressive symptoms. The role of a nurse in psychologist-physician-nurse team is crucial for better patients care and quality of life.

OC1.1

Familial gestational hyperthyroidism caused by Val597ile mutant of TSH receptor gene with human chorionic gonadotropin hypersensitivity

Philippe Caron[1], Marion Susini[1] & Frédérique Savagner[2]
[1]Department of Endocrinology and Metabolic Diseases, CHU Larrey, Toulouse, France; [2]Biochemistry and Genetic Laboratory, Toulouse, France.

Context
Familial gestational hyperthyroidism caused by mutations of TSH receptor gene, hypersensitive to hCG, is rare. Only two mutations at the same amino acid (lys183Arg, Lys183Asn) in the leucine-rich region of the extracellular N-terminal domain of the TSH receptor have been reported.
Patients
A 38-year-old woman was seen during the first trimester of her second pregnancy for weight loss (5 kgs), nausea and vomiting. Thyroid function test revealed thyrotoxicosis with increased $fT_3 = 8.3$ ng/dl (2.4–4.1 ng/dl) and free $T_4 =$ 2.3 ng/dl (0.8–1.3 ng/dl) concentrations and low TSH (<0.03 mU/l) levels without anti-TSH receptor antibody. Thyroid ultrasound showed a normal-sized thyroid gland with diffuse hyper-vascularization. Thyrotoxicosis persisted at 2nd trimester ($fT_3 = 7.0$ ng/dl, $fT_4 = 1.3$ ng/dl) and improved spontaneously during the 3rd trimester ($T_3 = 3.5$ ng/dl, $fT_4 = 1.3$ ng/dl). She gave birth to a girl (3300 gr, 48 cm). Interestingly she presented similar symptoms with a loss of 6 kgs during the first trimester of her first pregnancy with low TSH and normal fT_3 and fT_4 levels. Her mother had two children and reported similar symptoms during her first pregnancy. At the age of 66 years, she had normal thyroid function (TSH = 0.92 mU/l) and high gonadotropin (LH = 26.8 IU/l, FSH = 85.7 IU/l) levels.
Results
DNA sequencing of this woman and her mother, led to identify a heterozygous variant (c.1789 G > A) changing Valine to Isoleucine residue at codon 597 in the exon 10 of the TSH receptor. Functional studies of this mutant receptor showed high constitutive activity in regard to the basal level of cAMP and IP3 production (2 to 2.5-fold higher) while responses to TSH were reduced compared to that of wild type receptor (average 50%), and related to low cell surface expression (28% of the wild type receptor). This Val597Ile mutant presented a dose-dependent increase in cAMP in response to chorionic gonadotrophin and luteinizing hormone whereas the wild type receptor was insensitive to those hormones except at high concentration of chorionic gonodotrophin.
Conclusion
We describe familial gestational hyperthyroidism due to a new variant in TSH receptor gene with hCG hypersensitivity. This amino-acid, located in the 5th transmenbrane helix of the receptor, is highly conserved among the receptors for TSH and LH in different species. We analyzed clinical and hormonal data related to the increased constitutive activity of the Val507Ile receptor and thyroid hypersentivity to HCG and LH in women of this family.

Relationship between TSH values in the first trimester of pregnancy and obstetric and neonatal complications

Beatriz Torres Moreno[1], Gabriela Castillo Carvajal[1], Lucrecia Vegara Fernández[1], Teresa López del Val[1], Victoria Alcázar Lázaro[1], Lina Benfail[2], Covadonga Torres Carrera[2], Concepción García Lacalle[3], María Carmen Orizales Lago[4] & Leonardo Ramos Zuñiga[4]
[1]Service of Endocrinology and Nutrition of the University Hospital Severo Ochoa, Leganés (Madrid), Spain; [2]University Alfonso X El Sabio, Madrid, Spain; [3]Clinical Analysis Service of the Severo Ochoa University Hospital, Leganés (Madrid), Spain; [4]Service of Gynecology and Obstetrics of the University Hospital Severo Ochoa, Leganés (Madrid), Spain.

Introduction
In recent years, numerous studies on the relationship between the TSH of the first trimester of pregnancy and obstetric complications have been published, and in this context it has been recommended to treat with levothyroxine from certain values of TSH. The aim of this study was to determine the incidence of obstetric and neonatal complications in pregnancies with normal TSH (0.14 to 2.49 mcU/ml) as a basis for assessing complications in pregnancies with TSH between 2.5 and 4.9 mcU/ ml, both treated as not treated with levothyroxine.
Material and methods
Prospective and cohort study of 1184 pregnant women with TSH in between 0.14 and 4.9 mcU / ml in prenatal screening. Groups A were established: pregnancies with TSH 0.14–2.49 (903) and B: pregnancies with TSH 2.5–4.9 (281). Group B was divided by randomization into two subgroups: B1: no treatment with levothyroxine (146), and B2: treatment with levothyroxine (135). The variables spontaneous abortion, induced delivery, caesarean section, weight of the newborn and admission in neonates were collected and a descriptive and analytical analysis was performed with SPSS 19.0.
Results
There were no significant differences in the percentage of abortions between group A (2.7%), and groups B1 (4.8%), and B2 (4.4%). The percentage of deliveries induced in group A (12.7%) was significantly lower ($P<0.001$) than those of group B1 (39.0%), and group B2 (39.3%). The percentage of caesarean sections in group A (7.8%) were significantly lower ($P<0.001$) than those in group B1 (28.8%), and group B2 (23.0%). There were no significant differences in the weights of the newborns of group A (3186 ± 515 gr), B1 (3229 ± 460 gr), and B2 (3187 ± 449 gr) or in gestational age being in the group A of 38.7 weeks ± 2.7; B1 38.5 ± 5.28 and B2 38.42 ± 5. The mean age of pregnant women in group A was 33 years ± 5.04, B1 31.95 ± 5.22 and B2 31.95 ± 5.58. There was no significant difference in neonatal admissions between group A (8.9%) and B1 (11.0%). The percentage of admissions in neonates in group B2 (20.0%) was significantly higher ($P<0.05$) than in B1.
Conclusion
In pregnant women with TSH < 2.5 mcU / ml in the first trimester there are fewer induced births and caesarean sections than in women with TSH between 2.5 and 4.9 mcU/ml. The treatment with levothyroxine from week twelve does not modify this difference.

Thyroid hormone replacement therapy for subclinical hypothyroidism in adults: systematic review and meta-analysis of randomized-controlled trials

Marieke Snel[1], Martin Feller[2,3], Elisavet Moutzouri[2,3], Ian Ford[4], Jacobijn Gussekloo[1], Patricia Kearney[5], Simon Mooijaart[1], Terry Quinn[6], Drahomir Aujesky[3], David Stott[6], Rudi Westendorp[7], Nicolas Rodondi[2,3] & Olaf Dekkers[1]
[1]Leiden University Medical Center, Leiden, Netherlands; [2]Bern University Hospital, Bern, Switzerland; [3]Institute of Primary Health Care, Bern, Switzerland; [4]Robertson Centre for Biostatistics, Institute of Health and Wellbeing, Glasgow, UK; [5]School of Public Health, Cork, Ireland; [6]Institute of Cardiovascular Medicine, Glasgow, UK; [7]Department of Public Health and Center for Healthy Aging, University of Copenhagen, Copenhagen, Denmark.

Introduction
Although widely prescribed, the benefit of thyroid hormone replacement in subclinical hypothyroidism (SHypo) is unclear. We performed a systematic review and meta-analysis of randomized controlled trails (RCTs) to assess the impact of thyroid hormone therapy on clinical outcomes.
Methods
We followed the PRISMA guidelines and registered the study protocol on PROSPERO (CRD42017055536). We searched PubMed, Embase, Web of Science, COCHRANE Library, CENTRAL, Emcare and Academic Search Premier in April 2017. We included RCTs that assessed the impact of thyroid hormone replacement compared to placebo/no intervention in non-pregnant adults with SHypo. Data and bias-risk of included studies were extracted by two independent reviewers. Outcomes were quality of life, symptoms of depression, cognitive function, blood pressure, and the body mass index. We transformed differences in clinical scores (e.g. cognitive function) into standardized mean differences (SMD, positive values indicate levothyroxine benefit) and applied random-effects models.
Results
Overall, 19 of 2,793 initially identified studies met the inclusion criteria, with a total of 2,061 adults randomized. Levothyroxine lowered TSH into reference range in all studies, but showed no benefit regarding quality of life (five studies, SMD −0.03, 95%CI −0.10 to 0.04, I^2 21%), symptoms of depression (three studies, SMD −0.14, 95%CI −0.41 to 0.12, I^2 0%), and cognitive function (four studies, SMD 0.11, 95%CI −0.09 to 0.32, I^2 53%). Seven studies analysed blood pressure and found no clear benefit of levothyroxine therapy compared to placebo (−0.66 mmHg, 95%CI −2.46 to 1.14 mmHg, I^2 0%), and 13 evaluated the body mass index, again showing no benefit (−0.02 kg/m^2, 95%CI −0.40 to 0.36 kg/m^2, I^2 56%). Limitations were that participants from only two smaller studies (in total 99 persons) had a mean initial TSH of > 10 mU/l and that 16 out of 19 studies had an unclear or high risk of bias in at least three of the six domains of the Cochrane bias assessment.

Conclusion
This systematic review and meta-analysis does not support the use of thyroid hormone replacement therapy in adults with subclinical hypothyroidism, at least in adults with TSH <10 mU/l.

OC1.4

The impact of obligatory iodine prophylaxis on thyroid volume in schoolchildren

Malgorzata Trofimiuk-Muldner[1], Zbigniew Szybinski[2], Monika Buziak-Bereza[1], Grzegorz Sokolowski[3], Andrzej Lewinski[4], Arkadiusz Zygmunt[4], Krzysztof Sworczak[5], Marek Ruchala[6], Elzbieta Bandurska-Stankiewicz[7], Filip Golkowski[1] & Alicja Hubalewska-Dydejczyk[1]
[1]Chair and Department of Endocrinology, Jagiellonian University, Medical College, Krakow, Poland; [2]Polish Council for Control of Iodine Deficiency Disorders, Krakow, Poland; [3]Endocrinology Department, University Hospital in Krakow, Krakow, Poland; [4]Department of Endocrinology and Metabolic Diseases, The Polish Mother's Memorial Hospital- Research Institute, Lodz, Poland; [5]Chair and Department of Endocrinology and Internal Diseases, Medical University of Gdansk, Gdansk, Poland; [6]Chair and Department of Endocrinology, Metabolism, and Internal Medicine, Poznan University of Medical Sciences, Poznan, Poland; [7]Chair of Endocrinology, Diabetology, and Internal Diseases, Faculty of Medical Sciences, University of Warmia and Mazury, Olsztyn, Poland.

Poland was considered as a mild-to-moderate iodine deficiency area according to results of a nation-wide survey conducted in early 1990-ties. The obligatory iodine prophylaxis program based on iodization of house-hold salt (30 mg of iodide/l kg of salt) was therefore introduced in 1997.
The aim of the study was to assess the real impact of the Polish iodine prophylaxis model on thyroid volume in schoolchildren.
Material and methods
The study included 9210 Polish schoolchildren (4731 girls, 4479 boys) aged 6–12 years, examined between 1999 and 2011. The informed written parental consent for participation in the survey was obtained for each child. 3803 of children (1909 girls and 1894 boys) were born at least one year after introduction of the iodine prophylaxis (after 12/31/1997), which meant that their mothers were using iodized salt while being pregnant. In each child TV was assessed by ultrasound (7.5 MHz linear probe) and calculated according to Brunn's formula. Body surface area (BSA) was calculated according to the following formula: weight $(kg)^{0.425}$ * height $(cm)^{0.725}$ * 71.84 * 10^{-4}. Thyroid volume was then standardized to body surface area (TV in ml divided by BSA in m^2) to minimize the influence of child age. Urinary iodine concentration (UCI) in urine casual sample was measured by Sandell-Kolthoff method.
Results
The median standardized thyroid volume (TVs) was 3.96 ml/m^2 (LQ – 3.12 ml/m^2, UQ – 4.91 ml/m^2, respectively). The median UCI was 96.2 mcg/l (LQ – 64.0 mcg/l, UQ – 142.6 mcg/l, respectively). UCI was significantly higher in children born after introduction of obligatory iodine prophylaxis (mean 118.23 ± 74.68 mcg/l vs 104.59 ± 66.80 mcg/l, $P<0.001$, Mann-Whitney U test). Age, ultrasonographic thyroid autoimmunity features, gender, UIC and date of birth (before vs. after introduction of obligatory iodine prophylaxis) were significant, independent predictors of TVs in multiple stepwise regression model.
Conclusions
Iodine prophylaxis based on iodization of household salt is effective in reduction of thyroid volume in children living in an area previously considered mildly-to-moderate iodine deficient.

Low free T3 levels within the reference range independently predict cardiovascular mortality in the general population

João Sérgio Neves[1,2], Catarina Viegas Dias[3], Lia Leitão[4], Miguel Bigotte Vieira[5], Rita Magriço[6], Ana Isabel Oliveira[1], Inês Falcão-Pires[2], André Lourenço[2], Davide Carvalho[1,7] & Adelino Leite-Moreira[2]
[1]Department of Endocrinology, Diabetes and Metabolism, São João Hospital Center, Porto, Portugal; [2]Department of Surgery and Physiology, Faculty of Medicine, Cardiovascular Research Center, University of Porto, Porto, Portugal; [3]NOVA Medical School, Lisbon, Portugal; [4]Neurology Department, Hospital Professor Doutor Fernando Fonseca, Amadora, Portugal; [5]Nephrology and Renal Transplantation Department, Centro Hospitalar Lisboa Norte, Lisbon, Portugal; [6]Nephrology Department, Hospital Garcia de Orta, Lisbon, Portugal; [7]Instituto de Investigação e Inovação em Saúde da Universidade do Porto, Porto, Portugal.

Introduction
Several studies have suggested an association of thyrotropin (TSH) and free thyroxine (FT4) levels within the reference range with morbidity and mortality in the general population. Low free triiodothyronine (FT3) has also been associated with a poor prognosis in several conditions. However, the association between FT3 levels within the reference range and the risk of mortality in the general population remains uncertain.
Methods
We evaluated the association between FT3 levels and mortality in 6672 adults in the National Health and Nutrition Examination Survey (NHANES) 2001–2002, 2007–2008, and 2009–2010 cycles. Thyroid function was assessed at baseline. The mortality and cause of death were prospectively evaluated until December 31, 2011. Patients with a prior history of thyroid disease, patients receiving thyroid-related drugs, and those with TSH, FT4 or FT3 outside the reference range were excluded. We categorized participants according to FT3 tertiles. We used Cox proportional hazard models to estimate hazard ratios (HR) for all-cause mortality, cardiovascular mortality, cancer-related mortality and mortality from other causes. The models were fitted unadjusted and with adjustment for potential confounders: age, gender, race, BMI, smoking, education, annual salary, diabetes mellitus, hypertension, dyslipidemia, chronic kidney disease, previous cardiovascular disease, history of cancer, FT4 and TSH levels.
Results
During the follow-up period (28901 person-years, median follow-up: 45 months), a total of 353 deaths occurred (81 of cardiovascular disease, 97 of cancer and 175 of other causes). Compared to participants with FT3 levels in the upper tertile (3.3–3.9 pg/ml), participants with FT3 levels in the lower tertile (2.5–3.0 pg/ml) had higher all-cause mortality (HR 3.06 (1.71–5.45), $P<0.001$), cardiovascular mortality (HR 11.55 (3.92–34.04), $P<0.001$) and mortality from other causes (HR 2.90 (1.52–5.52), $P=0.002$). In the adjusted analysis, this association was not significant for all-cause mortality (HR 1.25 (0.66–2.38), $P=0.479$), cancer mortality (HR 1.09 (0.41–2.90), $P=0.851$) and mortality from other causes (HR 0.98 (0.41–2.38), $P=0.969$). On the other hand, compared to the highest FT3 tertile, the lowest FT3 tertile was associated with higher cardiovascular mortality, even after adjusting for confounders (HR 6.23 (1.66–23.37), $P=0.008$).
Conclusion
Low levels of FT3 within the reference range independently predict cardiovascular mortality. Our results suggest that FT3 levels may contribute to the stratification of cardiovascular risk in the general population.

Look who is controlling your gonads!

OC2.1

The *in vivo* and *in vitro* effects of kisspeptin on human ovarian function

Lisa Owens[1], Ali Abbara[1], Avi Lerner[1], Shannon O'Floinn[1], Georgios Christopoulos[1], Shirin Khanjani[1], Rumana Islam[1], Maneshka Liyanage[2], Kate Hardy[1], Stuart Lavery[2], Aylin Hanyaloglu[1], Waljit Dhillo[1] & Stephen Franks[1]
[1]Imperial College London, London, UK; [2]The Wolfson Fertility Centre Hammersmith Hospital, London, UK.

Background
Infertility is a common problem and the number of couples receiving assisted reproductive treatment (ART) is increasing. Using GnRH agonists (GnRHa) to trigger oocyte maturation has been shown to reduce risk of ovarian hyperstimulation syndrome (OHSS), a common complication of IVF, compared to the more traditional use of human chorionic gonadotropin (hCG). Kisspeptin has recently been shown to be a safe trigger of oocyte maturation in women at high risk of OHSS. Kisspeptin stimulates gonadotropin secretion indirectly by stimulation of hypothalamic GnRH neurons. Kisspeptin and its receptor are also expressed in the human ovary but direct actions of kisspeptin on the ovary are unknown.

Objectives
1. To compare effects of the maturation triggers hCG, GnRHa and kisspeptin on expression, in granulosa lutein (GL) cells, of genes involved in ovarian reproductive function and steroidogenesis and 2. To examine *in vitro* effects of kisspeptin treatment on ovarian steroidogenesis in GL cells. 3. To treat GL cells *in vitro* with Kisspeptin-10 and kisspeptin-54 and to measure activation of kisspeptin receptor through calcium signal generation and protein expression of phospho-ERK and phospho-AKT.
Materials & methods
GL cells were isolated from follicular fluid collected at the time of oocyte retrieval. RNA was extracted from the cells and RT-qPCR completed comparing expression of ovarian steroidogenesis and gonadotropin receptor genes. GL cells were cultured and treated with hCG or kisspeptin and gene expression was analysed. GL cells were treated with kisspeptin-54 and kisspeptin-10 at varying dosages and timepoints.
Results
GL cells from women who received kisspeptin trigger *in vivo* showed significantly higher expression, compared to other triggers, of FSH receptor, LH/CG receptor, steroid acute regulatory protein, 3-beta-hydroxysteroid dehydrogenase type 2, aromatase, inhibins A and B, oestrogen receptors α and β. Gene expression of kisspeptin receptor was unchanged. Whereas GL cells treated *in vitro* with hcG showed the expected increase in steroidogenic gene expression, kisspeptin treatment *in vitro* had no effects. There was no evidence of activation of kisspeptin receptor after administration of kisspeptin-10 and -54.
Conclusion
Kisspeptin-54, used as an oocyte maturation trigger, augments expression of genes involved in ovarian steroidogenenesis in human granulosa cells, when compared to traditional maturation triggers. However, there was no effect of kisspeptin administration *in vitro*, indicating that the *in vivo* effects are likely to be mediated by the action of kisspeptin on gonadotropin secretion rather than by direct effects on the ovary.

DOI: 10.1530/endoabs.56.OC2.1

OC2.2

Overexpressed kisspeptin/Kiss1R system in human granulosa cells may be involved in the pathogenesis of polycystic ovary syndrome (PCOS) by inhibiting ovulation

Kai-Lun Hu & Yang Yu
Peking University Third Hospital, Beijing, China.

The kisspeptin/Kiss1R and neurokinin B (NKB)/ tachykinin receptor 3 (TACR3) system in the hypothalamus are essential for reproduction. Recent study suggested that the two peptide systems were both expressed in the ovary, particularly in the granulosa cells. To investigate the two systems in regulating the ovarian function, we collected the granulosa cells and follicular fluids from the 80 infertile patients (42 infertile control women and 38 PCOS women) undergoing IVF in Peking University Third Hospital. The mRNA expression of *Kiss1*, *Kiss1R*, *Tac3*, *Tacr3*, *MMP9* and *COX2* in the collected granulosa cells were tested by quantitative RT-PCR and the concentration of kisspeptin and NKB in the follicular fluids were tested using ELISA kit. Circulating levels of hormones were measured with the radioimmunoassay method. We found that *Kiss1* and *Kiss1R* were significantly upregulated in the granulosa cells from patients with polycystic ovary syndrome (PCOS) compared to the normal control (both $P<0.01$), but no significant difference was detected between the obese group (BMI$>$25) and the non-obese group (BMI$\leq$25). The expression of *Tac3* and *Tacr3* did not show significant difference between the PCOS group and normal control group, but they were significantly downregulated in the obese group (both $P<0.01$). Interestingly, both the expression of *Kiss1* and *Tac3* were highly correlated with their receptor gene, respectively (both $P<0.0001$). Additionally, *Kiss1* mRNA level was correlated with the serum AMH levels ($P<0.01$). While *Kiss1R* mRNA level was correlated with the follicular number ($P<0.05$). The expression of *Kiss1*, *Kiss1R*, *Tac3*, *Tacr3* were not significantly correlated with oocyte maturation rate and circulating hormones levels, including E_2, progesterone, follicle-stimulating hormone (FSH), luteinized hormone (LH), and E_2, progesterone, LH levels in HCG day. Kisspeptin-10 significantly inhibited the expression of *MMP9* and *COX2* in a dose-dependent manner, which were attenuated by kisspeptin antagonist, P234. Kisspeptin-10 also significantly upregulated the expression of *Tacr3*. Senktide, an agonist of TACR3, inhibited the expression of *COX2*, but not *MMP9*. Our results suggest that the overexpressed kisspeptin/Kiss1R system in human granulosa cells may be involved in the pathogenesis of PCOS by inhibiting ovulatory function of the ovary. The expression of *Kiss1* in the granulosa cells may be an alternative marker for the ovarian reserve.

Whole exome sequencing in non-obstructive azoospermia allows the identification of a high-risk subgroup of infertile men for undiagnosed Fanconi Anemia, a cancer-prone disease

Csilla Krausz[1], Antoni Riera-Escamilla[2], Chiara Chianese[2], Daniel Moreno-Mendoza[2], Osvaldo Rajmil[2], Eduard Ruiz-Castañé[2] & Jordi Surrallés[3,4]
[1]Department of Experimental and Clinical Biomedical Sciences 'Mario Serio', Centre of Excellence DeNothe, University of Florence, Florence, Italy; [2]Andrology Department, Fundació Puigvert, Universitat Autònoma de Barcelona, Instituto de Investigaciones Biomédicas Sant Pau (IIB-Sant Pau), Barcelona, Spain; [3]Genetics Department and Biomedical Reseach Institute, Hospital de Sant Pau, Center for Biomedical Research on Rare Diseases (CIBERER), Barcelona, Spain; [4]Department of Genetics and Microbiology, Universitat Autònoma de Barcelona, Barcelona, Spain.

Background
The etiology of non-obstructive azoospermia (NOA) remains unknown in about 40% of cases and genetic factors are likely to be involved in a large proportion of them. Gene mutations involved in stem cell proliferation and DNA repair may cause isolated NOA or be responsible for syndromic diseases, such as Fanconi Anemia (FA). Although the most frequent presenting symptom in FA is bone marrow failure in childhood, in about 10% of cases the diagnosis is delayed until adulthood and in these late-onset cases the presenting syndrome is frequently a malignant tumor.
Methods
An idiopathic NOA patient (index case) with consanguineous parents was subjected to Whole-Exome Sequencing (WES) with the purpose to identify the etiology of NOA. In the second part of the study, two-steps Sanger sequencing of the *FANCA* gene in the brother of the index case and in 27 selected NOA patients was performed. DEB-induced chromosome breakage test was carried out to confirm the FA diagnosis.
Results
Through WES we identified a rare pathogenic homozygous *FANCA* variant (c.2639G$>$A) in the index case, affected by NOA due to Sertoli Cell only syndrome (SCOS). The patient's brother (also affected by NOA) has been found to be a homozygous carrier of the same mutation. The two brothers did not manifest overt anemia, though chromosomal breakage test revealed a reverse somatic mosaicism in the index case and a typical FA picture in the brother. Following this incidental finding of FA, we selected 27 NOA patients with similar testicular phenotype and borderline/mild hematological alterations. Sanger sequencing of the *FANCA* gene in this selected group of patients allowed the identification of one additional SCOS patient showing compound heterozygous variants (c.3788_3790delTCT and c.3913C$>$T). Following our investigation, the three subjects with *FANCA* mutations are now receiving specific medical attention including strict follow-up by oncohematologists.
Conclusions
Our study reports an unexpectedly high frequency of occult FA in a specific subgroup of NOA patients with mild or borderline hematological alterations (7.1%). The screening for *FANCA* mutations in such patients may allow the identification of undiagnosed FA before the appearance of other severe clinical manifestations of the disease. Our finding highlights the importance to introduce the systematic evaluation of hematological parameters into the routine andrological workup in NOA patients. Moreover, corroborates previous epidemiological observations reporting a higher risk of morbidity (including cancer) and a lower life expectancy in infertile men in respect to fertile, normozoospermic men.

Childhood obesity has become a major health problem, which is coupled to different adverse outcomes and diseases. The escalating prevalence of child obesity parallels that of alterations in pubertal timing, also linked to higher disease burden later on life. Yet, the mechanisms underlying for this association remain unfolded. Ceramides, ubiquitous signaling molecules involved in numerous biological processes, have emerged as mediators of metabolic disorders and transmitters for the central actions of key hormonal regulators of metabolism and puberty. We address herein the potential contribution of central ceramide signaling to the control of puberty and its alterations due to early-onset obesity. Postnatal overnutrition of female rats, which markedly elevated body weight and advanced puberty, was associated to consistent increases of different ceramide species in the hypothalamus. Pharmacological activation of central ceramide signaling in conditions of normal nutrition partially mimicked the advancement of puberty onset caused by obesity, without changes in body weight, while its persistent blockade with the inhibitor, myriocin, delayed puberty, both in lean and obese females. Myriocin prevented also the permissive effects of the puberty-activating signal, kisspeptin, on puberty onset, but failed to alter basal gonadotropin levels, hypothalamic *Kiss1* expression or kisspeptin-induced GnRH/LH release during the peripubertal period, therefore suggesting alternative pathways. We identify here a circuit, involving the paraventricular nucleus (PVN) and ovarian sympathetic innervation, as putative conduit for such novel kisspeptin-ceramide pathway, as (i) PVN received abundant kisspeptin fibers in pubertal rats; (ii) precocious puberty linked to early-onset obesity was associated with advanced maturation of the sympathetic tone at the ovary; and (iii) virogenetic interference of ceramide synthesis at the PVN, by silencing of serine palmitoyltransferase long chain base subunit 1 (SPTLC1), partially normalized ovarian sympathetic activity and the timing of puberty onset in obese rats. All in all, our data are the first to unveil a role of central ceramide signaling in the control of pubertal timing and its alterations due to early-onset obesity. Our results disclose an alternative pathway, linking PVN ceramide synthesis and sympathetic ovarian innervation, as key for such obesity-induced precocious puberty, which may help to define better strategies for the management of pubertal disorders associated to metabolic disease.

OC2.5

Effect of thyroxine replacement on leydig cell and sertoli cell function in men with hypothyroidism

Jayakumar Selvi Ambigapathy, Sadishkumar Kamalanathan, Jayaprakash Sahoo, Ritesh Kumar & Nandhini Lakshmana Perumal JIPMER, Pondicherry, India.

Background
Thyroid hormones play an important role in reproductive and sexual function in both males and females. Comprehensive information on the ill-effects of hypothyroidism on leydig cell, sertoli cell and germ cell function is lacking in the existing literature.
Objective
Our objective was to investigate the effect of hypothyroidism and its treatment on testicular function.
Patients and design
This study was carried out as a descriptive study with a before-after study design. Forty treatment naïve, overtly hypothyroid, consenting male patients were included. Hormones assessed were free T_3, free T_4, thyroid stimulating hormone, follicle stimulating hormone (FSH), luteinizing hormone (LH), prolactin, testosterone, inhibin B (INHB), and insulin like factor 3 (INSL3). Semen analysis was done according to WHO 2010 guidelines in 37 subjects. Sexual function questionnaires like Androgen Deficiency in Aging Male (ADAM), and Arizona Sexual Experience Scale (ASEX) were also used. All patients were treated with adequate dose of thyroxine sodium. After ensuring a euthyroid state for consecutive 6 months, reassessment of all parameters was done.
Results
At baseline, 72.5% had a low serum testosterone value ($<$ 230 ng/dl), 67.56% had low total sperm motility, 72.97% had low total progressive sperm motility, 80% had low ADAM score and 72.72% had low ASEX score. A raised prolactin level was seen in 32.5% of study subjects. Hypogonadotropic hypogonadism was more common than hypergonadotropic hypogonadism (89.66% vs 10.34%). On restoration of euthyroidism, all these parameters improved. Serum INSL3 and LH increased significantly after thyroxine replacement unlike FSH and INHB.
Conclusion
Leydig cell function was more severely affected by hypothyroidism as compared to sertoli cell function. Among sperm function parameters, motility was predominantly affected. Restoration of euthyroidism led to almost complete normalization of majority of the affected parameters.

UX023-CL303 is an ongoing, Phase 3, double-blind, multicenter study examining the efficacy and safety of burosumab, a fully human monoclonal antibody against FGF23, in adults with XLH. Eligible subjects had serum phosphorus levels <0.81 mmol/l and skeletal pain (BPI – Worst Pain ≥ 4). Subjects ($N=134$) were randomized 1:1 to receive burosumab 1 mg/kg or placebo subcutaneously every 4 weeks. After 24 weeks, subjects in the placebo group crossed-over to receive burosumab and all subjects continued treatment for an additional 24 weeks. A significantly greater percentage of subjects in the burosumab group attained the primary endpoint of mean serum phosphorus above the lower limit of normal (LLN) at the midpoint of the dosing intervals through week 24 compared with the placebo group (94.1% vs 7.6%; $P<0.0001$); increases were maintained between weeks 24–48 (crossover 89.4%, burosumab-only 83.8%). At baseline, 91 and 65 active fractures/pseudofractures (Fx/PFx) were present in 58% and 47% subjects in the crossover and burosumab-only group, respectively. At Week 24, 8% and 43% of Fx/PFx were healed after subjects received placebo and burosumab, respectively (odds ratio 16.8, $P<0.0001$). At Week 48, the burosumab-only group demonstrated additional Fx/PFx healing (63% Fx/PFx healed); the crossover group showed healing similar to that of the burosumab-only group at Week 24 (35%). For key secondary endpoints, burosumab had significantly greater decreases in stiffness score (-7.87 ± 3.04 vs 0.25 ± 3.13; $P=0.012$) than placebo at Week 24; and non-significant reductions in pain (LS mean change $\pm$ SE: burosumab -0.79 ± 0.21 vs placebo -0.32 ± 0.22; $P=0.092$) and physical functioning (-3.11 ± 2.55 vs 1.79 ± 2.72; $P=0.048$) scores. At Week 48, there were significant reductions from baseline (Week 24 for crossover) in stiffness (LS mean change $\pm$ SE: crossover -15.3 ± 3.5, burosumab-only -16.0 ± 3.3; both $P<0.0001$), physical functioning (crossover -6.4 ± 2.9, burosumab-only -7.8 ± 2.1; both $P<0.001$), and pain (crossover -1.5 ± 0.2, burosumab-only -1.1 ± 0.2; both $P<0.0001$) scores. Opioid use declined with burosumab (% subjects at Baseline, Week 24, Week 48: crossover 20%, 21%, 6%; burosumab-only 25%, 24%, 6%); NSAID use declined (crossover 65%, 58%, 17%; burosumab-only 69%, 63%, 19%). Fifteen subjects had serious AEs, none were drug-related. No meaningful changes in calcium, iPTH, or nephrocalcinosis scores occurred. Overall, burosumab was well tolerated in adults with XLH and associated with improvements in serum phosphorus, pain, stiffness, physical functioning, and Fx/PFx healing.

Can a bone protein protect against muscular dystrophy?

Jérôme Frenette
Université Laval, Québec, Canada.

Receptor-activator of nuclear factor kB (RANK), its ligand RANKL and the soluble decoy receptor osteoprotegerin (OPG) are the key regulators of osteoclast differentiation and bone remodelling. Although there is a strong association between osteoporosis and skeletal muscle atrophy, the functional relevance of a particular biological pathway that regulates synchronously bone and skeletal muscle physiopathology remain elusive. We thus hypothesized that RANK/RANKL/OPG, which is a key pathway for bone regulation, is involved in Duchenne muscular dystrophy (DMD) physiopathology. Our results show that muscle-specific RANK deletion (*mdx-RANK^{mko}*) in dystrophin deficient mdx mice improves specific force (54% gain of force) of EDL muscles with no protective effect against eccentric contraction-induced muscle dysfunction. In contrast, full-length OPG-Fc injections restore dystrophic EDL muscle force (162% gain in force), protect against eccentric contraction-induced muscle dysfunction *ex vivo* and significantly improve functional performance on downhill treadmill test and post-exercise mobility. Since OPG serves as a decoy receptor for RANKL and TRAIL, *mdx* mice were injected with anti-RANKL and anti-TRAIL antibodies to decipher the dual function of OPG. Injections of anti-RANKL and/or anti-TRAIL increase significantly dystrophic EDL muscle force (45 and 17% gains of force, respectively). In agreement, truncated OPG-Fc that contains only the RANKL domains produces similar gains, in terms of force production, than anti-RANKL treatments. To corroborate that full-length OPG-Fc also acts independently of RANK/RANKL pathway, dystrophin/RANK double-deficient mice were treated with full-length OPG-Fc for 10 days. Dystrophic EDL muscles exhibited a significant gain of force relative to untreated dystrophin/RANK double-deficient mice, indicating that the effect of full-length OPG-Fc is in part independent of the RANKL/RANK interaction. In addition, one key determinant of muscle contractility and performance is the Ca^{2+} pump called sarco/endoplasmic reticulum Ca^{2+} ATPase (SERCA). SERCA captures Ca^{2+} from the cytosol into the lumen of the sarcoplasmic reticulum, making Ca^{2+} available for the next contraction. SERCA activity is significantly depressed in dysfunctional and dystrophic muscles and full-length OPG-Fc treatment restored completely SERCA activity and markedly increased SERCA-2a expression. These findings demonstrate the superiority of full-length OPG-Fc treatment relative to truncated OPG-Fc, anti-RANKL, anti-TRAIL or muscle RANK deletion in improving dystrophic muscle function, integrity and protection against eccentric contractions. In conclusion, full-length OPG-Fc may be instrumental in the development of new treatments for muscular dystrophy in which a single therapeutic approach may be foreseeable to maintain both bone and skeletal muscle functions.

OC3.3

[^{18}F]-FDG PET/CT imaging: A tool to reveal the metabolic functions of bone marrow adipose tissue

Karla Suchacki, Adriana Tavares, Matthew Sinton, Carlos Alcaide, Nicholas Morton & William Cawthorn
University/BHF Centre for Cardiovascular Science, University of Edinburgh, Edinburgh, UK.

Introduction
White adipose tissue (WAT) and brown adipose tissue (BAT) are key regulators of systemic metabolic function. Bone marrow adipose tissue (BMAT) accounts for 10% of total adipose mass in healthy humans and therefore can be considered a third major adipose subtype. However, it is unclear if BMAT contributes to systemic energy homeostasis.
Objectives
Assess [^{18}F]-Fluorodeoxyglucose (FDG) uptake into bone and the marrow cavity (MC) following: i) insulin treatment in mice, ii) acute and chronic cold (CC) exposure in mice, or iii) conditions of BAT activation in humans.
Methods
Objective 1: mice were fasted for 4h and then treated with insulin (0.75 IU/g) or saline (0.9%), then immediately with [^{18}F]-FDG, and housed at room temperature (RT) for 1h before scanning. ***Objective 2:*** prior to [^{18}F]-FDG administration mice were fasted for 4 h at RT (control) or 4 °C (acute or CC), with CC mice further housed at 4 °C for 72 h before fasting. ***Objective 3:*** human subjects were exposed to mild cold (16 °C) for 2 h before [^{18}F]-FDG PET/CT scanning in i) participants who had received no medication or ii) three doses of prednisolone or placebo prior to attendance. All scans were analysed using PMOD software and measured activities of target tissues expressed as standard uptake values (SUV).
Results
The marrow cavity (MC) is the predominant site of [^{18}F]-FDG skeletal uptake. Insulin stimulated [^{18}F]-FDG uptake in the femur and the heart, as previously reported, but did not affect [^{18}F]-FDG uptake in the bone or MC at other skeletal sites. Despite suggestions that MAT is BAT-like, we found that neither bone nor the MC was cold-responsive during acute cold exposure. However, CC exposure profoundly increased [^{18}F]-FDG uptake in many of the tissues analysed. In cold-exposed humans, [^{18}F]-FDG uptake in the MC of the humerus and clavicle was very high, occurring at 10 and 28% of the level in BAT. Despite acutely increasing BAT activity, glucocorticoids decreased [^{18}F]-FDG uptake into the bone and had no effect of [^{18}F]-FDG uptake into the MC.
Conclusion
Glucose uptake within the MC does not respond to insulin or to acute activators of BAT. However, the MC is significant site of basal glucose uptake in humans and mice, and contributes to increased glucose uptake following CC exposure. Thus, BMAT might play a role in systemic glucose clearance and thereby influence metabolic homeostasis.

Renal function change in chronic hypoparathyroidism patients treated with recombinant human parathyroid hormone (1-84) (rhPTH[1-84]) and in a historical control cohort treated with standard therapy

Kristina Chen[1], Mishaela Rubin[2], Fan Mu[3], Elyse Swallow[3], Jing Zhao[3], Jessie Wang[3], Alan Krasner[1], Nicole Sherry[1], James Signorovitch[3], Markus Ketteler[4] & John Bilezikian[2]
[1]Shire Human Genetic Therapies, Inc., Lexington, Kentucky, USA; [2]Columbia University College of Physicians and Surgeons, New York, New York, USA; [3]Analysis Group Inc., Boston, Massachusetts, USA; [4]Division of Nephrology, Klinikum Coburg, Coburg, Germany.

Standard therapy (ST) for chronic hypoparathyroidism (HPT) includes calcium and active vitamin D supplementation, which can be associated with an increased risk of renal complications. This study compared renal function change, assessed by estimated glomerular filtration rate (eGFR) over 5 years between HPT patients receiving rhPTH1-84 as an adjunct to ST and a historical control cohort without rhPTH1-84. rhPTH1-84-treated HPT patients were selected from two single-arm, long-term, open-label studies, RACE (NCT01297309) and NCT02910466. Historical control patients were selected from the MedMining database using similar inclusion criteria to the two studies. Patients were required to have ≥ 2 eGFR measures, 5 years apart, after HPT diagnosis. Index date was defined as the baseline visit in the rhPTH1-84-treated cohort and as the 1st eligible eGFR measure date in the historical control cohort. eGFR change over time was compared using a multivariable model, adjusting for age, sex, history of hypertension, cardiac disorders, diabetes mellitus, hypercalcemia, hypocalcemia, concomitant nephrotoxic drug use, and baseline eGFR. A sensitivity analysis was conducted with a 3-year follow-up, which included patients with ≥ 2 eGFR measures, 3 years apart, after HPT diagnosis. One hundred and twenty two patients (N = 69 with and 53 without rhPTH1-84) were included in the 5-year analyses. At baseline, rhPTH1-84-treated patients were nominally younger (51.7 vs 55.8 years) and had lower eGFR (75.5 vs 82.5 ml/min per 1.73 mm^2). Race and sex were similar between cohorts. A lower proportion of rhPTH1-84-treated patients had concomitant nephrotoxic drug use or a history of hypocalcemia, hypercalcemia, hypertension, diabetes mellitus, or cardiac disorders. Characteristics were similar in the 3-year sensitivity cohorts (N = 75 with and 76 without rhPTH1-84). In the adjusted model, predicted eGFR change at year 5 was +5.80 vs −5.56 ml/min per 1.73 mm^2 in the rhPTH-treated vs historical control cohort. Annual rate of eGFR decline over 5 years of follow-up was significantly lower in rhPTH1-84-treated patients (difference in annual eGFR change = 2.13 ml/min per 1.73 mm^2; $P = 0.002$). The trend in eGFR change over 3 years was similar in the sensitivity analysis (difference in annual eGFR change = 2.96 ml/min per 1.73 mm^2; $P < 0.001$). In this non-randomized post-hoc analysis, patients with chronic HPT without rhPTH1-84 treatment exhibited significantly greater decline in eGFR than patients receiving rhPTH1-84 over 5 years, with and without adjusting for confounders. This difference was also observed over 3 years in similar cohorts. This analysis is hypothesis generating and further research is warranted.

OC3.5

Change in bone mineral density during the first 10 years of gender affirming hormonal treatment in transwomen and transmen

Chantal Wiepjes, Christel de Blok, Mariska Vlot, Renate de Jongh, Paul Lips & Martin den Heijer
VU University Medical Center, Amsterdam, Netherlands.

Background
Concerns about the effects of gender affirming hormonal treatment (HT) on bone mineral density (BMD) exists, particularly for transmen with decreasing estrogen levels. HT in transpersons affects BMD on short term, but long-term follow-up studies are lacking. Therefore this study aimed to investigate the change in BMD during the first 10 years of HT in adult transwomen and transmen, in order to determine whether it is necessary to assess BMD during HT.
Methods
A retrospective cohort study was performed in adult transpersons receiving HT at the VU University medical center Amsterdam (the Netherlands) between 1998 and 2015. Persons were included for analyses if they were gender affirming hormone naïve and had a dual-energy X-ray absorptiometry (DXA) scan at the start of HT. Follow-up DXA scans performed after 2, 5, or 10 years of treatment were used for analyses. The course of *Z*-scores of the lumbar spine during the first ten years of HT were analyzed using multilevel analysis, and the influence of age and serum sex hormone levels during HT were analyzed.
Results
Seven hundred and eleven transwomen (age 35 years, IQR 26–46) and 543 transmen (age 25 years, IQR 21–34) were included for analyses. Prior to the start of HT, 21.9% of transwomen and 4.2% of transmen had a low bone density, defined as a *Z*-score below −2.0. In transwomen, mean baseline *Z*-score was −0.93 (s.d. ± 1.32), which increased with +0.22 (95%CI 0.12 – 0.32) after ten years of HT. Transmen had a mean baseline *Z*-score of 0.01 (s.d. ± 1.14), which increased with +0.34 (95%CI 0.23 – 0.45) after ten years of HT. In both transwomen and transmen, *Z*-score increased more in the oldest age group (>40 years) compared with the younger age groups. In transwomen, higher estradiol level gave a higher increase in *Z*-score, while in transmen lower LH levels gave a higher increase in *Z*-score. Testosterone levels were not correlated with change in *Z*-score.
Conclusion
This study showed that HT does not have negative effects on BMD in transgender persons, which makes regularly assessment of BMD during HT not necessary. Higher estradiol levels in transwomen and lower LH levels in transmen gave a larger increase in *Z*-score, which indicates that adequate hormone substitution and therapy compliance should be stimulated. However, as even prior to HT a high percentage of low BMD is found, bone health remains an important health topic in transpersons.

Novel insights into prediabetes and type 2 diabetes

OC4.1

Dietary intervention modulates the expression of the splicing machinery in patients at high-risk of type 2 diabetes development: clinical implications

Mercedes del Rio-Moreno[1,2,3,4], Emilia Alors-Perez[1,2,3,4], Antonio Camargo[1,4,5], Javier Delgado-Lista[1,4,5], Juan L. Lopez-Canovas[1,2,3,4], Jose Lopez-Miranda[1,4,5], Raul M. Luque[1,2,3,4], Manuel D. Gahete[1,2,3,4] & Justo P. Castaño[1,2,3,4]
[1]Maimonides Institute of Biomedical Research of Cordoba (IMIBIC), Cordoba, Spain; [2]Reina Sofia University Hospital (HURS), Cordoba, Spain; [3]Department of Cell Biology, Physiology and Immunology, University of Cordoba, Cordoba, Spain; [4]CIBER Physiopathology of Obesity and Nutrition (CIBERobn), Cordoba, Spain; [5]Lipids and Atheroesclerosis Unit, Reina Sofia University Hospital, Cordoba, Spain.

Development of type-2 diabetes (T2D) is critically affected by the loss of phenotypic flexibility. There is emerging evidence suggesting that, under adverse metabolic conditions, alternative mRNA splicing is markedly dysregulated at different levels. For this reason, we hypothesized that such dysregulation could contribute to loss of phenotypic flexibility. Consequently, we aimed to explore whether changes in the splicing machinery in peripheral blood mononuclear cells (PBMCs) may serve as early indicator of T2D development, and if dietary intervention could modulate the expression of these components in order to reduce the risk of T2D. Thus, the expression pattern of selected components of the major ($n=13$) and minor ($n=4$) spliceosomes, and splicing factors (SFs; $n=28$) was determined in PBMCs, isolated from basal and 4 h postprandial blood, from non-T2D patients with high-risk to develop T2D (individuals with cardiovascular event included in the CORDIOPREV study). Specifically, 107 patients developed T2D in a median follow-up of 5 years (incident-T2D) and 108 non-T2D patients were randomly selected as controls. This analysis indicated that PBMCs of incident-T2DM patients exhibited lower levels of certain spliceosome components and SFs compared to non-T2D controls, which were significantly associated to the risk of T2D development. Altogether, these results showed that incident-T2D patients had an altered expression pattern at the inclusion in the study, suggesting a potential predictive value for T2D development. As these patients were randomly assigned to one of two healthy diets (Mediterranean and low-fat diets) in order to prevent T2D development, we also analyzed the expression of the splicing machinery components in the PBMCs from basal and 4 h postprandial blood from incident-T2DM and non-T2D patients after 3 years of follow-up under the two diet conditions. Results revealed that the expression of a reduced number of spliceosome components and SFs may be influenced by diet in a different manner in incicent-T2D and non-T2D subjects, as several spliceosomal components (e.g. SPFQ and SKIP) showed an alteration in their expression level in incident-T2D patients under the different diet conditions. Interestingly, changes were most remarkable during the post-prandial phase (e.g. RNU4 and RNU11) and associated to clinical parameters. Taken together, these data revealed the existence of pre-T2D development-associated spliceosome alterations that could be modulated by the diet and could be associated to the loss of phenotypic flexibility, suggesting that these changes might help to predict the development of T2D in high-risk patients.

Toe brachial index predicts major adverse cardiovascular events in patients with type 2 diabetes

Ioana Simona Chisalita[1], Magnus Wijkman[1], Lee Ti Chong[2], Anna Spångeus[1], Fredrik Nyström[3], Carl Johan Östgren[3] & Toste Länne[3]
[1]Department of Endocrinology and Department of Medical and Health Sciences, Linköping University, Linköping, Sweden; [2]Department of Emergency and Department of Medical and Health Sciences, Linköping University, Linköping, Sweden; [3]Department of Medical and Health Sciences, Linköping University, Linköping, Sweden.

Background
Earlier identification of diabetes patients at high risk of developing cardiovascular complication will help develop new therapeutic targets for the prevention of secondary diseases and death.
Objectives
We aim to test the predictive value of toe brachial index (TBI) as a risk marker of major adverse cardiovascular events (MACE) in patients with type 2 diabetes.
Methods
TBI was measured in 741 patients with type 2 diabetes (T2D) who participated in the epidemiological study CARDIPP (Cardiovascular Risk Factors in Patients with Diabetes-a Prospective Study in Primary Care; ClinicalTrials.gov identifier NCT010497377). Conventional risk markers for vascular disease as well as non-invasive measurements for arterial stiffness; carotid-femoral pulse-wave velocity (PWV, with applanation-tonometry) and intima-media thickness of carotid arteries (IMT, with B-mode ultrasound) were estimated. Patients were followed for incidence of major acute cardiovascular events using the national Swedish Cause and death and Hospitalization registries.
Results
During the follow-up for a period of 7 years 74 patients died or were hospitalized for MACE. TBI tertiles 1 versus 3 levels (crude) were negatively related to MACE (hazard ration HR for each unit of TBI 3.02, CI 1.71 to 5.99; $P<0.001$). TBI predicted MACE independently of age, sex, diabetes duration and treatment, anti-hypertensive treatment, previous cardiovascular diseases, HbA_{1C}, LDL cholesterol, eGFR, mean ambulatory systolic BP (HR 3.16, CI 1.50–6.70; $P=0.003$). This finding of increased MACE occurrence related to low TBI levels was also statistically significant when carotid-femoral PWW, atherosclerosis plaque identification, and IMT were added to the previous model (HR 3.12, 1.32–7.35; $P=0.009$).
Conclusions
In patients with type 2, TBI predicted the incidence of MACE independently of other cardio-metabolic as well atherosclerosis risk factors.

Effects of TRAIL delivery on an experimental model of type 2 diabetes and diabetic nephropathy

Stella Bernardi[1], Barbara Toffoli[2], Veronica Tisato[3], Andrea Lorenzon[4], Giorgio Zauli[3], Paola Secchiero[3] & Bruno Fabris[1]
[1]Università degli Studi di Trieste, Trieste, Italy; [2]IRCCS Burlo Garofolo, Trieste, Italy; [3]Università degli Studi di Ferrara, Trieste, Italy; [4]CBM scrl, Trieste, Italy.

Introduction
Experimental studies suggest that a circulating protein called TRAIL (TNF-related apoptosis-inducing ligand) has the potential to treat type 2 diabetes mellitus (T2DM). We have recently demonstrated that TRAIL delivery ameliorates T2DM in the high-fat diet-fed mouse. This study aimed at evaluating whether TRAIL had the potential to treat not only T2DM but also diabetic nephropathy.
Methods/design
Based on this background, 15 male db/H mice aged 8 weeks were randomly assigned to saline (CNT, $n=10$) or TRAIL treatment (CNT + T, $n=5$), together with 20 male db/db mice which were randomly assigned to saline (db/db, $n=10$) or TRAIL treatment (db/db + T, $n=10$). TRAIL was delivered at the dose of 20 microg/mouse twice per week. Body weight, food intake, fasting glucose and insulin, as well as albuminuria were measured at baseline and every 4 weeks. GTT (glucose tolerance test) and ITT (insulin tolerance test) were performed at the end of the study. Then, mice were sacrificed and bloods and tissues were collected for further analyses.
Results
In the db/db mouse, TRAIL treatment did not affect body weight and glucose metabolism, which might be due to the extreme phenotype exhibited by this genetic model of obesity. Nevertheless, TRAIL delivery significantly reduced glomerular hypertrophy and glomerulosclerosis, indicating a potential therapeutic effect on diabetic nephropathy. This might involve prosurvival/proapoptotic pathways and anti-inflammatory effects.
Conclusion
This study sheds light on TRAIL therapeutic potential against diabetic nephropathy.

Association between prediabetes and incidence of chronic kidney disease, incident albuminuria, or worsening of kidney function: a secondary analysis of the SPRINT trial

João Sérgio Neves[1,2], Miguel Bigotte Vieira[3], Rita Magriço[4], Lia Leitão[5], Catarina Viegas Dias[6], Rute Baeta Baptista[7], Ana Oliveira[1] & Davide Carvalho[1,8]
[1]Department of Endocrinology, Diabetes and Metabolism, São João Hospital Center, Porto, Portugal; [2]Department of Surgery and Physiology, Faculty of Medicine, Cardiovascular Research Center, University of Porto, Porto, Portugal; [3]Nephrology and Renal Transplantation Department, Centro Hospitalar Lisboa Norte, Lisbon, Portugal; [4]Nephrology Department, Hospital Garcia de Orta, Lisbon, Portugal; [5]Neurology Department, Hospital Professor Doutor Fernando Fonseca, Amadora, Portugal; [6]NOVA Medical School, Lisbon, Portugal; [7]Pediatric Nephrology Unit, Hospital de Dona Estefânia, Centro Hospitalar Lisboa Central, Lisbon, Portugal; [8]Instituto de Investigação e Inovação em Saúde da Universidade do Porto, Porto, Portugal.

Introduction
Diabetes is a major risk factor for chronic kidney disease (CKD). Previous studies have shown contradictory results regarding the effect of prediabetes in the development of CKD.
Methods
We performed a secondary analysis of the SPRINT trial (Systolic Blood Pressure Intervention Trial) involving 9361 patients without diabetes and with an increased cardiovascular risk (clinical or subclinical cardiovascular disease, estimated glomerular filtration rate [eGFR] 20–60 ml/min per 1.73 m^2, 10-year Framingham score $\geq 15\%$, or age ≥ 75 years). We divided patients according to fasting glucose into two groups: normoglycemia (fasting glucose <100 mg/dl) and prediabetes (fasting glucose ≥ 100 mg/dl). In non-CKD patients, we assessed the incidence of CKD (decrease in eGFR $\geq 30\%$ to <60 ml/min per 1.73 m^2) and the incidence of albuminuria (doubling of the ratio of albumin/creatinine from <10 mg/g to >10 mg/g). In patients with CKD, we evaluated the incidence of a decrease in the eGFR $\geq 50\%$, the incidence of albuminuria and the development of end-stage renal disease (ESRD) requiring dialysis or kidney transplantation. We used Cox proportional hazard models to estimate hazard ratios (HR) adjusting for age, sex, race, systolic blood pressure, BMI, smoking, prior cardiovascular disease, statin and aspirin use, and trial treatment arm.
Results
In the SPRINT trial, 5425 (58.2%) patients had normoglycemia and 3898 (41.8%) had prediabetes. The prevalence of CKD was similar between groups (29.1% in normoglycemia vs 27.4% in prediabetes, $P=0.09$). During a median follow-up of 3.26 years, there were 164 (1.8%) patients with incident CKD and 245 (2.6%) with incident albuminuria among non-CKD patients. In patients with CKD, there were 21 (0.2%) patients with a decrease in the eGFR $\geq 50\%$, 108 (1.2%) with incident albuminuria and 16 (0.2%) requiring dialysis or kidney transplantation. The adjusted HR for incidence of CKD in patients with prediabetes compared with normoglycemic patients was 1.02 (0.73–1.42, $P=0.91$) and for incident albuminuria in non-CKD patients was 1.06 (0.80–1.39, $P=0.69$). Among patients with CKD at baseline, the adjusted HR for decrease in the eGFR $\geq 50\%$ in prediabetes compared with normoglycemia was 1.64 (0.64–4.22, $P=0.30$), for incident albuminuria was 0.89 (0.57–1.39, $P=0.61$), and for the development of ESRD requiring dialysis or kidney transplantation was 0.45 (0.12–1.66, $P=0.23$).
Conclusions
In the SPRINT trial, prediabetes was not associated with a higher incidence of CKD, incident albuminuria or worsening of kidney function. Prediabetes does not appear to be a relevant risk factor for development or progression of CKD.

[1]Endocrinology and Nutrition Department, Research Group on Immunology and Metabolism, IRBLleida, University of Lleida, University Hospital Arnau de Vilanova, Lleida, Spain; [2]Vascular and Renal Translational Research Group, IRBLleida, Unit for the Detection and The treatment of Atherothrombotic Diseases (UDETMAV&R), University of Lleida, University Hospital Arnau de Vilanova, Lleida, Spain; [3]Pneumology Service, Translational Research in Respiratory Medicine, IRBLleida, University of Lleida, University Hospital Arnau de Vilanova, Lleida, Spain; [4]CIBER de Enfermedades Respiratorias, CIBERES, Instituto de Salud Carlos III (ISCIII), Madrid, Spain; [5]Clinical Neurosciences Group, IRBLleida, Stroke Unit, University of Lleida, University Hospital Arnau de Vilanova, Lleida, Spain; [6]Metabolic Pathophysiology Group, Department of Experimental Medicine, IRBLleida, University of Lleida, Lleida, Spain; [7]Borges Blanques Primary Health Care Unit, Lleida, Spain; [8]CIBER de Diabetes y Enfermedades Metabólicas Asociadas, CIBERDEM, Instituto de Salud Carlos III (ISCIII), Madrid, Spain.

Background and aims
There are growing evidence supporting the deleterious effect of type 2 diabetes (T2D) on respiratory function and sleep breathing disorders. However, there is no information about the characteristics of lung function in the prediabetes stage.
Methods
We assessed pulmonary function in 3,455 non-diabetic subjects, aged between 45 and 70 years, without vascular disease nor chronic pulmonary obstructive disease from the cross-sectional study ILERVAS (ClinTrials.gov Identifier: NCT03228459). Prediabetes was defined by an HbA1c between 5.7 and 6.5%. The spirometric parameters were evaluated according to the global initiative for chronic obstructive lung disease.
Results
The entire population included 1,093 (31.6%) individuals with prediabetes and 2,362 control subjects. Subjects with prediabetes exhibited a significantly lower forced vital capacity (FVC: 93 [82;105] vs 96 [84;107] % of predicted, $P<0.001$), forced expiratory volume in the first second (FEV_1: 95 [82;108] vs 97 [85;109] % of predicted, $P=0.004$) in comparison with control subjects. In addition, a higher percentage of subjects with FVC $<80\%$ (20.7% vs 16.3%) and $FEV_1<80\%$ (19.7% vs 16.6%) was present among patients with prediabetes ($P<0.001$ for both comparisons). In the bivariate analysis, HbA1c was negatively correlated with both lung parameters (CVF: $r=-0.130$, $P<0.001$; FEV_1: $r=-0.097$, $P=0.001$) in the prediabetes group; however, this relation disappeared in the control group. Finally, in the multivariate stepwise regression analysis, HbA1c independently predicted FVC ($R^2=0.082$, $\beta=-0.062$) and FEV_1 ($R^2=0.073$, $\beta=-0.055$).

Conclusions
The negative impact of T2D in lung function seems to be present also in the prediabetes stage. Whether the preventive, diagnostic, and therapeutic measures of the 'prediabetes lung' should be initiated before the diagnosis of T2D needs to be evaluated in the next future.

Is adrenal computed tomography accurate for the diagnosis of unilateral primary aldosteronism? A retrospective international cohort study

Tracy Ann Williams[1,2] & Martin Reincke[1]
[1]Ludwig-Maximilians-University, Munich, Germany; [2]University of Turin, Turin, Italy.

Background
Unilateral primary aldosteronism is the most common surgically correctable form of endocrine hypertension, usually diagnosed by adrenal vein sampling (AVS) or computed tomography (CT). We compared the outcomes of patients diagnosed by CT and AVS and determined if CT can reliably diagnose unilateral primary aldosteronism in young patients with an evident phenotype.
Methods
Patient data were obtained from 18 internationally distributed centres over 4 continents from January 1994 to June 2016. Data were retrospectively analysed for clinical and biochemical outcomes after unilateral adrenalectomy from CT ($n=235$ patients) or AVS ($n=526$ patients) management using the standardised PASO (primary aldosteronism surgical outcome) criteria.
Findings
A smaller proportion of patients achieved complete biochemical success (cure of primary aldosteronism) with CT compared with AVS management (80.0% vs 93.3%, $P<0.001$). Absent biochemical success was present in 12.3 and 1.9% of patients in the CT and AVS groups, respectively ($P<0.001$). A diagnosis by CT was associated with a decreased likelihood of complete biochemical success (adjusted OR 0.28, 0.16–0.50; $P<0.001$). The clinical outcomes between the CT and AVS groups were not significantly different but the absence of a post-surgical elevated aldosterone-to-renin ratio was a marker of complete clinical success (adjusted OR 14.8, 1.76–124.53; $P=0.013$) and of clinical benefit (complete + partial clinical success) (adjusted OR 45.5, 11.63–177.93; $P<0.001$) in the CT but not in the AVS group. In the CT group there were 11 patients aged <35 years with a single unilateral nodule (>10 mm diametre) and a normal contralateral gland. Absent or partial biochemical success (persisting primary aldosteronism) was present in three of these 11 patients and all three had baseline plasma aldosterone concentrations >554.8 pmol/l (20 ng/dl).
Interpretation
Patients with CT management for unilateral primary aldosteronism have an increased likelihood of an incorrect diagnosis (compared with AVS) and misdiagnosis can occur in young patients with a strong phenotype. Inappropriate aldosterone production driven by CT based surgery is associated with absent clinical outcomes. This supports the recommendation to perform AVS in all patients with primary aldosteronism independent of age and phenotype.

Steroid profiling by liquid chromatography tandem mass spectrometry in a large cohort of patients with adrenal incidentalomas

Guido Di Dalmazi, Flaminia Fanelli, Guido Zavatta, Eleonora Rinaldi, Elena Casadio, Silvia Ricci Bitti, Marco Mezzullo, Valentina Vicennati & Uberto Pagotto
Division of Endocrinology and Centre for Applied Biomedical Research, Department of Medical and Surgical Sciences, Alma Mater Studiorum, University of Bologna, Bologna, Italy.

Background
Steroid profiling by mass spectrometry (MS) provided novel insights into the pathogenesis of adrenocortical tumors and hypercortisolism. The aims of the study were (I) to analyze the steroid profiling by liquid chromatography-tandem MS (LC-MS/MS) in a large cohort of patients with adrenal incidentalomas and (II) to investigate the relationship between steroid profile and clinical outcomes.
Methods
We included 307 patients with mono- and bilateral benign adrenal tumors, after excluding pheochromocytoma, primary hyperaldosteronism, late-onset congenital adrenal hyperplasia, and Cushing's syndrome. We classified patients as non-secreting (NS) or with subclinical hypercortisolism (SH) according to cortisol after 1 mg-dexamethasone suppression test (DST) (≤ 50 and >50 nmol/L, respectively). LC-MS/MS serum steroid profiling included cortisol, cortisone, 21-deoxycortisol, 11-deoxycortisol, 11-deoxycorticosterone, corticosterone, progesterone, 17-hydroxyprogesterone, androstenedione, dehydroepiandrosterone (DHEA), and testosterone. Steroid profile was assessed in basal condition in all patients, after 1 mg-DST ($n=153$), and after stimulation with 1-24ACTH 250 μg ($n=91$). Data at follow-up (mean 39.6 months) were available for 207 patients.
Results
Basal steroid profiling revealed increased levels of cortisol ($P=0.001$) and 11-deoxycortisol ($P=0.002$), and lower DHEA ($P<0.001$) and androstenedione ($P<0.001$) in patients with SH vs NS. Comparable results were obtained in adenoma SH vs NS ($n=175$) and hyperplasia SH vs NS ($n=132$). 1-24ACTH stimulation revealed significant higher levels of all steroids, except for 21-deoxycortisol and androgens, in SH vs NS. Additionally, higher levels of 21-deoxycortisol ($P=0.006$) and lower levels of DHEA ($P=0.014$) and androstenedione ($P=0.034$) were observed in patients with adenoma associated with SH vs NS. Steroid profiling after 1 mg-DST revealed higher levels of cortisone, 11- deoxycortisol, and corticosterone ($P<0.001$ for all) in SH vs NS. Moreover, androgens were significantly lower in patients with SH. Logistic regression analysis showed that increasing corticosterone levels (Odds Ratio (OR) 1.122, 95% Confidence Interval (CI) 1.006–1.251, $P=0.038$) and reduced DHEA levels (OR 0.474, 95% CI 0.241–0.931, $P=0.030$) were associated with cardiovascular events, among all potential contributing factors. Increasing levels of 11-deoxycortisol were significantly associated with diabetes/impaired glucose tolerance (OR 3.002, 95% CI 1.143–7.889, $P=0.026$), with an independent contribution of age ($P=0.002$), BMI ($P=0.039$) and family history of diabetes (0.001). Patients with NS tumors who developed SH during follow-up (24/207, 11.6%) had basal lower DHEA, androstenedione, and ACTH levels, and showed higher cortisol after 1 mg-DST and larger adrenal tumors.
Conclusion
Patients with SH have a specific steroid profile with potential implications on cardiovascular and metabolic alterations.

***PRKACA* L206R mutation in adrenal Cushing's syndrome makes PKA RIIβ susceptible for caspase-mediated cleavage**

Isabel Weigand[1], Cristina L. Ronchi[1,2], Kerstin Höfner[1], Jens T. Vanselow[3], Sabine Herterich[4], Kerstin Bathon[5], Andreas Schlosser[3], Martin Fassnacht[1] & Davide Calebiro[2,5,6]
[1]Division of Endocrinology and Diabetes, University Hospital, Würzburg, Germany; [2]Institute of Metabolism and Systems Research, University of Birmingham, Birmingham, UK; [3]Rudolf Virchow Center for Experimental Biomedicine, University of Würzburg, Würzburg, Germany; [4]Central Laboratory, University Hospital, Würzburg, Germany; [5]Institute of Pharmacology and Toxicology and Bioimaging Center, University of Würzburg, Würzburg, Germany; [6]Centre of Membrane Proteins and Receptors (COMPARE), Universities of Birmingham and Nottingham, Birmingham, Nottingham, UK.

Protein Kinase A (PKA) consists of two catalytic and two regulatory subunits with several isoforms (Cα, β, γ and RIα, IIα, Iβ, IIβ, respectively). Type II regulatory subunits are phosphorylated by PKA in their inhibitory sites, while type I are not. Somatic activating mutations in the gene encoding the catalytic subunit α (Cα) of PKA (PRKACA) have been found in 30–40% of cortisol-producing adrenocortical adenomas (CPA). We recently described reduced levels of RIIβ in PRKACA-mutated CPA compared to *PRKACA* WT CPA. In NCI-H295R cells co-transfected with RIIβ and $C\alpha^{WT}$ or $C\alpha^{L206R}$, the L206R mutation led to a full degradation of RIIβ and this degradation could not be reversed by proteasome and lysosome inhibition but by caspase inhibition. Same co-transfections with RIα did not lead to its degradation. When the inhibitory site of RIIβ was replaced by the corresponding amino acids of RIα, $C\alpha^{L206R}$ did not lead to RIIβ degradation, while it was able to degrade RIα when its inhibitory site was replaced by the corresponding amino acids of RIIβ. Same results were observed

when point mutations were introduced into RIIβ or RIα in order to delete or introduce a serine into the inhibitory site (serine 114). In addition, a protein interacting with RIIβ only in $C\alpha^{L206R}$–transfected cells was identified by performing nanoLC-MS/MS analysis and interestingly, this protein is known to interact with caspases. Furthermore, a knockdown of RIIβ led to increased cortisol secretion in NCI-H295R cells. These results show that the phosphorylation of serine 114 in the inhibitory site of RIIβ plays a fundamental role in RIIβ stability and makes RIIβ susceptible for degradation in the presence of $C\alpha^{L206R}$, which is likely mediated by caspases. The resulting decreased levels of RIIβ could additionally contribute to increased cortisol levels in Cushing adenoma patients.

Assessment of Tissue Sodium Content by ^{23}Na-MRI in Patients with Adrenal Insufficiency – a Pilot Study

Andreas Weng[1], Stephanie Burger-Stritt[2], Irina Chifu[2], Martin Christa[3], Bernhard Petritsch[1], Thorsten Bley[1], Herbert Köstler[1] & Stefanie Hahner[2]
[1]Department of Diagnostic and Interventional Radiology, University Hospital Würzburg, Würzburg, Germany; [2]Department of Endocrinology and Diabetology, University Hospital Würzburg, Würzburg, Germany; [3]Comprehensive Heart Failure Center, University Hospital Würzburg, Würzburg, Germany.

Introduction
Patients with chronic primary adrenal insufficiency (PAI) depend on lifelong gluco- (GC) and mineralocorticoid (MC) replacement therapy. Reduced subjective well-being is however often described by these patients in absence of clinical or laboratory abnormalities and is thus a strong indicator of the gap between the concept of adequate hormone substitution and patients' requirements. The aim of this study was to investigate the potential role of ^{23}Na-MRI for noninvasive monitoring of steroid replacement in PAI.
Methods
Sodium content (SC) was analyzed both in the calf muscle and skin of 16 patients and 16 sex-, age- and BMI-matched controls. Patients were classified into three groups (optimal, subtherapeutic, supraphysiological) according to the quality of GC and MC substitution assessed separately by clinical scores based on subjective wellbeing and clinical/laboratory parameters. Muscle and skin sodium content (Muscle-SC, Skin-SC) were determined using a ^{23}NA-MRI protocol on a 3T scanner implementing a 3D sequence.
Results
Plasma renin concentration and Muscle-SC were significantly higher in patients compared to controls (43.2 vs 11.7 ng/l, $P=0.014$ and 19.1 vs 16.0 mmol/l, $P=0.002$), whereas no significant differences in plasma/urinary electrolytes or Skin-SC were detected. These results were replicated in the subgroups receiving optimal GC and MC replacement, respectively. Skin-SC significantly correlated with 24h-urine sodium level in the whole cohort. When comparing Muscle-SC and Skin-SC with obtained clinical scores a trend from lower SC for low scores to higher SC for higher scores was observed (Table 1).
Conclusion
Interestingly, patients under sufficient replacement therapy exhibited significantly higher Muscle-SC compared to controls, whereas Skin-SC and laboratory parameters did not differ between groups. This discrepancy suggests that mechanisms involved in tissue sodium homeostasis might elude classical feedback regulation. Chronic mineralocorticoid depletion – suggested by elevated plasma renin concentration- might induce tissue sodium storage for the purpose of providing a sodium reservoir. The agreement between tissue SC and clinical scores indicates that ^{23}Na-MRI might be a quantitative method to assess steroid replacement. Further studies on a larger cohort are, however, needed to prove these initial findings.

Table 1 Tissue SC (mmol/l) according to obtained clinical scores

	Tissue SC (mmol/l)	Subtherapeutic	Optimal	Supraphysiological
GC replacement	Muscle-SC	17.27±5.15	19.21±2.12	20.96±0
	Skin-SC	15.12±1.25	16.08±3.03	18.4±0
MC replacement	Muscle-SC	18.09±2.44	19.01±3.17	20.91±0.5
	Skin-SC	15.06±2.14	15.22±2.3	18.94±3.95

Cullin 3 is a partner of Armadillo Repeat Containing 5 (ARMC5), the product of the gene responsible for Primary Bilateral Macronodular Adrenal Hyperplasia

Isadora Cavalcante[1,2], Eric Clauser[3], Anna Vaczlavik[1], Ludivine Drougat[1], Claudimara Lotfi[2], Maria Fragoso[4], Marthe Rizk-Rabin[1], Jérôme Bertherat[1,5] & Bruno Ragazzon[1]
[1]Inserm U1016, CNRS 8104, Institut Cochin, Paris Descartes University, Paris, France; [2]Department of Anatomy, Institute of Biomedical Sciences, São Paulo, Brazil; [3]Inserm U970, Paris Cardiovascular Center, Paris Descartes University, Paris, France; [4]Adrenal Unit, Laboratory of Hormones and Molecular Genetics LIM/42, University of Sao Paulo, São Paulo, Brazil; [5]Department of Endocrinology, Cochin Hospital, Assistance Publique Hôpitaux de Paris, Centre de référence des maladies rares de la surrénale, Centre de référence des cancers rares de la surrénale, Paris, France.

Background
ARMC5 (armadillo repeat containing 5) has been identified as the gene responsible for PBMAH (Primary Bilateral Macronodular Adrenal Hyperplasia). *ARMC5* inactivating mutations are reported in 20 to 25% of PBMAH patients. *ARMC5*, is considered as a tumor suppressor gene controlling apoptosis and regulating steroidogenesis. The mechanisms of action of *ARMC5* are unknown. The structure of the ARMC5 protein contains ARM repeats and a BTB domain, patterns known to play a role in protein-protein interactions. Therefore identification of proteins that interact with ARMC5 and study of the mechanisms of this interaction will help to understand its function. By co-immunoprecipitation followed by mass spectrometry in HEK293 cells we identified a potential interaction between ARMC5 and Cullin3 (Cul3), also suggested in online databases and by 2 Hybrid Assay (Hu *et al*, Nat Com 2017). Cul3 is an E3 ligase that mediates the ubiquitination process and subsequent degradation of specific protein substrates. Therefore, the aim of this study was to confirm this interaction and to investigate its mechanisms.
Methods
We used immunoprecipitation experiments with HA-tagged Cul3 and the bioluminescence resonance energy transfer (BRET) proximity assay in HEK293 cells in order to confirm and investigate the interaction of ARMC5 with Cul3.
Results
ARMC5 co-immunoprecipitated with HA-Cul3 and a hyperbolic BRET saturation curve was observed with YFP-Cul3 and ARMC5-Luc indicating a specific close proximity between these two proteins. We have also observed that a missense mutation in the BTB domain (p.L754P) of ARMC5 causes the loss of its interaction with Cul3. Altogether, these complementary approaches demonstrate that ARMC5 and Cul3 form a complex involving the BTB domain of ARMC5.
Conclusion
These data demonstrate that Cul3 is an ARMC5 partner. A likely direct interaction involves the BTB domain of ARMC5 and can be altered by pathogenic ARMC5 missense mutations. This suggests that ARMC5 participates in the ubiquitination process and open new perspectives in the pathophysiology of PBMAH.

Genetic and environmental determinants of obesity and insulin resistance

OC6.1

5β-reductase (AKR1D1) is a potent regulator of hepatic insulin sensitivity, carbohydrate and lipid metabolism *in vitro* and *in vivo*

Nikolaos Nikolaou[1], Laura Gathercole[1,2], Lea Marchand[3], Sara Althari[1], Charlotte Green[1], Catriona McNeil[1], Shelley Harris[1], Martijn van de Bunt[1], Wiebke Arlt[4], Leanne Hodson[1] & Jeremy Tomlinson[1]
[1]University of Oxford, Oxford, UK; [2]Oxford Brookes University, Oxford, UK; [3]Catholic University of Lyon, Lyon, France; [4]University of Birmingham, Birmingham, UK.

Non-alcoholic fatty liver disease (NAFLD) is the hepatic manifestation of metabolic disease. 5β-reductase (AKR1D1) is highly expressed in human liver where it inactivates steroid hormones and, in parallel, catalyzes a fundamental step in bile acid synthesis. Steroid hormones, including glucocorticoids, as well as bile acids (BAs) are established regulators of metabolic phenotype. We have hypothesized that AKR1D1 plays a crucial regulatory role in hepatic metabolic

homeostasis. Genetic manipulation of AKR1D1 (over-expression, siRNA knockdown) was performed in human liver HepG2 and Huh7 cells. Gene expression changes were confirmed by qPCR. Functional activity, assessed using gas chromatography-mass spectrometry to measure cortisone clearance and tetrahydrocortisone generation was paralleled by the anticipated changes in glucocorticoid receptor activation, as measured by luciferase reporter assays. In addition, total BA production was decreased, resulting in disturbed BA composition. RNA sequencing analysis following AKR1D1 knockdown defined discrete dysregulated metabolic pathways, notably those impacting upon insulin action and fatty acid storage and utilization. Insulin sensitivity was enhanced with increased insulin-stimulated phosphorylation of AKT, mTOR and GSK-3β following AKR1D1 knockdown. Endorsing our cellular observations, hepatic total AKT levels in 12-week AKR1D1 knockout male mice were higher than in wild-type controls, with evidence of increased phosphorylation upon insulin stimulation. *In vitro*, AKR1D1 knockdown increased glucose transporter mRNA expression with an associated decrease in extracellular glucose concentrations (15.3 ± 1.5 vs 12.1 ± 0.9 mmol/mg, $P < 0.05$) and increased intracellular glycogen accumulation (18.9 ± 0.3 vs 22.7 ± 0.3 ug/ml, $P < 0.05$). In addition, Fatty Acid Synthase (FASN) and Acetyl CoA Carboxylase 1 (ACC1) expression, the rate-limiting step in *de novo* lipogenesis, (DNL), were increased, resulting in enhanced phosphorylation of ACC and increased intracellular triglyceride accumulation (54.3 ± 12.7 vs 73.3 ± 11.0 nmol/mg, $P < 0.01$). Mass spectrometry analysis of lipid composition demonstrated increased palmitic and palmitoleic acid synthesis, consistent with increased DNL and fatty acid saturation. Cell media 3-hydroxybutyrate levels were reduced (18.7 ± 2.3 vs 11.4 ± 2.7 nmol/mg, $P < 0.01$), indicative of impaired fatty acid oxidation. Pharmacological manipulation of BA receptor activation, using the FXR agonist GW4064 and LXR antagonist 22(S)-Hydroxycholesterol, prevented the induction of lipogenic genes, suggesting that the observed metabolic phenotype is likely to be driven through BA rather than steroid hormone availability. In conclusion, AKR1D1 has the ability to regulate hepatocyte insulin sensitivity as well as carbohydrate and lipid metabolism, and therefore may have an as yet unexplored role in the pathophysiology of NAFLD.

Deep transcranial magnetic stimulation acutely modulates neuro-endocrine pathways underlying obesity

Anna Ferrulli[1], Michela Adamo[1], Stefano Massarini[2] & Livio Luzi[1,2]
[1]IRCCS Policlinico San Donato, San Donato Milanese (MI), Milan, Italy; [2]University of Milan, Milan, Italy.

Deep Transcranical Magnetic Stimulation (dTMS) is a non-invasive modulation technique of cortical excitability that has shown to affect the mesolimbic and mesostriatal dopaminergic pathways. Consistent with these assets, dTMS is widely used as a therapeutic tool in neuro-psychiatric disorders associated with abnormal cortical excitability and dopaminergic activity, as addiction. Hence, considering the dysfuncional role of PFC and dopaminergic reward system in controlling appetite, dTMS was suggested to be affective in reducing food craving and in controlling body weight in obese subjects. However, the underlying physiological mechanisms of the dTMS effects are not fully know. Aim of this study was to investigate the effects of a single dTMS session on neuro-endocrine pathways in obesity. Fourty obese patients (11 M, 29 M; age: 48.0 ± 1.6; BMI: 36.3 ± 0.7) were assigned to receive one session of high frequency (18 Hz, HF), low frequency (1 Hz, LF) or Sham stimulation via an H-coil dTMS. H-coil was targeted to stimulate Prefrontal Cortex and Insula, bilaterally. Metabolic and neuro-endocrine parameters were evaluated before and after a single dTMS session. Following the 18 Hz dTMS session, a significant increase of norepinephrine was found (5.6 ± 0.9 vs 6.5 ± 1.2 ng/ml, $+18.0 \pm 6.8\%$, $P = 0.01$; $P = 0.05$ vs LF); a rise in β-endorphins levels was also shown (0.338 ± 0.049 vs 0.372 ± 0.048 ng/ml, $+13.9 \pm 4.6\%$, $P = 0.017$; $P = 0.010$ vs Sham; $P = 0.011$ vs LF). In the same group, glucose levels significantly increased (90.2 ± 4.1 vs 96.2 ± 4.2 mg/dl, $+7.0 \pm 1.8\%$, $P = 0.002$), whilst leptin levels significantly decreased (66.9 ± 10.5 vs 56.3 ± 9.0 ng/ml, $-16.3 \pm 3.0\%$, $P = 0.002$). Furthermore, pituitary hormones significantly decreased after a single 18 Hz dTMS session, specifically TSH (2.71 ± 0.25 vs 2.09 ± 0.18 μU/ml, $-20.7 \pm 4.7\%$, $P = 0.001$) and prolactin (17.1 ± 1.3 vs 10.6 ± 0.8 ng/ml, $-34.7 \pm 4.7\%$, $P < 0.0001$). In the LF, a significant reduction of salivary cortisol was also observed ($-29.4 \pm 9.3\%$, $P = 0.015$). These results suggest that dTMS can acutely affect orexygenic pathways and metabolic parameters mainly via modulation of the sympathetic activity and hypothalamic-pituitary-adrenal axis. The increase of β-endorphins could suggest a potential role of HF dTMS in inducing the dopaminergic system activation and therefore, in modulating the food reward system. Together these findings support the role of dTMS as a novel promising treatment for obesity.

Visceral fat assessment in lamin A/C mutation carriers: phenotype – genotype correlation

Maxime Kwapich[1], Stéphanie Espiard[1], Kristell Le Mapihan[2], Corinne Vigouroux[3,4] & Marie-Christine Vantyghem[1,5,6]
[1]Endocrinology and Metabolism, CHU Lille, Lille, France; [2]Endocrinology and Metabolism, CGU Lille, Lille, France; [3]Department of Molecular Biology and Endocrinology, Assistance Publique-Hopitaux de Paris, CHU Saint Antoine Paris, Paris, France; [4]Reference Center for Rare Disorders of Insulin Secretion (PRISIS), Paris, France; [5]INSERM 1190, University of Lille, Lille, France; [6]PRISIS, Lille, France.

Background
Lamin A/C mutations show heterogeneous phenotypes expanding from cardiopathies to lipodystrophies. R482-*LMNA* gene mutation is the hot-spot for familial partial lipodystrophic syndromes (FPLD2) and is characterized by an increase of intra-abdominal (visceral) fat. In contrast, the visceral fat phenotype of non-R482-*LMNA* mutated patients has not been well studied.
Objectives
To compare the fat amount and visceral repartition of non-R482, R482-*LMNA* mutated patients, and non-mutated healthy controls.
Methods
This study included 29 carriers of Non-R482 lamin A/C gene mutation (non-R482 group), 29 R482-*LMNA* mutated patients, and 19 normal-weight healthy controls, in a single university hospital (Clin.gov2009-AO-1169-48). Body composition (DEXA/MRI), metabolic/inflammatory parameters, and circulating leptin levels were compared between the three groups.
Results
Gender and age did not differ between the two *LMNA*-mutated groups. R482 carriers had lower BMI (23.9 (22.2; 27.0) vs 27.5 (22.5; 29.4) kg/m^2; $P < 0.05$), leptin (5.2 (2.8; 8.0) vs 15.9 (5.2; 22.3) ng/ml; $P < 0.01$), HDL cholesterol (40 (30; 40) vs 48 (40; 50) mg/dl; $P < 0.05$) and fat mass (20 (17.7; 22.8) vs 29.7 (18.7; 38.1) %; $P < 0.001$), and higher intra/total abdominal fat ratio (0.59 (0.47; 0.67) vs 0.36 (0.22; 0.45); $P < 0.001$), fasting blood glucose (117 (94; 199) vs 91 (83; 97) mg/dl; $P < 0.001$), prevalence of diabetes ((82.7% vs 41.4%); $P < 0.01$) and hypertriglyceridemia (55.2% vs 27.6%; $P < 0.05$) than non-R482 carriers, respectively. In the control group, BMI (22 (21; 24) kg/m^2), leptin (4.6 (4.1; 10.7) ng/ml), fasting blood glucose (85 (83; 94) mg/dl, intra/total abdominal fat ratio (0.20 (0.11; 0.30)) were lower, and HDL-cholesterol (56 (44; 70) mg/dl) was higher than in *LMNA*-mutated patients, whatever the type of mutation. The fat mass (22 (20; 30) %) of the control group was intermediate between the two *LMNA*-mutated groups.
Conclusion
The non-R482 group had the highest BMI, percentage of fat mass (DEXA), and leptin level of the three groups. The intra/total abdominal fat mass and the frequency of metabolic syndrome were however intermediate between healthy controls (no metabolic syndrome) and FPLD2 who were twice more often diabetic (80%) than non-R482 mutated patients (40%). The visceral fat assessment is one of the most reliable diagnosis criteria of *LMNA*-mutated syndromes and correlates with the metabolic syndrome.

Anthropometric measurements and metabolic syndrome in relation to glucocorticoid receptor polymorphisms in (local) corticosteroid users

Mesut Savas[1,2], Vincent L. Wester[1,2], Anand M. Iyer[1,2], Erica L.T. van den Akker[2,3] & Elisabeth F.C. van Rossum[1,2]
[1]Internal Medicine, Division of Endocrinology; Erasmus MC, University Medical Center Rotterdam, Rotterdam, Netherlands; [2]Obesity Center CGG (Centrum Gezond Gewicht), Erasmus MC, University Medical Center Rotterdam, Rotterdam, Netherlands; [3]Pediatric Endocrinology; Erasmus MC, University Medical Center Rotterdam, Rotterdam, Netherlands.

Introduction
Corticosteroids are amongst the most prescribed drugs and their use has been linked to cardiometabolic adverse events including weight gain and abdominal adiposity. We previously showed that users were also more likely to have the metabolic syndrome (MetS). Since an essential role in the pathway of glucocorticoid (GC) action is reserved for the glucocorticoid receptor (GR), it could be proposed that GC sensitivity altering polymorphisms could affect the vulnerability for these adverse effects. We therefore assessed the relationships between functional GR polymorphisms with anthropometric measurements and MetS in users of corticosteroids.
Methods
We included 10,619 adult participants in the population-based Lifelines cohort study. Subjects were evaluated for drug use, body mass index (BMI), waist circumference (WC), blood pressure, and fasting metabolic parameters. Genotyping was performed for GR polymorphisms associated with a relatively increased (Bcl*I* and N363S) or decreased (ER22/23EK and 9β) GC sensitivity. All included subjects had complete information on MetS components, and were classified as wild type (WT) (2 wild type alleles), GC hypersensitive (1 or 2 copies Bcl*I* and/or N363S), or GC resistants (1 or 2 copies ER22/23EK and/or 9β). Analyses were performed between nonusers (genotypes combined) and users (specified) and were adjusted for various covariates.
Results
Overall corticosteroids use was associated with a significantly higher BMI and WC in GC hypersensitive (BMI: mean difference +0.67 kg/m^2 (95% CI, 0.32–1.02); WC: +2.09 cm (1.16–3.02), both $P<0.001$), and WT users (BMI: +0.57 kg/m^2 (0.04–1.11), $P=0.04$; WC: +1.90 cm (0.48–3.31), $P<0.01$) but not in GC resistant users. In particular, the use of inhaled corticosteroids was associated with similar findings in GC hypersensitive (BMI: +1.68 kg/m^2 (1.15–2.20); WC: +4.72 cm (3.33–6.10), both $P<0.001$), and WT users (BMI: +1.07 kg/m^2 (0.25–1.89), $P=0.01$; WC: +3.53 cm (1.35–5.70), $P<0.01$). In regard to MetS, again only GC hypersensitive (odds ratio (OR) 1.23 (95% CI, 1.01–1.50)) and WT users (OR 1.43 (1.06–1.93)) were more likely to have MetS in comparison to nonusers. This was predominantly found in users of only inhaled corticosteroids (GC hypersensitive users, OR 1.44 (1.08–1.91); WT users, OR 1.64 (1.05–2.54)).
Conclusion
Corticosteroid users, in particular of inhaled corticosteroids, have an increased BMI, WC and more often MetS in comparison to nonusers. These relationships are significantly evident in carriers of GR genotypes associated with GC hypersensitivity or the wild type genotype, but not in users harboring GC resistant polymorphisms.

Associations of different body fat deposits with serum 25-hydroxyvitamin D concentrations

Rachida Rafiq[1], Floor Walschot[1], Paul Lips[1], Hildo Lamb[2], Albert de Roos[2], Frits Rosendaal[2], Martin den Heijer[1,2], Renate de Jongh[1] & Renée de Mutsert[2]
[1]VU University Medical Center, Amsterdam, Netherlands; [2]Leiden University Medical Center, Leiden, Netherlands.

Introduction
Overall and abdominal obesity are both well-established risk factors of vitamin D deficiency. However, it is unclear which fat depot is most strongly related to serum 25-hydroxyvitamin D (25(OH)D) concentrations.
Objective
This study aims to distinguish specific contributions of total body fat, abdominal subcutaneous adipose tissue (aSAT), visceral adipose tissue (VAT) and hepatic fat on 25(OH)D concentrations.
Methods
This study is a cross-sectional analysis of the baseline measurements of the Netherlands Epidemiology of Obesity study, a population-based cohort study in men and women aged between 45 and 65 years. We used linear regression analyses to examine associations of total body fat, aSAT, VAT ($n=2441$) and hepatic fat ($n=1980$) with serum 25(OH)D concentrations. In the analyses we adjusted for age, ethnicity, education, chronic diseases, smoking, alcohol consumption and physical activity. Standardized values were used to compare the different adiposity measures.
Results
Mean (S.D.) age and serum 25(OH)D concentrations of the study population was 56 (6) years and 70.8 (24.2) nmol/l, respectively. Total body fat was inversely associated with 25(OH)D concentrations in women, but not in men. One percent higher total body fat was associated with 0.40 nmol/l (95%CI: −0.67–−0.13) lower 25(OH)D. VAT was inversely associated with serum 25(OH)D concentrations in both men and women. 1 cm^2 higher VAT was associated with 0.05 nmol/l (−0.09–−0.02) lower 25(OH)D in men, and 0.06 nmol/l (−0.10–−0.01) lower 25(OH)D in women. Hepatic fat was only associated with 25(OH)D in men. A tenfold increase in hepatic fat was associated with 6.21 nmol/l (−10.70–−1.73) lower 25(OH)D. aSAT was not associated with 25(OH)D concentrations in both men and women. Regressions with standardized values showed VAT was most strongly related to serum 25(OH)D concentrations.
Conclusions
The relationship between different adiposity measures and 25(OH)D concentrations was different for men and women. In women, total body fat and VAT were inversely related to 25(OH)D concentrations. In men, VAT and hepatic fat were related to 25(OH)D concentrations. In both men and women, VAT was most strongly associated with 25(OH)D concentrations. This implies that specific attention for vitamin D deficiency should be given to individuals with a high amount of VAT.

Benign adrenal tumors correspond to a spectrum of distinct tumors, including uni- and bilateral diseases with distinct morphological features, and various steroid hormone secretion types and levels. The aim is to study this variability at the molecular level using pan-genomic approaches.
Methods
One hundred and forty six benign adrenal tumors, including adrenocortical adenomas (ACA, N=), primary macronodular adrenal hyperplasia (PMAH, N=), and primary pigmented micronodular dysplasia (PPNAD, N=Cushing's disease (CD, N=) were included. ACAs secretion was either cortisol (N=), no secretion (N=), mild cortisol secretion (N=), or aldosterone (N=6). Transcriptome, methylome, miRnome and mutational status were generated using Affymetrix U133plus, Illumina Infinium 27k, Illumina sequencing or Life Technologies ampliseq targeted NGS respectively.
Results
Four main molecular groups were identified by transcriptome, methylome, miRnome and mutational status. The largest group gathered cortisol producing tumors, independently of tumor types (ACAs, PMAHs, PPNADs and CDs). These tumors all show cAMP/PKA pathway activation, by distinct mechanisms. Transcriptome identified a steroidogenic signature in this subgroup. The second group gathered the ACAs with no or mild cortisol secretion, and included the majority of beta-catenin mutations. The third group gathered PMAHs with *ARMC5* mutations, showing an ovarian expression signature. The last group was exclusively composed of aldosterone-producing ACAs, apart from other benign tumors. Epigenetic alterations and steroidogenesis seemed associated, including CpG island hypomethylation in tumors with no or mild cortisol secretion, miRNA specific patterns in different subgroups, and direct regulation of steroidogenic enzyme expression by methylation.
Conclusion
This first large-scale pangenomic characterization of benign adrenocortical lesions identifies the main molecular subgroups, and represents an important resource to for the study of adrenocortical tumorigenesis and steroidogenesis.

Urine steroid metabolomics as a diagnostic tool for detection of adrenocortical malignancy – a prospective test validation study

Irina Bancos[1,2], Angela Taylor[2], Vasileios Chortis[2], Alice Sitch[2], Katharina Lang[2], Alessandro Prete[2], Massimo Terzolo[3], Martin Fassnacht[4], Marcus Quinkler[5], Darko Kastelan[6], Dimitra Vassiliadi[7], Felix Beauschlein[8,9], Urszula Ambroziak[10], Michael Biehl[11], Jonathan Deeks[2] & Wiebke Arlt[2]
[1]Mayo Clinic, Rochester, USA; [2]University of Birmingham, Birmingham, UK; [3]University of Turin, Turin, Italy; [4]University of Wuerzburg, Wuerzburg, Germany; [5]Endocrinology Charlottenburg, Berlin, Germany; [6]University Hospital, Zagreb, Croatia; [7]Evangelismos Hospital, Athens, Greece; [8]Ludwig-Maximilians-University, Munich, Germany; [9]University of Zuerich, Zuerich, Switzerland; [10]Medical University of Warsaw, Warsaw, Poland; [11]University of Groningen, Groningen, Netherlands.

Background
Adrenal masses are discovered in 5% of abdominal imaging scans. Accuracy of currently available imaging tests to diagnose malignancy is poor. In a proof-of-concept study (JCE&M 2011;96(12):3775-84), we had demonstrated 90% sensitivity and specificity in detecting adrenocortical carcinoma (ACC) for urine steroid metabolomics, the combination of mass spectrometry-based steroid profiling and machine learning-based data analysis. This diagnostic performance is superior to costly imaging procedures currently used for differentiating benign from malignant adrenal masses, which lead to a high rate of unnecessary surgery. Implementation of our novel test in routine practice requires prospective validation.
Methods
We undertook a prospective multi-center international test validation study, powered to achieve recruitment of 2000 patients with an anticipated ACC rate of 5%, with prospective recruitment of patients with newly diagnosed adrenal mass >5 mm, biochemical exclusion of pheochromocytoma and 24-h urine collection; recruitment was carried out in 13 centers (11 countries) of the European Network for the Study of Adrenal Tumors (ENSAT). Urinary steroid excretion was quantified by high-throughput liquid chromatography-tandem mass spectrometry and results processed by an algorithm based on generalized matrix relevance learning vector quantization (GMLVQ). Reference standard (benign/malignant) was based on histology and imaging follow-up.
Results
We enrolled 2017 patients, 1767 (87.6%) with a benign adrenocortical adenoma (ACA), 98 (4.9%) with ACC, and 87 (4.3%) and 65 (3.2%) with other benign and malignant adrenal masses, respectively. Risk of ACC was highest in patients <40 years (13%; vs 4% in >40 years, $P<0.0001$) and adrenal masses >4 cm (20%; vs 0.13% in <4 cm, $P<0.0001$). Unenhanced CT imaging of the adrenal mass was available for 1328/1767 patients with ACA; 68% of masses had a radiodensity <10 HU indicative of a benign lesion; 17% had borderline results (10–20 HU) and 15% were suspicious of ACC (>20 HU). MRI with chemical shift indicated suspicion of ACC in 22% of 273 benign ACA. Adrenalectomy was performed in 21% (370/1767) of ACA patients. Urine steroid metabolomics demonstrated an excellent diagnostic performance with AUROC of 94.6% for 15 steroids (Sens = Spec 87.1%).
Conclusions
Overall risk of ACC in adrenal tumors is 4.9% and almost exclusively relates to adrenal masses >4 cm. ACAs are frequently misclassified as malignant by routine imaging, resulting in a high rate of imaging and unnecessary adrenalectomies. Urine steroid metabolomics demonstrates high accuracy for detection of ACC and should become standard-of-care in patients with indeterminate adrenal tumors.

LncRNAs profiling reveals epigenetic heterogeneity among human parathyroid tumor

Annamaria Morotti[1], Chiara Verdelli[2], Vito Guarnieri[3], Filomena Cetani[4], Rosa Silipigni[5], Silvana Guerneri[5], Alfredo Scillitani[6], Leonardo Vicentini[7], Edoardo Beretta[8], Valentina Vaira[1] & Sabrina Corbetta[9]
[1]Division of Pathology, Department of Pathophysiology and Transplantation, University of Milan, Fondazione IRCCS Ca' Granda Ospedale Maggiore Policlinico, Milan, Italy; [2]Laboratory of Experimental Endocrinology, IRCCS Istituto Ortopedico Galeazzi, Milan, Italy; [3]Genetic Medicine, IRCCS Casa Sollievo della Sofferenza, San Giovanni Rotondo (FG), Italy; [4]Endocrine Unit 2, University Hospital of Pisa, Pisa, Italy; [5]Medical Genetics Laboratory, Fondazione IRCCS Cà Granda, Ospedale Maggiore Policlinico, Milan, Italy; [6]Endocrinology Unit, IRCCS Casa Sollievo della Sofferenza, San Giovanni Rotondo (FG), Italy; [7]Endocrine Surgery, Istituto Auxologico Capitanio, Milan, Italy; [8]Endocrine Surgery, IRCCS Ospedale San Raffaele, Milan, Italy; [9]Endocrinology Service, Department of Biomedical Sciences for Health, IRCCS Istituto Ortopedico Galeazzi, University of Milan, Milan, Italy.

Long noncoding RNAs (LncRNAs) are transcripts of more than 200 nucleotides not translated into proteins. They carry out diverse functions, including transcriptional regulation in *cis* or *trans*, organization of nuclear domains, and regulation of proteins or RNA molecules. Aberrant expression of LncRNAs has been reported in human cancers; indeed, data in parathyroid tumors are lacking. Based on the profiling through lncProfilers™ qPCR Array with SYBR® green detection of 90 LncRNAs in a preliminary set of 4 parathyroid carcinomas (PCas), 12 parathyroid adenomas (PAds) compared wit 2 normal parathyroid glands (PaNs), SAM significance analysis identified 9 differentially expressed LncRNAs: 3 lncRNAs were upregulated in PCas (BC200, HOXA6-AS, WT1-AS), 4 lncRNAs were downregulated in PAds (HAR1B, HOXA3-AS, MEG3, NEAT1) and 2 downregulated in both PAds and PCas compared to PaNs (KCNQ1OT1, SNHG6). The 9 lncRNAs were validated in a second independent series of parathyroid samples including 7 PCas, 6 atypical PAds, 26 PAds and 4 PaNs. Unsupervised analysis of the LncRNAs expression levels in this set of 40 parathyroid samples, identified three clusters: cluster 1 was characterized by LncRNAs general donwnregulation, cluster 3 showed LncRNAs diffuse upregulation, while cluster 2 presented an intermediate pattern. Cluster 2 included all the 4 PaNs and a subset of PAds, while clusters 1 and 3 included PCas, atypical PAds and the remaining PAds. Patients affected with cluster 2 tumors had lower total and ionized calcium as well as PTH levels than patients with clusters 1 and 3 tumors. We characterized the genetic background of the parathyroid tumors by Array Comparative Genomic Hybridization (aCGH), direct sequencing of the *MEN1* and *CDC73* genes and MLPA for the *MEN1* region. Array CGH identified monosomy of chromosome 11 in 9 (42%) PAds and loss of 1p in 7 (27%) PAds. *MEN1* mutations were detected in 5 PAds, while *CDC73* was mutated in 4 PCas. Interestingly, chromosome 11 monosomy and *MEN1* mutations were more frequent in cluster 2 PAds; cluster 1 included most PAds with loss of 1p, while PCas had wild-type *CDC73*; *CDC73*-mutated PCas were grouped in cluster 3. Considering the *MEN1* expression levels, we observed that PAds with downregulated *MEN1* mRNA levels had low KCNQ1OT1, NEAT1 and SNHG6 expression levels, suggesting an epigenetic role for menin. Experiments aimed to investigate the effect of *MEN1* silencing on the *MEN1*-associated LncRNAs are ongoing. In conclusion, parathyroid tumors show genetic and epigenetic heterogeneity affecting clinical presentation.

Integrative genomics studies of paragangliomas (PGL) have shown that PGL susceptibility genes are the main drivers of tumorigenesis. Comprehensive genetic analyses have identified germline *SDHB* and, to a lesser extent, *FH* gene

mutations, as predominant causes of metastatic PGL. However, some suspicious cases remain unexplained. We performed whole-exome sequencing of a paraganglioma exhibiting an *SDHx*-like molecular profile in the absence of *SDHx* or *FH* mutations and identified a germline mutation in the *SLC25A11* gene. This gene encodes the mitochondrial 2-oxoglutarate/malate carrier. Germline *SLC25A11* mutations were identified in six other patients, five of whom had a metastatic disease. These mutations were associated with loss of heterozygosity and loss of SLC25A11 protein expression, suggesting that *SLC25A11* acts as a tumour suppressor gene. Pseudo-hypoxic and hypermethylator phenotypes comparable to that described in *SDHx*- and *FH*-related tumours were observed both in tumours with mutated *SLC25A11* and in *Slc25a11*$^{\Delta/\Delta}$ immortalized mouse chromaffin knockout cells generated by CRISPR-Cas9 technology. These data show that *SLC25A11* is a novel PPGL susceptibility gene, for which loss of function correlates with metastatic presentation. Its identification expands the role of mitochondrial dysfunction in paraganglioma tumorigenesis and reveals a new pathway linking metabolic defects and cancer.

Background
Administration of α-adrenergic receptor antagonists is recommended before resection of a pheochromocytoma (PCC) in order to prevent perioperative cardiovascular complications. For this purpose either phenoxybenzamine (PXB) or doxazosin (DOX) is commonly prescribed. We conducted the first randomized controlled trial comparing the efficacy of PXB and DOX in controlling perioperative hemodynamics in patients undergoing PCC resection (ClinicalTrials.gov:NCT01379898).
Methods
Patients ≥18 years with benign PCC were randomized to pretreatment with PXB or DOX. Preoperative BP targets were: <130/80 mmHg (supine) and systolic BP 90–110 mmHg (upright). β-blockers were added if heart rate was >80/min (supine) or >100/min (upright). Anesthetic procedures were standardized. Primary endpoint was the percentage of intraoperative time outside the BP target range (i.e. MAP<60 mmHg and systolic BP>160 mmHg). Size of the study population was calculated at 134 patients. Data are presented as mean ± s.d. or median (IQR). Two-sided *P*-values <0.05 were considered significant.
Results
One hundred and thirty four patients were included (52% female), aged 54±15 years. Pretreatment with DOX ($n=68$) or PXB ($n=66$) was administered in a dose of 40 (32–48) mg and 120 (78–140) mg, respectively. BP values and heart rate just before anesthesia were not different between groups. β-receptor antagonists were initiated in 66 and 89% of the patients on DOX or PXB, respectively ($P=0.002$). Intraoperative time outside BP target range was 12 (5–20) % in the DOX group and 11 (4–21) % in the PXB group ($P=0.75$). The number of intraoperatively administered vasodilating agents was 0, 1 or >2 among 21, 34 and 45% in the DOX group, respectively. Respective percentages in the PXB group were 45, 32 and 23% ($P=0.02$). Cumulative intravenous dose of magnesium sulphate was 3 (0–4) grams in the DOX group and 0 (0–3) grams in the PXB group ($P=0.005$). The number of intraoperatively administered inotropic/vasopressive agents was 0, 1 or ≥2 among 18, 40 and 42% in the DOX group, respectively. Respective percentages in the PXB group were 26, 36 and 38% ($P=0.38$). Cumulative intravenous dose of phenylephrine and norepinephrine was 0 (0–300) μg and 137 (0–580) μg in the DOX group and 0 (0–425) μg, 55 (0–660) μg in the PXB group, respectively ($P=0.98$ and $P=0.59$).
Conclusions
The results of this RCT demonstrate an equal efficacy of DOX- and PXB-pretreatment in intraoperative hemodynamic control during PCC resection. Patients pretreated with PXB required more b-blockers preoperatively, presumably via enhanced reflex tachycardia, but fewer vasodilating agents during surgery.

MicroRNAs as biomarkers in endocrine diseases

OC8.1

Plasma microRNA expression in patients with Cushing's disease differs from ACTH-ectopic Cushing's syndrome

Zhanna Belaya[1], Patimat Khandaeva[1], Alexey Nikitin[2], Alexander Solodovnikov[3], Ivan Sitkin[1], Tatjana Grebennikova[1], Alexander Vorontsov[1], Liudmila Rozhinskaya[1], Galina Melnichenko[1] & Ivan Dedov[1]

[1]The National Research Centre for Endocrinology, Russian Federation, Moscow, Russia; [2]Federal Research and Clinical Center FMBA, Russian Federation, Moscow, Russia; [3]Ural State Medical Academy, Ekaterinburg, Russian Federation, Moscow, Russia.

According to previous research microRNA (miR) are expressed differently in corticotropinoma and ACTH-secreting neuroendocrine tumors. MiR are released into circulation by several mechanisms and considered to be promising biomarkers.
Objective
To evaluate whether preselected miR are differently expressed in plasma samples of patients with ACTH-dependent Cushing's syndrome (CS).
Materials and methods
The blood samples were collected in the morning from fasting patients with ACTH-dependent CS and stored at −80C. Twenty three miR, which were previously reported to be differently expressed in the ACTH-secreting tumors vs healthy tissue samples (has-miR-10-5p, has-miR-129-5p, has-miR-133a-5p; has-miR-141-3p; has-miR-143-3p; has-miR-145a-5p; has-miR-150-3p; has-miR-15a-5p; has-miR-16-5p; has-miR-145-5p; has-miR-146a-5p; has-miR-150-3p; has-miR-15a-5p; has-miR-185-3p; has-miR-191-5p; has-miR-203a-5p; has-miR-210-5p; has-miR-211-5p; has-miR-31-5p; has-miR-409-3p; has-miR-431-5p; has-miR-488-3p; has-miR-7g-5p) were quantified in plasma by qPCR (Applied Biosystems, USA).
Results
We enrolled 28 patients (4 men and 24 women) with Cushing's disease (CD) with a mean age of 37 (95% CI 33–42); body mass index (BMI) 29.81 (27–32) kg/M^2 and 13 patients with ACTH-ectopic syndrome (seven men and six women with a mean age of 43 years (33–52), BMI- 30.16 (28.82–31.50) kg/M^2; and the healthy control group (2 men and 9 women) with a mean age of 39 years (33-44), BMI 28.21 (22.29-34.13) kg/M^2. Patients with ACTH-depended CS were not different in 24hUFC or ACTH levels. Among measured miRs expressions, we found statistically significant differences in the expression of miR-16-5p (45.04 (95%CI 28.77–61.31) in CD vs 5.26 (2.65–7.87) in patients with ACTH-ectopic syndrome $P<0.001$; $q=0.001$); miR-145-5p (0.097 (0.027–0.167) in CD vs no expression in ACTH-ectopic CS $P=0.008$; $q=0.087$) and less evident in miR7g-5p (1.842 (1.283–2.400) in CD vs 0.847 (0.187–1.507) in ACTH-ectopic syndrome $P=0.02$; $q=0.14$). MiR- 16-5p was differently expressed in plasma samples from healthy subjects compared to both CD and ACTH-ectopic CS. MiR- 145-5p expression differed between ACTH-ectopic CS vs healthy subjects, but not CD vs healthy subjects; whereas miR- 7g-5p was differently expressed in CD vs healthy control, but did not differ from ACTH-ectopic CS vs healthy subjects
Conclusions
Plasma miR-expression differs in patients with CD and ACTH-ectopic CS. In particular miR-16-5p, miR—145-5p and miR—7g-5p are promising biomarkers for further research to differentiate ACTH-dependent CS.

OC8.2

MicroRNA expression profiling and functional annotation analysis of their targets in patients with diabetic kidney disease

Tais Silveira Assmann[1], Mariana Recamonde-Mendoza[2], Aline Costa[1], Márcia Puñales[3], Balduíno Tschiedel[3], Luis Henrique Canani[2], Andrea Carla Bauer[2] & Daisy Crispim[1]
[1]Hospital de Clínicas de Porto Alegre, Porto Alegre, Brazil; [2]Universidade Federal do Rio Grande do Sul, Porto Alegre, Brazil; [3]Instituto da Criança com Diabetes, Porto Alegre, Brazil.

Context
Diabetic kidney disease (DKD) is a common microvascular complication that affects approximately 40% of patients with diabetes mellitus (DM). This complication is the leading cause of end-stage renal disease (ESRD) in patients starting renal replacement therapy and is associated with increased cardiovascular mortality. Although a tight glycemic control is able to reduce the development and delay the progression of DKD, current therapies are still not totally effective in preventing progression to ESRD. Therefore, additional mediators and mechanisms leading to DKD need to be identified for more effective diagnosis and treatment of this complication. In this context, emerging evidence suggests a role for epigenetic factors, such as microRNAs (miRNAs), in the DKD development. MiRNAs are small non-coding RNAs that regulate gene expression. Moreover, circulating miRNAs are ideal noninvasive biomarkers because they are stable in body fluids and can be detected using established techniques for quantification, such as quantitative PCR. However, the identification of the specific miRNAs expression profile involved in DKD remains incomplete.
Objective
To investigate a miRNA expression profile in plasma of type 1 DM (T1DM) patients with DKD (cases) compared to T1DM patients without DKD (controls), and to perform bioinformatic analysis to investigate the potential roles of the miRNAs.
Design
Expression of 48 miRNAs was investigated in plasma of 58 T1DM patients (23 controls, 18 with moderate DKD, and 17 with severe DKD) using Stem-loop RT-PreAmp Real-time PCR and TaqMan Low Density Array cards (Thermo Scientific Inc). Then, five differently expressed miRNAs were chosen for validation in an independent sample of 10 T1DM controls and 19 DKD cases, using RT-qPCR. Bioinformatic analyses were performed to explore the putative target genes and biological pathways regulated by these miRNAs.
Results
Nine miRNAs were differently expressed in plasma of patients with different stages of DKD (hsa-miR-141-3p, hsa-miR-16-5p, hsa-miR-192-5p, hsa-miR-204-5p, hsa-miR-21-3p, hsa-miR-215-5p, hsa-miR-29a-3p, hsa-miR-378a-5p, and hsa-miR-503-5p) compared to T1DM controls. After validation in an independent sample, hsa-miR-21-3p and hsa-miR-378-3p were upregulated; while hsa-miR-16-5p and hsa-miR-29a-3p were downregulated in DKD cases. Additionally, these miRNAs and their targets participate in pathways of known relevance for DKD pathogenesis, such as TGF-β, PI3K/Akt, longevity, AGE-RAGE signaling pathway in diabetic complications, and relaxin signaling pathways.
Conclusions
Our study demonstrates that four miRNAs were differently expressed in DKD patients, constituting potential biomarkers of this chronic diabetic complication.

Circulating levels of microRNAs associate with blood pressure and left ventricular mass in primary hypertensive patients

J.C. van Kralingen[1], C.K. Larsen[2], J.M. Connell[3], E.M. Freel[1], M.C. Zennaro[2], S.M. MacKenzie[1] & E. Davies[1]
[1]Institute of Cardiovascular and Medical Sciences, University of Glasgow, Glasgow, UK; [2]INSERM, UMRS 970, Paris Cardiovascular Research Centre, Paris, France; [3]School of Medicine, University of Dundee, Dundee, UK.

Introduction
MicroRNA (miRNA) has been shown to post-transcriptionally regulate physiological systems modulating blood pressure, including the adrenal biosynthesis of aldosterone. This raises the possibility that levels of specific miRNAs circulating in plasma might reflect these functional effects and have diagnostic value in the identification of hypertension and its various underlying causes. In a previous study, we measured plasma levels of miRNAs originating from the miR-24-1 cluster on chromosome 9, which correlated with the phenotype of patients with primary hypertension and primary aldosteronism. For this study, we have expanded our studies to measure a much larger array of 179 different circulating microRNAs in a population of 50 primary hypertensive patients, and assessed their correlation with relevant phenotypic traits, including systolic and diastolic blood pressure (SBP, DBP) and left ventricular mass index (LVMI).
Methods
Patients with primary hypertension ($n=50$) were drawn from the British Genetics of Hypertension (BRIGHT) study. Circulating miRNA was isolated from 200 µl EDTA plasma and analysed using Serum/Focus microRNA PCR panels (Exiqon), which employ simultaneous quantitative real-time PCR assays to measure 179 endogenous miRNAs and 13 control miRNAs. Statistical analysis was then used to identify correlation of miRNA level with phenotypic characteristics including systolic blood pressure (SBP), DBP, LVMI, age and BMI.
Results
Levels of 16 miRNAs correlated with either SBP and/or DBP ($P<0.05$). Of these, 2 miRNAs showing positive correlation with SBP or DBP, hsa-miR-28 and hsa-miR-1, were also found to correlate positively with left ventricular mass index (LVMI) in the 16 patients for whom we had this data ($P<0.05$). Interestingly, these miRNAs are each predicted to target mRNA transcribed from the *CYP11B2* (aldosterone synthase) gene. Levels of hsa-miR-27b, which originates from the miR-24-1 cluster, positively correlated with age ($P<0.05$).
Conclusions
We have expanded our analysis of circulating miRNA levels in hypertension to encompass an array of 179 miRNAs in 50 patients. Several novel associations of circulating miRNAs with SBP, DBP, LVMI and BMI have been observed. Future work will concentrate on verifying these correlations, assessing their utility for diagnostic purposes, and identifying the mechanisms by which these miRNAs target expression of specific genes and exert phenotypic effects.

Detecting blood micro-RNAs and proteins associated with Graves' disease and orbitopathy

Filippo Biscarini[1], Lei Zhang[2], Giulia Masetti[2], Danila Covelli[3], Giuseppe Colucci[3], Anja Eckstein[4], U Kaiser[4], Shazli Draman[2], Ilaria Muller[2], Luigi Lucini[5], Marian Ludgate[2] & Mario Salvi[3]
[1]Consiglio Nazionale Ricerche, Milan, Italy; [2]Cardiff University, Cardiff, UK; [3]University of Milan, Milan, Italy; [4]University of Essen, Essen, Germany; [5]Università Cattolica, Piacenza, Italy.

Graves' Disease (GD) affects about 2% of the population in the UK, with female predominance. A proportion of GD patients (5–50%) develop orbitopathy (GO), which is characterized by tissue remodeling in the orbit leading to protrusion of the eye (proptosis). Blood biomarkers associated with GD or GO could be useful diagnostic or prognostic tools for researchers and clinicians. Within the framework of INDIGO IAPP-612116 (Investigation of Novel biomarkers and Definition of the role of the microbiome In Graves' Orbitopathy) we aimed at seeking proteins and microRNA (miRNA) that could be markers of the development of GD and GO in patients from three European centers. Blood samples were collected from 33 patients (14 GD, 19 GO) and 13 healthy controls from Cardiff, Milan and Essen for miRNA and protein sequencing (Illumina's HiSeq2000 and Agilent-6550 Funnel quadrupole-time-of-flight mass spectrometer). Euclidean distances based on miRNA and protein quantification were visualized through multidimensional scaling (MDS). The differential expression of miRNA and proteins among groups was analysed with multinomial regression models. Additionally, miRNA and proteins, both separately and together, were used to predict whether individuals belonged to the GD, GO or control groups. Lasso-penalised multinomial regression was used for predictions on 150 resampled datasets. This allowed the estimation, along with the accuracy of prediction, of the relative importance of specific miRNA and proteins. In total, 3025 miRNAs and 1886 proteins were detected. The MDS plot showed good separation of the three groups (GD, GO, controls). From 10-fold cross-validation, the accuracy of predictions was 0.71 or 0.81 with miRNA or protein data alone and 0.86 with miRNA and proteins combined. Comparable accuracy was measured within-group. Matching results from differential expression analysis and predictive models, 5 miRNA and 20 proteins have been identified as potential biomarkers. These include the novel miRNA Novel:19_15038, and the proteins Zonulin, Alpha-2 macroglobulin, Beta-2 glycoprotein 1 and Fibronectin. The functional analysis of miRNA targets and proteins identified relevant metabolic pathways, including hippo signaling pathway, bacterial invasion of epithelial cells, complement and coagulation cascades, longevity regulating pathway, mRNA surveillance pathway. Overall, results reveal differential expression of blood miRNA and proteins between GD and GO patients and healthy controls. Helpful biomarkers have been identified, which may be used for early diagnosis and prognosis of Graves disease, including the likelihood of its progression to orbitopathy, and represent a step forward in the direction of technology-driven precision medicine.

MicroRNA profiles in diabetic octogenarians with and without historical and prospective hip fractures

Ines Foessl[1], Petra Kotzbeck[1], Vito Francic[1], Christoph Haudum[1], Andrea Groselj-Strehle[1], Jutta Claudia Piswanger-Sölkner[1], Harald Dobnig[2,1], Astrid Fahrleitner-Pammer[1] & Barbara Obermayer-Pietsch[1]
[1]Medical University of Graz, Graz, Austria; [2]Schilddrüsen/Endokrinologie/Osteoporose Institut Dobnig GmbH, Graz, Austria.

Objective
Type 2 diabetes mellitus (T2DM) patients have a higher risk for bone fractures, especially in the elderly. However, bone mineral density (BMD) does not reflect their increased bone fragility, potentially based on disturbed bone metabolism or quality. MicroRNAs are promising new biomarkers for fracture risk detection. This study aimed to find specific miRNAs in a large cohort of elderly patients with and without T2DM at risk for osteoporotic fractures.
Methods
This nursing home cohort includes 249 T2DM patients and 301 nonT2DM patients as controls. Fractures were recorded within 2 years after the first visit. Mobility scores of the patients, fracture and medical history were documented and blood samples were taken to measure bone turnover and vitamin D. miRNA sequencing using serum samples was performed by QIAGEN microRNA-seq Service. Surrogate markers were used to correlate candidate miRNAs with bone biomarkers. Target predictions were performed with online target prediction tools (miRanda, TargetScan).
Results
Mean age of the cohort was 84.4 ± 6.3 years, mean BMI 25.4 ± 4.7. Hip fractures occurred in 34% of the T2DM patients within 2 years after the first visit, compared to 15% in the nonT2DM group ($P < 0.0001$). NonT2DM patients without fractures had significantly higher mobility scores ($P < 0.01$) as compared to nonT2DM patients with fractures or the respective T2DM groups. Vitamin D levels were different between nonT2DM with- and without fracture ($P < 0.01$) but not between the T2DM and the nonT2DM patients. Comparison of miRNA sequencing results between T2DM patients with and without fractures showed specific differences in the miRNA sequencing profiles among the two groups.
Summary and Conclusion
In this cohort of very old patients with and without T2DM of comparable age and BMI, we found a very low vitamin D status, though fracture groups showed slightly higher vitamin D. We found a number of microRNA differences between diabetic fracture and non-fracture patients, with most promising candidates. MicroRNAs might serve as important biomarkers in the prediction of bone fracture risk in osteoporotic and especially T2DM patients, where existing diagnostic tools do not allow for concise fracture risk prediction.

Thyroid from basics to clinics

OC9.1

Increased urinary iodide precedes hypothyroidism in *Dehal1* knockout mice

Cristian González-Guerrero[1], Federico S. Lucia[1], Yago Alcaina[1], Ana M. González-López[1], Antonio Buño[2], Roberto Mora[3], María Paz De Miguel[4] & José C. Moreno[1]
[1]Thyroid Molecular Laboratory, Institute for medical and Molecular Genetics (INGEMM), La Paz University Hospital, Madrid, Spain; [2]La Paz University Hospital, Madrid, Spain; [3]Analytical Chemistry, La Paz University Hospital, Madrid, Spain; [4]Cell Engineering Laboratory, IdiPAZ, La Paz Hospital Research Institute, Madrid, Spain.

Thyroid hormones (TH) synthesis requires iodine, a scarce element whose recycling is mediated by the iodotyrosine dehalogenase (encoded by the *DEHAL1* gene) through deiodination of mono- and di-iodotyrosines. In humans, biallelic mutations in *DEHAL1* lead to a severe form of congenital hypothyroidism (CH) non detectable by neonatal screening programs, which involves the risk of mental retardation. The timing and triggering factors of this particular type of hypothyroidism remain unknown and may require iodine storage depletion. Our aim was to study the amount of iodinated metabolites and TH profile in newly generated *Dehal1* knockout mice under controlled iodine diets. Heterozygus ($Dehal1^{+/-}$), homozygous ($Dehal1^{-/-}$) and Wildtype (WT) mice were fed during 4 weeks with pellets containing very low iodine amounts. Additionally, the drinking water was iodine enriched leading to three experimental groups: sufficient, non-sufficient and deficient iodine treated mice (7.0, 1.2 and 0.2 μg/day, respectively; 4 months old mice, $n = 6$ per treatment and genotype,). At the beginning (d0) and the end (d28) of the experiment, urine iodine concentration (UIC; respect to creatinine) and serum total T_4 and T_3 were determined by the Kolthof-modified method and radioimmunoassays, respectively. The status of *Dehal1* gene in knockout mice were validated via genotyping (mouse tail DNA PCR), vector gene reporter staining (X-gal for β-galactosidase activity) and tissue specific protein expression (western blot and immunohistochemistry). At d0, UIC were significantly increased ($P < 0.05$) in both $Dehal1^{+/-}$ and $Dehal1^{-/-}$ (on average, 2.8 ± 1.0 μg/ml) compared to WT mice (1.1 ± 0.6 μg/ml), while T_4 and T_3 were similar between groups (on average, 62.4 ± 5 and 0.63 ± 0.1 ng/ml, respectively). At d28, in mice undergoing iodine sufficient and deficient treatments, UIC and TH levels were similar between groups. Remarkably, under non-sufficient iodine conditions TH levels were lower in $Dehal1^{+/-}$ and $Dehal1^{-/-}$ compared to WT mice ($P < 0.05$). Our data show that an increased loss of iodine in urine anticipates a hypothyroidism in *Dehal1* deficient mice which is triggered by a non-sufficient iodine intake. Therefore, iodinated metabolites may provide new opportunities for early detection of *Dehal1* deficiency preventing mental alterations related to late diagnosed CH.

Anti-tumoral effects of metformin on metastatic bone lesions of thyroid cancer

Sun Wook Cho, Hyo Sik Shin, Hyun Jin Sun, Young Joo Park & Ka Hee Yi
Seoul National University Hospital, Seoul, Republic of Korea.

Background
Metformin plays anti-tumoral roles in human cancers including breast and thyroid. However, its effects on metastatic lesions are undetermined. We studied the effects of metformin on bone metastasis of thyroid cancer.
Method
Luciferase-tagged anaplastic FRO and follicular FTC 133 thyroid cancer cells were used. In vivo effects of metformin were evaluated in both ectopic tumor model and bone metastasis model generated by intratibial injection.
Result
Metformin treatment significantly reduced viabilities of FRO and FTC133 thyroid cancer cells *in vitro*. However, oral administration of metformin to ectopic tumor model showed limited therapeutic effect only. To evaluate the effects of metformin in bone metastasis model, luciferase-tagged FRO or FTC133 cells were injected into tibia in nude mice and metformin was administrated via drinking water. Bioluminescence imaging showed that tumor growth was significantly decreased from 2 to 4 wks in metformin-treated tumors than controls in both FRO and FTC133 cell injected groups. In FRO cell group, total tumor volume per bone volume (TmV/BV) was significantly reduced in metformin-treated group than control by 30% at 4 weeks. The number of osteoclasts per bone was significantly decreased and the reactive bone formation was significantly reduced in metformin-treated group than in control group. To investigate the molecular mechanisms, the effect of metformin on osteoblasts in tumor microenvironment were studied. Conditioned medium of FRO (FRO-CM) was harvested and treated into murine osteoblastic cells with or without metformin. RT-PCR analysis showed that treatment of FRO-CM increased *RANKL* and decreased *OPG* while, treatment of metformin reversed FRO-CM mediated changes of *OPG/RANKL* ratio.
Conclusion
The anti-cancer effects of metformin on thyroid cancer were more sensitive in bone metastasis rather than in ectopic tumor model, owing to the regulatory actions of metformin on metastatic niche of bone.

DOI: 10.1530/endoabs.56.OC9.2

A mouse model of BRAF V600E mutated papillary thyroid cancer imitating sporadic conditions

Iva Jakubíková[1,2], Elin Schoultz[3], Ellen Johansson[3], Shawn Liang[3], Konrad Patyra[4], Jukka Kero[4], Pavel Zak[1,2] & Mikael Nilsson[3]
[1]4th Department of Internal Medicine – Haematology, University Hospital Hradec Králové, Hradec Králové, Czech Republic; [2]Faculty of Medicine in Hradec Králové, Charles University, Hradec Králové, Czech Republic; [3]Institute of Biomedicine, Sahlgrenska Cancer Center, University of Gothenburg, Göteborg, Sweden; [4]Department of Physiology, Institute of Biomedicine, University of Turku, Turku, Finland.

Introduction
Worldwide constantly rising incidence of thyroid cancer promotes research activities. Nowadays the most speculated issue is the clinical significance of BRAF mutation. For sure BRAF mutation is a cancer-specific somatic mutation consistent with papillary thyroid cancer phenotype, otherwise, its role in tumor aggressiveness, progression, and the overall poor outcome is controversial. As far as several clinical studies claim opposing opinions, the learning aspect of mouse models comes to its point.
Objective
To evaluate the effect of BRAF V600E mutation on follicular cells of the thyroid gland in a mouse model, which imitates sporadic oncogenic pathway.
Methods
A transgenic mouse model of a spontaneous Cre activation in the absence of tamoxifen leading to focal instead of global BRAF V600E activation, under the Thyroglobulin promoter, was observed at several time points. Thyroid glands of these mice underwent different immunohistochemical stainings (IHCS), that were compared with wild-type controls.
Results
BRAF V600E mutation was gradually activated in follicular cells and some areas of the thyroid gland revealed after 6 months papillary formations with typical nuclear characteristics for carcinoma. From the very beginning, the follicles and so the whole thyroid gland was growing in size, without causing breathing impairment. Blood measurements were performed, confirming normal serum levels of T_4 and TSH. The oldest sacrificed mouse, aged 18 months, shown in each of its thyroid lobes several foci of papillary thyroid carcinoma (PTC). There were mainly areas of classical PTC, then solid PTC as well as the hobnail variant pattern. The proliferative rate (including Ki67 IHCS) was overall very low. Loss of thyroglobulin expression occurred early after mutant BRAF activation i.e. before overt tumor formation. In larger tumor formations further loss of dedifferentiation was documented by the loss of E-cadherin and weaker expression of Nkx2-1 (TTF-1) in 12 months or older mice. The tumor niche did not show any rapid involvement of inflammatory cells.
Conclusion
This mouse model imitates a sporadic oncogenic tumor initiation under the activation of BRAF V600E point mutation solely expressed in follicular cells of mice thyroid gland. The model recapitulates BRAF V600E-mediated tumor initiation, development, and progression that may be used for further investigation such as drug treatment with tyrosine kinase inhibitors or solely BRAF kinase inhibitors in different phases of papillary cancer growth.

Background
Differentiated thyroid cancer (DTC) is usually associated with an excellent prognosis. The main cause of death is due to distant metastases, but distant metastatic DTC (dmDTC) presents an interpatient heterogeneity. Some patients with distant metastases live with stable disease for many years, while others die very early. Still no effective biomarkers are available to predict either which patients will eventually develop distant metastases or what will be the final outcome of patients with dmDTC. The key for the future development of predictors probably lies in a better understanding of the (epi)genetic wiring of dmDTC. DNA methylation, one of the most studied epigenetic mechanism, affects CpG sites and is associated with transcriptional repression. While major progress has been made in understanding DNA methylation in DTC, the epigenetic architecture of dmDTC is completely unknown.
Objective
The aim of this study was to characterize the DNA methylomes of dmDTC and to identify biomarkers that predict the development of distant metastases.
Methods
We profiled DNA methylation of a series of 98 formalin-fixed paraffin-embedded tissues including 30 low risk non-metastatic DTC, 35 dmDTC, 18 metastases and 15 adjacent normal tissues using the Illumina Infinium HumanMethylationEPIC platform. We selected candidate biomarkers using the Simple Logistics classifier implemented in RWeka, and validated them by bisulfite-PCR-sequencing, bisulfite pyrosequencing and MethylQuant.
Results
We identified a signature of 156 CpGs associated with dmDTC independently of histology and mutations in BRAF and RAS. DNA methylation differed between distant metastatic (synchronous and metachronous) and low-risk non-metastatic primary tumors, while the paired primary tumor and distant metastases were similar, suggesting that molecular alterations of the primary tumors may dictate the ability to metastasize. The signature was enriched in hypomethylations and over half were located in promoters and enhancers, pointing out their role in the regulation of gene expression. We selected 10 independent CpGs with high classification power, and quantified DNA methylation by different techniques to develop a simplified quantitative and cheap assay implementable in the routine clinical practice. Based on preliminary results MethylQuant analysis appeared as the best alternative for on its simplicity, performance and cost-effectiveness.
Conclusion
We identified a 10-epigenetic biomarker panel associated with distant metastases in thyroid cancer and established new quantitative DNA methylation assays.

Sentinel lymph node biopsy using methylene blue dye in papillary and medullary thyroid carcinomas and microcarcinomas in decision for lateral neck dissection

Radan Dzodic[1,2], Nada Santrac[1], Ivan Markovic[1,2], Merima Goran[1], Marko Buta[1,2] & Gordana Pupic[3]
[1]Surgical Oncology Clinic, Institute for Oncology and Radiology of Serbia, Belgrade, Serbia; [2]Medical Faculty, University of Belgrade, Belgrade, Serbia; [3]Department of Pathology, Institute for Oncology and Radiology of Serbia, Belgrade, Serbia.

Introduction
Surgical management of clinically N0 (cN0) patients with thyroid carcinomas remains debatable due to various reported frequencies of lymph node (LN) metastases. Preoperative ultrasound identifies only half of LN metastases found at surgery. The aim of this report was to present our experience with sentinel lymph node biopsy (SLNB) of jugulo-carotid regions, after methylene blue dye (MBD) mapping and frozen section analysis (FSA), in detection of LN metastases in lateral neck compartments and selection of cN0 patients with papillary and medullary thyroid carcinomas and microcarcinomas for additional one-time lateral neck dissection (LND).
Materials & methods
We present results of three studies from our Surgical Oncology Clinic that analyzed usefulness of *Dzodic's original SLNB method for LN staging in thyroid carcinomas* (published in *Word J Surg, 2006*): the first with 153 cN0 papillary thyroid carcinomas (PTC), the second with 111 cN0 micro-PTCs and the third with 17 cN0 medullary thyroid microcarcinomas (micro-MTC) with serum calcitonin levels <1000 pg/ml. All patients underwent injection of 1%-MBD subcapsullary in both lobes, total thyroidectomy, prophylactic central neck dissection and SLNB of jugulo-carotid regions, since blue-stained LNs in central compartment are routinely dissected. All sentinel-LNs were sent to FSA. One-time LND was performed in patients in whom FSA of sentinel-LNs showed metastases. In other patients, with benign findings, surgery was not extended.
Results
LN metastases were histologically verified in 40.9% of cN0 PTCs and 25% of cN0 micro-PTCs. Only one patient with hereditary micro-MTC had LN metastases in central and both lateral regions. *Dzodic's SLNB method* enabled detection of LN metastases in lateral neck compartments in 21% of patients. Skip

metastases were detected in about 4% of patients with PTCs and micro-PTCs, while there were no skip metastases in micro-MTCs. Method's overall accuracy was high in all studies, but the highest in the study with micro-MTCs (100%). None of the patients had allergic reactions to MBD.
Conclusion
Dzodic's SLNB method with MBD mapping and frozen section examination of sentinel-LNs from jugulo-carotid regions is accurate in detection of LN metastases in lateral neck compartments of cN0 patients with papillary and medullary thyroid carcinomas and microcarcinomas. It optimizes surgery for patients without metastases in examined sentinel-LNs and helps in decision for one-time LND in patients with histologically proven sentinel-LN metastases. This method also facilitates central neck dissection and diminishes the possibility of accidental removal of parathyroid glands (that remain non-colored), even in less experienced surgeons' hands.

Glucocorticoid replacement-doses and cardiovascular events in autoimmune Addison's disease – a population based retrospective cohort study

Jakob Skov[1], Anders Sundström[2], Jonas Ludvigsson[3], Olle Kämpe[2] & Sophie Bensing[1]
[1]Department of Molecular Medicine and Surgery, Karolinska Institutet, Stockholm, Sweden; [2]Department of Medicine, Solna, Karolinska Institutet, Stockholm, Sweden; [3]Department of Medical Epidemiology and Biostatistics, Karolinska Institutet, Stockholm, Sweden.

Objective
Mortality in autoimmune Addison's disease (AAD) is increased twofold compared to matched populations. Cardiovascular disease (CVD) is the most common cause of death, but little is known of cardiovascular morbidity. Inadequate glucocorticoid replacement has been implicated in the increased risk of CVD, but evidence is lacking. The objective of this study was to examine cardiovascular morbidity and mortality in AAD, and to investigate the effects of glucocorticoid and mineralocorticoid dosing on the CVD-burden.
Methods
A population-based retrospective cohort study conducted in Sweden. The National Patient Register (NPR) and the Prescribed Drug Register (PDR) were used to identify 1500 patients with both an ICD-diagnosis consistent with AAD, and on combination treatment with hydrocortisone/cortisone acetate and fludrocortisone. 13 758 matched controls were randomly identified in the Register of Population. Patients and controls were collected 1964–2012. Drug prescription patterns were collected 2005–2012. The main outcome was CVD defined as recorded events of ischemic heart disease or cerebrovascular disease in the NPR or the Cause of Death Register. Adjusted hazard ratios (HR) and 95% confidence intervals (95% CI) were analyzed using the Cox proportional hazard model. Daily doses of glucocorticoid and mineralocorticoid replacement were estimated using the PDR. Doses were stratified into tertiles to examine dose-dependent risks of CVD.
Results
AAD was associated with a significantly increased risk of CVD (HR 1.62, 95% CI 1.25–2.16). This risk remained after adjusting for diabetes and chronic obstructive pulmonary disease (HR 1.54, 95% CI 1.16–2.04). Incidence rate ratios (IRR) were 1.9 (95% CI 0.95–3.9) for intermediate-dose and 2.1 (95% CI 1.1–4.3) for high-dose glucocorticoid replacement compared to low-dose glucocorticoid replacement. For mineralocorticoids IRR were 1.1 (95% CI 0.53–2.1) for intermediate-dose and 1.4 (95% CI 0.77–2.7) for high-dose replacement.
Conclusion
Cardiovascular morbidity and mortality is increased in AAD. The risk appears to be positively correlated with increasing glucocorticoid replacement doses, but not with mineralocorticoid replacement doses.

Introduction
Treatment with sodium glucose co-transporter2(SGLT2) inhibitors was found to reduce the incidence of cardiovascular events in diabetic patients.Herein, we investigated the effects of long-term treatment with canagliflozin on atherosclerosis development in the aorta of Apolipoprotein E knockout (Apo-E$^{(-/-)}$) mice as well as on biochemical and immunohistochemical markers related to atherosclerosis.
Methods
At 4 weeks of age, mice were switched from normal to a high-fat diet. At 8 weeks of age, Apo-E$^{(-/-)}$ mice were divided into control-group (6 mice) treated with 0.5%hydroxypropyl methylcellulose per os (po.) and Cana-group (6 mice) treated with canagliflozin (10 mg/Kgr d., po.). After 5 weeks, animals were sacrificed and heart and aorta were removed. Sections stained with hematoxylin-eosin (H&E) were used for histomorphometry whereas Masson's stained tissues were used to quantify the collagen content. Aorta root sections were stained for MCP-1, CD68, a-smooth muscle actin, MMP-2, MMP-9. q-PCR experiments were carried out to quantify the mRNA expression of MMP-2, MMP-9 their inhibitors TIMP-1 and TIMP-2, IL-6, VCAM-1, ICAM-1 and MCP-1 in the aorta.
Results
Cana-group was found to have lowered LDL-cholesterol, triglycerides and glucose levels ($P<0.01$) compared to control group. Heart rate was lowered in Cana-group compared to control-group ($P<0.05$). Histomorphometry analysis revealed that one out of six mice of Cana-group vs four out of six mice in control group developed atheromatosis, while the plaque area in aortic root was significantly lower and collagen was two times more intense in Cana-group compared to control. Immunohistochemistry showed that MCP-1, a-actin and CD68 were less expressed in aortic root of Cana-group compared to control, whereas MMP-2 expression was more intense. VCAM-1 mRNA levels were lower while TIMP-1 expression was significantly higher in Cana-group compared to control. No significant differences in MMP-9, MMP-2, TIMP-2 ICAM-1 and IL-6 mRNA levels were observed between two groups. There was a decrease in MCP-1 and increase in MMP-9 mRNA expression in Cana-group compared to control, however not statistically significant.
Conclusion
Preclinical data revealed that long-term administration of Canagliflozin attenuates the progression of atherosclerosis via reducing i) hyperlipidemia and hyperglycemia, ii) inflammatory process, by lowering the expression of inflammatory molecules such as MCP-1 and VCAM-1. Moreover, Canagliflozin was found to increase the stability of atheromatous plaque through increasing the expression of TIMP-1 (MMP-2-inhibitor).

ARMC5 variants and risk of hypertension in African Americans: Minority Health-GRID study

Mihail Zilbermint[1,2,3,4], Amadou Gaye[5], Annabel Berthon[1], Fady Hannah-Shmouni[1], Fabio Faucz[1], Minority Health-GRID Network[5], Adam Davis[5], Gary Gibbons[5], Maya Lodish[1] & Constantine Stratakis[1]
[1]Section on Endocrinology and Genetics, Eunice Kennedy Shriver National Institute of Child Health and Human Development, National Institutes of Health, Bethesda, Maryland, USA; [2]Division of Endocrinology, Diabetes, and Metabolism, Johns Hopkins University School of Medicine, Baltimore, Maryland, USA; [3]Johns Hopkins Community Physicians at Suburban Hospital, Bethesda, Maryland, USA; [4]Carey Johns Hopkins University Business School, Baltimore, Maryland, USA; [5]National Human Genome Research Institute (NHGRI), Genomics of Metabolic, Cardiovascular and Inflammatory Disease Branch, Cardiovascular Section, Bethesda, Maryland, USA.

Context
Hypertension is one of the most preventable risk factors for cardiovascular disease and death. Up to 42.1% of non-Hispanic African-American subjects have hypertension. We recently found that germline *ARMC5* variants may play a role in primary aldosteronism, particularly in African-Americans.
Objective
We investigated a cohort of participants in the Minority Health Genomics and Translational Research Bio-Repository Database (MH-GRID) study. We hypothesized a direct association between *ARMC5* variants and increased risk of hypertension in African-Americans.
Methods
MH-GRID Whole Exome Sequencing data of 1377 African-American subjects was analyzed. Cases are individuals on two or more anti-hypertensive medications of different classes, including a diuretic and controls are individuals with optimal blood pressure (BP $\leq$ 120/80 mmHg) and normal kidney function (eGFR $>$ 90 ml/min). Target single-variant and gene-based association analyses were carried out using the *ARMC5* locus information from genome-build GRCh37: chromosome $=$16, start position $=$3146941 and end position $=$31478484. Single-variant analysis of common variants (minor allele frequency, MAF $\geq$ 0.05) within *ARMC5* was conducted in PLINK 1.9. Gene-based analysis combining, common, low frequency (MAF $\geq$ 0.01 and $<$ 0.05) and rare variants (MAF $<$ 0.01) within *ARMC5* was carried out using the optimal unified kernel association test. The analyses were adjusted for age, gender, HDL, LDL, smoking and African-European admixture.
Results
44 SNPs within *ARMC5* (3 common, 4 low frequency and 37 rare variants) were considered for analysis. An *ARMC5* variant common in MH-GRID (rs116201073, MAF$=$0.07) reached nominal significance ($P=0.044$) and odds ratio (OR) $=$0.7, suggesting a protective effect for this variant. In the gene-based analysis, a set of 16 rare variants was significantly associated with hypertension (adjusted $P=0.0402$). A total of 17 variants (the 16 rare variants and rs116201073) were also significantly associated with hypertension at a lower *p*-value (adjusted $P=0.0121$).
Conclusions
We identified one common SNP of the *ARMC5* gene that was associated with risk of hypertension in African Americans and a set of 16 rare variants associated with hypertension in African Americans. These results extend our previous report of increased germline *ARMC5* variants that may be linked to severe hypertension in African-Americans, perhaps due to low-renin hypertension. Further genetic and molecular studies are needed to confirm and complement these findings.

Improvement in the control of hypertension in diabetic patients screened for hyperaldosteronism

Inés Jimenez[1], Irene Crespo[2], Martin Cuesta[1], Carlos Elvira[1], Paz de Miguel[1], Alejandro Santiago[1], Luzdivina Fernandez[1], Maria Victoria Saez de Parayuelo[1], Alfonso Calle[1] & Isabelle Runkle[1]
[1]Hospital Clínico San Carlos, Madrid, Spain; [2]Hospital Gomez Ulla, Madrid, Spain.

Introduction
Control of hypertension (HT) is essential to reduce cardiovascular events in diabetic patients (DPts). However, studies indicate that only 50% of DPts with treated hypertension present adequate blood pressure (BP) control. Yet Endocrine-Society-Guideline (ESG) screening for primary hyperaldosteronism (PHA) is rarely applied. Furthermore, in patients with essential hypertension (EH), longer-acting hypertension medication (HM) improves 24-hour BP when compared to related agents with a short half-life (SHL). We evaluated the application of the ESG for PHA in DPts, and the result of therapy using only HM with an extended-half-life (EHL) in EH-DPts.
Material and methods
A retrospective observational study. Over 2 years (2013–2014), in an Endocrine-outpatient clinic, 162 consecutive patients, 73/162 DPts, were screened for PHA in application of ESG. Aldosterone/renin ration(ARR) was determined, screening considered positive with ARR$\geq$25, aldosterone and renin by RIA in pg/ml. PHA diagnosis: aldosteronemia$\geq$130 and/or ARR$\geq$50 2 hours post-25 mg captopril. Low-renin hypertension (LRH): patients not fulfilling these criteria maintaining renin levels$\leq$5.5. throughout the test, and/or basal ARR$\geq$50. These patients were changed to mineralocorticoid-receptor blockers (MRB). In the remaining patients, EH was diagnosed. If BP control was inadequate, and EH patients were receiving any SHL HM ($<$16 hours), a switch was made to EHL: Irbesartan/telmisartan, when needed amlodipine, with clorthalidone as 3rd potential agent. At least one medication was administered in the evening. Office BP was compared in DPts immediately before and 2–6 weeks post-HM modification. Results in mean (standard deviation). Student's *T*-test.
Results
In DPts. *Age:* 70.3 (12.5), age at HT diagnosis: 55.7 (13.3). Women: 53.4%. PHA: 8/73 (11%). LRH: 6/73 (8.2%), EH: 59/73 (80.8%). Main Indications for screening: moderate HT in 46.6%, severe HT in 40%. Following MRB, aldosteronism patients (PHA$+$LRH) presented a systolic BP (SBP) decrease from 146 mmHg (18.7) to 124 (7.74) ($P=0.019$), diastolic BP(DBP) from 83.6 mmHg (11.94) to 73 (9.14) ($P=0.01$). EH: 6 lost-to-follow-up. In the 37 EH with SHL, following LAM switch, SBP dropped from 148mmHg (22.6) to 126 (12) ($P=0.001$); DBP from 84 mmHg (15.3) to 71 (8.3) ($P=0.01$). The switch was accompanied by a reduction in the number of HM: from 2.21 (0.75) to 1.71 (0.6) ($P=0.007$).
Conclusions
11% of our diabetic patients with hypertension and indication for screening presented Primary Hyperaldosteronism. Given its high morbimortality, the Endocrine-Society Hyperaldosteronism Guideline should be applied in DPts. In DPts with Essential Hypertension, long-acting medication could permit improved BP control.

Increased risk of antithyroid drug-induced agranulocytosis with amiodarone

Michal Gershinsky[1,2,3], Idit Lavi[4], Chen Shapira[1,3] & Naomi Gronich[4]
[1]Clalit Health Services, Haifa, Israel; [2]Lady Davis Carmel Medical Center, Haifa, Israel; [3]Ruth and Bruce Rappaport Faculty of Medicine, Technion - Israel Institute of Technology, Haifa, Israel; [4]Department of community Medicine and Epidemiology, Clalit Health Services, Haifa, Israel.

Aim
Antithyroid drugs (ATD) methimazole and propylthiouracil (PTU) are the drugs of choice for treatment of hyperthyroidism. Agranulocytosisis, the most severe side effect of these medications, occurs in 0.2–0.5% of patients. ATDs are used also in patients with amiodarone-induced thyrotoxicosis (AIT). Our objective was to evaluate the risk for agranulocytosis, associated with ATDs, in patients with AIT, and to compare the risk with the risk of ATD-associated agranulocytosis in thyrotoxicosis due to other etiologies.
Methods
A retrospective cohort study within Clalit Health Care database was conducted of all patients with thyrotoxicosis, newly treated with ATD between 1.1.2002-31.12.2015 and followed until 3 months from the last ATD prescription dispensing, or an event of agranulocytosis. High ATD dose was defined if either methimazole or PTU was administered in an average daily dose above the median dose for that drug.
Results
The cohort included 14,781 patients with thyrotoxicosis treated with ATDs. 39 patients (0.3% of the cohort) developed agranulocytosis during 40,551 years of follow-up: incidence rate 9.62 (6.84–13.15) for 10,000 years of follow up. Mean follow-up time was 2.7 years (S.D. 3.1 years). Agranulocytosis occurred after a median of 55 days. Higher ATD dose was independently associated with higher risk for agranulocytosis HR 3.53 (1.64–7.63) regardless of amiodarone. Age was also associated with increased agranulocytosis risk in univariate Cox regression analysis with HR$=$1.02 (1.01–1.04) for each 1-year increase. Five hundred ninety three of 14,781 patients were treated with amiodarone at cohort entry. 1.3% of AIT patients developed agranulocytosis on ATD therapy, as opposed to only 0.2% of patients with thyrotoxicosis due to other etiologies. In a Cox regression multivariable model amiodarone treatment at cohort entry was associated with significantly higher risk for developing agranulocytosis during ATD treatment independently of dose and age, HR 5.15 (2.10–12.60).
Conclusion
AIT patients are at increased risk for ATD-associated agranulocytosis. Higher ATD dose is an independent risk factor for agranulocytosis. We suggest closer monitoring of ATD-treated AIT patients for agranulocytosis, and initiation with lower ATD dose in AIT patients, reserving dose escalation for irresponsive cases.

Targeted molecular analysis in adrenocortical carcinomas: a way towards improved personalized prognostication

Juliane Lippert[1], Silke Appenzeller[2], Raimunde Liang[3], Silviu Sbiera[3], Stefan Kircher[4], Barbara Altieri[3,5], Indrajit Nanda[1], Isabel Weigand[3], Andrea Gehrig[1], Sonja Steinhauer[3], Clemens Mueller[1], Matthias Kroiss[3], Simone Rost[1], Andreas Rosenwald[4], Martin Fassnacht[3] & Cristina Ronchi[3,6]
[1]Institute of Human Genetics, University of Wuerzburg, Wuerzburg, Germany; [2]Core Unit Bioinformatics, University of Wuerzburg, Wuerzburg, Germany; [3]Division of Endocrinology, University Hospital of Wuerzburg, Wuerzburg, Germany; [4]Department of Pathology, University of Wuerzburg, Wuerzburg, Germany; [5]Division of Endocrinology, Catholic University of the Sacred Heart, Rome, Italy; [6]Institute of Metabolism and System Research, University of Birmingham, Birmingham, UK.

Adrenocortical carcinoma (ACC) has heterogeneous prognosis and no effective targeted therapies. Pan-genomic studies identified complex molecular patterns related to outcome. Our study aimed at identification of an 'easy-to-apply' molecular signature for better personalized prognostic stratification. A total of 107 ACC patients were enrolled. Clinical/histopathological parameters of prognostic relevance were evaluated. Targeted molecular analysis was performed on DNA isolated from FFPE tumor samples, including mutations and copy number alterations, methylation of promoter regions. Primary endpoint was progression-free survival (PFS). The association of age ≥ 50 years, tumor- or hormone-related symptoms, ENSAT tumor stage, resection status and ki67 proliferation index (modified GRAS classification) could prognosticate recurrence risk in the present series ($P<0.0001$; chi-square=49.0) and in an independent cohort of 368 ACC patients ($P<0.0001$; chi-square=202.5). The most frequent genetic alterations were mutations at *TP53* (22%), *CTNNB1* (17%), *NF1* (11%), *ZNRF3* (9.3%), *APC* (8.4%), *MEN1* (7.4%), and CN gains of *CDK4* (43%) and *TERT* (12%). Some recurrent mutations were also observed in genes previously not associated with ACC (e.g. *NOTCH1, CIC, KDM6A, BRCA1* and *BRCA2*). Interestingly, the combination between clinical/histopathological data and specific molecular alterations (>1 somatic mutation, alterations in Wnt/β-catenin and/or p53 pathways and high methylation pattern) showed the best prediction of PFS ($P<0.0001$; chi-square=68.6). Searching for potentially druggable targets, CN gains at *CDK4* locus and mutations affecting *NF1* or members of the DNA repair system or mismatch repair were the most frequent. This study shows the feasibility of DNA analysis on FFPE tumor tissues in the clinical practice. We demonstrate that selected clinical/histopathological parameters might predict the clinical outcome of ACC patients. However, the combination with specific molecular alterations increases the power of the prognostic stratification and may identify new potential drug targets. Our findings might pave the way to a precision medicine approach in ACC.

Background
Adrenocortical cancer (ACC) is an aggressive tumour with heterogeneous prognosis. Pan-genomic studies identified molecular subgroups of ACC, remarkably associated with outcome. For routine prospective use, targeted molecular measures are needed, combined into reasonably easy and cheap techniques. The aim was to develop and validate different combinations of targeted molecular markers reflecting the molecular subgroup, and compare their prognostic value to standard prognostic factors of ACC.
Patients and methods
We performed a meta-analysis of pan-genomic studies in a training cohort of 144 ACC, determining their transcriptome (C1A or C1B), methylome (CIMP or nonCIMP), chromosomal alterations (Noisy or Chromosomal/Quiet) and mutational (Cell-cycle and Wnt-betacatenin pathways) profiles. A subset of 72 ACC was studied by targeted measures, including BUB1B-PINK1 differential expression by RT-qPCR and CpG islands methylation of 4 genes (PAX5-GSTP1-PYCARD-PAX6) by MS-MLPA. An independent cohort of 224 ACC from 21 ENSAT centers was used for prognostic validation with RT-qPCR, MS-MLPA, SNP array and targeted NGS. Analyses of disease-free survival (DFS) –for stage I-III ACC- and overall survival (OS) –for stage IV ACC- were performed using Cox models.
Results
Pan-genomic studies identified 4 molecular groups: I) C1A, CIMP and Noisy, II) C1A, (CIMP OR Noisy), III) C1A, nonCIMP and Chromosomal/Quiet and IV) C1B, showing major survival differences (logrank $P<10^{-11}$). In the training cohort, targeted measures were combined into three distinct targeted classifiers: i) a 3D-targeted classifier, recapitulating most comprehensively the pan-genomic classification, combining gene expression, chromosome alterations and methylation profiles; ii) a PCR-based classifier, measurable by PCR-based techniques, combining gene expression and methylation profiles; iii) a DNA-based classifier, using tumor DNA only and so forth combining methylation, chromosome alteration and mutational statuses. All these targeted classifiers presented a strong association with the pan-genomic molecular classification (Fisher $P<10^{-9}$). The prognostic value of targeted molecular classifiers was confirmed in the validation cohort. In localized ACC, all three molecular classifiers were identified as independent prognostic factors of recurrence (DFS HR: 5.96, 5.24 and 2.61, $P=0.003$, 0.002 and 0.006 for the 3D-, PCR-based and DNA-baseed markers respectively) in multivariable models including ENSAT stage and tumor grade. In metastatic ACC, molecular classifiers were associated with overall survival (OS HR=3.16, 4.53 and 3.02, $P=0.18$, 0.08 and 0.006 for the 3D-, PCR-based and DNA-based markers respectively in univariate analysis).
Conclusion
Molecular classification can be recapitulated with targeted molecular measures. In localized ACC, molecular classifiers are strong prognostic independent markers of recurrence, usable in clinical routine.

Clinical and histopathological differences between MEN1 carriers and MEN1 phenocopy patients

Tatjana Isailovic[1], Djuro Macut[1], Ivana Milicevic[2], Milan Petakov[1], Sanja Ognjanovic[1], Valentina Elezovic Kovacevic[2], Bojana Popovic[1], Ivana Bozic Antic[1], Tamara Bogavac[2], Dusan Ilic[2], Mirjana Sumarac Dumanovic[1], Mirjana Stojkovic[1] & Svetozar Damjanovic[1]
[1]Clinic for Endocrinology, Diabetes and Metabolic Diseases, Clinical Center of Serbia, School of Medicine, University of Belgrade, Belgrade, Serbia; [2]Clinic for Endocrinology, Diabetes and Metabolic Diseases, Clinical Center of Serbia, Belgrade, Serbia.

Introduction
Multiple endocrine neoplasia type 1 (MEN1) is a rare multitumour syndrome, characterized by the occurrence of parathyroid (PHPT), pituitary adenoma (PA) and pancreatic neuroendocrine tumors (pNETs). The gene responsible is *MEN1* gene, however 10 to 20% of patients are not carriers of *MEN1* mutation. Recently, a study has shown that these patients have less aggressive course of the disease, and more favorable life expectancy than their mutation-positive counterparts. Nevertheless, their clinical and histopathological features are still unknown.
Study design
Genetic, clinical and histopathological features were analyzed in a retrospective, single-center study of 102 consecutive patients with MEN1. Direct sequencing and MLPA of *MEN1* gene were performed in all patients, and *CDKN1b* gene in *MEN1* mutation-negative patients.
Results
We found 34% of mutation-negative cases among all patients, or 47% among index cases. None of these patients had gene alterations in *CDKN1b* gene. Women were more prevalent among all patients, but this was especially pronounced in mutation-negative patients (86% vs 59% in mutation-positive, $P<0.01$). All major MEN1 tumors appeared earlier in mutation carriers, and none of mutation-negative patients had more than two major MEN1-tumors. The most frequent phenotype was PA/PHPT in mutation-negative, and PA/PHPT/pNET in mutation-positive patients. PAs were more frequent in mutation-negative than in mutation-positive patients (83% vs 57% respectively, $P<0.01$). Acromegaly appeared almost exclusively in mutation-negative patients (41% vs 3% in mutation positive, $P<0.001$). Conversely, pNETs predominantly appeared in mutation-positive (45% vs 9% in mutation-negative, $P<0.01$), and majority of them were multiple (58%). PHPT was equally distributed, but the presence of polyglandular disease was a major feature of mutation carriers (77% vs none in mutation-negative). Bronchial NETs were more prevalent among mutation-negative patients ($P<0.05$), and adrenal tumors were equally distributed ($P>0.05$). There was no difference in age of death and OS between mutation-positive and mutation-negative patients ($P>0.05$).
Conclusion
MEN1 phenocopy differs from genetically confirmed MEN1 syndrome in several aspects: the presence of only two, solitary, coexisting major MEN1-tumors that develop later in life, marked female predominance, frequently occurring acromegaly, and rare pNETs. It appears that other, non-hereditary factors are involved in initiation and development of multiple-organ NETs in MEN1 phenocopy patients. However, the contribution of low-penetrant mutations in other genes cannot be entirely excluded.

Introduction
Cushing's disease (CD) is caused by pituitary tumors hypersecreting adrenocorticotropin (ACTH). Until now somatic mutations in the 14-3-3 binding domain of Ubiquitin Specific Peptidase 8 gene (*USP8*) were the only recurring, driver mutations and were described in about 40% of the 446 CD samples that have been analysed wordwide. We wanted to assess if other driver mutations might be the pathogenetic cause of CD in those tumors without *USP8* mutations.
Methods
We performed next generation exome sequencing in matching tumor and germline DNA from 16 corticotroph tumors causing CD and 2 tumors causing Nelson's syndrome, all of them negative for *USP8* mutations. Hotspot Sanger sequencing was performed in tumor DNA from further 86 CD and 8 Nelson's tumors. *In vitro* de-ubiquitination assays were performed in transfected HeLa cells using purified K48- and K63-linked ubiquitin chains.
Results
Exome sequencing revealed *TP53* mutations in 4 out of 16 (25%) CD tumors and two in both Nelson's tumors (100%). Three were missense mutations and three, including those in the Nelson tumors, were frameshift mutations and deletions, and were distributed over the whole sequence of *TP53*. Furthermore, we found also the point missense mutation c.G1245A(p.M415I) in a new deubiquitinase, the Ubiquitin Specific Peptidase 48 gene (*USP48*) in three further samples (19%). While all tumors had other co-occuring mutations, *TP53* and *USP48* mutations were mutually exclusive in our cohort. The *USP48* mutation was found in further 10 of the 94 samples analyzed by Sanger sequencing (11%), including one Nelson tumor. This mutation increaseed significantly the deubiquitinating activity of USP48 *in vitro* both for K48 and K63 ubiquitin chains.
Conclusion
We describe here recurring mutations in *TP53* and *USP48* genes that associate with CD. *TP53* mutations suggest an impaired TP53 function in those tumors. The recurrent mutation *USP48* was shown to increase deubiquitinating activity *in vitro*, similar to those activating *USP8* mutations that have been reported in CD.

Natural history of Rathke's Cleft Cysts: a multicenter experience

Elisa Sala[1,2], Justin M Moore[2], Alvaro Amorin[2], Giulia Carosi[1], Griffith R Harsh[2], Maura Arosio[1], Giovanna Mantovani[1] & Laurence Katznelson[3]
[1]Unit of Endocrinology, Department of Clinical Sciences and Community Health, Fondazione IRCCS Ca ' Granda - Ospedale Maggiore Policlinico, University of Milan, Milan, Italy; [2]Department of Neurological Surgery, Stanford University Hospital, Stanford, California, USA; [3]Department of Neurological Surgery, Department of Medicine, Stanford University Hospital, Stanford, California, USA.

Objective
Rathke's Cleft Cyst (RCC) is a common incidental type of sellar lesion, and, depending on size, may cause local mass effects with visual impairment, hypopituitarism, and headaches. In this study, we sought to define the natural history of RCC.
Methods
We performed a retrospective study of patients diagnosed with RCC between 2000 and 2016 at Stanford University Hospital, US, and Ospedale Maggiore Policlinico di Milano, Italy. Aim of the study is to investigate tumor size and pituitary function in adult patients with RCC who underwent surgery vs conservative monitoring.
Results
Patients were divided into: Group A, 72 subjects who underwent surgical resection of symptomatic RCC; and Group B, 62 subjects who did not undergo surgery and underwent serial monitoring. Compared to Group B, Group A subjects had more RCC $>$ 10 mm (79% vs 22%, $P < 0.001$); supra and extrasellar extension in 72% vs 33%, $P< 0.001$, hypopituitarism in 41.5% vs 16%, $P< 0.001$; and diabetes insipidus (DI) in 18 and 1.6% $P=0.002$, respectively. The presence of hyperprolactinemia was similar between groups (18 vs 16%). In Group A, after a mean follow up of 53.7 months, 12.5% of patients had recurrence and underwent a second surgical procedure. Surgery resulted in recovery of pituitary function in 35% of patients. Hyperprolactinemia (26.6%) and hypogonadism (66.6%) were the most common axes that recovered after surgery. Prevalence of diabetes insipidus (20.1%) did not change significantly after surgery. In addition, 16.6% of patients experienced a new pituitary deficit after surgery. In Group B, the majority of patients had stable RCC dimension with a mean follow up of 41 months: 6.4% had cyst enlargement, without need of surgical intervention. After a mean hormonal follow up of 37.2 months, no patients in Group B developed a new pituitary deficit.
Conclusion
We evaluated the natural history of RCC in subjects who underwent surgery for symptomatic RCC vs those who had conservative monitoring. Following surgery,

the majority of patients had stable remission as well as improvement in endocrine function over the 3 years follow up. In addition, subjects who are followed conservatively remained stable with regard to tumor size and hormone function. Our data offer important context in decision making about follow up of RCC patients, confirming the safety of non-surgical treatment in asymptomatic patients.

Novel aspects of puberty development and Cushing's disease

OC12.1

Growth hormone signaling in leptin receptor expressing cells, but not in Kiss1 expressing neurons, regulates the timing of puberty

Tabata M Bohlen, Thais T Zampieri, Isadora C Furigo, Pryscila DS Teixeira, Jose Donato Jr & Renata Frazao
University of Sao Paulo, Sao Paulo, Brazil.

Growth hormone (GH) is an important factor involved in the regulation of multiple biological functions. Although the influence of GH is widespread throughout several organs and tissues, the effects of GH on brain functions, such as those related to reproductive functions, are still elusive. GH deficiency or resistance can be related to late puberty onset, lack of sexual maturation and infertility. In contrast, GH therapy can accelerate puberty onset or be used to increase pregnancy rates in woman treating fertility-related problems. Thus, GH seems to modulate reproduction. However, the molecular and cellular mechanisms by which GH could potentially modulate the reproductive system are not fully understood. To understand whether GH signaling in the brain is required for sexual maturation and maintenance of reproductive functions, we used the Cre-LoxP technology to induce GH receptor (GHR) deletion in specific neuronal populations (kiss1-Cre or leptin receptor-Cre mice). Sexual maturation was assessed daily by determining the age and weight at the vaginal opening and at the first occurrence of vaginal cornification in the vaginal lavage (first estrus). These parameters were monitored daily until 80 days of age. Body weight was monitored weekly and at each specific stage of sexual maturation. The uterine mass and local fat pad mass were also determined in adult female mice. We observed that specific GHR deletion from Kiss1 expressing cells induced no effect on sexual maturation or body weight of female mice. In contrast, LepR GHR KO female exhibited delayed onset of first estrus, despite no changes on the age of vaginal opening or body weight at the specific stages of sexual maturation. However, LepR GHR KO female were lighter compare to the littermate controls throughout the development, suggesting that LepR GHR KO females need to reach a specific body weight before having sexual maturation. Accordingly, adipose fat pads weight was significantly reduced in adult LepR GHR KO females compared to control. Taking together, our results suggest that GHR expression on *Kiss1* expressing cells is not required for puberty onset in female mice. However, growth hormone signaling on LepR expressing cells seems to regulate the puberty timing. Whether the observed effects on sexual maturation are dependent on body weight needs to be further investigated.

Oligogenicity in Kallmann syndrome - an underestimated phenomenon?

Małgorzata Kałużna[1], Bartłomiej Budny[1], Michał Rabijewski[2], Szymon Dębicki[1], Małgorzata Trofimiuk-Muldner[3], Agnieszka Dubiel[3], Marek Ruchała[1] & Katarzyna Ziemnicka[1]
[1]Department of Endocrinology, Metabolism and Internal Medicine, Poznan University of Medical Sciences, Poznan, Poland; [2]Department of Reproductive Health Center of Postgraduate Education, Warsaw, Poland; [3]Nuclear Medicine Unit, Department of Endocrinology, Jagiellonian University Medical College, Krakow, Poland.

Isolated hypogonadotropic hypogonadism (IHH) is caused by impaired gonadoliberin (GnRH) gene regulation, synthesis or secretion of GnRH. Genetic factors of more than 50% of the IHH are still unknown. One the most common types of IHH is the Kallmann syndrome (KS) associated with anosmia or hyposmia. In view of technological progress and new possibilities for detecting changes in human genome a comprehensive targeted analysis using next-generation sequencing (NGS) was carried out. Screening encompassed 31 patients (27 men; 4 women) with isolated hypogonadotropic hypogonadism to search for genetic background underlying IHH. The targeted sequencing of the IHH genes was conducted on Ion Torrent Personal Genome Machine™. The panel of IHH genes (dedicated library) was constructed and designed using Ion AmpliSeq™ Designer and included coding regions for 16 genes involved in the pathogenesis of IHH (e.g. *KAL1/KS1, FGFR1/KS2, PROKR2/KS3, PROK2/KS4, CHD7/KS5, FGF8/KS6, GNRHR/HH7, NELF (NSMF)/HH9, GNRH1/HH12, WDR11/HH14, HS6ST1/HH15, LRRIQ3, GLI2, OTX2, TAC3/HH10, TACR3/HH11 genes*). In 25 patients (80.6%) different mutations in examined genes were found. In 13 (52%) cases monogenic mutations were identifed, whereas in 12 (48%) cases oligogenicity (alteration present in more than one *IHH*-associated gene in a given patient) was discovered. In the literature oligogenic inheritance is reported at the level of 10–20% of all IHH cases. Our results suggest that oligogenicity in IHH could be an underestimated phenomenon. Wide NGS analysis as a high-throughput method provide a valuable insights regarding molecular mechanisms, mutational landscape and variability of the disease.

Evaluation of genetic predisposition in severe and mild phenotypes of isolated hypogonadotropic hypogonadism

Biagio Cangiano[1,2], Paolo Duminuco[2], Valeria Vezzoli[2], Fabiana Guizzardi[2], Luca Persani[1,2] & Marco Bonomi[1,2]
[1]Dipartimento di Science Cliniche e di Comunità, Università degli Studi di Milano, Milan, Italy; [2]Divisione di Medicina ad indirizzo endrocrino-metabolico e Lab. di ricerche endocrino-metaboliche, IRCCS Istituto Auxologico Italiano, Milan, Italy.

Introduction
Isolated hypogonadotropic hypogonadism (IHH) often occurs in the pre-pubertal period but it can also manifest in post-puberal age. Recent position statements and guidelines differentiate between a 'true' hypogonadotropic hypogonadism, intended as congenital or acquired organic defect (characterized by frankly pathological total Testoterone values, TTe <3.5 nmol/l), and a 'false' or functional hypogonadism, associated to older age and comorbidity and characterized by a less severe reduction of TTe levels. However, there is no clear evidence that these two nosological entities are distinct from a pathogenetic point of view. We decided to investigate genetic predisposition in IHH individuals comparing them on the basis of disease onset and degree of hypogonadism.
Patients and methods
We evaluated 115 male patients affected with IHH, both normal and hypo/anosmic. Each patient underwent a genetic investigation, using Next Generation Sequencing (NGS), to search for rare, non intronic, nonsynonymous allelic variants in the candidate genes known for IHH. We performed the same analysis in 79 controls. We compared the prevalence of mutations between patients with severe hormone deficiency (sIHH: TTe ≤ 3.5 nM), patients with mild/moderate hormone deficiency (mIHH with TTe 3.5–11.0 nM but with low calculated free Te) and in controls with Te >11.0 nM).
Results
The genetic analysis showed a statistically significant difference between the prevalence of mutations in the causal genes of IHH affecting both patients with severe hypotestosteronemia and mild hormone deficiency when compared to controls ($P<0.001$ and $P<0.035$ respectively); on the contrary there was no statistically significant difference comparing the two groups of cases. BMI was similar in the groups of IHH patients (sIHH: 27.8 Kg/m^2 vs mIHH 24.75 Kg/m^2). We found no statistically significant difference in the prevalence of oligogenic defects in the two groups of cases ($P=0.75$).
Conclusions
These data suggest a similar genetic predisposition in both severe and mild phenotypes of IHH, suggesting that IHH of genetic origin is associated with a wide spectrum of GnRH disfunctions.

Late-night salivary cortisol (LNSC) levels in a Phase III study of long–acting pasireotide in patients with Cushing's disease (CD)

John Newell-Price[1], Rosario Pivonello[2], Antoine Tabarin[3], Maria Fleseriu[4], Przemysław Witek[5], Mônica Gadelha[6], Stephan Petersenn[7], Libuse Tauchmanova[8], Shoba Ravichandran[9], Michael Roughton[8], André Lacroix[10] & Beverly MK Biller[11]

[1]The Medical School, University of Sheffield, Sheffield, UK; [2]Università Federico II di Napoli, Naples, Italy; [3]Department of Endocrinology, CHU of Bordeaux, Bordeaux, France; [4]Northwest Pituitary Center, Oregon Health & Science University, Portland, Oregon, USA; [5]Department of Gastroenterology, Endocrinology and Internal Diseases, Military Institute of Medicine, Warsaw, Poland; [6]Hospital Universitário Clementino Fraga Filho, Universidade Federal do Rio de Janeiro, Rio de Janeiro, Brazil; [7]ENDOC Center for Endocrine Tumors, Hamburg, Germany; [8]Novartis Pharma AG, Basel, Switzerland; [9]Novartis Pharmaceuticals Corporation, East Hanover, New Jersey, USA; [10]Centre hospitalier de l'Université de Montréal, Montreal, Canada; [11]Neuroendocrine Clinical Center, Massachussetts General Hospital, Boston, Massachussetts, USA.

Introduction

LNSC has shown high sensitivity and specificity for the initial diagnosis of CD and detection of disease recurrence; however, the use of LNSC to monitor medical treatment of CD is not well established. The results of an exploratory analysis evaluating changes in LNSC in CD patients receiving long-acting pasireotide during a Phase III study (CSOM230G2304; Lacroix *et al. Lancet Diabetes Endocrinol* 2018) are reported here.

Methods

Patients ($N=150$) with persistent, recurrent or *de novo* (non-surgical candidates) CD and mean urinary free cortisol (mUFC) 1.5–5x the upper limit of normal (ULN) were randomized to monthly pasireotide 10 mg ($n=74$) or 30 mg ($n=76$). mUFC $\leq$ ULN at month (M) 7 was the primary endpoint, with change in LNSC an exploratory objective. At each time point, mean LNSC (mLNSC) was calculated as the mean of two measurements from single samples collected at 23:00 ($\pm$1 h) on the same days as the first two of three 24-hour UFC measurements. UFC and LNSC samples were analysed at central laboratories by LC-MS/MS.

Results

Mean (s.d.) mLNSC at baseline was 10.4 (8.2) nmol/l, with mLNSC > ULN (3.2 nmol/l) in 125/137 (91.2%) evaluable patients. Mean (95%CI) changes in mLNSC from baseline to M7 and M12 were −1.6 (−3.7,0.5) and −3.3 (−5.6,−1.0) nmol/l, respectively. Mean (95%CI) change from baseline to M7 in mLNSC was greatest in patients with mUFC $\leq$ ULN at M7 (−5.1 (−8.3,−2.0) nmol/l). Changes in blood pressure (BP) and weight by mUFC and/or mLNSC response among 113 evaluable patients at M7 are shown in the Table.

Mean (95%CI) percentage change from baseline to M7 in BP and weight by mUFC/mLNSC response at M7

	Both mUFC and mLNSC $\leq$ ULN $N=20$	mUFC $\leq$ ULN only $N=36$	mLNSC $\leq$ ULN only $N=5$	Both mUFC and mLNSC > ULN $N=52$
Systolic BP	−10.8 (−15.7,−5.9)	−3.9 (−7.7,0.0)	−7.4 (−16.6,1.9)	−1.2 (−3.9,1.5)
Diastolic BP	−10.5 (−16.1,−5.0)	−4.7 (−10.2,0.9)	−4.5 (−18.7,9.7)	−0.8 (−4.6,2.9)
Weight	−5.7 (−9.1,−2.3)	−3.7 (−5.8,−1.6)	−2.0 (−10.9,7.0)	−4.3 (−5.8,−2.7)

Conclusion

Long-acting pasireotide decreased mLNSC levels, with greatest reductions seen in patients with controlled mUFC at M7. More patients achieved normal mUFC than normal mLNSC at M7, with few patients having normal mLNSC but elevated mUFC. Greatest reductions in BP were seen for patients with normal mUFC and mLNSC. Further studies designed to assess the effect of medical therapies on LNSC in CD patients are warranted.

Background

Patients with active Cushing's syndrome (CS) have increased mortality.

Aims

Evaluate cause of death in a large cohort of CS patients, and establish factors associated with increased mortality.

Methods

We analysed 1514 patients included in the European Registry on Cushing's syndrome (ERCUSYN): 1022 (68%) had pituitary-dependent CS (PIT-CS), 379 (25%) adrenal-dependent CS (ADR-CS), 71 (5%) had an ectopic source (ECT-CS) and 42 (3%) other causes (OTH-CS). Median duration of follow-up was 139 weeks.

Results

Fifty-one patients died (3.3%): 23 (2.2%) PIT-CS, 7 (1.8%) ADR-CS, 18 (20%) ECT-CS and three (6.7%) OTH-CS. The commonest cause of death in patients with PIT-CS and ADR-CS were infectious ($n=8$), cardiovascular ($n=3$), and cerebrovascular diseases ($n=3$). The commonest cause of death in patients with ECT-CS was progression of the underlying tumor ($n=10$), infections ($n=3$) and cardiovascular disease ($n=2$). The median (interquartile range) time from diagnosis to death was 67 (11–203) weeks in patients with PIT-CS and ADR-CS and 9 (3.6–48) weeks in patients with ECT-CS ($P=0.007$). Patients who died had a higher prevalence of diabetes mellitus (59 vs 35%; $P=0.001$) and muscle weakness (86 vs 69%; $P=0.012$) at diagnosis. The prevalence of hypertension, skin manifestations and depression at diagnosis did not differ between groups. By regression analysis, age (Odds ratio (OR) 1.05 (95% CI 1.02–1.07); $P<0.001$), diabetes (OR 2.14 (95% CI 1.07–4.27); $P=0.030$), and muscle weakness (OR 2.5 (95% CI 1.01–6.15); $P=0.045$) were significantly associated with mortality. Of 51 deceased patients, 23 (45%) died within 90 days from start of treatment and 3 (6%) before any treatment initiation. Of these, 7 (33%) had PIT-CS, 5 (24%) had ADR-CS, 12 (57%) had ECT-CS, and 2 (10%) OTH-CS. The commonest cause of death in these patients was infection ($n=9$). Two-thirds of patients who died within 90 days from start of treatment had diabetes, vs.35% in the whole ERCUSYN cohort ($P=0.001$). By regression analysis, age (OR 1.06 (95% CI 1.03–1.10); $P<0.001$) and diabetes mellitus (OR 2.9 (95% CI 1.1–7.2); $P=0.025$) were independently associated with death within 90 days from start of treatment.

Conclusion

Mortality was highest in patients with ectopic CS. Irrespective of etiology, older age, muscle weakness and diabetes at diagnosis were independently associated with increased mortality. Infectious diseases were the commonest cause of death soon after diagnosis and initiation of treatment, and patients with diabetes mellitus seem to be especially vulnerable, emphasizing the need for careful clinical vigilance at that time.

Postoperative use of somatostatin analogs and mortality in patients with acromegaly

Mark R Postma[1], Thalijn LC Wolters[2], Gerrit van den Berg[1], Antonius E van Herwaarden[3], Anneke C Muller Kobold[4], Wim J Sluiter[1], Margreet A Wagenmakers[2,5], Alfons CM van den Bergh[6], Bruce HR Wolffenbuttel[1], Ad RMM Hermus[2], Romana T Netea-Maier[2] & André P van Beek[1]
[1]Department of Endocrinology, University Medical Center Groningen, Groningen, Netherlands; [2]Department of Internal Medicine, Division of Endocrinology, Radboud University Medical Center, Nijmegen, Netherlands; [3]Department of Laboratory Medicine, Radboud University Medical Center, Nijmegen, Netherlands; [4]Department of Laboratory Medicine, University Medical Center Groningen, Groningen, Netherlands; [5]Department of Internal Medicine, Centre for Lysosomal and Metabolic Diseases, Erasmus MC, Rotterdam, Netherlands; [6]Department of Radiation Oncology, University Medical Center Groningen, Groningen, Netherlands.

Objective
To assess the effect of somatostatin analogs (SSTA) on mortality in relation to metabolic control of acromegaly after pituitary surgery.
Design
A retrospective study in two large tertiary referral centers in The Netherlands.
Patients and methods
Three hundred and nineteen patients with acromegaly in whom pituitary surgery was performed as primary therapy between January 1980 and July 2017 were included (total follow-up: 3887 patient years). Postoperative treatment with SSTA was prescribed to 174 (55%) patients because of persistent or recurrent disease. Metabolic control at last visit was assessed by local IGF1 standard deviation score (SDS). Adequate metabolic control was defined as an IGF-1 SDS $\leq$ 2. Univariate determinants of mortality and standardized mortality ratios (SMR) were calculated for groups with and without SSTA at any moment postoperatively and at last visit.
Results
In total, 27 deaths were observed. SSTA use was not associated with increased mortality. In univariate analysis, determinants of mortality were inadequate metabolic control (RR 3.41, $P=0.005$), surgery by craniotomy/combined approach (RR 3.53, $P=0.013$) and glucocorticoid substitution (RR 2.11, $P=0.047$). The SMR of patients with adequate metabolic control who used SSTA at any moment postoperatively (1.06, $P=0.959$) and at last visit (1.19; $P=0.769$) was not increased. Insufficiently controlled patients had a significantly raised SMR (3.94, $P<0.001$).
Conclusion
Postoperative use of SSTA is not associated with increased mortality in patients with acromegaly when adequately controlled. In contrast, inadequate metabolic control, primary surgery by craniotomy/combined approach, and glucocorticoid substitution are associated with increased mortality.

Time trends of mortality in patients with GH secreting and non-functioning pituitary adenoma

Simona Galoiu[1,2], Simona Silea[1], Ionela Baciu[1,2], Raluca Alexandra Trifanescu[1,2], Dan Niculescu[1,2], Cristina Capatina[1,2], Serban Radian[1,2], Anda Dumitrascu[2], Andra Caragheorgheopol[2] & Catalina Poiana[1,2]
[1]Carol Davila University of Medicine and Pharmacy, Bucharest, Romania; [2]C.I.Parhon National Institute of Endocrinology, Bucharest, Romania.

Background and aims
Patients with GH secreting or nonfunctioning pituitary adenoma (NFPA) have high mortality ratios, despite enhancement of the old therapies. The aim of the study is to analyze the relationship between mortality and risk factors, including therapy, in patients with acromegaly (ACM) and NFPA evaluated in the last 16 years.
Methods
We evaluated retrospectively 749 patients with pituitary adenoma (435F/314M), 386 with ACM and 363 with NFPA, between 2001–2007 and 2008–2016. Standard mortality ratio (SMR) was calculated as the ratio between observed and expected number of deaths. A multivariable Cox regression was used to calculate hazard ratios (HR) for all-cause mortality risk factors.
Results
In patients with ACM- follow-up 3286.88 person-years (median 8.5 years), mortality ratio was increased (observed deaths: $n=62$) against expected ($n=38$): SMR = 1.60 (95% Confidence Interval (CI) 1.23–2.06), while in NFPA- follow-up 2570.70 person-years (median 7.5 years), SMR was 1.38 (95% CI 1.05–1.79). Females with both ACM and NFPA had doubled mortality ratio: SMR = 2.19 (95% CI 1.57–2.98) and 2.00 (95% CI 1.28–2.97), respectively. At multivariate regression analysis, age, post-treatment GH and tumor diameter were independently correlated to mortality in ACM (HR 1.085 (95%CI 1.058–1.114, $P<0.001$; HR 1.018 (95%CI 1.006–1.031, $P=0.003$), and respectively HR 1.041 (95%CI 1.004–1.080, $P=0.03$), while age and remnant tumor diameter were correlated to mortality in NFPA patients (HR 1.07 (95%CI 1.044–1.099, $P<0.001$ and respectively HR 1.02(95%CI 1.008–1.051, $P=0.018$)). Patients diagnosed before 2008 died more frequently than patients diagnosed since 2008 (109/415 vs 14/334, respectively), but with longer follow-up (10.99 ± 3.94 vs 4.34 ± 2.45 years, respectively). Regarding pituitary tumor treatment, proportion of patients with ACM receiving neurosurgery (58.5% before 2008 vs 73.68% since 2008, $P=0.002$), radiotherapy (61.96% before 2008 vs 20.39% after 2008, $P<0.001$) and medical treatment (52.13% vs 65.13%, $P=0.008$) changed, but the ratio of cured and medically controlled ACM did not changed (54.93%vs 56.57%, respectively, $P=0.06$). Pituitary insufficiency was more frequent in patients diagnosed before 2008 on all axes (gonadic/thyroid/adrenal: 37.17/26.49/16.66%) vs patients diagnosed after 2008 (21.19/11.92/5.9%, respectively), reflecting the greater proportion of irradiated patients and longer follow-up. Average post treatment GH, IGF1 levels and pituitary tumor remnant diameter were not different before or after 2008.
Conclusion
Patients with GH secreting or nonfunctioning pituitary adenoma had still high mortality ratios, especially in females. Efficacy of changes in therapy after 2008 need longer follow up to see changes in mortality.

Molecular profiling for assistance to pharmacological treatment of acromegaly

Manuel Puig-Domingo[1], Joan Gil[1], Miguel Sampedro[2], Susan M Webb[3], Guillermo Serra[4], Isabel Salinas[5], Alberto Blanco[5], Montse Marques-Pamies[6], Antonio Pico[6], Araceli García-Martínez[8], Concepción Blanco[7], Carlos Del Pozo[8], Gabriel Obiols[9], Cristina Alvarez-Escolá[10], Rosa Cámara[11], Carmen Fajardo[12], Raúl Luque[13], Justo Castaño[13], Mercedes Robledo[14], Mireia Jordà[15], Ignacio Bernabéu[16] & Mónica Marazuela[17]
[1]Institut Germans Trias i Pujol, Badalona, Spain; [2]Hospital La Princesa, Madrid, Spain; [3]Hospital de Sant Pau, Barcelona, Spain; [4]Hospital Son Espases, Palma de Mallorca, Spain; [5]Hospital Germans Trias, Badalona, Spain; [6]Hospital General Universitario, Alicante, Spain; [7]Hospital Príncipe de Asturias, Alacalá de Henares, Spain; [8]Hospital Mutua, Terrassa, Spain; [9]Hospital Vall d'Hebron, Barcelona, Spain; [10]Hospital La Paz, Madrid, Spain; [11]Hospital La Fe, Valencia, Spain; [12]Hospital de la Ribera, Alzira, Spain; [13]IMIBIC, Córdoba, Spain; [14]CNIO, Madrid, Spain; [15]Institut Germans Trias, Badalona, Spain; [16]Complexo Hospitalario, Santiago de Compostela, Spain; [17]Hospital de la Princesa, Madrid, Spain.

Pharmacologic treatment of acromegaly is currently based upon assay-error strategy in which first generation somatostatin analogs (SSA) is the first-line treatment. However, about 50% of patients do no respond adequately to SSA. We aimed to evaluate the potential usefulness of including studies of molecular markers identifying poor response to SSA for prescription of pharmacologic treatment in acromegalic patients in which SSA was prescribed before surgical therapy.
Methods
Retrospective study in which 68 acromegalic patients (59% females, median age 44) from a national cohort from 12 hospitals participated. All patients were treated with SSA preoperatively during at least 6 months under maximal effective therapeutic doses according to IGF-I values normalization. Response to SSA treatment was categorized as: complete response (C) when IGF-I achieved normal values; partial (P) response if IGF-I was between $>2<3$ SDS requiring combined treatment with pegvisomant or non-responders (NR) when IGF-I was >3 SDS and patient required monotherapy with pegvisomant. Somatotropinoma tissue from surgical specimen was obtained, RNA-later embedded and further processed for evaluation of the expression of 11 genes related to SSA response: *SSTR2*, *SSTR5*, *AIP*, e-cadherin (*CDH1*), Ki67, Kallikrein 10 (*KLK10*), arrestin beta-1 (*ARRB1*), ghrelin (*GHRL*), intron 1 Ghrelin (*in1-Ghrelin*), ZAC1

(*PLAGL1*) and Raf Kinase inhibitory protein (*PEBP1*). Measurements were made by RT-qPCR and obtained levels were normalized by the expression of *MRPL19*, *TBP* and *PGK1* as reference genes. Furthermore, we analysed the gene GNAS (*gsp*) looking for mutations in the 201 and 227 codons using conventional PCR and Sanger Sequencing.
Results
According to therapeutic response there were 26 patients (38%) with complete, 17 (25%) with partial response and 25 (37%) no response. SSTR2 expression and CDH1 were associated to complete response ($P=0.05$ and $P<0.001$, respectively). Moreover, CDH1 was able to discriminate between the three different therapeutic response categories (C, P, NR) None of the other previously described genes related to SSA therapeutic response showed statistically significant different expression between C, P or NR patients. The best discriminator between C and NR was CDH1 (ROC AUC=0.74, $P<0.01$).
Conclusions
Somatotropinomas are heterogeneous tumours depicting a high variable molecular expression of genes associated to SSA response. CDH1 is the best molecular discriminator of therapeutic response to SSA. Thus, it may be useful in subsequent treatment decision after surgical failure in acromegalic patients.

Effects of pegvisomant on glucose metabolism in acromegaly: A meta-analysis of prospective interventional studies

Tiziana Feola[1], Alessia Cozzolino[1], Giulia Puliani[1], Emilia Sbardella[1], Daniele Gianfrilli[1], Valeria Hasenmajer[1], Ilaria Simonelli[2], Patrizio Pasqualetti[2], Andrea Lenzi[1] & Andrea M. Isidori[1]
[1]Department of Experimental Medicine, Sapienza University of Rome, Rome, Italy; [2]Medical Statistics and Information Technology, AFaR, Fatebenefratelli Hospital, Isola Tiberina, Rome, Italy.

Introduction
Glucose metabolism impairment is a common complication of acromegaly. Pegvisomant (PEG) is used as second-line medical treatment in acromegaly. Data from literature suggest a positive effect of PEG on glucose metabolism but a meta-analysis has never been performed.
Aim
To address the following questions: i) does PEG affect glucose metabolism? ii) does the effect correlate with disease control?
Methods
We performed a meta-analysis of prospective interventional studies reporting the use of PEG for the treatment of acromegaly. We searched MEDLINE, EMBASE, and SCOPUS for English-language studies. Inclusion criteria: minimum 6-month follow-up, glyco-metabolic outcomes before and after PEG treatment. The pooled estimate of a weighted mean was obtained for all outcomes using a random effects model.
Results
Fifteen studies met inclusion criteria. PEG treatment induced a significant decrease in fasting plasma glucose (FPG) (effect size (ES) −0.90 mmol/l, 95%CI: −1.15–−0.66; $P=0.000$), HbA1c (ES −0.48%, 95%CI: −0.59–−0.37; $P=0.000$), fasting plasma insulin (FPI) (ES −5.12 mU/l, 95%CI: −8.99–−1.22; $P=0.010$) and HOMAi (ES −0.80, 95%CI: −1.38–−0.22; $P=0.007$), without changes of triglyceridemia, glucose load (2h-OGTT), HOMAβ, weight and BMI. Meta-regression was possible only for FPG and FPI and it revealed not significant effect of post-pre treatment IGF-1 mean difference on the pooled estimate.
Conclusions
PEG induces a significant decrease in FPG, HbA1c, FPI and HOMAi. These results suggest that PEG treatment improves glucose metabolism in acromegaly and this effect seems to be independent from disease control.

Growth hormone acts in AgRP neurons to control energy expenditure during food restriction and promotes counter-regulatory responses to hypoglycemia via the ventromedial hypothalamus

Isadora C Furigo[1], Pryscila DS Teixeira[1], Gabriel O Souza[1], Eduard List[2], John Kopchick[2] & José Donato Jr[1]
[1]Institute of Biomedical Sciences, University of Sao Paulo, Sao Paulo, Brazil; [2]Edison Biotechnology Institute, Ohio University, Athens, Ohio, USA.

Growth hormone (GH) responsive cells are extensively distributed in central nervous system, including in neurons of the arcuate (ARH) and ventromedial nucleus (VMH) of hypothalamus, areas that control food intake, energy expenditure and blood glucose. During metabolic stresses, such as food restriction and hypoglycemia, GH secretion is stimulated and may be important to maintain survival. In the present study, we first verified that an acute GH injection stimulates food intake by increasing AgRP and NPY mRNA expression in the hypothalamus of wild-type mice. Then we generated mice lacking GH receptor (GHR) specifically in AgRP neurons or in steroidogenic factor-1 (SF1) cells, which include neurons in the VMH, in order to evaluate whether these cells mediate the effects of GH during conditions of metabolic stress. AgRP GHR KO mice exhibited similar body weight, food intake, energy expenditure, glucose tolerance and leptin sensitivity, compared to control animals. However, fasting induced a lower cFOS expression in the ARH of AgRP GHR KO than control animals. Remarkably, while control mice adapted to a 60% food deprivation period by progressively saving energy, AgRP GHR KO mice exhibited a blunted metabolic adaptation to starvation, which led to higher energy expenditure and weight loss, followed by higher T_4 production and UCP-1 mRNA expression in the iBAT. Blockage of sympathetic system with propranolol equalized the energy expenditure between the groups. In contrast, SF1 GHR KO mice exhibited similar responses to control group in food restriction, but a blunted counter-regulatory response evoked by 2-deoxyglucose (2DG) administration, indicating that GH may act in VMH cells to reverse the hypoglycemic state. In summary, GH signaling in AgRP neurons regulates the metabolic adaptations to starvation, while GH signaling in the VMH controls the counter-regulatory responses to hypoglycemia. These findings indicate a previously unidentified function of GH by acting in specific neuronal populations in order to ensure survival via the induction of appropriate metabolic responses.

What is new in gestational and type 1 diabetes?

OC14.1

Does insulin treatment differ in their impact on placental vascular circulation in obese and non obese women with gestational diabetes mellitus?

Marina Shargorodsky[1,2], Gulia Barda[1,2], Jacob Bar[1,2] & Letizia Shraiber[1,2]
[1]Wolfson Medical Center, Holon, Israel; [2]Sackler Faculty of Medicine, Tel Aviv University, Tel Aviv, Israel.

Objective
The present study was designed to investigate the impact of insulin treatment on placental maternal and fetal vascular circulation in obese and non-obese women with gestational diabetes mellitus (GDM).
Design and methods
One hundred and ninety two women with GDM who gave birth and underwent a placental histopathological examination at Wolfson Medical Center were included in the study: 123 women who were treated with diet (Group 1) and 69 women who were treated with diet plus insulin (Group 2). Additionally, each group was divided into two subgroups according to pre-pregnancy BMI: non-obese (A) and obese (B).
Results
Maternal vascular malperfusion lesions did not differ significantly between groups. Vascular lesions related to fetal malperfusion were significantly lower in GDM women treated by insulin and diet compared to women with diet alone ($P=0.027$). Among fetal malperfusion lesions, villous changes consistent with fetal thrombo-occlusive disease (FTOD) increased from Group 1 to Group 4 in a continuous fashion and were higher in diet treated obese women than in other study groups (0, 3.5, 13 and 26.5%, $P=0.009$). In the logistic regression analysis, insulin treatment was significantly associated with a decreased rate of villous changes consistent with FTOD (OR 0.97, 95% CI 0.12–0.80, $P=0.03$).
Conclusion
Combination of obesity and GDM increased rate of villous changes consistent with FTOD and prevalence of gestational hypertension in both treatment groups. Insulin plus diet treatment was associated with improved fetal placental vascular circulation. Prevention of obesity throughout women's childbearing age may translate to improved placental circulation and better pregnancy outcomes.

Profiling of activation patterns of placental mTOR in pregnancies complicated by gestational diabetes mellitus

Anna Papadopoulou[1], George Valsamakis[2], Irini Thymara[3], Anastasia Laryngaki[1], Spyridoula Theodorou[4], Dimitris Grammatopoulos[5], Vasiliki Papaevangelou[1] & George Mastorakos[2]
[1]3rd Department of Pediatrics, Medical School, University General Hospital 'Attikon', National and Kapodistrian University Athens, Athens, Greece; [2]Unit of Endocrinology, Diabetes Mellitus and Metabolic diseases, Aretaeion Hospital, Medical School, National and Kapodistrian University Athens, Athens, Greece; [3]1st Laboratory of Pathology, Medical School, School of Health Sciences, University of Athens, National and Kapodistrian University Athens, Athens, Greece; [4]3rd Department of Obstetrics and Gynecology, Medical School, University General Hospital 'Attikon', National and Kapodistrian University Athens, Athens, Greece; [5]Division of Translational Medicine, Clinical Sciences Research Laboratories, Warwick Medical School, University of Warwick, University Hospital, Coventry, UK.

The mammalian target of rapamycin (mTOR) is a serine kinase that couples energy and nutrient abundance to cell growth and is critically involved in the onset and progression of diabetes, cancer and ageing. Placental mTOR is involved in nutrient sensing and transfer to the fetus. Animal models suggest that placental mTOR is upregulated in pregnancies complicated by gestational diabetes (GDM). Our aim was to characterize expression, and cellular localization of mTOR and whether the activated fraction is affected by GDM. Our study consisted of i) GDM-mothers ($n=40$) and their offspring and ii) mothers ($n=33$) with normal pregnancies (non-GDM) and their infants. At delivery, fetal glucose was measured in cord blood and total and phospho-mTOR (Ser2448) expression were determined in placental biopsies using Western blot (WB) and immunohistochemistry (IHC) analysis. Newborn anthropometric parameters were also determined at delivery. GDM pregnant women were older (30.81 ± 4.87; 33.39 ± 5.38, $P<0.02$) and presented with higher fasting glucose levels than non-GDM (94.82 ± 19.96 mg/dl; 73.08 ± 9.77 mg/dl; $P<0.001$). No significant difference was found in birth weight or baby length between GDM and non-GDM infants. IHC analysis showed that both total and activated mTOR were predominantly expressed in trophoblasts and to a lesser extend in synciotrophoblasts, in both GDM and non-GDM placentas. GDM placentas exhibited a higher mTOR H-score compared to non-GDM ($P<0.009$), and WB analysis showed a higher phospho-mTOR signal intensity ($P=0.047$) in the same group. However, total mTOR expression was relatively increased in GDM placentas resulting in a decreased phospho/total (P/T) ratio in GDM than non-GDM placental tissues (0.95 vs 0.8, $P=0.001$). mTOR expression was increased in both GDM syncitiotrophoblasts and endothelial cells compared to non GDM ($P<0.001$) whereas a reduced signal was detected in stromal phospho-mTOR ($P=0.004$). No difference was found in trophoblasts or endothelial cells between the two study groups suggesting that activation of this kinase is tightly regulated and is relatively independent of changes in total kinase levels. The upregulation of the total mTOR levels led to a decreased P/T mTOR ratio in GDM syncytiotrophoblasts compared to non-GDM ($P<0.001$). A positive correlation was found between endothelial P/T mTOR ratio and baby length ($P=0.025$) and a negative correlation with BMI, maternal fasting glucose and fetal glucose ($P=0.005$; $P=0.025$; $P=0.026$ respectively). Placental mTOR/PmTOR expression is differentially regulated across different placental cell types and is sensitive to hyperglycaemia associated with gestational diabetes mellitus.

Patrolling monocytes are activated in diabetes and provide protection to retinal vessels in the context of leukostasis

Francesco Tecilazich[1,2,3,4], Toan Phan[1], Fabio Simeoni[3], Zeina Dagher-Mansour[1] & Mara Lorenzi[1,2,3]
[1]Schepens Eye Research Institute, Massachusetts Eye and Ear Infirmary, Boston, Massachusetts, USA; [2]Harvard Medical School, Boston, Massachusetts, USA. [3]IRCCS San Raffaele, Milan, Italy; [4]IRCCS Burlo Garofalo, Triest, Italy.

Background
Diabetes is characterized by a prolonged latency between the onset of metabolic abnormalities and the clinical appearance of microvascular disease, consistent with the occurrence of vascular repair in the early stages. Patrolling monocytes (PMo), a subset of circulating monocytes, survey microvessels by crawling on the endothelium; their functional and biosynthetic characteristics suggest they play a role in the protection of the endothelium from vascular stress.
Hypothesis
In early diabetes, PMo adhere to retinal microvessels and exert protective functions, a potential mechanism for the latency that precedes the appearance of retinopathy.
Methods
Streptozotocin-diabetes was induced in male NR4A1-deficient mice (KO) that lack PMo, and in age-matched C57BL6/J controls (WT). To study retinal leukostasis, whole-mounted retinas from mice perfused intracardially were immunostained for CD45 (pan-leukocytic) and CD16.2 (PMo-specific) to identify and enumerate cells firmly adherent to microvessels. Retinal microangiopathy was assessed by counting acellular capillaries (AC) on retinal trypsin digests. To study their biosynthetic characteristics, RNA was isolated from circulating PMo sorted from mice after 5 months of diabetes using anti-CD45, CD11b, CD3, CD19, NK1.1, Ly6G, CD115, and Ly6C; and analyzed by RNAseq and qPCR.
Results
In WT mice, 3 months of diabetes increased firmly adherent leukocytes (Controls (C): 58 ± 23/retina, Diabetes (DM): 93 ± 18, $P<0.001$)) as well as PMo (C: 10 ± 4/retina, DM: 37 ± 6, $P<0.001$). Conversely, diabetes did not increase firmly adherent leukocytes in KO mice. AC were not increased after 4 months of diabetes in WT, nor KO mice. In WT mice, 6 months of diabetes increased AC (C: 5 ± 1/mm^2 retina, DM: 7 ± 1; $P<0.01$); the AC increase was more pronounced in KO-DM (12 ± 3) when compared to WT-DM and KO-C (5 ± 1) ($P<0.001$ vs both). RNAseq and qPCR of PMo from diabetic mice showed a pro-adhesive, anti-inflammatory, anti-apoptotic, vasculo-protective signature.
Conclusion
These data demonstrate several features of the role of PMo in diabetes including (i) more severe retinal microangiopathy in mice lacking PMo after 6 months of diabetes, (ii) increased PMo adherence to retinal microvessels at early time points of diabetes; and (iii) a vasculo-protective biosynthetic program of circulating PMo. Collectively, the findings suggest that in early diabetes PMo deliver to retinal microvessels protective/healing activities that counteract the damaging effects of diabetes. Leukostasis may thus represent, at least in part, a mechanism for healing, rather than a pro-inflammatory event as currently proposed.

OC14.4

The variability of glycemia and the metabolic composition of brain cells in patients with type 1 diabetes mellitus

Maria Rotkank, Julia Samoylova, Natalia Zhukova, Mariia Matveeva, Ivan Tolmachev & Olga Leyman
Siberian State Medical University, Russian Federation, Tomsk, Russia.

Actuality
At present, the role of chronic hyperglycemia in type 1 diabetes mellitus (DM1) in the onset of diabetic encephalopathy has been proven. At the same time, violations in the metabolic composition of brain cells were detected in persons with DM1, estimated with the proton magnetic resonance spectroscopy (^{1}H-MRS). However, the relationship between the results of these studies has not yet been studied.
The aim
To reveal the relationship between the measures of glycemic variability and the results of ^{1}H-MRS of patients with DM1.
Materials and methods
Fifty-eight patients with DM1 at the age of 29 (25–32) years. A complete clinical and laboratory examination was carried out. Using the EasyGV© software, the measures of glycemic variability was calculated (standard deviation (SD), continuous overlapping net glycemic action (CONGA), lability index (LI), low blood glucose index (LBGI), high blood glucose index (HBGI), mean of daily differences (MODD), mean amplitude of glycemic excursions (MAGE)). The ^{1}H-MRS of the brain was performed to determine the main spectra of choline (Cho), creatine/creatine phosphate (Cr, PCr), N-acetylaspartate (NAA).
Results
The fasting glycemia in patients with DM1 was 8.6 (7.3–9.6) mmol/l, the average level of HbA1c was 8.4 (7.5-8.9)%. The measures of glycemic variability were calculated: S.D. 6.25 (3.1–7.7) mmol/l, CONGA 4.65 (3.3–7.3) mmol/l, LI 4.25 (3.3–5.1) (mmol/l)^2/hour, LBGI 3.85 (2.6–5.2), HBGI 7.75 (5.6–12.5), MODD 3.85 (2.9–5.6) mmol/l, MAGE 7.6(4.6–8.9) mmol/l. Based on the results of the ^{1}H-MRS, an analysis of the relationship with the measures of glycemic variability was carried out. A positive correlation with the parameters of Cr ($P=0.003$) and PCr ($P<0.001$) in the right hippocampus, PCr in the gray matter on the right

($P=0.036$), NAA in the gray matter on the left ($P=0.024$) was found on the CONGA. LI - negative correlation with Cho in the left hippocampus ($P=0.044$) and PCr in the right hippocampus ($P=0.023$). LBGI – positive correlation with NAA in the left hippocampus ($P=0.012$) and in white matter ($P=0.026$). MODD – positive correlation with NAA in gray matter on the left ($P=0.001$). No statistically significant correlations were found for the SD, HBGI and MAGE ($P>0.05$).

Conclusions

The study revealed a direct and inverse relationship between the measures of glycemic variability and metabolites that characterize the state of cell membranes, the neuronal integrity and metabolism of brain cells, which indicates the effect of glycemic variability on biochemical processes in the brain.

Type 1 diabetes mellitus: defining the best cut-off points of arterial stiffness for predicting cardiovascular risk according to the Steno Type 1 Risk Engine

Albert Cano[1], Gemma Llauradó[2,3], Lara Albert Fàbregas[1], Isabel Mazarico[1], Montserrat González-Sastre[4] & José Miguel González-Clemente[1,3]
[1]Department of Endocrinology and Nutrition, Parc Taulí Hospital Universitari, Institut d'Investigació i Innovació Parc Taulí I3PT, Universitat Autònoma de Barcelona, Sabadell, Spain; [2]Department of Endocrinology and Nutrition, Hospital del Mar, Barcelona, Spain; [3]Centro de Investigación Biomédica en Red de Diabetes y Enfermedades Metabólicas Asociadas (CIBERDEM), Instituto de Salud Carlos III, Madrid, Spain; [4]Department of Ophthalmology, Parc Taulí Hospital Universitari, Institut d'Investigació i Innovació Parc Taulí I3PT, Universitat Autònoma de Barcelona, Sabadell, Spain.

Background

Cardiovascular disease (CVD) is the leading cause of death in persons with type 1 diabetes (T1DM). However, there are no CVD-risk prediction models for this population in widespread use and those developed from general population and type 2 diabetes have been shown to underestimate CVD-risk in T1DM. Recently, the Steno Type 1 Risk Engine (ST1RE) was developed for predicting CVD in a cohort of T1DM persons without clinical CVD. We investigate the relationship between the scores obtained from that engine and preclinical atherosclerosis measured as arterial stiffness (AS), in order to identify potential cut-off points of AS of interest in clinical practice.

Methods

One-hundred and seventy-nine persons (18–65 years old) with T1DM of >1-year duration and without clinical CVD were consecutively evaluated for: i) clinical and anthropometric data (including classical cardiovascular risk factors), ii) microvascular complications and iii) aortic pulse-wave velocity (aPWV) determined by applanation tonometry, the gold-standard for measuring AS. The ST1RE was used to estimate the 10-year CVD-risk and classify these persons into three groups: low-risk (<10%; $n=105$), moderate-risk (10–20%; $n=53$) and high-risk (>20%; $n=21$).

Results

One hundred and seventy nine persons were included (men: 50.8%, age: 41.2±13.1 years, duration of T1DM: 16 (12–23) years). As compared with subjects in the low- and moderate-risk group, those in the high-risk were older (32.5±8.3, 50.8±6.0, 60.7±6.6 years; $P<0.001$), had higher prevalence of hypertension (14.3, 37.7, 66.7%; $P<0.001$) and dyslipidaemia (36.4, 77.8, 89.5%; $P<0.001$), higher BMI (24.3±3.2, 26.6±3.8, 27.8±4.4 Kg/m^2; $P<0.001$), higher insulin resistance (eGDR: 9.2±1.8, 7.0±2.1, 5.5±1.8 mg·kg^{-1}·min^{-1}; $P<0.001$) and worst glycaemic control (HbA1c: 7.6, 8.0, 8.5%; $P<0.001$). They also had higher prevalence of microvascular complications (27.2, 43.4, 81.0%; $P<0.001$) and higher aPWV (6.4±1.0, 8.4±1.3, 10.3±2.6 m/s; $P<0.001$). aPWV was positively associated with the ST1RE score ($r=0.777$; $P<0.001$). The best cut-off point of AS for identifying subjects in the moderate-high risk group was >7.3 m/s (Se: 86%, Sp: 83%; C-statistic: 0.914 (95CI:0.873–0.95)), and for identifying those in the high-risk, > 8.7 m/s (Se: 76%, Sp: 86%; C-statistic: 0.879 (95%CI:0.809–0.948)).

Conclusions

AS was highly and positively correlated with the ST1RE score. We provide cut-off points of AS that discriminate T1DM subjects with moderate-high and high CVD-risk that could be of great interest in clinical practice.

Retinal vessel abnormalities in acromegaly

Laila Füchtbauer[1], Daniel S Olsson[1], Lise-Lott Norrman[2], Bengt-Åke Bengtsson[1], Ann Hellström[3] & Gudmundur Johannsson[1]
[1]Department of Endocrinology, Sahlgrenska University Hospital, Gothenburg, Sweden; [2]Departement of Internal Medicine, Södra Älvsborgs Sjukhus, Borås, Sweden; [3]Department of Pediatric Ophthalmology, Sahlgrenska Academy, The Queen Silvia Children's Hospital, Gothenburg, Sweden.

Growth hormone (GH) and insulin like growth factor 1 (IGF-I) modulate and stimulate angiogenesis and endothelial function. Excess of GH, as in acromegaly, is associated with cardiovascular morbidity and mortality, which is reversible after normalization of IGF-I and GH. Diabetes mellitus (DM) is a common comorbidity in acromegaly, but the prevalence of diabetes retinopathy in patients with acromegaly is unknown. Also, the roles of GH and IGF-I in diabetes retinopathy are not fully understood. We examined retinal vessels of 26 patients with acromegaly at diagnosis and one year after initiated treatment compared to the retina of 13 healthy controls. Fundus photographs were analyzed for vessel tortuosity, branching points and optic nerve morphology by a computer assisted mapping system. Subjective analysis for diabetes retinopathy was performed in a masked fashion. At diagnosis one patient had type-1 DM, 6 patients had type-2 DM and 6 patients had impaired glucose tolerance. The prevalence of pre-proliferative diabetes retinopathy in the patients with acromegaly and DM was 43%. Independent of diabetic status patients with acromegaly had 34.3 [30.0;39.0] (Median [interquartile range]) branching points while healthy controls had 27.0 [24.0–29.0], $P<0.001$. No difference in tortuosity of arterioles and venules or optic disc morphology was observed. The high amount of branching points remained unchanged at 1-year follow-up. In conclusion, patients with acromegaly had increased number of retinal vascular branching points without altering macroscopic vessel morphology that remained unchanged although hormone levels normalized 1 year after treatment. The prevalence of diabetes retinopathy in our patients with acromegaly and diabetes seemed to be higher than in the general type-2 diabetic population in Sweden (28.6% in 2017) according to the Swedish National Diabetes Registry.

[1]Leeds Centre for Diabetes and Endocrinology, Leeds Teaching Hospitals NHS Trust, Leeds, UK; [2]Division of Cardiovascular and Diabetes Research, Leeds Institute of Cardiovascular and Metabolic Medicine (LICAMM), University of Leeds, Leeds, UK; [3]Department of Clinical Biochemistry, Leeds Teaching Hospitals NHS Trust, Leeds, UK.

Background
Growth Hormone (GH) and insulin-like growth factor 1 (IGF-1) are the biomarkers used to assess disease activity in acromegaly. Consensus guidelines from the Endocrine Society (2014) recommend a normal (age/sex-adjusted) IGF-1 in combination with a suppressed random GH <1 µg/l for biochemical remission. However, these results are discordant in some patients. The clinical significance of the IGF-1/GH dichotomy in the follow-up of these patients is unclear and makes treatment decisions challenging.
Methods
We conducted a cross-sectional study to assess the frequency of IGF-1/GH discordance and to identify putative risk factors for its occurrence. Consecutive patients who attended our pituitary service over past 15 years were identified from the local Acromegaly Registry and medical records analysed.
Results
109 patients with acromegaly were identified (56% male, age 57.4 $\pm$ 13.6 years). Ninety-six patients (88%) underwent surgery. Fifty-six patients (51%) received radiotherapy. Fifty-six patients (51%) were on medical therapy at the time of their most recent biochemical assessment of disease status, with the majority (48 patients, 94%) receiving somatostatin analogue (SSA) therapy. Fifty-four patients (50%) had achieved biochemical remission, of whom 29 patients (54%) were not receiving long-term medical therapy. Twenty patients (18%) had both raised IGF-1 and GH >1 µg/l. Thirty-five patients (32%) had discordant IGF-1/GH results (63% ($n=22$) had high IGF-1 and normal GH (high IGF-1 discordance) and the remaining 13 patients the reverse (high GH discordance)). Age, gender, renal and liver function did not predict IGF-1/GH discordance. Higher BMI (coeff $=-2.72$, $P=0.03$) and higher GH level at diagnosis (coeff $=-2.31$, $P=0.01$) were significant negative predictors of discordance. Neither surgery nor radiotherapy were associated with an increased risk of IGF-1/GH discordance, although a high IGF-1 discordance was more prevalent post-radiotherapy (coeff $=0.43$, $P=0.02$) within the discordant group of patients. One-third ($n=16$) of patients on SSA therapy had discordant results. Being on SSA at the time of analysis was not associated with discrepant results. However, previous/current exposure to SSA was a positive predictive factor of IGF-1/GH dichotomy (coeff $=0.44$, $P=0.03$), although there was no association with treatment duration.
Conclusion
Despite the move to more robust criteria for biochemical remission of acromegaly, IGF-1/GH dichotomy remains present in around one-third of patients. In our cohort, exposure to SSA therapy, a lower BMI and lower GH level at diagnosis were significant determinants of IGF-1/GH discordance.

Efficacy and safety of switching to pasireotide LAR monotherapy or in combination with pegvisomant in acromegaly patients controlled with combination therapy of somatostatin analogues and pegvisomant (PAPE study): a prospective, open-label 48 week study

Eva C Coopmans, Ammar Muhammad, Joseph AMJL Janssen, Aart J van der Lely & Sebastian JCMM Neggers
Erasmus University Medical Center, Rotterdam, The Netherlands.

Background
In the core phase of the PAPE study until 24 weeks we have shown that switching to pasireotide LAR (PAS-LAR) in well-controlled acromegaly patients receiving combination therapy of somatostatin analogues and pegvisomant (PEGV), normalizes IGF1 levels in the majority of patients. PAS-LAR induced a significant PEGV sparing effect, but this was at the expense of a higher incidence of diabetes. This extension study until 48-weeks assesses the efficacy, safety and quality of life (QoL) of PAS-LAR monotherapy or in combination with PEGV by optimization of PAS-LAR and PEGV dose.
Methods
59 out of 61 patients entered the extension phase. Well-controlled patients receiving PAS-LAR monotherapy continued with the same dose, while uncontrolled patients had to restart PEGV therapy. In patients on PAS-LAR and PEGV combination therapy, the PEGV dose was titrated based on a protocol with the goal to achieve normalized IGF1 levels. At baseline, an oral glucose tolerance test (OGTT) was performed, and at each study visit QoL was assessed using the AcroQoL and PAQ3 questionnaires.
Results
At the start of the present study, median IGF1 was 0.94 $\times$ the Upper Limit of Normal (ULN) with a mean PEGV dose of 134 mg/week, and 32.8% of patients had pre-existing diabetes. At 48 weeks, median IGF1 was 0.98 $\times$ ULN, and 77% of patients achieved normal IGF1 levels with a mean PEGV dose of 64 mg/week. Cumulative PEGV dose reduction between baseline and 48 weeks was 52%. After 48 weeks IGF1 levels were normal in 93% of patients receiving PAS-LAR monotherapy, and 71% of patients receiving combination therapy. The incidence of diabetes increased to 77%. Nine patients discontinued PAS-LAR therapy, mainly due to hyperglycemia-related adverse events. Pasireotide-induced hyperglycemia was inversely related to insulin secretion during OGTT at baseline (Stumvoll, $r=-0.37$, $P=0.005$). Global AcroQoL score significantly improved (5.5%, $P<0.0001$) during treatment with PAS-LAR. The greatest improvement was observed in the physical dimension.
Conclusions
Switching to PAS-LAR monotherapy or in combination with PEGV controlled IGF1 levels in the majority of acromegaly patients after about fifty percent reduction in cumulative PEGV dose, however this coincides with a higher incidence of diabetes. The main driver of pasireotide-induced hyperglycemia seems residual β-cell function at baseline. Long-term treatment of acromegaly with PAS-LAR is a trade-off between the benefits of biochemical control and an improvement in QoL versus the burden of long-term sequelae of the pasireotide-induced diabetes.

The importance of *MEN1* gene variants in *AIP* mutation negative FIPA patients

Sema Yarman[1], Feyza Nur Tuncer[2], Esin Serbest[2] & Yeliz Ogret[3]
[1]Division of Endocrinology and Metabolic Diseases, Department of Internal Medicine, Istanbul Faculty of Medicine, Istanbul University, Istanbul, Turkey; [2]Department of Genetics, Aziz Sancar Institute of Experimental Medicine, Istanbul University, Istanbul, Turkey; [3]Department of Medical Biology, Istanbul Faculty of Medicine, Istanbul University, Istanbul, Turkey.

Introduction
Pituitary adenomas (PAs) that occur in a familial setting account for no more than 5%, which can be part of familial tumor syndromes such as Multiple Endocrine Neoplasia type 1 (MEN1) and type 4 (MEN4), Carney Complex (CNC) or Familial Isolated Pituitary Adenoma (FIPA). The presence of two or more cases of PAs without MEN1 or CNC characteristics in the same family, enable FIPA diagnosis. Heterozygous germline inactivating mutations in the *aryl hydrocarbon receptor-interacting protein* (*AIP*) gene confer predisposition to PAs in different races in the setting of FIPAs. However, we have previously reported our cohort of FIPA patients as negative for *AIP* point mutations. Therefore, the aim of this study was to detect copy number variations (CNVs) in *AIP* and *MEN1*, and to investigate *MEN1* gene variations in this cohort.
Patients and methods
Seven families including 16 patients with FIPA diagnosis were involved in this study. Among these families, heterogenous and homogenous FIPA were composed of three and four families, respectively. All homogenous FIPA patients had somatotropinoma. Mean follow-up period of the cohort was 13 (5–40) years. Only 12 patients from these families were available for genetic analyses, who did not have hypercalcemia and other components of familial syndromes. Patients' genomic DNA were isolated from peripheral blood. All exons, exon-intron boundaries and UTR regions of *AIP* and *MEN1* genes were PCR amplified, followed by Sanger sequencing to detect point mutations. CLC Main Workbench 6.5 was used in sequence data analysis against the reference sequences NM_003977.3 and NM_000244.3 for *AIP* and *MEN1* genes, respectively. Multiplex ligation-dependent probe amplification (MLPA) was performed in CNV detection, where commercially obtained reagents and probe-mixes were used according to the manufacturer's instructions (P244-AIP-MEN1-CDKN1B, MRC-Holland, the Netherlands).
Results
In our cohort, initial screen of *AIP* gene revealed no mutations and MLPA anlaysis also showed no CNVs. Afterthan, *MEN1* sequencing exhibited novel heterozygous variants including c.1846T>A (p.*616Argext*21); rs778272737:T>C; rs972128957:C>T in 2 families having patients diagnosed with Cushing disease, non-functional PA, and acromegaly, respectively. Among them, c.1846T>A (p.*616Argext*21) is a stop codon read-through, whereas the others are 3′UTR variations. Overall, *MEN1* variation frequency was detected 15% in our cohort.
Conclusion
In the long term clinically followed-up of FIPA patients without hypercalcemia, *MEN1* gene can be of significance and screening should be offered especially to young first-degree relatives with or without MEN1 syndrome features.

IGF-I response to pasireotide LAR treatment in acromegaly is mainly driven by somatostatin receptor subtype 2 expression

Ammar Muhammad[1], Eva Coopmans[1], Federico Gatto[2], Sanne Franck[1], Joseph Janssen[1], Aart Jan van der Lelij[1], Leo Hofland[1] & Sebastian Neggers[3]
[1]Erasmus University Medical Center, Rotterdam, The Netherlands; [2]Università degli Studi di Genova, Genova, Italy; [3]Erasmus MC University Medical Center, Rotterdam, The Netherlands.

Background
The response to first-generation long-acting somatostatin analogues (LA-SSA) treatment in acromegaly depends on the expression of the somatostatin receptor (SSTR) subtypes. In contrast to octreotide and lanreotide which preferentially bind to SSTR2, pasireotide targets multiple SSTRs, with the highest binding affinity for SSTR5. It has previously been suggested that SSTR5 expression could predict the response to pasireotide LAR (PAS-LAR) treatment in acromegaly.
Aim
To assess whether the IGF-I response to LA-SSA monotherapy correlates with the IGF-I response to PAS-LAR treatment, and whether SSTR2 and SSTR5 expression correlate with response to PAS-LAR treatment in acromegaly.
Methods
We included 52 patients from a cohort of patients that initially received LA-SSA treatment, followed by LA-SSA and pegvisomant (PEGV) combination treatment and subsequently PAS-LAR treatment during the PAS-LAR and PEGV (PAPE) study. We excluded patients that had received radiotherapy and LA-SSA therapy $\leq$ 4 months. In 14 of 52 patients, somatotroph adenoma tissues samples were available for evaluation of SSTR2 and SSTR5 expression using a semiquantitative immunoreactivity score (IRS). The response to LA-SSA treatment was defined as IGF-I levels after $\geq$ 4 months LA-SSA monotherapy. The response to PAS-LAR treatment was based on the PAPE study and defined as IGF-I levels at 24 weeks and the percentage PEGV dose reduction at 48 weeks.
Results
The mean percentage IGF-I (x ULN) reduction was similar after LA-SSA monotherapy and after PAS-LAR treatment (resp. 32.1% and 30.0%) and IGF-I levels after both treatments were directly correlated ($r=0.50$, $P=0.0002$, $n=52$). The SSTR2 IRS was inversely correlated with IGF-I levels after PAS-LAR treatment at 24 weeks($r=0.63$, $P=0.016$), but no correlation was observed with SSTR5 ($r=-0.61$, $P=0.029$, $n=14$). After exclusion of patients receiving LA-SSA pretreatment, SSTR2 IRS was correlated with the percentage PEGV dose reduction at 48 weeks after switching from LA-SSA/PEGV combination treatment to PAS-LAR treatment ($r=0.70$, $P=0.035$), while SSTR5 IRS showed no correlation ($r=0.35$, $P=0.36$).
Conclusion
In contrast to previous reports, SSTR5 expression does not predict the IGF-I response to PAS-LAR treatment, but appears to be mainly driven by SSTR2 expression.

Familial cancer clustering in patients with pituitary adenoma

Sandra Pekic Djurdjevic[1,2], Ivan Soldatovic[2,3], Mirjana Doknic[1,2], Dragana Miljic[1,2], Marko Stojanovic[1,2], Milan Petakov[1,2] & Vera Popovic[2]
[1]Clinic for Endocrinology, Diabetes and Diseases of Metabolism, University Clinical Center, Belgrade, Serbia; [2]School of Medicine, University of Belgrade, Belgrade, Serbia; [3]Institute of Medical Statistics and Informatics, Belgrade, Serbia.

Objective
People are at higher risk for malignancy as they get older or have a strong family history of cancer.
Aim
To collect family history of cancer in a large cohort of patients with pituitary adenomas (PA) in Outpatient clinic from years 2005–2017.
Results
Overall 46% of 1100 patients with PA had a family member affected with cancer. Breast cancer in family members was reported in 15.3% of patients with prolactinomas which was significantly higher than in families of patients with non-functioning pituitary adenomas (NFPA) (10.0%, $P=0.020$) or acromegaly (6.8%, $P=0.002$). Lung cancer in family members was reported in 12.1% of patients with prolactinomas,significantly higher than in families of NFPA patients (7.0%, $P=0.012$). Colorectal cancer in the relatives of patients was reported with any type of PA. Furthermore, patients with a positive family history of malignancy were diagnosed with PA at an earlier age than patients with a negative family history. In a separate analysis 75 (6.8%) patients with PA were diagnosed with cancer (NFPA, 38/470; acromegaly 20/221; prolactinoma 14/372, M.Cushing 3/37). Overall age incidence patterns showed higher risk at older age. Almost 50% of patients with PA who had cancer had a positive family history of malignancy.
Conclusion
These results suggest familial cancer clustering in patients with PA. In particular there is a strong association between prolactinoma and family history of breast and lung cancers, borderline with colorectal cancer. These results suggest that patients with PA and associated tumors in the family share genetic susceptibility. The results also emphasize the value of readily available family cancer history in the clinical genetic risk assessment for screening and prevention strategies in patients with PA.

ACRONIS, a European observational study in patients with uncontrolled acromegaly who are being treated with long acting pasireotide: first interim analysis

Christof Schöfl[1], Annamaria Colao[2], SJCMM Neggers[3], Ulla Feldt-Rasmussen[4], Eva Maria Venegas Moreno[5], Gesine Enderle[6], Daniela Mesenska[7], Philippe Andry[7] & Antoine Tabarin[8]
[1]Endokrinologie im Zentrum, Bamberg, Germany; [2]Universita' Federico II di Napoli, Naples, Italy; [3]Erasmus MC-Sophia Children's Hospital, Rotterdam, The Netherlands; [4]Copenhagen University Hospital, Copenhagen, Denmark; [5]Campus Del Hospital Universitario Virgen del Rocio, Sevilla, Spain; [6]Novartis Farma S.p.A, Origgio, Italy; [7]Novartis s.r.o., Prague, Czech Republic; [8]CHU de Bordeaux, Bordeaux, France.

Acromegaly is a morbid condition mainly caused by overproduction of growth-hormone (GH) from a pituitary adenoma leading to excessive growth. Normalisation of insulin-like growth factor-1 (IGF1) is an important goal for the treatment of acromegaly. The second-generation somatostatin analog (SSA) long acting pasireotide (la-PAS) has recently been introduced for the management of patients uncontrolled by first-generation SSA. The ACRONIS study (CSOM230CIC05) will provide real-world evidence on the efficacy and safety of la-PAS in acromegaly patients from twelve countries, either already treated with monthly la-PAS for $\geq$6 months (retrospective set) or going to be treated (prospective set). Results of the first interim analysis reflecting the retrospective set are presented. The mean age of the enrolled retrospective patients (n=60) was 45.4 years; 55% female and 76.7% Caucasian. Mean time since diagnosis was 53.2 months (S.D. 54.5 months); 83.3% had previous surgery and 40.0% radiotherapy. 98.3% had taken prior medication: mainly first-generation SSAs (73.3% octreotide, 31.7% lanreotide), growth hormone receptor antagonists (53.3%) or dopamine agonists (48.3%) in mono- or combination therapy, respectively. 23.3% and 13.3% of patients were diabetic or pre-diabetic prior to la-PAS prescription, respectively. All patients were la-PAS naïve at baseline. 81.4% of patients started with la-PAS 40mg, 1.7% with 20mg and 16.9% with 60mg. After a mean duration of 8.2 months (range 6–25 months, n=59 (all patients within the retrospective set having $\geq$1 post-baseline safety assessment and with $\geq$1 dose of la-PAS)), 62.7% remained on starting dose, 32.2% were up-titrated, 5.1% down-titrated. At 6 months, IGF1 was normalised [$\leq$1 times upper limit of normal (ULN)] in 42.5%, (n=40). IGF1 normalisation and GH $<$1 ($<$2.5 µg/l) was achieved by 14.3% (21.4%) of 28 evaluable patients. These results are in line with the pivotal PAOLA study (*NCT01137682*) where 25% and 26% of patients on the 40 mg (n=65) and 60 mg (n=65) doses, respectively, achieved normalised IGF values; 15.4% and 20% respectively, achieved both IGF1 $<$1 ULN and GH $<$2.5 µg/l. The adverse events (AEs) most commonly reported were diabetes mellitus (18.6%), hyperglycaemia (13.6%), headache (10.2%) and diarrhoea (10.2%). The only reported grade 3/4 AE was headache (1.7%). The overall percentage of glucose metabolism-related AEs (33.9%) seems lower than previously reported. The safety profile of la-PAS in the ACRONIS study was consistent with its known safety profile. In conclusion, the results of retrospective ACRONIS dataset confirm the efficacy and tolerability of long-acting pasireotide in previously uncontrolled acromegaly patients in clinical practice.

Pregnancy and acromegaly – clinical outcomes from the Irish Pituitary Network

Anne Marie Hannon[1], Triona O'Shea[1], Rosemary Dineen[2], Aftab Khattak[3], Domhnall O'Halloran[3], Steven Hunter[4], Mark Sherlock[2] & Chris Thompson[1]
[1]Academic Department of Endocrinology, Beaumont Hospital, Dublin, Ireland; [2]Department of Endocrinology and Diabetes, Adelaide and Meath Hospital, Dublin, Ireland; [3]Department of Endocrinology and Diabetes, Cork University Hospital, Cork, Ireland; [4]Department of Endocrinology and Diabetes, Royal Victoria Hospital, Belfast, UK.

Acromegaly is a rare disease characterised by excessive Growth hormone (GH) production from a pituitary adenoma. Subfertility is common in acromegaly and has various aetiologies, therefore pregnancy in acromegaly is rare. We present a case series of 19 pregnancies in 13 women with acromegaly from the newly formed Irish National Pituitary Registry. Twelve women had pituitary macroadenomas, one woman had a microadenoma. The age of the women ranged from 28 to 40 years with a median of 34 years. Only 5/19 pregnancies had optimal biochemical control of acromegaly pre-conception, as defined by IGF-1 concentration in the age-related reference level and plasma GH concentration of $<$2 µg/l. There were 18 singleton pregnancies and one twin pregnancy. Four women were receiving treatment with somatostatin analogues pre-pregnancy, all 4 women discontinued therapy with the first positive pregnancy test. No woman continued somatostatin analogue treatment during pregnancy. All 4 of these pregnancies had normalisation of the plasma IGF-1 concentration in spite of the withdrawal of somatostatin analogue therapy. 7/19 pregnancies continued dopamine agonist treatment during pregnancy.

Effect of pregnancy on acromegaly; No patient had a change in visual field during pregnancy. 9/14 IGF-1 plasma concentrations that were elevated pre-conception normalized during pregnancy, with a reduction in IGF-1 seen in a further 4 pregnancies.

Effect of acromegaly on pregnancy; 17 healthy babies were born at term. 1/19 pregnancies had pre-eclampsia and an emergency C-section was performed at 32 weeks. 1/19 pregnancies (twin pregnancy) had an elective caesarean section at 35 weeks. 0/19 pregnancies developed gestational diabetes.

Our data suggests that pregnancy in women with acromegaly is generally safe, from a maternal and foetal perspective. Furthermore, biochemical control tends to improve in spite of the withdrawal somatostatin analogue therapy during pregnancy.

Human growth hormone (GH) isoforms during oral glucose tolerance test in patients with acromegaly and in healthy subjects

Esther Ulmer[1], Katharina Schilbach[1], Michael Haenelt[1], Shiva Sophia Nicolay[1], Laura Schwerdt[1], Júnia Ribeiro de Oliveira Longo Schweizer[2], Christopher Bartel[3], Jochen Schopohl[1], Christian Strasburger[3], Zida Wu[3] & Martin Bidlingmaier[1]
[1]Endocrine Research Unit, Medizinische Klinik und Poliklinik IV, Klinikum der Universitaet Muenchen, Munich, Germany; [2]Federal University of Minas Gerais (UFMG), Belo Horizonte, Brazil; [3]Department of Clinical Endocrinology, Campus Charité Mitte, Universitaetsmedizin Berlin, Berlin, Germany.

GH consists of various molecular isoforms. Most abundant is 22 kDa-GH (80–90% of total GH), followed by 20 kDa-GH (5–15% of total GH). The biological significance of 20 kDa-GH remains unclear, but its effects appear comparable to those of 22 kDa-GH. Acromegaly is characterized by chronic GH excess. Data on GH isoforms in acromegaly are scarce, but an increased 20 kDa-/22 kDa-GH-ratio (20k-ratio) has been described. Our aims were to compare the 20k-ratio in a larger cohort of treatment-naïve patients with acromegaly and healthy controls, to investigate the potential impact of BMI on the 20k-ratio and to compare the dynamics of the 20k-ratio during oral glucose tolerance test in the groups. Forty-one treatment-naïve patients with acromegaly (ACR, 13 microadenomas, 28 macroadenomas) and 137 controls (CON) were included in this study. Serum samples were collected at baseline and 30, 60, 120 and 180 min after oral glucose load (75 g). 22 kDa-GH was measured in all samples using the 22 kDa-GH-specific CLIA-IDS-iSYS (limit of quantification (LoQ) 0.05 ng/ml). In samples with 22 kDa-GH$>$0.4 ng/ml 20 kDa-GH was measured using an in-house IFMA (LoQ 0.025 ng/ml). Subjects were assigned to BMI-groups A, B, C with BMI$<$25 kg/m^2, 25–30 kg/m^2 and $>$30 kg/m^2, respectively. At baseline, 20kDa-GH was measurable in 100% (n=41) and 53% (n=73) of ACR and CON, respectively. 60 min following glucose load, 20 kDa-GH was detectable in 100% (n=41) and 31% (n=43) of ACR and CON, respectively. The baseline 20k-ratio was significantly higher in ACR (mean 20k-ratio 13.8% (range 7–26%); CON: 10.1% (range 2–18%); $P<0.0001$). There was no difference between macro- and microdenomas. In CON the 20k-ratio was lower with higher BMI (A (n=43): 11.3%; B (n=19): 8.9% and C (n=11) 7.8%; A vs B and A vs C: $P<0.05$). In ACR we could not detect a significant impact of BMI on the 20k-ratio ($P>0.05$ between all BMI-groups). Following glucose load, the mean 20k-ratio significantly increased in CON, starting at 10.1%, increasing to 12.7% and 15.5% after 30 and 60 min respectively, before returning to baseline at 180 min (10.5%). In contrast, the 20k-ratio remained unchanged in ACR. In CON the 20k-ratio was lower with higher BMI and furthermore increased temporarily after glucose load. Our data confirm that the 20k-ratio is higher in ACR, but is, unlike to CON, not regulated by BMI or acute glucose load. Thus, increased GH secretion from somatotrope adenomas seems to be associated with alterations in the regulation of isoform composition.

Observational, multicentre study to evaluate the effectiveness in routine clinical practice of Lanreotide Autogel 120 mg at extended dosing intervals (>4 weeks) for the treatment of acromegaly: SOMACROL study

Cristina Álvarez Escolá[1], Carmen Fajardo[2], Mónica Marazuela[3], Fernando Cordido Carballido[4], Eva María Venegas[5], Pedro de Pablos Velasco[6], Gonzalo Piedrola Maroto[7], Ma del Pilar Olvera Márquez[8], Isabel Pavón de Paz[1], Davide Carvalho[9], Carme Romero[10], Guillermo De la Cruz[11] & Ignacio Bernabéu[12]
[1]Hospital Universitario La Paz, Madrid, Spain; [2]Hospital Universitario de La Ribera, Valencia, Spain; [3]Hospital Universitario La Princesa, Madrid, Spain; [4]Hospital Universitario A Coruña, A Coruña, Spain; [5]Hospital Universitario Virgen del Rocío, Sevilla, Spain; [6]Private Consultation, Las Palmas, Spain; [7]Private Consultation, Granada, Spain; [8]Hospital Universitario De Candelaria, Santa Cruz de Tenerife, Spain; [9]Centro Hospitalar São João, Porto, Portugal; [10]Adknoma Health Research S.L., Barcelona, Spain; [11]IPSEN PHARMA, Barcelona, Spain; [12]Hospital Clínico Universitario Santiago de Compostela, Santiago de Compostela, Spain.

Background
Acromegaly is usually caused by a benign pituitary tumour, with increased production of growth hormone (GH) and insulin-like growth factor 1 (IGF-1). Treatment options include surgery, followed by pharmacological treatment with dopamine agonists, somatostatin analogues, GH receptor antagonists or radiotherapy. Treatment optimization is important to decrease the burden of this often-chronic disease on the patient.
Objectives
To evaluate the effectiveness in IGF-1 control of Lanreotide Autogel (LAN) 120 mg at extended dosing intervals (EDIs) (>4 weeks) in patients with acromegaly in routine clinical practice.
Methods
Observational, retrospective study at 38 sites (36 Spanish, 2 Portuguese) (NCT02807233). Targeted enrolment was 100 adult patients diagnosed with acromegaly, receiving LAN 120 mg at EDIs for ≥6 months, with available data on treatment start/schedule and blood GH and IGF-1 assay immediately before study visit, and no radiation therapy in the 6 months preceding. The primary outcome was the percentage of patients with normalized IGF-1 level after at least 6 months of LAN treatment at prolonged doses. Secondary outcomes included percentages of patients with GH levels ≤2.5 ng/ml or ≤1 ng/ml, and treated with EDIs of 5, 6, 7 or 8 weeks. Treatment satisfaction, quality of life (QoL) and treatment compliance were assessed.
Results
Of 114 patients included, 109 were evaluable. Mean (±s.d.) age was 59.1 (±13.2) years. 69.7% had tumour resection performed on average 12.8 (±9.4) years ago. 25.7% received radiotherapy on average 17.9 (±9.4) years ago. 83.5% had comorbidities, with hypertension the most common (64.4%). 77.1% had concomitant medication for conditions besides acromegaly. LAN had been the first-line pharmacological treatment for 67.0% of the patients. 91.7% had normalized IGF-1 values. 80.6% had GH levels ≤2.5 ng/ml, and 58.3% had levels ≤1 ng/ml. The EDIs most commonly used in routine clinical practice were 8 weeks (35.8%) and 6 weeks (37.6%). AcroQoL questionnaire showed that patients had a medium level of physical [59.7 (±24.5)] and psychological [64.9 (±20.1)] QoL. TQ10M-9 questionnaire revealed that patients were satisfied with treatment [75.1 (±16.6)], and considered it effective [70.6 (±18.7)] and convenient [69.1 (±17.6)]. General therapeutic compliance during preceding 6 months was 94.5%.
Conclusions
LAN 120 mg at EDIs (>4 weeks) during at least 6 months provided IGF-1 control in more than 90% of patients with acromegaly, with good levels of treatment satisfaction and compliance.

Cumulative effects of growth hormone and insulin-like growth factor-1 exposure on cardiovascular, cerebrovascular and metabolic co-morbidities in acromegaly patients

Khyatisha Seejore[1], Nikolaos Kyriakakis[1,2], Marilena Giannoudi[1], Julie Lynch[1], Steve M Orme[1], Julian H Barth[3] & Robert D Murray[1,2]
[1]Leeds Centre for Diabetes and Endocrinology, Leeds Teaching Hospitals NHS Trust, Leeds, UK; [2]Division of Cardiovascular and Diabetes Research, Leeds Institute of Cardiovascular and Metabolic Medicine (LICAMM), University of Leeds, Leeds, UK; [3]Department of Clinical Biochemistry, Leeds Teaching Hospitals NHS Trust, Leeds, UK.

Background
Acromegaly is characterised by growth hormone (GH) and insulin-like growth factor (IGF-1) hypersecretion. The disease is associated with increased cardiovascular, cerebrovascular and metabolic co-morbidities, resulting in excess mortality. A target GH <1 μg/l and normalised IGF-1 values correlate with mortality risk reduction. However, there is lack of consensus over which biomarker, GH or IGF-1, better predicts increased morbidity and/ or mortality.
Objective
To investigate the relationship between surrogates of vascular risk and disease activity and assess the impact on cardiovascular/cerebrovascular outcomes.
Methods
Medical records of 109 patients, identified from our local Acromegaly Registry over past 15 years, were retrospectively examined (56% male, age at diagnosis 42.6±14.0 years, 1612 person-years from diagnosis).
Results
Fifty-four patients (50%) were in biochemical remission; 35 (32%) had discordant IGF-1/GH results and 20 (18%) had elevated IGF-1 and GH>1 μg/l at last biochemical assessment of disease status. Prevalence of vascular risk factors: Hypertension – 46 patients (42%); insulin resistance (IR) – 29 patients (27%); dyslipidaemia – 32 patients (29%). Nearly half (30/61) of patients with recently documented weight were obese (BMI>30 kg/m^2). The rates of hypertension (16/35, 46% vs 10/20, 50%) and IR (8/35, 23% vs 11/20, 55%) were higher in the discordant and uncontrolled groups. The presence of IR was predicted by a higher BMI (coeff=0.438, P=0.006) and older age at diagnosis (coeff=2.03, P=0.016). Longer duration of active disease also positively correlated with IR (coeff=0.947, P=0.001), although GH/IGF-1 measurements displayed no association. No significant correlation was demonstrated between age, gender and disease activity with hypertension, dyslipidaemia nor obesity. Sixteen patients (15%) had a history of cardiovascular /cerebrovascular disease (CVD/CVA), with the majority arising in the discordant GH/IGF-1 group (8/16, 50%), although no significant correlation was identified with disease activity. Dyslipidaemia was a positive predictive factor of CVD/CVA (coeff=0.42, P=0.018) whilst the other vascular risk factors were independent. A higher GH level at last biochemical assessment was also associated with a higher cardiovascular risk (coeff=0.599, P=0.010). No association was found between CVA and radiation therapy.
Conclusion
Patients with acromegaly have an unfavourable metabolic profile, in particular dyslipidaemia and insulin resistance which increase cardiovascular risk. In our cohort, high ambient GH level was a reliable biomarker for development of adverse cardiovascular events. In cases of GH/IGF-1 dichotomy, we recommend adjuvant medical treatment, especially in high GH discordance, to lower GH excess.

Adrenal schwannoma presenting as an adrenal incidentaloma in a pregnant woman

Rosa Pilar Quilez Toboso[1], María Macarena Moreno Martínez[1], María Olmos Aleman[2], Cortes Jiménez Martínez[2], Silvia Aznar Rodríguez[2], Antonio Hernández López[2], Luz Maria López Jiménez[2], Cristina Lamas Oliveira[2], José Joaquín Alfaro Martínez[2] & Francisco Botella Romero[2]
[1]Hospital General De Villarrobledo, Villarrobledo (Albacete), Spain; [2]Hospital General De Albacete, Albacete, Spain.

Introduction
Adrenal schwannomas are very rare tumors that are difficult to diagnose properatively. They represent only 1–3% of all retroperitoneum masses.
Case report
A 30-year-old woman was referred to the outpatient to evaluate an adrenal mass incidentally found on abdominal ultrasonographic images obtained for self-limit abdominal pain. Her medical and family histories were unremarkable. Clinically asymptomatic, only referred amenorrhea for two months. Physical examination showed BMI 20 kg/m^2, blood pressure 125/75 mmHg, pulse rate 88 lpm. The rest of the exploration was within normal. The patient's endocrinologic data were as follows: Plasma metanephrine 34 pg/ml (<65), plasma normetanephrine 52 pg/ml (<169), urinary metanephrine 240 μg/24 h (<341), urinary normetanephrine 189 μg/24 h (<444), urinary vanillymandelic acid 2.8 mg/24 h (< 9), Cromogranine A <5 ng/ml, DHEA-S 0.8 mcg/ml (<4), Testosterone 0.8 ng/ml (<0.48), urinary free cortisol 124.1 μg/24 h (<176), Aldosterone 217 pg/ml (< 160), PRA > 11.5 ng/ml per hour (<5.7), LH 0.1 mUI/ml, FSH 0.1 mUI/ml,

Estradiol 1502 pg/ml, Progesterone 39.9 ng/ml, hCG 161250 mUI/ml (compatible with pregnancy of 6–12 weeks). Ultrasonography of the abdomen demonstrated a well-circumscribed hypoechoic mass with cystic and necrotic components that measured 32×27 mm, dependent of the right adrenal gland. MRI without gadolinium (2nd trimester) showed a 40×32 mm heterogeneous adrenal mass with necrotic and cystic components, located in the right adrenal gland, low intensity on T1-weighted images and high intensity on T2-weighted images, suggestive of pheochromocytoma as the most likely option, without being able to rule out an adrenal carcinoma. With these results we request a gynecological examination; which showed a 6-week gestation. After much deliberations, a laparoscopic adrenalectomy was performed under the suspicion of a malignant tumor or a non-functioning pheocromocytoma, in week 22 of gestation. Microscopically, the surgial specimen showed a tumor formed by fusiform cells, without atypia, with a swirling pattern and degenerative areas.Tumor cells express s100 protein and the proliferative index ki67 was 1%. The diagnosis was an ancient adrenal schwannoma. After surgery, pregnancy and delivery developed normally.

Conclusions

Adrenal swchannomas are extremely rare tumors, specially during pregnancy. Surgical resection is the primary means of management of adrenal schwannomas, as it is not possible to distinguish the schwannoma from malignant entities or pheocromocithoma simply base on imaging. In pregnant woman, like our patient, adrenalectomy should be performed in the second trimester, between weeks 12 and 24 of gestation.

GP14

Sporadic paraganglioma and the importance of genetic screening

Maria Belén Ojeda Schuldt, Isabel Mateo Gavira, Laura Larrán Escandón, Julián Tamayo Serrato, Begoña Sánchez Lechuga, Daniel Medina Rivero & Manuel Aguilar Diosdado
Hospital Universitario Puerta del Mar, Cádiz, Spain.

Introduction

Paragangliomas are neuroendocrine tumors derived from the extra-adrenal paraganglionar system and are closely related to pheochromocytoma. About 50% are associated with genetic syndromes.

Case report

We report a case of a sporadic paraganglioma incidentally found in a 30-year-old man, with no family or personal history of interest, in the context of abdominal pain study where a mass of 5×3×3 cm is detected in the abdominal aorto-cava area ultrasound. Scintigraphic study showed a focal increase of MIBG uptake in the level of anterior planes of the right paraumbilical abdominal region without any other pathological findings. Urinary cathecolamines and metanephrines were normal. A fine needle aspiration citology was made and confirmed the diagnostic of paraganglioma. Clinical study was completed with 24-hour ambulatory blood pressure monitoring, being diagnosed with arterial hypertension and starting treatment with labetalol 100 mg per day. Finally the patient underwent by right retroperitoneal lumbotomy. Histological examination revealed a paraganglioma that reaches focally the edge of the main surgical piece with no evidence of tumor in five lymph nodes. Clinical evolution was favorable with normalization of blood pressure without requiring pharmacological treatment and with negative morphological study during follow-up. Despite not having a family history of known pheochromocytoma/paraganglioma and given the age of the patient, a genetic study was performed and confirmed c.591del/p.Ser198Alafs*22 mutation in the SDHB gene. It has been described in the Mediterranean population that individuals with mutations in SDHB have a probability of developing the disease in 8, 18 and 30% at 40, 60 and 80 years respectively. Given the dominant nature of the disease, it is convenient to realize a genetic study on other relatives who are at risk of being carriers of the disorder and who do not yet know their condition. Besides, carriers of a germline mutation in SDHB have a probability around 45% of developing metastasis.

Conclusions

The genetic analysis of apparently sporadic cases reveals that up to 25% of them have a genetic mutation. Therefore, genetic screening allows early identification of the family members carrying the same mutation and carrying out the pertinent study and follow-up. In our case, despite the favorable evolution of the patient and given the greater malignant potential of this mutation, we will maintain a long-term morphological follow-up.

GP15

Etomidate for the management of severe hypercortisolaemia in different clinical scenarios – a case series

Agnieszka Łebek-Szatańska, Karolina M Nowak, Wojciech Zgliczyński & Lucyna Papierska
Department of Endocrinology, Centre of Postgraduate Medical Education, Warsaw, Poland.

Cushing's syndrome is associated with life-threatening complications, as well as high rates of perioperative mortality and morbidity. Authors present clinical scenarios, in which one should consider the usage of intravenous etomidate as an accurate, safe and effective drug for hypercortisolaemia.

Case 1

23-year-old female with severe Cushing's syndrome due to metastatic adrenocortical carcinoma was admitted to the Department of Endocrinology. She presented with uncontrolled diabetes and hypertension, hypokaleamia, hypocalcaemia and symptoms of an upper respiratory tract infection. Post-adrenalectomy, mitotane, ketoconazole, metyrapone and spironolacton were used to control the disease with poor effect. Her cortisol levels persisted at 90–128 μg/dl, so she was put on the continuous intravenous infusion of Hypnomidate with fast improvement in her clinical condition. She was able to start chemotherapy after one week of etomidate treatment. 8 days later, she was admitted again with chemotherapy-induced leucopenia and diarrhea with electrolyte disturbances. Etomidate infusion was introduced again, until her blood parameters and gastrointestinal symptoms improved.

Case 2

45-year-old male with the history of recently diagnosed diabetes, refractory hypokalaemia and mild cushingoid features, was admitted to the Department of Endocrinology. Hormonal evaluation revealed ACTH-dependent Cushing's syndrome. Treatment with ketoconazole was started. In the sixth day of ineffectual oral therapy, the patient's clinical state deteriorated with fever, spinal pain and exhaustion, due to Staphylococcus aureus sepsis. Cortisol level reached 160 μg/dl, so Etomidate-Lipuro was given intravenously. With short breaks, the infusion was carried on for 50 days. During that time, diagnostic process was completed with the final diagnosis of pituitary corticotropinoma and subsequent effective neurosurgical intervention.

Case 3

66-year-old female with ectopic Cushing's syndrome due to metastatic lung carcinoid tumour was referred to the Department of Endocrinology with severe hypercortisolaemia, decompensation of diabetes, deep hypokalaemia and mood disorders. She already had her left adrenal removed 3 months ago. As she was mentally and physically unstable, she was put on Etomidate-Lipuro infusion with an immediate improvement in her status. The course of her hospitalization was complicated with cephalic vein thrombosis, candidiasis, sepsis and post-antibiotic enterocolitis pseudomembranacea, until she was able to undergo complete adrenalectomy (after 58 days of etomidate), without further complications.

Conclusions

In doses far lower than those used for anesthesia, etomidate works as a useful cortisol-lowering therapy in patients intolerant of or unable to take oral medications. Also if urgent medical intervention is necessary, clinicians should be aware of such therapeutical option.

Pheochromocytoma associated with cutaneous and uterine leiomyomatosis and renal cancer in a patient with a germline mutation in the FH gene

Marta Morón Díaz, Mauro Boronat Cortés, Juan Luis Afonso Martín, Carolina Fernández-Trujillo Moujir, Ana María González Lleo, Adriana Ibarra González, Nuria Pérez Martín & Francisco Javier Nóvoa Mogollón
Complejo Hospitalario Universitario Insular Materno-Infantil de Gran Canaria, Las Palmas de Gran Canaria, Spain.

Introduction

Most of pheochromocytomas (PCC) and paragangliomas (PGL) are sporadic. However, up to 40% of them have an inherited origin due to germline mutations in at least 15 known PCC/PGL genes, being the VHL and SDHx genes the ones most frequently affected. The fumarate hydratase (FH) is a Kreb's cycle enzyme encoded by the FH gene.Its inactivating mutations increase intracellular levels of fumarate, leading to tissular pseudohypoxia and transcription of genes involved in tumor growth, thus acting as a tumor-supressor gene. Germline heterozygous mutations in the FH gene have been associated with the hereditary

leiomyomatosis and renal cell cancer syndrome (HLRCC).More recently, FH mutations have been also related to rare cases of inherited PCC/PGL with an apparently high predisposition to malignant disease. However, none of the reported cases combined PCC/PGG and HLRCC.

Case report

In April 2007 a 44-year-old woman with a previous history of hysterectomy due to uterine myomatosis and with family background of uterine myomatosis in her mother, looked for medical attention because of frequent episodes of palpitations, headache, facial flushing and dizziness, associated with elevation of blood pressure. Laboratory tests showed increased levels of plasma and urine normetanephrine and norepinephrine.Abdominal CT scan revealed a 1.3× 1.3×9.6 cm predominantly cystic mass in the left kidney and a 9 cm left adrenal tumor with peripheral enhancement after contrast administration and a central area of necrosis. After pre-surgical preparation, adrenalectomy and ipsilateral nephrectomy were done, with clinical improvement and normalization of urinary normetanephrine and norepinephrine. Pathological examination confirmed a 9.5 cm pheochromocytoma with foci of necrosis without vascular invasion and a 10 cm Fuhrman's grade 4 renal carcinoma with extensive cystic degeneration and tubulo-papillary pattern. A preliminary genetic study was negative for RET, VHL and SHDB genes, but a further investigation with a genetic panel covering 14 PCC/PGG genes, showed a splice site mutation in the FH gene (c555 + 1G > A). This mutation had been previously reported in a Spanish family with uterine and cutaneous leiomyomatosis.Clinical reexamination of the patient revealed pink papules up to 2 cm of diameter on the forearms and trunk, whose biopsy confirmed to be cutaneous leiomyomas.Follow-up chest/abdomen CT scans and ^{123}I-MIBG SPECT have ruled out local recurrence or metastases.

Conclusions

Subjects carrying germline pathogenic mutations of the FH gene are at risk of developing both PCC/PGG and HLRCC.Both conditions should be routinely screened once diagnosis has been established.

GP17

A rare cause of endocrine hypertension

Bernardo Marques[1], Joana Couto[1], Manuel Lemos[2], Ricardo Godinho[3], Raquel Martins[4], Jacinta Santos[1], Teresa Martins[1] & Fernando Rodrigues[1]
[1]Endocrinology Department, Portuguese Institute of Oncology of Coimbra FG, EPE, Coimbra, Portugal; [2]Faculty of Health Sciences, Health Sciences Research Centre, University of Beira Interior, Covilhã, Portugal; [3]Urology Department, Portuguese Institute of Oncology of Coimbra FG, EPE, Coimbra, Portugal; [4]Endocrinology Department, Portuguese Institute of Oncology of Coimbra FG, EPE, Coimbra, Puerto Rico.

Introduction

Just-glomerular tumours (reninomas) are rare causes of secondary hypertension (HT). They typically present with difficult to manage-HT, hypokalemia, hyperreninemia and secondary hyperaldosteronism. They are usually small lesions (< 1 cm) and are more common in adolescents or young adults. Despite being rare, they should be considered in the diagnostic approach of secondary HT, as it they are a potentially curable cause.

Case report

Female patient, 45 years old, with personal history of difficult to manage-HT associated with hypokalemia since age 35, medicated with perindopril/amlodipine, metoprolol and spironolactone. She was sent to our department and, after suspension of spironolactone and correction of hypokalemia, we confirmed secondary hyperaldosteronism, with aldosterone of 44.3 ng/dl (4–28 ng/dl) and renin > 1000 mIU/ml (4.4–46.2 mIU/ml). She performed an abdominal CT, which identified a heterogeneous nodule located in the middle third of the right kidney, with 37 mm; renal arteries had normal diameter. Partial nephrectomy was performed afterwards and histological analysis confirmed the diagnosis of reninoma, with 27 mm of diameter. After surgery, the patient had normal levels of aldosterone (9.2 ng/dl) and renin (1.20 mIU/ml). She remains without any antihypertensive medication and underwent an ambulatory blood pressure monitoring for 24 h, which confirmed the normalization of blood pressure.

Conclusion

Reninomas are very rare tumours and a potentially curable cause of endocrine hypertension. They are usually benign and its diagnosis should be considered in patients with difficult to control-HT, hypokalemia and secondary hyperaldosteronism, in whom renovascular or parenchymal disease has been excluded. In this case, considering the surgical indication proposed by the urologist regardless of the tumor's functional behavior, the high clinical suspicion and the patient's comfort, we chose not to suspend the antihypertensive medication, except for spironolactone. Surgical resection of the tumor is the treatment of choice and leads to normalization of blood pressure.

Bilateral testicular masses and adrenal insufficiency in a young adult: is congenital adrenal hyperplasia the only possible diagnosis?

Alberto Stefano Tresoldi[1,2], Nazarena Betella[3], Alessandro Pizzocaro[3] & Andrea Gerardo Antonio Lania[3,4]
[1]Dipartimento di Scienze Cliniche e di Comunità, Università degli Studi di Milano, Milano, Italy; [2]Institute of Metabolism and Systems Research, College of Medical and Dental Sciences, University of Birmingham, Birmingham, UK; [3]Endocrinology Unit, IRCCS Humanitas Research Hospital, Humanitas University, Rozzano (MI), Italy; [4]Department of Biomedical Sciences, Humanitas Clinical and Research Center, Humanitas University, Rozzano (MI), Italy.

Testicular adrenal rest tumours (TARTs) are benign tumours deemed to originate from ectopic adrenal cells that descend with the testes during fetal development. These cells grow under chronic ACTH stimulation, typically in patients with congenital adrenal hyperplasia (CAH). TARTs have also been rarely described in other conditions characterised by chronically elevated ACTH, such as autoimmune primary adrenal insufficiency (PAI). These are benign lesions, but could be misdiagnosed as Leydig cell tumours (LCT). X-linked adrenoleukodystrophy (X-ALD) is a peroxisomal disorder of beta-oxidation that results in accumulation of very long chain fatty acids (VLCFA) in various tissues. The phenotypic spectrum is heterogeneous, with different age of onset and severity of neurological involvement. More than 50% of patients have PAI, but only 10% have ALD-associated PAI without neurological involvement, this usually presenting before the age of 10. A 19-year-old young male was referred to our Unit for assessment of elevated ACTH. He had previously undergone bilateral enucleation of presumed LCTs at the age of 8, and follow-up scans later showed persistent bilateral lesions compatible with TARTs, stable through the years. His past medical history was otherwise unremarkable, and clinical examination was normal. We also performed a semen analysis, which showed asthenoteratospermia. In order to exclude CAH, an androgen profile was requested, which showed a slightly elevated 17OHP (2.8 ng/ml) and normal androstenedione, DHEA-s and testosterone. An ACTH stimulation test was performed, which showed insufficient response of cortisol (6.7 μg/ml at 30′), but also a flat response of 17OHP to stimulus (2.8 ng/ml at 60′), confirming the diagnosis of PAI but ruling out CAH. Aldosterone and renin were normal, indicating a preserved mineralocorticoid production. Adrenal antibodies were negative. A serum VLCFA panel was consistent with X-ALD, with subsequent gene testing confirming the diagnosis (mutation c.346G > A of *ABCD1* gene). A brain MRI was normal, supporting the diagnosis of Addison-only ALD.

Conclusion

Adrenoleukodystrophy should always be considered in any case of primary adrenal insufficiency diagnosed in young males, even when the clinical picture could suggest a different aetiology. We expect to confirm that the testicular lesions are indeed TARTs (a follow-up ultrasound is due to be performed, and histological revision of the previously resected testicular lesions is awaited) - this would be the first case ever reported of TARTs in a patient with ALD-associated PAI. This could warrant additional investigation for a potentially reversible cause of infertility in these patients.

GP19

Nonclassical congenital adrenal hyperplasia in a young patient with Type 1a Glycogen storage disease: is there a novel link between glucose metabolism and adrenal steroidogenesis?

Eleni Kandaraki[1], Olga Papalou[1], Dourakis Spyridon[2], Pantelis Konstantoulakis[3] & Evanthia Diamanti-Kandarakis[1]
[1]Department of Endocrinology and Diabetes, Hygeia Hospital, Athens, Greece; [2]2nd Department of Internal Medicine and Research Laboratory, Medical School, National and Kapodistrian University of Athens, Hippokration Hospital, Athens, Greece; [3]Bioanalytica Genotype, Athens, Greece.

Introduction
Glycogen storage disease type Ia is a rare genetic disorder that develops due to deficient activity of the enzyme glucose 6-phosphatase and manifests clinically early in life with hypoglycemia and failure to thrive, as well as with organ dysfunction, due to excess glycogen accumulation, including hepatomegaly and kidney dysfunction. Endocrine manifestations are commonly encountered in these patients. However, due to their rarity, endocrine dysfunction has not been well-acknowledged and studied.
Case presentation
A 17-year old girl with glycogen storage disease type Ia diagnosed in neonatal life, presented with oligomenorrhea since menarche (14 years of age). Clinical examination revealed a normally grown girl, Tanner Stage V, with BMI = 24.2 kg/m^2 and normal blood pressure (120/70 mmHg). No signs of hyperandrogenism or acanthosis nigricans were noticed. A full hormonal workup revealed normal thyroid function, increased LH/FSH ratio, normal testosterone and elevated levels of 17-OH progesterone (17-OH prog = 5.04 ng/ml). Additionally, the patient displayed elevated levels of aldosterone, with suppressed plasma renin activity, leading to an aldosterone-to-renin ratio of 36. Due to the above findings, the patient was submitted to adrenocorticotropic hormone (ACTH) stimulation test, which showed adequate excretion of cortisol, along with increased levels of 17-OH progesterone and androstenedione following stimulation. The renin-aldosterone axis was further assessed with IV saline infusion test, which, however, was not diagnostic due to technical difficulties. In a 24-hour urine collection, an increased excretion of potassium, with normal potassium levels in the plasma, was noticed. Consequently, due to the possibility of a non-typical form of congenital adrenal hyperplasia (NCAH) and a coexisting subclinical hyperaldosteronism, genetic testing to analyze both CYP21A and CYP11B1 genes from genomic DNA of the patient was undertaken. The molecular testing results revealed 4 variations in homozygosity and 1 in heterozygosity at the CYP21A2 gene, as well as 1 variation in heterozygosity at the CYP11B1 gene, which, however, are not reported in all databases reviewed and their clinical significance remains unknown. The results of genetic testing of both parents, which will illuminate further this case, are pending.
Conclusions
The clinical and hormonal phenotype of NCAH in a girl with glycogen storage disease type 1A, in combination with a genomic analysis revealing mutations in both CYP21A2 and CYP11B1 genes, pose a question whether there is a novel link between these two clinical entities.

GP20

Cushing's syndrome revealing carney complex due to novel PRKAR1A mutation

Catherine D Zhang & Irina Bancos
Mayo Clinic, Rochester, New York, USA.

Introduction
Carney complex (CNC) is a rare multiple neoplasia syndrome characterized by pigmented lesions of the skin and mucosa in association with various endocrine and non-endocrine tumors. The disease can be inherited in an autosomal-dominant fashion or occur sporadically due to novel mutations in the PRKAR1A gene. Primary pigmented nodular adrenocortical disease (PPNAD) is a common endocrine manifestation of CNC.
Case description
A 20-year-old woman with bilateral avascular necrosis of the femoral heads was referred for suspected Cushing's syndrome. She reported a 34 kg weight gain, significant stretch marks, rounding of the face, and worsening anxiety over the past year. Physical examination revealed facial plethora, dorsal fat pad, truncal obesity, and multiple striae. In addition, she had several hyperpigmented macules on her lips. Biochemical investigation showed 24 hour urine free cortisol of 22 μg/24 h (reference range 3.5–45 μg/24 h) and non-suppressible serum cortisol levels of 9.5 μg/dl (262 nmol/l) and 13.0 μg/dl (359 nmol/l) following 1 and 8 mg overnight dexamethasone administration respectively. Adrenocorticotrophic hormone (ACTH) was undetectable at <5.0 pg/ml (reference range 10–60 pg/ml), suggestive of ACTH independent Cushing's syndrome. Non-contrast CT imaging of the abdomen failed to identify an adrenal mass and was read as normal. On closer examination, however, there appeared to possible bilateral adrenal micronodular disease present. She subsequently underwent bilateral laparoscopic adrenalectomy, and pathology confirmed PPNAD. Genetic testing revealed a novel frameshift pathogenic variation in the PRKAR1A gene, consistent with a Carney complex diagnosis. Screening echocardiogram and thyroid ultrasound did not reveal cardiac myxoma or thyroid disease. Femoral head necrotic lesions resolved without the need for orthopedic intervention.
Discussion
We present a case of Cushing's syndrome revealing CNC due to a novel inactivating PRKAR1 mutation. PPNAD, in association with CNC, should be considered in the differential for ACTH independent Cushing's syndrome, especially when adrenal imaging appears normal.

DOI: 10.1530/endoabs.56.GP20

GP21

The importance of the follow-up after bilateral adrenal adenomectomy for Cushing's syndrome

Nicoleta Daniela Calinescu[1], Amalia Ioana Arhire[1] & Carmen Gabriela Barbu[1,2]
[1]Endocrinology Department, Elias University Hospital, Bucharest, Romania; [2]Endocrinology Department, Carol Davila University of Medicine and Pharmacy, Bucharest, Romania.

Introduction
We report a case of adrenal tumor recurrence after bilateral adenomectomy for Cushing's syndrome.
Case report
A 44-year-old female diagnosed in June 2014 with Cushing's syndrome caused by bilateral adrenocortical tumors, which were identified by an abdominal CT (right tumor-2.6/ 2/1.8 cm, left tumor-3/2/2 cm). At presentation, the patient had typical signs and symptoms of hypercortisolism and complications such as: arterial hypertension, dyslipidemia, severe osteoporosis with fragility rib fracture. Biological: an altered circadian cortisol rhythm (0800 h cortisol-19 μg/dl, 1100 h cortisol-28 μg/dl), decreased ACTH (ACTH < 5 pg/ml) and unsuppressed cortisol by either low and high doses of dexamethasone (cortisol 24.3 μg/dl after 1 mg DXM and 16.6 μg/dl after DXM 2×2, respectively). As adrenal venous sampling showed that the right adrenal mass has secreted more cortisol than the left one, we decided to perform right adrenal adenomectomy (histopathological result showed nodular adrenal hyperplasia). The postoperative follow-up revealed persistent hypercortisolism and left adrenal adenomectomy was performed as well (anatomopathological examination confirmed adrenocortical adenoma). We initiated the replacement therapy with Hydrocortisone 25 mg/day for the functional adrenal insufficiency. The patient was monitored every 6 months, but there were no significant changes in clinical, hormonal or CT characteristics until the last re-evaluation (October 2017) when the CT scan performed showed a tumoral recurrence of 20/13 mm size in the extern arm of right residual adrenal gland and, also multiple hypoenhancing images dispersed in the sixth segment of the liver, as well as several pulmonary nodules in the lower part of both lungs. The hormonal investigations were unaffected, so the patient continued the glucocorticoid replacement therapy. These findings raised the need for extensive evaluation for digestive malignancy and the adrenal neoplasm could not be excluded as well.
Conclusion
The follow-up is mandatory in patients with nodular hyperplasia, as adrenal adenomectomy may not solve the problem and recurrences may occur even after several years.

Hypoadrenalism in advanced HIV: a pilot study

Ian Ross[1], Robert P Millar[2,3], Thabiso RP Mofokeng[4], Fazleh Mahomed[4], Ashley Grossman[5], Joel Dave[1], Naomi Levitt[1], Tahir Pillay[1,6,7], Rajiv Erasmus[8], Peter Raubenheimer[1] & Gudmundur Johannsson[9]
[1]University of Cape Town, Cape Town, South Africa; [2]Centre of Neuroendocrinology, University of Pretoria, Pretoria, South Africa; [3]Institute of Infectious Diseases and Molecular Medicine, Cape Town, South Africa; [4]Department of Medicine University of the Free State, Bloemfontein, South Africa; [5]University of Oxford, Oxford, UK; [6]Chemical Pathology University of Pretoria, Pretoria, South Africa; [7]NHLS, Pretoria, South Africa; [8]University of Stellenbosch, Cape Town, South Africa; [9]Institute of Medicine Sahlgrenska, Gothenberg, Sweden.

Background
Addison's disease is probably under-diagnosed in South Africa, given that the prevalence is considerably lower than reported in Western countries (Chabre O

2017); this is important as patients may be dying from a highly treatable condition. In addition, large populations of HIV and tuberculosis infected patients in South Africa may have some symptoms erroneously attributed to these conditions, rather than Addison's disease. We determined the prevalence and aetiology of Addison's disease among hospitalised HIV-infected patients.

Methods

HIV-positive patients with a CD4 count of less than 100 cells/mm^3 and concurrent opportunistic infection, who were admitted to a medical ward were assessed with simultaneous early morning plasma cortisol and ACTH analysed by immunoassay (Roche Cobas 6000 platform). Where the basal cortisol was less than 550 nmol/l, a 250 μg *Synacthen* test was performed. Patients were excluded if they had received any steroids in the three months prior to enrolment.

Results

A total of 60 patients (23 males and 37 females) were evaluated in this interim analysis. The age median and interquartile range at presentation was 36.0 (32.0–40.0) years. The median duration of feeling unwell, prior to admission was 26.0 (14.0–60.0) days. Intercurrent pulmonary tuberculosis (TB) was diagnosed in 60% of these patients and 11 (18%) were already on antiretroviral treatment. Despite being severely ill, 37 (61%) had a basal cortisol of less than 550 nmol/l and the basal ACTH was elevated in 12%, whereas in the remainder it was in the reference range. A 250 μg *Synacthen* test was performed in 21 (35%). Of these four patients had an inadequate cortisol reserve at 30 min (<550 nmo/l), of whom three patients had central hypoadrenalism and one patient had primary hypoadrenalism, suggesting an overall prevalence of hypoadrenalism in this group of 6.7%. The median maximal cortisol following a *Synacthen* test was 697.0 (558.0–793.0) nmol/l, with at least five additional patients demonstrating an increment of less than 200 nmol/l.

Conclusions

In this severely ill patient group, at least 8% demonstrated relative adrenal insufficiency, which could contribute to the future high mortality Preliminary data indicate a relatively low prevalence of overt hypoadrenalism (6.7%), but since it is a life-threatening illness it warrants screening in the future.

Adrenocortical Carcinoma (ACC) is an aggressive malignancy with poor response to chemotherapy. Here we evaluated a potential new treatment target for ACC, focusing on the mitochondrial NADPH generator Nicotinamide Nucleotide Transhydrogenase (NNT). NNT has a central role within mitochondrial antioxidant pathways, protecting cells from oxidative stress. Inactivating human NNT mutations result in congenital adrenal insufficiency. We hypothesized NNT silencing in ACC cells will induce toxic levels of oxidative stress. To explore this hypothesis, we transiently knocked down NNT in NCI-H295R ACC cells. As predicted, this manipulation increased intracellular levels of oxidative stress; this resulted in a pronounced suppression of cell proliferation and higher apoptotic rates, as well as sensitization of cells to chemically induced oxidative stress. Steroidogenesis was paradoxically stimulated by NNT loss, as demonstrated by mass spectrometry-based steroid profiling and real-time PCR. Pharmacological inhibition of antioxidant pathways downstream of NNT also displayed potent anti-tumour effects in vitro. Next, we generated a stable NNT knockdown model in the same cell line to investigate the longer-lasting effects of NNT silencing. After long-term culture, cells adapted metabolically to chronic NNT knockdown, restoring their redox balance and resilience to oxidative stress, although their proliferation remained suppressed. This was associated with higher rates of oxygen consumption. The molecular pathways underpinning these responses were explored in detail by RNA sequencing and non-targeted metabolome analysis. Transient NNT knockdown induced major alterations in core molecular pathways that control cellular proliferation and viability, and had far-reaching effects on cell metabolism. Stable knockdown was associated with changes in protein processing in the Endoplasmic Reticulum and up-regulation of polyamine synthesis, which may facilitate the observed adaptation to oxidative stress. Our study provides the first pre-clinical evidence of the therapeutic merit of antioxidant targeting in ACC as well as illuminating the long-term adaptive response of cells to oxidative stress.

The cytochrome P450 2W1 (CYP2W1) is an orphan enzyme able to activate anticancer pro-drugs and to metabolise endogenous substances as fatty acids and lysophospholipids. Aim of the study was to evaluate the frequency of CYP2W1 polymorphisms in patients with adrenocortical carcinoma (ACC) and correlate it with the sensitivity to mitotane, which represents the only approved drug for the treatment of advanced ACC.

Methods

A multicenter retrospective study including 182 Caucasian ACC patients (F/M = 121/61) treated with mitotane monotherapy in adjuvant ($n = 103$) or palliative ($n = 79$) setting from six centers belonging to the European Network for the Study of Adrenocortical Tumors (ENSAT) was performed. DNA was extracted from whole-blood and three CYP2W1 polymorphisms were genotyped by PCR and sequencing: CYP2W1*2 (p.A181T), CYP2W1*5 (p.Q482H) and CYP2W1*6 (p.P448L). Clinico-pathological data and an accurate follow-up during mitotane monotherapy were annotated. The response to therapy was evaluated by time to progression (TTP) from the start of mitotane treatment.

Results

The frequencies for allele*2 and *6 were in Hardy-Weinberg equilibrium. CYP2W1*5, which is only reported in non-Caucasian population, was not found. We didn't observe any correlation between the presence of CYP2W1*2 allele and clinical outcome. However, considering the incompletely resectable, metastasized or recurrent ACC, patients with CT/TT genotype at CYP2W1*6 showed a worse response to mitotane (median TTP 3 *vs.* 8 months, $P = 0.019$, HR 1.77) and a higher rate of progressive disease (71% *vs.* 41%; $P = 0.018$, chi-square = 5.57) than the wild-type group. Looking at mitotane plasma levels, 76% of CT/TT patients did not reach the target therapeutic levels (14–20 mg/L) in comparison to 52% of wild-type group ($P = 0.052$, chi-square = 3.794). No relevant impact of CYP2W1*6 was observed in patients treated with mitotane in adjuvant setting.

Conclusion

We demonstrated that ACC patients with advanced disease and CT/TT genotype at CYP2W1*6 had a worse response to mitotane treatment. Thus, this study suggests a possible use of germline CYP2W1*6 polymorphism as a new predictor marker of response to mitotane treatment in advanced ACC, avoiding useless drug administration leading to toxicities for patients.

Metabolic fingerprints after Cushing syndrome cure

Guillermo Garcia-Eguren[1], Pedro Vizan[2], Mar Gonzalez[2], Enrique Blanco[2], Marina Rojo[1], Mireia Mora[1,3], Oriol Giró[1], Irene Halperin[1,3], Luciano Di Croce[2] & Felicia A Hanzu[1,3]
[1]Laboratory of Endocrine Disorders IDIBAPS/CIBERDEM, Barcelona, Spain; [2]Center of Genomic Regulation, Barcelona, Spain; [3]Endocrinology Department Hospital Clinic, Barcelona, Spain.

Introduction
Active hypercortisolism of Cushing syndrome (CS) determines major changes in the plasticity and function of metabolic key target tissues as the adipose tissue (AT). Persistence of target tissue altered metabolic memory after the cure/remission of Cushing syndrome is still at debate as clinical observational studies are limited due to confounder factors both in endogenous as exogenous CS. We postulate that after remission of hypercortisolism, adipose tissue (AT) present persistent deregulations for a long time after the cure of CS contributing to the maintaining of a metabolic syndrome-like phenotype and an increased cardiovascular risk. The aim of this study was to investigate the metabolic phenotype and the adipose tissue after the cure of CS employing an established reversible CS animal model (doi: 10.1073/pnas.1323681111).
Methods
Prospective study in animal C57BL/6 mice with reversible CS studied in active hypercortisolism and after the reversion to eucortisolism. Groups: j). Mice with active CS (ACS) induced by oral chronic treatment with glucocorticoids (GC); (jj). Mice with obesity induced by hypercaloric diet (HCD); (jjj). Controls (CTR). Mice from group's j and jj received treatment (GC *vs.* HCD) during 5 weeks (W). All animals were metabolically and hormonal phenotyped at treatment end (at 5W) and at 15W. Adipose tissue distribution (MRI), plasticity (histology) and function (RNAseq, rt-PCR, cytokine arrays) were analyzed in all groups.
Results
GC treated mice presented after 5W of treatment the complete CS phenotype. Reversible CS mice (RCS) presented at 15W after the end of the active treatment no significant changes in body weight but an increase in white adipose tissue (WAT) ($P<0.005$), and marked insulin resistance (HOMA-IR: $P<0.05$ and ITT: $P<0.01$) as respect to CTR and HCD. WAT of RCS presented low turnover, hypertrophic adipocytes ($P<0.05$). Heat map, PCA and t-SNE analysis and the persistence of 488 up- and 388 down- regulated genes between active ACS and RCS indicate profound alterations of WAT in RCS mice. Genes validation, pathway and adipocytokines analysis are in process.
Conclusion
This is the first study in a murine animal model reporting the persistence of an altered metabolic phenotype marked by insulin resistance and changes in the adipose tissue plasticity after cure of CS.

Segmental adrenal venous sampling may give a key to solution about the debate of cosyntropin stimulation or not

Fumitoshi Satoh[1,2], Yuta Tezuka[1,2], Ryo Morimoto[2], Kei Omata[1,2], Yoshikiyo Ono[2], Yasuhiro Igarashi[2], Masataka Kudo[2], Kei Takase[3] & Sadayoshi Ito[2]
[1]Division of Clinical Hypertension, Endocrinology and Metabolism, Tohoku University Graduate School of Medicine, Sendai, Japan; [2]Division of Nephrology, Endocrinology and Vasucular Medicine, Tohoku University Hospital, Sendai, Japan; [3]Department of Radiology, Tohoku University Hospital, Sendai, Japan.

Background
Adrenal venous sampling (AVS) is critical to differentiate unilateral primary aldosteronism (PA) subtype. However, there are large discrepancies between institutions in the diagnostic criteria of AVS. Especially, the most major debate is in whether cosyntropin stimulation should be used for localization diagnosis or not. Segmental AVS (S-AVS) is a refinement of central AVS (C-AVS) in which samples are taken from the tributaries of the central adrenal veins allowing the identification of the intra-adrenal aldosterone secretion in far more precise fashion.
Objective
To examine C-AVS data before and after cosyntropin by those of S-AVS.
Methods
The results of both C-AVS and S-AVS procedures in all 248 cases (133 APA and 115 BHA) performed in our institution were interpreted with diagnostic criteria of lateralized index (LI) by C-AVS. All of the APA cases underwent unilateral laparoscopic adrenalectomy based on the S-AVS findings, and were reconfirmed by pathologically and by postoperative clinical characteristics.
Results
If surgery-indicated LI of C-AVS before cosyntropin (pre-LI) were ≥ 3, the right dominant were 109 cases (62 right APA (56.9%) and 2 left APA) and 45 BHA cases (41.3%)), and the left dominant were 52 cases (48 left APA (92.3%) and 4 BHA cases (7.7%)). All of 66 PA cases with pre-LI <3 were diagnosed as BHA by S-AVS. The cases with LI of C-AVS after cosyntropin (post-LI) ≥ 4 were all 104 APA cases, and the cases with post-LI <4 of C-AVS were 144 cases (29 APA cases (20.0%) and 115 BHA cases (80.0%)) diagnosed by S-AVS. ROC analysis of unilateral versus bilateral judged by S-AVS could give us the most suitable pre-LI and post-LI cutoff values of C-AVS for localization diagnosis of aldosteronism.
Conclusions
S-AVS data gave us the more precise localization of hyperaldosteronism as compared to C-AVS data. If we use pre-LI of C-AVS for surgery-indication, we should be very careful about the high prevalence of BHA in right dominant cases. If we use post-LI ≥ 4 of C-AVS, we should also consider the possibility of overlooking at surgery-adaptive APA cases in the cases with post-LI <4.

The short synacthen test can be used to predict recovery of hypothalamo-pituitary-adrenal axis function and guide clinical practice

Riccardo Pofi[1,2], Chona Feliciano[3], Emilia Sbardella[2], Nicola Argese[4], Conor P Woods[5], Ashley B Grossman[1], Bahram Jafar-Mohammadi[1], Helena Gleeson[3], Andrea Lenzi[2], Andrea M Isidori[2] & Jeremy W Tomlinson[1]
[1]Department of Endocrinology, Oxford Centre for Diabetes, Endocrinology and Metabolism, Oxford, UK; [2]Department of Experimental Medicine, Sapienza University of Rome, Rome, Italy; [3]Centre for Endocrinology, Diabetes and Metabolism, Queen Elizabeth Hospital, Birmingham, UK; [4]Department of Endocrinology, S.S. Annunziata Hospital, Taranto, Italy; [5]Department of Endocrinology, Naas General Hospital, Kildare and Tallaght Hospital, Dublin, Ireland.

The 250 mg short synacthen test (SST) is the most commonly used tool to assess the integrity of hypothalamic-pituitary-adrenal (HPA) axis. There are many instances when compromise to HPA-axis function is potentially reversible (including the use of suppressive dose of prescribed glucocorticoids), but currently there are no data to guide clinicians as to the frequency of repeat testing or to the likelihood of HPA-axis recovery. We performed an observational, retrospective, analysis of data from 1912 SSTs from 776 patients (335 men, 441 women, mean age 53 ± 18 years) in whom potentially reversible causes of HPA-axis compromise and adrenal insufficiency(AI) were identified. At least two SSTs were performed in each patient, the median duration of follow-up was 250 days (95%CI, 224-272). Irreversible causes (pituitary radiotherapy, Addison's disease, congenital adrenal hyperplasia, adrenal metastases, bilateral adrenalectomy) were excluded. A separate cohort analysis was performed on patients who had been treated with suppressive dose of glucocorticoids ($n=110$). SST 30-min cortisol level was the best predictor of HPA-axis recovery in patients with reversible AI not exposed to suppressive doses of glucocorticoids (AUC ROC $=0.85$). Patients with 30-minute cortisol levels >350 nmol/l had a significantly shorter time to HPA-axis recovery (341 *vs.* 1580 days, $P=4.4\times10^{-10}$). In this group, 99% of patients recovered HPA-axis within 4-years, contrasting with 34% in those with a 30-min cortisol <350 nmol/l. In the group with a 30-min cortisol <350 nmol/l, a subsequent random cortisol of <200 nmol/l (1-year after the initial SST), identified a population in whom only 11% recovered HPA-axis function. In those patients treated with suppressive dose of glucocorticoids, delta cortisol (30-min – basal) was the best predictor of recovery (AUC ROC $=0.77$). Delta cortisol $>$ 100 nmol/l predicted a shorter estimated median recovery time (262 *vs.* 974 days, $P=7.0\times10^{-6}$). 4-year recovery rates were also different (95% *vs.* 67%). Moreover, no patient with a delta cortisol <100 nmol and a subsequent random cortisol <200 nmol/l recovered HPA-axis function within the 4-year duration of the study. Using a SST 30-min cortisol in patients with reversible causes of AI, and a delta cortisol in those exposed to high doses of glucocorticoids, can predict recovery of HPA-axis function. We believe that these data will help to guide the frequency of repeat dynamic testing and provide a unique dataset that will inform both clinicians and patients as to the likelihood of restoration of intact HPA-axis function.

Immunohistochemical staining for histopathological subclassification of primary aldosteronism: nationwide 10-year results from Iceland

Hrafnhildur Gunnarsdottir[1], Bjarni A Agnarsson[1,2], Sigurros Jonasdottir[1,2], Guðjon Birgisson[3] & Helga Agusta Sigurjonsdottir[1,4]
[1]Faculty of Medicine, University of Iceland, Reykjavik, Iceland; [2]Department of Pathology, Landspitali University Hospital, Reykjavik, Iceland; [3]Department of General Surgery, Landspitali University Hospital, Reykjavik, Iceland; [4]Division of Endocrinology, Department of Medicine, Landspitali University Hospital, Reykjavik, Iceland.

Introduction
Primary aldosteronism (PA) is an important cause of hypertension. Adrenal hyperplasia (AH) and aldosterone-producing adrenocortical adenoma (APA) are considered the most frequent causes of PA. Histopathological analysis of unilateral PA has been difficult since no clear morphological criteria existed for defining aldosterone-producing cells. Recently, the distribution of adrenal cells forming aldosterone and cortisol has been studied by using specific monoclonal antibodies against the enzymes CYP11B2 and CYP11B1, catabolizing the final steps of aldosterone and cortisol production, respectively. In addition to APA and AH, the antibodies allow identification of unilateral multiple micronodules (UMN), expressing CYP11B2 in the zona glomerulosa (ZG), and aldosterone-producing cell clusters (APCC) extending beyond the ZG. The aim of this study was to review the histopathological diagnoses of all patients who underwent adrenalectomy for unilateral PA in Iceland in 2007–2016, using immunohistochemical staining.
Methods
Tissue slides from all patients, aged $\geq$18 years, who underwent adrenalectomy for unilateral PA in Landspitali University Hospital (LUH) in 2007–2016, were accessed and appropriate slides from each patient selected. Antibodies; anti-CYP11B1 (clone 80-7 Mabs 502, rat), and anti-CYP11B2 (clone 41-17B Mabs 1251, mouse), were purchased from Merck Millipore and diluted 1 : 200 using EnVision Flex Antibody Diluent (DM830, Daco). The PA tissue slides were stained along with control samples from healthy adrenal glands using AutostainerLink 48 (Daco). Microscopic evaluation was thereafter performed. All necessary permissions were obtained.
Results
In 2007–2016, a total of 25 patients underwent adrenalectomy as treatment for unilateral PA in LUH. Twenty of them had originally been diagnosed with APA, four with AH and one as inconclusive. After performing the immunohistochemical staining, 7 of the 25 patients' (28%) histopathological diagnoses were changed. In total, 20 of the 25 patients (80%) had APA, three (12%) had APCC and two (8%) had UMN. Out of four patients previously diagnosed with AH, two had APA, one had APCC and one had UMN. One patient previously diagnosed with APA turned out to have APCC and another one UMN. The inconclusive sample proved to contain APCC.
Conclusions
Most of the patients turned out to have APA, with APCC being the second most prevalent histopathological diagnosis. Interestingly, no-one had AH. These findings emphasize the importance of the immunohistochemical staining for the proper histopathological diagnosis of PA patients. Further research is needed regarding APCC and UMN. Moreover, it is important to make further assessment on treatment response in context with precise histopathological diagnosis.

Salivary cortisol and cortisone in Cushing diagnosis – reference ranges and clinical cut off limits

Nils Bäcklund[1], Göran Brattsand[2], Marlen Israelsson[2], Oskar Ragnarsson[3], Pia Burman[4], Britt Edén Engström[5], Charlotte Høybye[6], Katarina Berinder[6], Jeanette Wahlberg[7] & Per Dahlqvist[1]
[1]Department of Public Health and Clinical Medicine, Umeå University, Umeå, Sweden; [2]Clinical Chemistry, Department of Medical Biosciences, Umeå University, Umeå, Sweden; [3]Department of Endocrinology, Sahlgrenska University Hospital and Institute of Medicine, Sahlgrenska Academy, University of Gothenburg, Gothenburg, Sweden; [4]Department of Endocrinology, Skåne University Hospital Malmö, University of Lund, Malmö, Sweden; [5]Department of Medical Sciences, Endocrinology and Metabolism, Uppsala University Hospital, Uppsala, Sweden; [6]Department of Endocrinology, Metabolism and Diabetology, Karolinska University Hospital and Department of Molecular Medicine and Surgery, Karolinska Institute, Stockholm, Sweden; [7]Department of Endocrinology and Department of Medical and Health Sciences, Linköping University, Linköping, Sweden.

Introduction
Cushing's syndrome is rare, but assessment of patients with clinical suspicion of Cushing's and/or adrenal incidentaloma is frequently required. Thus, there is a need for biochemical screening methods that with high sensitivity and specificity identifies or rule out hypercortisolism. Analysis of late night salivary cortisol allows an easy sampling procedure performed at home and is independent of variations in plasma CBG levels. Analysis by liquid chromatography tandem mass spectrometry (LCMS) allows high analytical specificity and simultaneous analysis of salivary cortisol and cortisone, but robust reference limits and clinical cut-off levels are needed. Analysis of both cortisol and cortisone also allows quality control for contamination by blood or exogenous hydrocortisone.
Objective
Establishing solid reference intervals and clinical cut off levels for salivary cortisol and cortisone in the evening and after low dose dexamethasone suppression (LDDST) test using LCMS.
Methods
Salivary samples were collected at 0800, 2300 and at 0800 h after 1 mg dexamethasone from 175 reference subjects and 24 patients with Cushing syndrome using Salivette® cortisol tubes. Half of the reference group also collected samples at 2000 and 2200. Salivary cortisol and cortisone was analysed with LCMS. Reference interval (2.5th and 97.5th percentile) was calculated non-parametrically and the best cut-off level for discrimination between Cushing patients and reference population was calculated using receiver operating characteristics analysis.
Results
The 97.5th percentile of the cortisol:cortisone ratio was 0.81. Samples with a ratio $\geq$1.0 was excluded from the reference samples for suspicion of contamination of blood or exogenous hydrocortisone. The reference range and cut-off levels for Cushing patients vs. reference population for salivary cortisol and cortisone are presented in the table below. There was no significant difference in salivary cortisol or cortisone at 2200 h compared with 2300 h, whereas the levels were were significantly higher at 2000 h.
Conclusion
A robust reference range for late night salivary cortisol and cortisone and after LDDST for the LCMS method was established. Patients with Cushing's syndrome were separated from the reference population with high sensitivity and specificity and salivary cortisone appeared slightly superior to salivary cortisol. Late night samples may be collected at 2200–2300 h.

Saliva-	2.5th (nmol/l)	97.5th (nmol/l)	Cut-off (nmol/l)	Sensi-tivity (%)	Specificity (%)
cortisol 23.00	0.20	3.61	2.41	100	95.3
cortisone 23.00	1.53	13.50	14.85	100	100
cortisol LDDST	0.02	0.79	0.37	100	85.8
cortisone LDDST	0.59	3.54	4.95	100	100

The urinary cortisol metabolome in patients with adrenal insufficiency: dual-release hydrocortisone is less deleterious than conventional hydrocortisone therapy

Stéphanie Espiard[1,2], Johanna McQueen[1,2], Mark Sherlock[3], Oskar Ragnarsson[1,2], Ragnhildur Bergthorsdottir[1,2], Pia Burman[4], Per Dahlqvist[5], Bertil Ekman[6], Britt Edén Engström[7], Anna G Nilsson[1,2], Stanko Skrtic[2,8], Jeanette Wahlberg[6], Paul M Stewart[9] & Gudmundur Johannsson[1,2]
[1]Department of Endocrinology, Sahlgrenska University Hospital, Gothenburg, Sweden; [2]Institute of Medicine, University of Gothenburg, Gothenburg, Sweden; [3]Department of Endocrinology and Diabetes, Beaumont Hospital, Dublin, Ireland; [4]Department of Endocrinology, Skåne University Hospital, Malmö, Sweden; [5]Department of Public Health and Clinical Medicine, Umeå University, Umeå, Sweden; [6]Department of Endocrinology, Department of Medical and Health Sciences, Department of Clinical and Experimental Medicine, Linköping University, Linköping, Sweden; [7]Department of Medical Sciences, Endocrinology and Metabolism, Uppsala University Hospital, Uppsala, Sweden; [8]AstraZeneca R&D, Mölndal, Sweden; [9]Faculty of Medicine and Health, University of Leeds, Leeds, UK.

Introduction
Oral once-daily dual-release hydrocortisone (DR-HC) therapy provides a more physiological cortisol profile than conventional thrice-daily (TID) replacement therapy and has demonstrated improved metabolic profile among patients with adrenal insufficiency (AI). The mechanisms by which this metabolic improvement occurs may be due to less total exposure, changed cortisol time exposure profile, but also modified metabolism of cortisol.
Objective
The aim was to study steroid enzyme activities related to corticosteroids during DR-HC and TID.
Methods
Patients with primary AI received DR-HC or an equal total daily dose of TID hydrocortisone in a 12-week crossover multi-center study. 24 h urinary collection was performed during both treatment and in 124 healthy controls. Urinary cortisol metabolites were measured using gas chromatography/mass spectrometry providing an index of total cortisol exposure and metabolism.
Results
Fifty patients (22 female, mean age 47 years (range 19–71)) and 124 healthy controls [73 females, mean age 48 years (range 20–81)] were included in the study. Total cortisol metabolites (F, E, THF, 5αTHF, THE, cortols, cortolones) were significantly decreased during DR-HC treatment [median: 6380 µg/24h] compared to TID (8825 µg/24 h); $P<0.001$] and returned to similar value compared to controls (6850 µg/24 h; $P=0.089$). Compared to controls, the urinary THF + 5αTHF/THE ratio reflecting 11βHSD1 activity was increased during both DR-HC ($P<0.001$) and TID treatments ($P<0.001$), being more marked in TID compared to DR-HC ($P<0.05$) compatible with cortisol induced 11βHSD1 activity. Urinary F/E reflecting 11βHSD2 activity was slightly higher in TID versus controls ($P<0.01$), but normalized during DR-HC ($P=0.358$). The 5α-reduced metabolite, 5αTHF, was similar in patients compared to control but decreased significantly with DR-HC compared to TID ($P<0.001$). The 5β-reduced metabolite, THF, was higher in patients compared to control ($P<0.001$) but decreased significantly with DR-HC compared to TID ($P<0.001$). The urinary 5αTHF/THF ratio increased significantly in patients (controls: 1.3; TID: 2.3, $P<0.001$; DR-HC: 2, $P<0.001$) indicating that the main driver for this was an increase in 5β-reductase activity during TID and to a lesser extent during DR-HC.
Conclusion
The urinary cortisol metabolome shows more striking abnormalities in patients receiving TID compared to DR-HC replacement therapy and maybe a more sensitive marker of "optimal cortisol replacement". The increased 11βHSD1 activity in patients on TID may account for the deleterious metabolic phenotype reported in patients with AI and its reduced activity during DR-HC may also mediate some of the beneficial effects previously seen with this treatment.

Circular RNA circ0066659 functions as a competitive endogenous RNA by sponging miR-506-3p in adrenocortical carcinoma

Yunze Xu & Yiran Huang
Renji Hospital, School of Medicine, Shanghai Jiaotong University, Shanghai, China.

Introduction and objectives
Circular RNAs (circRNAs) represent a class of endogenous noncoding RNAs that have recently been recognized as important regulators of gene expression and pathological networks. However, investigations on adrenocortical carcinoma (ACC) initiation and progression mechanisms only focus on key encoding genes, but neglect shedding an insight into circRNAs.
Materials and methods
We investigated the expression profile of circRNAs in three primary ACC and three Adrenocortical adenoma (ACA) tumor samples using a high-throughput circRNA microarray. Bioinformatic analyses were applied to study these differentially expressed circRNAs. Furthermore, qRT-PCR was performed to confirm these results. The expression levels and functions of circ0066659 were evaluated in ACC clinical specimens and cell lines.
Results
Here we identified 1447 differentially expressed circRNAs in primary ACCs as compared with ACAs, of which 849 were significantly upregulated and 598 were downregulated. Differential circRNAs expression between the two groups were validated by qRT-PCR assay. High expression of cricRNA0066659, one of the upregulated circRNAs in ACC, is closely correlated with a low cumulative survival rate and metastatic progression in ACC patients. Furthermore, our experimental analyses identified that cricRNA0066659 specifically binds to miR-506-3p and has a negative correlation with miR-506-3p, indicating that miR-506-3p as a direct target of cricRNA0066659.
Conclusion
Overall, the differential expression of multiple circRNAs and their clinical significance in ACC tissues as revealed by our study suggests that cricRNA0066659 is a novel metastatic factor and prognostic marker in ACC, we propose that cricRNA0066659 could be used as a potential target in ACC therapy.

***PRKACA* L206R mutation in adrenal Cushing induces histone H1.4 hyper-phosphorylation**

Kerstin Bathon[1], Isabel Weigand[2], Jens T Vanselow[3], Cristina L Ronchi[4,5,6], Silviu Sbiera[2], Andreas Schlosser[3], Martin Fassnacht[2,4] & Davide Calebiro[1,5,7]
[1]Institute of Pharmacology and Toxycology and Bio-Imaging Center, University of Würzburg, Würzburg, Germany; [2]Department of Internal Medicine I, Endocrine and Diabetes Unit, University Hospital Würzburg, Würzburg, Germany; [3]Rudolf Virchow Center, University of Würzburg, Würzburg, Germany; [4]Comprehensive Cancer Center Mainfranken, University of Würzburg, Würzburg, Germany; [5]Institute of Metabolism and Systems Research, University of Birmingham, Birmingham, UK; [6]Centre for Endocrinology, Diabetes and Metabolism (CEDAM), Birmingham Health Partners, Birmingham, UK; [7]Centre of Membrane Proteins and Receptors (COMPARE), Universities of Birmingham and Nottingham, Birmingham, UK.

We previously identified mutations in *PRKACA*, coding for the catalytic a (Ca) subunit of protein kinase A (PKA), as the main genetic alteration in cortisol-producing adrenal adenomas (CPAs) responsible for Cushing's syndrome. Here, we further investigated the mechanism of action of all *PRKACA* mutations identified so far by our team (L206R, L199_C200_insW, S213R_L212_K214insIILR, C200_GlyinsV, W197R, del244-248 + E249Q and E32V). Five out of seven mutants showed reduced binding to at least one of the two tested regulatory subunits (RIa and RIIb). Similarly, not all mutants show increased basal PKA activity. This suggested that the reported mechanism of increased basal activity due to interference with holoenzyme formation was unlikely to be the sole mechanism of action of *PRKACA* mutations. Since most of these mutations lie close to the active site of PKA, we hypothesized that they might alter substrate specificity. Consistent with this hypothesis, a Western blot analysis of PKA phosphorylated substrates using an antibody recognizing the phosphorylated PKA consensus suggested that each *PRKACA* mutation induced specific changes in PKA phosphorylation pattern. These findings were further corroborated by an *in silico* prediction of substrate specificity. Thus, we used a quantitative mass spectrometry method (NanoLC-MS/MS) to precisely analyze and compare the phosphorylation patterns induced by the different mutants. We found that all three tested mutants (L206R, del244-248 + E249Q, C200_G201insV) induced relevant changes in substrate specificity. Among all PKA substrates with increased phosphorylation with the mutants compared to wild-type Ca subunit, histone H1.4 was hyper-phosphorylated at Ser36 by all three mutants. Importantly, we found that CPAs harboring the L206R *PRKACA* mutation ($n=3$) had increased H1.4 phosphorylation at Ser36 compared to non-mutated adenomas ($n=4$). Since H1.4 Ser36 phosphorylation has been shown to be required for mitosis and chromatin condensation, H1.4 hyperphosphorylation might play a relevant part in the mechanisms linking *PRKACA* mutations to increased proliferation of adrenocortical cells. Altogether, these findings indicate that several mechanisms, including a change in substrate specificity, contribute to the development of CPAs caused by *PRKACA* mutations.

Alterations in Clock genes expression in human benign adrenal tumors

Anna Angelousi[1], Narjes Nasiri-Ansari[1], Angeliki Karapanagioti[1], Chrysanthi Aggeli[2], Georgios Zografos[2], Georgios Chrousos[1], Gregory Kaltsas[1] & Eva Kassi[3]
[1]National and Kapodistrian University of Athens, Athens, Greece; [2]General Hospital of Athens 'Georgios Gennimatas', Athens, Greece; [3]National and Kapodistrian University, Athens, Greece.

Introduction
Alteration in the expression of clock-related genes has been observed in various diseases. Adrenal sensitivity to adrenocorticotropic hormone (ACTH) apart from the hypothalamo-pituitary-adrenal axis is also regulated by the intrinsic adrenal clock. A link between clock genes and glucocorticoid adrenal production has been suggested by *in vitro* and animal studies. In the present study we investigated clock genes expression in human benign tumors of the adrenal cortex. Methods: Sixteen fresh frozen adrenal tissues were collected from November 2016 to December 2017. All patients (13 females/3 males) had adrenalectomy either because of tumor size ($n=7$) or secretory syndrome ($n=9$). *CLOCK*, *BMAL1*, *CRY1* and *PER1* genes expression were analysed with qRT-PCR in benign adrenal tissues (13 adenomas and 3 hyperplasias) and in the peritumoral normal tissue. Protein expression of the aforementioned genes was evaluated by Western Blot analysis. Clinical, biochemical and histological data of the operated patients were also collected retrospectively.
Results
Patients' mean age was 50 ± 13 years old. Four out of 16 patients had overt Cushing syndrome, 2 had subclinical Cushing, 3 had Conn adenomas, and the remaining 7 patients had non functional adenomas (NF). Mean tumor size was 3.7 ± 1.2 cm, Ki-67 was 1–2% and Weiss score 0-1. All clock-related genes exhibited lower expression in adrenal tumors compared to the peritumoral tissue, in the t test paired analysis. However only *CLOCK* and *BMAL1* were significantly down-regulated ($P<0.05$). Moreover, *PER1* showed significant lower expression in NF adenomas compared to cortisol-secreting adenomas, in the Mann-Whitney test (non-parametric analysis).
Conclusion
Our *in vivo* preliminary data demonstrated for the first time that the core clock genes *CLOCK*, *BMAL1*, *CRY1* and *PER1* are differently expressed in adrenal adenomas compared to peritumoral normal tissues, suggesting that dysregulation of the local circadian clock system may play a role in either the development or evolution of adrenal adenomas.

Effects of replication of the physiological and non-physiological cortisol rhythm on insulin sensitivity in muscle: a molecular *in vitro* analysis on synchronized muscular cells

Mariarosaria Negri[1], Gilda Di Gennaro[1], Claudia Pivonello[1], Chiara Simeoli[1], Mary Anna Vennery[2], Federica Barbagallo[2], Davide Iacuaniello[1], Maria Cristina De Martino[1], Andrea Maria Isidoro[2], Annamaria Colao[1] & Rosario Pivonello[1]
[1]Dipartimento di Medicina Clinica e Chirurgia, Sezione di Endocrinologia, Università Federico II di Napoli, Naples, Italy; [2]Department of Experimental Medicine, Sapienza University of Rome, Rome, Italy.

Adrenal insufficiency is a rare endocrine disorder characterized by low levels of cortisol associated with increased mortality, also due to inadequate replacement therapy. The replacement with the thrice-daily immediate release hydrocortisone (IRH), in contrast to the once-daily modified-release hydrocortisone (MRH), more appropriately mimicking the physiological circadian rhythm of cortisol (PCRC), is associated with metabolic disorders, mainly due to the non-physiological peak of cortisol in the evening. The aim of the current *in vitro* study was to compare the effects of exposure to concentrations achieved *in vivo* during the different phases of day after IRH and MRH administration, compared to PCRC, on muscle insulin sensitivity. To this purpose, a mouse skeletal muscle cell line (C2C12), has been used and the *in vitro* oscillation of 24-hour peripheral clock genes expression (BMAL-1, PER-1, PER-2, CRY-2) has been induced by serum shock treatment and analysed by RT-qPCR, allowing to calculate treatment schedules of morning, afternoon and evening exposure (»0800 h, »1300 h and »0600 h), respectively. Simultaneously, the relative expression levels of 84 genes classically involved in muscle insulin sensitivity have been analysed by genomic microarrays and compared between PCRC, IRH and MRH simulated therapies at different times of treatment schedules. In particular, for the evening exposure, microarray analysis showed identical gene expression between IRH treatment and PCRC, whereas MRH caused significant down-regulation of 21 genes relative expression ($P<0.05$) including insulin receptor ($P=0.02$), IRS-1 ($P=0.02$), IRS-2 ($P=0.01$), PI3KCA ($P=0.03$), ADIPOR-2 ($P=0.02$), additionally confirmed by RT-qPCR. Moreover, WB analysis revealed that evening exposure to IRH might reduce intracellular phosphorylated levels of IRS-1 at Tyr608 and of Akt at Ser473 compared to MRH and PCRC treatments suggesting a robust involvement in muscle insulin resistance. In conclusion, these preliminary data demonstrate that, especially for the evening exposure, MRH might preserve the muscle insulin sensitivity otherwise compromised by IRH.

The circadian rhythm of glucocorticoid administration entrains clock-controlled genes in blood mononuclear cells: a DREAM trial ancillary study

Mary Anna Venneri[1], Valeria Hasenmajer[1], Daniela Fiore[1], Emilia Sbardella[1], Riccardo Pofi[1,2], Chiara Graziadio[1], Daniele Gianfrilli[1], Claudia Pivonello[3], Mariarosaria Negri[3], Fabio Naro[1], Ashley B Grossman[2], Andrea Lenzi[1], Rosario Pivonello[3] & Andrea M Isidori[1]
[1]Sapienza University of Rome, Rome, Italy; [2]University of Oxford, Oxford, UK; [3]Università Federico II di Napoli, Napoli, Italy.

Introduction
Adrenal insufficiency requires life-long glucocorticoid replacement. Conventional therapies fail to mimic endogenous cortisol circadian rhythm. Clock genes are essential components of the molecular machinery controlling organ's circadian function and are influenced by glucocorticoids. However, clock genes expression has never been investigated in patients with adrenal insufficiency (AI).
Aim
To evaluate the effect of the timing of glucocorticoid administration on circadian genes expression in peripheral blood mononuclear cells (PBMCs) of AI patients enrolled in the DREAM trial.
Methods
We enrolled 89 AI patients taking conventional glucocorticoid therapy, that were randomly assigned to continue their standard multiple times a day therapy or switch to an equivalent dose of once-daily, modified-release hydrocortisone and 25 healthy matched controls. 83 subjects consented gene expression analysis by realtime qRT-PCR.
Results
Compared to healthy controls, 19 of the 68 genes detected in the PBMC were found differentially expressed in AI patients, at baseline, and 18 restored to control levels 12 week after switching from the standard to once-daily modified-release hydrocortisone, including the core of the clock-machinery: ARNTL[B-MAL] ($P=0.024$), CLOCK ($P=0.016$), PER3 ($P<0.001$) and TIMELESS (<0.001); the Creb-related AANAT ($P=0.021$), CAMK2D ($P<0.001$), CREB1 ($P=0.010$), CREB3 ($P=0.037$), MAPK1 ($P<0.001$), MAT2A ($P=0.013$), PRKAR1A ($P=0.006$), PRKAR2A ($P=0.006$) and PRKCB ($P=0.006$); the transcription factors SP1 ($P<0.001$) and WEE1 ($P<0.001$) and the other circadian-related CSNK1A1 ($P<0.001$), ONP3 ($P<0.001$) and PRF1 ($P<0.001$). Changes in gene expression in PBMCs correlated with metabolic and immune findings.
Conclusions
AI patients on standard multiple times a day replacement therapy exhibit a dysregulation of circadian genes in peripheral blood cells. The switch to the once daily modified-release hydrocortisone reconditions peripheral tissue gene expression to an extent that correlates with the clinical outcomes of the DREAM trial [NCT02277587].

Identification of new *ARMC5* missense mutations in Primary Bilateral Macronodular Adrenal Hyperplasia (PBMAH) and their functional studies *in vitro*

Anna Vaczlavik[1], Stéphanie Espiard[1], Marie-Odile North[2], Ludivine Drougat[1,3], Marthe Rizk-Rabin[1], Karine Perlemoine[1], Bruno Ragazzon[1] & Jérôme Bertherat[1,2]
[1]Institut Cochin, Paris, France; [2]Hôpital Cochin, Paris, France; [3]NIH, Bethesda, Maryland, USA.

Introduction
ARMC5 germline and somatic inactivating mutations were discovered in patients treated by adrenalectomy for hypercortisolism due to primary bilateral macronodular adrenal hyperplasia (PBMAH). Since then, several *ARMC5* germline variants have been described in PBMAH patients. Genetic alterations are spread all over *ARMC5* coding sequence and many are missense variants. For them, geneticist conclusions are based on in silico predictions. As for now, no functional assay is routinely performed to study their pathogenic consequences. *ARMC5* is considered as a tumor suppressor gene with proapoptotic function. Our center performs routine germline *ARMC5* sequencing by next generation sequencing for patients all over the country. New missenses have been recently identified. We aimed to develop a functional test to confirm bioinformatics predictions.
Method
In a series of 352 French index cases, 10 new exonic missense variants, not classified as benign polymorphisms by SIFT® and Polyphen2® softwares have

been recently found. For *in vitro* analysis, constructs encoding the potentially pathogenic ones are made in a pIRES vector. Transfections are performed in HEK293 cells to study recombinant ARMC5 protein levels by western blot and cell apoptosis using AnnexinV and propidium iodide staining for flow cytometry (FACS) analysis. Loss of the proapoptotic function of ARMC5 was considered as a marker of mutant pathogenicity.
Results
Seven of these variants were predicted as deleterious or possibly damaging by both SIFT® and Polyphen2®; for the three others, the two softwares predictions were discordant and they were not described in exomes databases. The known variants Leu548Pro, p.Leu331Pro, p.Cys139Arg were previously selected for *in vitro* studies and compared with the predicted benign p.Phe14Tyr variant and wild-type ARMC5. Kinetic analysis were done to study cells apoptosis and ARMC5 protein levels in each condition at three different times between 10 and 16 h of transfection. Preliminary results for these damaging mutants showed decreased markers of apoptosis by FACS assay in comparison with the wild-type and the "benign" variant. Interestingly, the protein levels of the p.Leu548Pro, p.Leu331Pro and p.Cys139Arg "damaging" variants were higher at the longest transfection time than wild-type ARMC5 protein, consistent with more cell death in ARMC5 wild-type expressing cells. Method must be applied to the newly identified missense variants.
Perspective
This approach will help to demonstrate the pathogenicity of the missense variants found in PBMAH patients. This demonstration would be important along with in silico analysis to improve genetic conselling for PBMAH patients and their relatives.

MicroRNA expression profiling in adrenal myelolipoma, adrenocortical cancer and adrenocortical adenoma

Abel Decmann[1], Pal Perge[1], Gábor Nyírő[2], Otto Darvasi[3], István Likó[3], Katalin Borka[4], Tamás Micsik[5], Attila Patócs[3] & Péter Igaz[2,4]
[1]2nd Department of Medicine, Faculty of Medicine, Semmelweis University, Budapest, Hungary; [2]MTA-SE Molecular Medicine Research Group, Hungarian Academy of Sciences and Semmelweis University, Budapest, Hungary; [3]Hereditary Endocrine Tumors Research Group, Hungarian Academy of Sciences and Semmelweis University, Budapest, Hungary; [4]2nd Department of Pathology, Faculty of Medicine, Semmelweis University, Budapest, Hungary; [5]1st Department of Pathology and Experimental Cancer Research, Faculty of Medicine, Semmelweis University, Budapest, Hungary.

Background
Adrenal myelolipoma (AML) is a relatively common and invariably benign tumor composed of adipose tissue and hematopoietic elements. Due to the variable proportion of fat and hematopoietic elements, it is sometimes challenging to differentiate AML from adrenocortical carcinoma (ACC). MicroRNAs have been identified as promising biomarkers in many tumors, including adrenocortical neoplasms, but the microRNA expression of adrenal myelolipoma has not been investigated, yet.
Aims
To perform a large scale microRNA expression profiling in adrenal myelolipoma, benign and malignant adrenocortical tumors to identify potential microRNA biomarkers.
Methods
Next-generation sequencing (NGS) on 30 formalin-fixed paraffin-embedded archived tissue samples (discovery cohort: 10 adrenocortical adenoma (ACA), 10 ACC and 10 myelolipoma) was performed by Illumina MiSeq. Significantly differentially expressed microRNAs were validated by real-time RT-qPCR in an independent validation cohort comprised of 14 ACA, 15 myelolipoma and 12 ACC samples.
Results
We have found relative overexpression of miR- 451a, miR-486-5p, miR-363-3p and miR-150-5p in myelolipoma compared to the other two tumor groups by NGS. For ACC, we have found up-regulation of miR-184, miR-483-5p, miR-431-5p and miR-183-5p compared to myelolipoma and ACA. Validation by RT-qPCR, confirmed significant overexpression of miR-451a, miR-486-5p, miR-363-3p and miR-150-5p in myelolipomas relative to ACA and ACC, whereas significant overexpression of miR-184 was confirmed in ACC relative to the other 2 groups. The overexpression of miR-483-5p has not turned out to be significant in ACC relative to myelolipomas in the validation cohort.
Conclusions
Overexpressed miR-451a, miR-486-5p, mir-363-3p and miR-150-5p might be potential tissue markers of adrenal myelolipoma. The lack of significance in the expression of miR-483-5p between ACC and myelolipoma is remarkable, as miR-483-5p has been considered to be the best marker of adrenal malignancy to date.

Identification of a new target of *PRKAR1A* (Carney complex gene): KCTD20 (potassium channel tetramerization domain containing 20) and study of its role in adrenal Cushing

Bruno Ragazzonn[1], Bo Yu[1], Abdelghani Bouchekioua[1], Jerome Bertherat[1,2] & Marthe Rizk-Rabin[1]
[1]INSERM U1016, CNRS UMR8104, Paris Descartes University, Paris, France; [2]Department of Endocrinology, Center for Rare Adrenal Diseases, Hôpital Cochin, Paris, France.

Introduction
The inactivating mutations of the Carney complex gene *PRKAR1A* (regulatory subunit RIA of PKA) cause bilateral adrenocortical tumors (PPNAD: Primary Pigmented Nodular Adrenocorticel disease) over-secreting cortisol. This leads to stimulation of PKA activity, however the mechanisms of adrenal tumorigenesis and cortisol dysregulation are not fully understood. In order to identify target genes of PRKAR1A inactivation in adrenal cortex we undertook a comparative transcriptome analysis. This work aims to understand the role of the major identified target in cortisol dysregulation and PPNAD development.
Methods
Comparison of the transcriptome of PPNAD tissues, normal human adrenals, and H295R adrenal cortical cells with and without inactivation of *PRKAR1A* identified a main gene whose expression is decreased following *PRKAR1A* inactivation: KCTD20 (potassium channel tetramerization domain containing). The H295R and HEK293 cells were used to understand the transcriptional regulation of KCTD20 by PKA RIA and evaluate the consequences of the inactivation (siKCTD20) and the overexpression of KCTD20 (vector-KCTD20).
Results
The decreased KCTD20 expression after *PRKAR1A* inactivation is independent of PKA activity. Overexpression of KCTD20 increases apoptosis and decreases proliferation. Inactivation of KCTD20 protects against apoptosis ($P<0.01$), increases the activity of the Star-Luc reporter ($P<0.001$), the expression of the Star ($P=0.01$) and CYP11B1 genes ($P=0.05$), and cortisol production of H295R cells ($P<0.05$). These effects seem independent of PKA activity. Invalidation of KCTD20 results in membrane depolarization in response to KCL and increases intracellular calcium ($P<0.001$).
Conclusion
PKA RIA acts on KCTD20 via a PKA independent pathway. KCTD20 may play a role in adrenal Cushing by mechanisms independent of PKA activity. Its role in calcium signalling could be an important element to study.

Gene mutation analysis and overal survival among the patints with neuroendocrine tumors of the lung and gastroenteropancreatic neuroendocrine tumors

Darko Katalinic[1], Ivan Aleric[1], Aleksandar Vcev[1], Stephan Bildat[2] & Lilly Soerensen[3]
[1]Faculty of Medicine, J. J. Strosmayer University of Osijek, Osijek, Croatia; [2]Herford Teaching Hospital, Herford, Germany; [3]Department of Cancer Medicine, Oslo, Norway.

Introduction
Neuroendocrine tumors (NET) arise from tissue mucosal cells known as enterochromaffin cells. The clinical behavior of NET has been recognized over the past 30 years and genome analysis are needed for further follow up. Here we conduct integrated genome analyses on data from chromosomal gene copy number and transcriptome sequencing as well as analysis of overal survival of patients diagnosed with NET.
Material and methods
The study accrued 65 patients with NET over a period of 2 years, from 2015 to 2017. During the study period, 36 patients were diagnosed with early and advanced neuroendocrine tumors oft the lung (NETL) and 29 neuroendocrine tumors of the gastroenteropancreatic system (GEP-NET). Tumor-DNA were isolated from fresh-frozen tumour tissue. Whole-genome sequencing was performed using a read length of 2×100 bp. Survival analysis oft the subjects was performed using Kaplan–Meier and Cox regression methods.

Results
Although no significant focal copy number alterations were observed across the tumours analysed, we have detected a copy number pattern compatible with chromothripsis in a sample of carcinoid and pancreatic neuroendocrine tumors. The genomic aterations found in those samples were restricted to chromosomes 3 and 13, and led to the expression of several chimeric transcripts. Wide range of mutations ($n=346$) were identified in chromatin-remodelling genes such as MEN1 and ARID1A. Overal survival was generally good in both groop of subjects, especially in patients with early stage disease (T1-2N0M0: 2-year survival rates of between 88% and 96%). We have not found any relations between gene profile of MEN1 and ARID1A genes and overal survival in both groups of patients.
Conclusion
The overal prognosis of NETL and GEP-NET is much better than the other primary thoracic and abdominal malignancies and is strictly related to tumor classification and TNM stage. We propose a furter gene studies to identify and then confirm genetic predictors of survival in key molecular signaling pathways among patinets with NET. This raises exciting possibilities for treating this disease in the future.

GP40

Long term imaging follow-up of non-functioning adrenal adenomas at Vilnius University Hospital Santaros Klinikos (VUHSK): 2010–2017

Žydrūnė Visockienė[1,2], Kristina Švaikevičienė[1,2], Julius Trapikas[1], Valentinas Jakubkevičius[1], Greta Kazakevičiūtė[1] & Jogintė Anužytė[1]
[1]Vilnius University Faculty of Medicine, Vilnius, Lithuania; [2]Vilnius University Hospital Santaros Klinikos, Vilnius, Lithuania.

Background
Currently, the European Society of Endocrinology guidelines asserted against additional imaging during follow-up (FUP) in patients with non-functioning adrenal masses <4 cm in size with clear benign features on imaging studies. Our analysed literature data suggests that an increase (minimum 1 cm) in an initially benign adrenal mass during follow-up occurs in 3.5–20% of patients with adrenal incidentalomas.
Aim
To analyse the change in size of non-functioning adrenal masses detected by computerized tomography (CT) in patients who had FUP at VUHSK from 2010 to 2017.
Materials and methods
A retrospective single-center study of non-functioning adrenal masses was conducted. The following ICD-10 classification codes were used to retrieve cases from our database: D35.0; D44.1; C74.1; C74.9; E26.0; E27,8; E24,8. For the retrospective study of CT scans, electronic data capture system was applied. We considered significant increase as the growth in tumour size by more than 20% and a minimum 5 mm increase in largest diameter.
Results
1250 patients were assessed for adrenal masses from 2010 to 2017. Out of 1250 patients there were 302 subjects (24.16%) with adenomas and at least one FUP and obvious benign features on CT scan were seen, these 302 patients were included in the study. Mean age of study subjects were 65.4 years, 83.2% of them were female. The average tumour size at baseline was 21.5 ± 10.9 mm. Average follow-up (FUP) time was 3.16 years (from 2 to 8) during which tumour size increased in 123 (40,7%), decreased – in 105 (34,8%), did not change - in 74 (24,5%) of cases. Significant increase in tumour size was observed in 22 (7,3%) of cases. Average size of 22 significantly enlarged tumours changed from 19.0 ± 8.5 mm to 33.9 ± 14.9 mm during FUP. Significantly increased tumours were more common in younger age subjects. Subjects age during the tumour discovery: significantly increased 57.3 years (±10.1), insignificantly increased – 61.4 years (±10.5), stayed the same size – 62.6 years (±11.0), $P=0.02955$. None of the observed tumours became functioning during the observation period.
Conclusions
We have demonstrated a significant enlargement of initially benign non-secreting adrenal masses during 3.16 years FUP in 7.3% of cases and the association with younger age. Nevertheless, larger prospective studies with extended FUP are necessary to affirm the time-frame for suitable FUP schemes in order not to miss the significant enlargement of the adrenal mass that necessitate surgical procedures.

The need for depression screening in patients with adrenal incidentalomas and (possible) autonomous cortisol secretion – the role of integrated care

Ljiljana Marina[1,2], Miomira Ivovic[1,2], Milina Tancic-Gajic[1,2], Zorana Arizanovic[1], Antoan Stefan Sojat[2], Srdjan Pandurevic[2], Nevena Radonjic[3], Bojana Dunjic-Kostic[4], Andja Cirkovic[5], Aleksandra Kendereski[1,2], Dragan Micic[2] & Svetlana Vujovic[1,2]
[1]Clinic for Endocrinology, Diabetes and Metabolic Diseases, Clinical Centre of Serbia, Belgrade, Serbia; [2]Faculty of Medicine, University of Belgrade, Belgrade, Serbia; [3]Department of Psychiatry, University of Connecticut School of Medicine, Farmington, Connecticut, USA; [4]Institute of Psychiatry, Clinical Center of Serbia, Belgrade, Serbia; [5]Institute of Medical Statistics and Informatics, Belgrade, Serbia.

Hypercortisolism is associated with high prevalence of psychiatric disorders and major depression occurs in 50–60% of patients. According to the available literature it is still unknown if patients with (possible) autonomous cortisol secretion ((P)ACS) carry the risk of depressive disorders. The Beck Depression Inventory II (BDI-II) is a commonly used instrument for detecting and quantifying levels of depression and its validity as a screening instrument is well established. The aim of this study was to screen patients with adrenal incidentalomas (AI) – nonfunctional and the ones with (P)ACS, for presence of depression. The study was conducted in Clinic for endocrinology, diabetes and metabolic diseases, Belgrade, Serbia. The total studied group consisted of 72 patients: 40 AI patients (mean age 56.4 ± 7.3 years, mean body mass index (BMI) 28.9 ± 4.6 kg/m^2 and mean adrenal tumor size (ATS) 33.2 ± 9.8 mm) and age matched 32 healthy controls (HC)(mean age 57.6 ± 9.2 years, mean BMI 26.6 ± 4.4 kg/m^2). Based on levels of cortisol after 1 mg-dexamethasone suppression test AI patients were divided in two groups: <50 nmol/l, 17 with nonfunctional AI (NAI) and >50 mmol/l, 23 with ((P)ACS). BDI-II screening tool was used to assess presence of depression. The patients with AI had significantly higher BDI-II score when compared with HC: 19-mild vs. 9-minimal depression, $P=0.002$. In AI group, patients with (P)ACS had significantly higher BDI-II score when compared to NAI: 25-moderate vs. 11-minimal depression. Furthermore, there was a significant positive correlation between the BDI-II score and the levels of midnight cortisol ($\rho=0.527$, $P<0.001$), cortisol after 1mg dexamethasone suppression test ($\rho=0.594$, $P<0.001$) and the ATS ($\rho=0.362$, $P=0.02$). Patients with AI had significantly higher BMI than HC ($P=0.037$). In multivariate regression analysis with levels of midnight cortisol, BMI and ATS, midnight cortisol was the independent predictor of severe depression (OR 1.029, 95%CI OR 1.01–1.05, $P=0.01$). Our study shows that patients with (P)ACS exhibit high prevalence of moderate depressive symptoms. The significant and positive correlation of BDI score with ATS, levels of midnight cortisol and levels of cortisol after 1mg dexamethasone suppression test point to cortisol contribution to the etiology of depression. Our results suggest that patients with (P)ACS should be screened for depression and would benefit from integrated care with psychiatric team.

Pituitary adenoma and pheochromocytoma/paraganglioma: a multicausal association of tumors

Fernando Guerrero[1], Carmen Fajardo[2], Elena Torres Vela[3], Olga Giménez-Palop[4], Arturo Lisbona Gil[5], Tomas Martín[6], Natividad González[6], Juan José Díez[7], Pedro Iglesias[7] & Carles Villabona[1]
[1]Hospital Universitari de Bellvitge, Hospitalet de Llobregat, Spain; [2]Hospital Universitario de la Ribera, Valencia, Spain; [3]Hospital Universitario San Cecilio, Granada, Spain; [4]Hospital Universitari Parc Taulí, Sabadell, Spain; [5]Hospital Universitario Central de la Defensa, Madrid, Spain; [6]Hospital Universitario Virgen Macarena, Sevilla, Spain; [7]Hospital Universitario Ramón y Cajal, Madrid, Spain.

Background
Pituitary adenomas (PA) and pheochromocytomas/paragangliomas (PCC/PGL) are the main components of MEN1 and MEN2, respectively. Although the presence of both tumors (3P association, 3PAs) in the same patient could be as a result of coincidence, at least in some cases, a common pathogenic mechanism has been involved. Recently has been confirmed that germline mutations in genes coding succinate dehydrogenase (SDH) play a role in pituitary tumorigenesis. Furthermore, MEN1 germline mutations have also been identified in patients with 3PAs.

Aim
To report the clinical data, management outcome and genetic mutations found in a multicenter retrospective study of 10 patients with 3PAs.
Results
Six patients were female and 4 male. Mean age at diagnosis of the first tumor was 51.6 years (range 36–73). PA was firstly detected in 6 patients and PCC/PGL in 4 cases. Acromegaly was present in 6 cases (3 microadenomas). The remaining PA were prolactinoma (3 patients) and non-functioning PA (NFPA) in 1 patient. Regarding PCC/PGL, 7 patients had a single tumor (4 PCC and 3 PGL) and in 3 cases multiple or bilateral disease was diagnosed (2 PGL and 1 PCC). Patients with acromegaly and the patient with NFPA underwent surgery. Patients with prolactinomas received medical treatment with dopamine agonist and one case required surgery because of drug intolerance. Unilateral adrenalectomy was undergone in all single 4 PCC and a bilateral procedure was performed in the patient with a bilateral tumor. Single tumor was resected in two cases with PGL. In one of the patients with multiple PGL, the largest cervical mass was removed and in other patient the mediastinal tumor was unresectable because of close proximity to vascular structures. In all cases, genetic tests were implemented. In 4/10 patients genetic investigation was positive. We found SHDB (1p36) mutation in one patient, SDHB exon 1 delection in one patient, SDHD (P81L exon 3) mutation in one patient and 1 MEN1 mutation in a further patient. In the remaining 6 patients genetic tests performed were negative.
Conclusion
The 3PAs is a very uncommon event and recent data provides strong evidence that PA can develop in patients with germline SDH mutations. MEN1 germline mutations have also been related to these patients. Genetic testing should be considered in all patients with this tumor association.

[1]Department of Medical Genetics, Cambridge University, Cambridge, UK; [2]Department of Endocrinology, Cambridge University Hospital, Cambridge, UK; [3]Cancer Research UK Cambridge Institute, Cambridge, UK; [4]Department of Oncology, Cambridge University, Cambridge, UK; [5]Department of Histopathology, Cambridge University Hospital, Cambridge, UK; [6]Department of Medical Oncology, Cambridge University Hospital, Cambridge, UK; [7]Cancer Research UK Cambridge Institute, Cambridge, UK; [8]Department of Radiology, Cambridge University Hospital, Cambridge, UK.

Recent discoveries in mutations in TCA cycle enzymes; succinate dehydrogenase (SDH), fumarate hydratase (FH), iso-citrate dehydrogenase (IDH) and malate dehydrogenase MDH2, have reinforced the link between mitochondrial dysfunction and cancer[1]. Phaeochromocytoma and paraganglioma (PPGL) are now recognised to be the most heritable tumour, with 40%[1] having a genetic defect. Mutations in the *SDH* genes are the most frequently implicated genetic abnormality in hereditary PPGL and are also implicated in the development of wild type GIST tumours. The aim of this study was to evaluate the translational utility of *ex vivo* metabolomics profiling of PPGL and GIST tumours by HRMAS ^{1}H NMR spectroscopy. HRMAS ^{1}H NMR data acquisition was performed on 30 fresh frozen tumour samples (26 PPGL and 4 GIST). Absolute metabolite concentrations were estimated by fitting the metabolite signals in the water-suppressed HRMAS ^{1}H NMR spectrum in LCModel and using tissue water signal as internal standard for absolute concentration[2]. The lactate, glutamate and glycero-phosphocholine (GPC) concentrations were significantly lowered in *SDH* mutated tumours compared to wild type (WT) tumour tissues, whereas succinate was several folds higher in *SDH* mutated tumours tissues. A cut off of greater than 0.61 mmol/l was established to distinguish between *SDH* mutated tumours and wild type or other hereditary causes of PPGL, with a sensitivity of 95% and specificity of 100% on ROC curve analysis. Significantly lower lactate indicates down regulation of glycolysis in *SDH* mutated tumours compared to WT tumours. Lowered glutamate, aspartate and choline containing compounds (GPC and t-Choline) indicates reduced amino-acid and membrane phospholipid metabolism in *SDH* mutated tumours. These key differences in the metabolomic fingerprint of *SDH* mutated tumours suggests specific metabolic vulnerability and requires further investigation to determine if this vulnerability can be exposed for therapeutic intervention. One paraganglioma sample was detected to have 2 hydroxyglutarate (2HG) accumulation and subsequent genetic sequencing identified a somatic *IDH1 (R132C)* mutation in the PGL. Detection of succinate accumulation in a single wild type GIST tumour was relevant in determining the pathogenicity of a novel *SDHA* variant, identified in the germline of that patient.

Mortality in patients with Pheochromocytoma: a population-based study 1977–2016

Andreas Ladefoged Ebbehøj[1,2], Esben Søndergaard[1], Sarah Forslund Jacobsen[3], Christian Trolle[1], Maciej Grzegorz Robaczyk[4], Åse Krogh Rasmussen[3], Ulla Feldt-Rasmussen[3], Reimar Wernich Thomsen[5], Kirstine Stochholm[1] & Per Løgstrup Poulsen[1]
[1]Department of Endocrinology and Internal Medicine, Aarhus University Hospital, Aarhus, Denmark; [2]Institute of Clinical Medicine, Aarhus University, Aarhus, Denmark; [3]Department of Endocrinology, Rigshospitalet, Copenhagen, Denmark; [4]Department of Endocrinology, Aalborg University Hospital, Aalborg, Denmark; [5]Department of Clinical Epidemiology, Aarhus University Hospital, Aarhus, Denmark.

Background
Pheochromocytomas and catecholamine-secreting paragangliomas (PPGL) are rare catecholamine-producing tumors. Due to the rarity, limited data on prognosis exists and data are mainly from tertiary centers with potential referral bias. Here, we present population-based mortality data over an observation period of 40 years.
Materials and methods
We identified a cohort of 198 PPGL patients diagnosed 1 January 1977 to 31 December 2016 in North and Central Denmark (population 1.75 million). Data on tumor size, tumor location, surgery and recurrence were obtained from health records. Date of death or emigration was obtained from the Civil Registration System. Hazard rate-ratios (HRR) for death or tumor recurrence were calculated using Cox regression and adjusted for sex and age at diagnosis.
Results
Radically operated ($n=162$, 81.8%) patients (median age 52.0 years (Q1–Q3: 39.3–63.0)) had an overall 5- and 10-year survival after surgery of 90.8% (CI95%: 84.5–94.6) and 78.7% (CI95%: 69.8–85.2) and a recurrence-free 5- and 10-year survival of 87.0% (CI95%: 80.1–91.7) and 75.7% (CI95%: 66.7–82.7), respectively. HRR for death or recurrence was not associated with tumor size or with extra-adrenal location of tumor. Twelve (6.1%) PPGL patients did not undergo radical surgery as they either died before surgery ($n=2$), had disseminated disease ($n=4$), abstained from surgery ($n=4$) or since radical surgery was not technically possible ($n=2$). For these patients, median time from diagnosis to death was 5.3 years (Q1–Q3: 0.3–16.4). Twenty-four (12.1%) PPGL patients were diagnosed at autopsy. Based on autopsy reports, PPGL was regarded the underlying cause of death in 5 (20.8%) patients, a contributing cause in 14 (58.3%) patients and an incidental finding in 5 (20.8%) patients.
Conclusion
PPGL patients who undergo radical surgery have a good long-term prognosis with three-fourths of patients living more than ten years after surgery. Those who are not radically operated are a heterogeneous patient group with a relatively short life expectancy. This, combined with the fact that PPGL was considered a direct or contributing cause of death in many patients diagnosed at autopsy, underlines the importance of early diagnosis and treatment of PPGL.

Introduction
A substantial proportion of pheochromocytomas (PCC) are detected during the work-up of an adrenal incidentaloma. Recently it has been suggested that in case of an adrenal incidentaloma with an unenhanced attenuation value <10 Hounsfield Units (HU) on CT imaging biochemical testing to rule out PCC is unnecessary. We aimed to determine the sensitivity of the 10 HU cut-off value to detect pheochromocytoma.
Methods
Retrospective multicenter study with reassessment of preoperative unenhanced CT-scans performed in patients in whom a histopathologically proven PCC had been diagnosed from 2000 until 2017. Tumor characteristics including unenhanced attenuation values, were determined independently by two experienced radiologists. Sensitivity of the 10 HU threshold was calculated and interobserver consistency was assessed using the intraclass correlation coefficient (ICC). Data are provided as mean $+/-$SD or median with IQR, where appropriate.
Results
For this analysis 214 patients were identified harboring a total number of 222 PCC. Maximum tumor diameter was 51 [39–74] millimeter. The mean attenuation value in the transversal plane was 36 ± 10 HU. There was only one pheochromocytoma with an attenuation value <10 HU resulting in a sensitivity of 99.6% (95% CI: 97.5–99.9). ICC was 0.81 (95% CI: 0.75–0.86) with a standard error of measurement of 7.3 HU between radiologists.
Conclusion
The likelihood to encounter a PCC with an unenhanced attenuation value <10 HU on CT imaging is very low. This supports the recommendation to only perform biochemical testing to rule out pheochromocytoma in patients with an adrenal incidentaloma demonstrating unenhanced attenuation values >10 HU. The interobserver consistency in attenuation measurement is excellent.

Comparative study between incidental and symptomatic pheochromocytoma

Elisa Santacruz[1], Andrés Ortiz-Flores[1], Juan José Díez[1], Héctor Pian[2], Agustina P Marengo[3], Paula García-Sancho[3], Inmaculada Peiró[4], Carles Villabona[3] & Pedro Iglesias[1]
[1]Department of Endocrinology, Hospital Universitario Ramón y Cajal, Madrid, Spain; [2]Department of Pathology, Hospital Universitario Ramón y Cajal, Madrid, Spain; [3]Department of Endocrinology, Hospital Universitari Bellvitge, L'Hospitalet de Llobregat, Barcelona, Spain; [4]Clinical Nutrition Unit. Institut Català d'Oncologia, L'Hospitalet de Llobregat, Barcelona, Spain.

Introduction
The widespread use of abdominal computed tomography and magnetic resonance imaging has led to a rise in the diagnosis of incidental adrenal lesions, some of them are pheochromocytomas (Pheo).
Objective
To investigate the differences between incidental (IPheo) and symptomatic Pheo (SPheo).
Methods
A multicenter retrospective study on clinical and pathological characteristics, treatment and outcome in patients with Pheo followed up in neuroendocrinology units who underwent surgery between 1981 and 2016 was performed. The diagnosis of IPHeo was established when the adrenal lesion was discovered on a previous imaging study performed for an unrelated reason.
Results
Seventy-two patients with Pheo [44 SPheo (61%) and 28 IPheo (39%)] were studied. Age at diagnosis was significantly higher in IPheo than in SPheo patients [mean age 57 ± 13 year vs 49 ± 14 year; $P=0.018$]. There were no significant differences in sex distribution.The tumor was sporadic in 86% ($n=24$) of IPheo and in 80% ($n=35$) of SPheo (NS). The prevalence of hypertension at diagnosis was similar in both groups of patients [10 (35.7%) IPheo and in 18 (40.9%) SPheo, NS]. The 24-hour urinary fractionated metanephrines were less frequently elevated in IPheo than in SPheo patients (31% vs 70%, $P=0.024$). The elevation of 24-hour urinary catecholamines excretion was similar in both groups (78% vs 70%, NS). One patient (3.6%) had normal urinary catecholamines and metanephrines in IPheo group vs 3 (7.6%) in SPheo (NS). Complications during surgery were similar in both groups (15% in IPheo vs 29% in SPheo, NS). The tumor size was significantly lower in IPheo than in SPheo [4.9 ± 2.3 cm (range, 1.5–10) vs 6.4 ± 2.9 cm (range, 2.4–13), $P=0.037$]. There were no differences in both capsular and vascular invasion [5 (19%) IPHeo vs 7 (18%) SPheo, NS], as well as in the presence of necrosis [6 (24%) IPHeo vs 7 (19%) SPheo, NS], and recurrence rate between both groups. No patient had metastasic or persistant disease in IPheo group while 3 patients (6.8%) showed it in SPheo. One patient (3.6%) had recurrent disease in IPheo group vs 6 (13.6%) in SPheo (NS).
Conclusion
In our series IPheo affect older people and are smaller than SPheo. Urinary metanephrine are less frequently elevated in IPheo than in SPheo. Any incidental adrenal mass should be investigated for possible pheochromocytoma despite the absence of symptoms. Lastly, a normal hormonal study does not completely rule out the presence of a Pheo.

Identifying active steroids, steroid receptors and pathways in the normal breast and their potential relationship to obesity and cancer development

Keely McNamara[1], Ayako Kanai[1], Ju-Yeon Moon[2], Man-Ho Choi[2], Hironobu Sasano[1] & Kristy Brown[3]
[1]Tohoku University, Sendai, Japan; [2]KIST, Seoul, Republic of Korea; [3]Weill-Cornell Medicine, New York, USA.

Introduction
While a great degree of focus has recently been placed on identifying novel steroidogenic pathways that are active in cancer development (e.g. Androgen metabolism and Androgen Receptor (AR) Signalling, Glucocorticoid Metabolism and Glucocorticoid receptor (GR) signalling) very few studies have examined these pathways in normal breast samples taken under non-pathological conditions. Furthermore, very few studies have examined the steroid levels in non-pathological breast samples.
Methodology
To address this we examined the immunoreactivity of AR, GR and their related enzymes in forty paraffin embedded-formalin fixed samples taken from mammary reduction surgery. In parallel, we examined the levels of steroids via GC–MS/MS in distal to tumour, histological normal samples, taken during surgery for breast cancer in order to identify the steroids present in these samples and any changes between these and tumour levels of steroids.
Results
AR, 5αR1 and 17βHSD5 as well as GR, 11βHSD1 and 11βHSD2 were apparent in the lobules and ducts of normal breast tissues. In an initial analysis of a subset of the samples, both receptors were associated with their cognate enzymes, although these associations did not reach statistical significance. Most interestingly, GR expression was correlated with that of androgen-altering enzymes (<0.01, 5αR1 $R^2=0.33$ and 17βHSD5 $R^2=0.56$). As BMI is considered a potential risk factor in the development of breast cancer, we tested the correlation between BMI and the level of expression of GR and AR. This analysis showed that a higher BMI correlated with higher expression of AR ($P=0.04$, $R^2=0.23$). When analysing the levels of steroids present in histological normal, distal to cancer tissues we found that the most abundant sex steroid was DHEA with the following hierarchy of steroids DHEA$>$Adione$>$T$>$E2$>$DHT, and the two steroids that varied significantly between matched normal and cancer samples were E2 (increased in cancer) and Adione (decreased in cancer) suggesting the importance of localised metabolism of steroids.
Conclusions
Our data suggests the importance of intracrine conversion of steroids in the normal breast and the presence of complete (ligand, enzyme and receptor) significant intracrine pathways. It also suggests some linkage between obesity, a potential risk factor in breast cancer development, and expression of GR and AR in breast cancer tissues.

In vitro studies reveal a potential therapeutic role of the combination of biguanides and statins for the treatment of prostate cancer

Vicente Herrero-Aguayo[1,2,3,4], Juan M Jiménez-Vacas[1,2,3,4], Enrique Gómez-Gómez[1,3,5], Antonio J León-González[1,2,3,4], Prudencio Saéz-Martínez[1,2,3,4], Maria J Requena-Tapia[1,3,5], Manuel D Gahete[1,2,3,4], Justo P Castaño[1,2,3,4] & Raul M Luque[1,2,3,4]
[1]Maimonides Institute of Biomedical Research of Cordoba (IMIBIC), Cordoba, Spain; [2]Department of Cell Biology, Physiology and Immunology, University of Cordoba, Cordoba, Spain; [3]Reina Sofia University Hospital (HURS), Cordoba, Spain; [4]CIBER Physiopathology of Obesity and Nutrition (CIBERobn), Cordoba, Spain; [5]Urology Service, HURS/IMIBIC, Cordoba, Spain.

Prostate cancer (PCa) is the most common tumor pathology in men worldwide. The medical treatments currently used as first-line therapy after surgery are anti-androgens like abiraterone or enzalutamide, which, unfortunately, fail to stop the disease in a high percentage of cases, resulting in progression towards aggressive castration-resistant PCa. Therefore, new therapeutic tools to manage PCa are urgently needed. Biguanides and statins, two types of drugs commonly used in metabolism-related pathologies (i.e. type 2 diabetes, hypercholesterolemia and obesity) have been recently shown to exert antitumoral actions in several cancers. Here, we aimed to determine the antitumoral capacity of biguanides, statins and their combination in human PCa cells. To that end, different biguanides [metformin (5 mM), buformin and phenformin (1 mM)], statins [atorvastatin, simvastatin and lovastatin (10 μM)] and selected combinations were tested in PCa-derived cell-lines (22RV1, LNCaP, PC3 and DU145), in the normal prostate cell-line (RWPE-1), and in normal primary prostate cell-cultures obtained from healthy donors, by using different functional assays (i.e. cell proliferation, migration, tumorosphere formation, clonogenic assay, etc). Results revealed that all biguanides and statins reduced cell proliferation at 48- and 72-h in all the PCa cell lines tested (except statins in DU145 cells), being the effect of phenformin and simvastatin significantly higher compared with metformin/buformin and atorvastatin/lovastatin, respectively, in most of the PCa cell-lines. Interestingly, the combination of metformin with atorvastatin or simvastatin exerted a synergistic inhibitory effect on cell proliferation. Of note, the inhibitory effect caused by biguanides, statins or their combination in cell proliferation was significantly less pronounced in normal prostate cells (RWPE-1 and primary cell cultures) compared to that observed in PCa cell lines. In addition, metformin, simvastatin and its combination significantly reduced cell migration in all PCa cell-lines, being this effect additive when both compounds were co-administrated in LNCaP and DU145 cell-lines. Furthermore, the strong antitumoral effect of biguanides and statins observed in PCa cells was reinforced with the results showing that combined treatment with both compounds inhibited tumorosphere and colony formation. Altogether, our results revealed that biguanides and statins are able to reduce tumor aggressiveness *in vitro*, being this effect significantly higher when these compounds are combined, suggesting a potential therapeutic role of these compounds, especially their combination, for the treatment of PCa.

Targeted destruction of FSHR-positive cancer cells by a lytic Phor21-FSHb conjugate

Marcin Chruściel[1,2], Joanna Stelmaszewska[3], Milena Doroszko[1], Donata Ponikwicka-Tyszko[2], Jorma Toppari[1,4], Sławomir Wołczynski[3], Adam Ziecik[2], Ilpo Huhtaniemi[1,5] & Nafis Rahman[1,3]
[1]University of Turku, Turku, Finland; [2]Institute of Animal Reproduction and Food Research, Polish Academy of Sciences, Olsztyn, Poland; [3]Medical University of Bialystok, Białystok, Poland; [4]Turku University Hospital, Turku, Finland; [5]Imperial College London, London, UK.

Expression of the follicle-stimulating hormone receptor (FSHR) has been shown in gonads, gonadal tumors, and in endothelial tumor vessel cells of various cancers. We investigated the specificity and cytotoxicity of a fusion lytic peptide Phor21, conjugated to different FSHβ-chain fragments to ablate FSHR expressing cancer cells *in vitro* and *in vivo*. Cytotoxicity of 12 different Phor21-FSHβ conjugates was tested in HEK-293 cells, stably transfected with human FSHR cDNA (HEK293-FSHR) or mock-transfected HEK-293 cells used as FSHR-negative control cells. Phor21 linked to FSHβ33-53 fragment with cysteine (Cys) replaced by serine (Ser) (Phor21-FSHβ33-53C/S) displayed dose-dependently the highest specific cytotoxicity towards HEK293-FSHR cells vs. other compounds. Competitive studies with recombinant human FSH (rhFSH, 100 IU/l) significantly decreased the cytotoxicity of Phor21-FSHβ33-53C/S conjugate in HEK293-FSHR cells. *In vivo* Phor21-FSHβ33-53C/S treatment significantly inhibited the growth of HEK293-FSHR xenografts inducing necrosis. The efficacy of Phor21-FSHβ33-53C/S was enhanced by the GnRH antagonist cetrorelix (CTX) co-treatment. CTX alone displayed pro-apoptotic action. The growth of LNCaP cell xenografts, with previously reported FSHR-positive tumor vessel endothelial cells, was significantly inhibited by CTX, whereas Phor21-FSHβ33-53C/S showed no effect. We, therefore, revisited the expression of *Fshr* in LNCaP xenograft murine vessels. No *Fshr* transcripts in the endothelium of tumor vessel cells could be found. Our results emphasize the strong need to clarify the functional FSHR expression in the tumor vessel endothelial cells and different cancer cell lines. We proved the principle that the Phor21-FSHβ33-53C/S conjugate may provide a novel specific therapeutic lead into the targeted destruction of FSHR expressing cancer cells.

Evolution of mesenteric metastasis in small intestinal neuroendocrine tumours (SI-NETs)

Anela Blazevic, Wouter T Zandee, Johannes Hofland, Gaston JH Franssen, Marie-Louise F van Velthuysen, Tessa Brabander, Richard A Feelders & Wouter W de Herder
Erasmus MC, Rotterdam, The Netherlands.

Background
A metastatic mesenteric mass is a hallmark of small intestinal neuroendocrine tumours (SI-NETs). However, little is known about the evolution of a SI-NET-associated mesenteric mass over time.
Methods
Retrospectively, 530 patients with proven SI-NET and $\geq$2 available CT-scans were assessed for clinical characteristics at diagnosis and the presence and growth of a mesenteric mass on every consecutive CT-scan until end of follow-up or resection and in correlation with receiving Peptide Receptor Radionuclide Therapy (PRRT).
Results
A mesenteric mass was present in 64.2% of the patients of whom 13.5% showed growth of mesenteric mass according to RECIST 1.1. In patients without a mesenteric mass, only 2.6% showed growth of preexisting small nodule or development of new mesenteric mass. The median time to growth was 37.1 months. Independent predictors of growth were having a mesenteric mass (OR 8.14, 95% CI: 2.41–27.44, $P=0.001$) and male gender (OR 1.97, 95% CI: 1.03 – 3.75, $P=0.04$). Furthermore, of the patients treated with PRRT ($n=132$), only 4.4% had a reduction of their mesenteric mass according to RECIST 1.1.
Conclusion
Absence of a mesenteric mass at diagnosis of a SI-NET is associated with a low chance on development of a mesenteric mass over time. If present, we found that the hallmark dominant mesenteric mass in SI-NETs shows a highly inert behavior when assessed by RECIST 1.1 criteria and the only independent predictors of growth were having a mesenteric mass and male gender. Additional studies are needed to explore a possible role of sex steroids in the pathogenesis of SI-NET-associated mesenteric mass. Finally, shrinkage of the mesenteric mass after PRRT occurred in a small subset of patients, indicating a differential response to PRRT compared to other NET localizations.

Epidemiology and clinical significance of clinical hormonal syndromes in patients with neuroendocrine tumors

Bojana Popovic, Djuro Macut, Ivana Bozic Antic, Tamara Bogavac, Dusan Ilic, Tatjana Isailovic, Valentina Elezovic, Sanja Ognjanovic & Svetozar Damjanovic
Clinic for Endocrinology, Diabetes and Metabolic Diseases, Belgrade, Serbia.

Introduction
Hormonal syndromes are significant cause of morbidity in patients with neuroendocrine tumors (NET), requiring special treatment, rarely completely efficient. Effect on mortality is also presumed. Our aim was to investigate epidemiological characteristics of NET with hormonal production in our group of patients.
Patients and methods
We analyzed 822 patients with NET of various primary tumor sites, treated at our department during period of 2004–2017. Tumors were graded and staged according to pathohistological characteristics, and extent of dissemination. Hormonal analyses were done routinely according to clinical presentation. Immunohistochemical staining for specific hormonal products was performed in tumors with proven clinical syndrome, and in gastro-entero-pancreatic (GEP) NET irrespective of presence of clinical syndrome. Statistical analysis was done with SPSS software.
Results
A total of 155 patients (18.9%) had hormonal clinical syndrome in our group of patients with NET. Immunohistochemical positivity without clinical syndrome was verified in additional 63 patients with GEP NET, making it a total of 218 (26.5%) tumors producing some type of hormonal product. Serotonin production was most frequently detected (126 tumors, 15.3%), followed by insulin in 21 tumors (2.6%), gastrin in 20 tumors (2.4%), ACTH in 15 tumors (1.8%), somatostatin in 10 tumors (1.2%), and calcitonin in 8 tumors (1.0%). Less frequently, ghrelin, glucagon, GHRH, VIP, PTHrP and ADH production was detected (in less than 1.0% each). In 39 patients without carcinoid syndrome, serotonin immunopositivity was detected in tumor tissue. Conversely, 6 patients with clinical carcinoid syndrome stained negative for serotonin. Same was observed in about 50% of patients with clinical ectopic Cushing's syndrome. Only one patient immuno-positive for somatostatin actually presented with clinical syndrome. Hormonal clinical syndrome was most frequently present in patients with intestinal NET (47 patients, 30.3%), followed by pancreatic (46 patients, 29.7%), and lung NET (26 patients, 16.8%). Significant proportion consisted of tumors of unknown primary site (30 patients, 19.4%). Clinical syndrome was rarely present in poorly differentiated NET, only in 11 patients with grade 3 tumors. Overall survival in patients with hormonal syndromes was 126.0 months (95%CI 61.6–190.4), with 5-year survival of 62.5%. This was not significantly different when compared to non-functioning grade 1 and grade 2 NET ($P=0.929$). Only presence of Cushing's syndrome significantly affected survival (median 4.0 monhs, 95%CI 0.0–12.1)
Conclusion
Clinical hormonal syndrome in patients with NET has a significant impact on overall morbidity, but seems not to affect survival, except in case of ectopic Cushing's syndrome.

Online bots could help in prevention and treatment of osteoporosis

Vadim Krylov
Sechenov University, Moscow, Russian Federation.

Introduction
It is too much easier and cheaper to prevent a decrease a bone density and fractures, than in the future to treat osteoporosis and its complications.
Materials and methods
We used an online system for patient education based on the video lessons to convey the necessary information on good nutrition, necessary to do exercises and the need for exposure to the sun. Also we added individual online doctors management.
Study results
Watching the short movies, the patients formed the habits of good nutrition during the first month already, which includes a diet with restriction of fat, digestible carbohydrates and daily consumption of low-fat dairy products, slow carbohydrates, protein and fiber. Were also presented recommendations for compliance with the physical activity, as well as vitamin D and calcium consumption. Also we added individual online doctors management, which include everyday motivation and chatting with doctors 24 hours a day. We examined data from a survey of 520 patients registered in the online system www.rightdiet.ru and 50 patients control group who were given the same recommendations on the appointment and 67 patients with online management. Surprisingly, the consumption of milk and dairy products increased by 2.6 times, compared with patients in the control group and 3.4 in management group. The exposure to the sun was observed 15–30 min daily, compared with the control group 5 min. Regular physical activity were the main group of 260 min per week, in control group 80 min and 380 min in management group.
Conclusions
Very important how we can make delivery of the material. We live in a World of high technologies and lack of time. Often the patient has no opportunity to go to the doctor for an appointment, and during reception it is not always possible to discuss all aspects, and even if it was possible, some information is forgotten by patients. Everyday management group has better results because of increasing motivation and reminders. So, we would like to use online bots for everyday motivation and answer a simply questions to improve the quality and duration of life of more our patients.

Effect of inhaled corticosteroidson trabecular bone score in patients with asthma

Yong Jun Choi[1], Hyun Young Lee[2] & Young-Min Ye[2,3]
[1]Department of Endocrinology and Metabolism, Ajou University School of Medicine, Suwon, Republic of Korea; [2]Clinical Trial Center, Ajou University Medical center, Suwon, Republic of Korea; [3]Department of Allergy and Clinical Immunology, Ajou University School of Medicine, Suwon, Republic of Korea.

Background
In asthmatic patients, in addition to conventional risk factors for osteoporosis, inflammatory factors and treatment with corticosteroids may also lead them to further bone loss. The trabecular bone score (TBS) is a new indirect parameter of bone quality. There has been no study which evaluates TBS in asthmatic patients according to use of corticosteroids.
Objective
This study evaluated the TBS according to the severity of asthma and the correlation of TBS with steroid dose and the severity of asthma in patients with asthma.
Methods
This study had a cross-sectional design. Six hundred twenty-seven patients with asthma and the same number of non-asthmatic controls matched for gender and age were included in this study. The TBS was calculated in the lumbar region, based on two dimensional (2D) projections of dual-energy X-ray absorptiometry (DXA) assessments.
Results
Patients with severe active asthma exhibited a lower vertebral TBS than those with non-severe asthma, non-active asthma, and non-asthmatic subjects, whereas there were no significant differences in bone mineral density (BMD) among the study groups. TBS was significantly associated with the cumulative systemic steroid dose and high inhaled corticosteroids (ICSs) exposure over 3000 mg during previous 1 year, even after adjusting for confounding factors. TBS was also significantly correlated with FEV1/FVC and methacholine PC 20 suggesting that airway inflammation.
Conclusion
Severe active asthma patients exhibited a lower vertebral TBS regardless of age groups. TBS was significantly associated with the cumulative systemic steroid dose and high ICS exposure over 3000 mg of fluticasone equivalent dose, which was not correlated with BMD. TBS can be used for an early detector of the alterations in bone quality which are a consequence of glucocorticoid therapy or possibly the exacerbation of asthma.

Association between diabetes and the risk of falls: a nationwide population-based study

Se Hwa Kim[1], Yoo Mee Kim[1], Young Jun Won[1] & Soo Kyong Kim[2]
[1]Catholic Kwandong University College of Medicine, International St. Mary's Hospital, Incheon, Republic of Korea; [2]CHA University, CHA Bundang Medical Center, Seongnam, Republic of Korea.

Background
This study examined the associations between diabetes (DM) and falls in Korean using data from a large population-based survey.
Methods
This study analyzed 126 200 men and women (aged ≥50 years) who participated in Korean Community Health Survey in 2013. Logistic regression was used to assess the relationship between DM and falls.
Results
The mean (±S.D.) of age, and body mass index was 64.9±10.0 years and 23.2±2.9 kg/m^2. We identified 18,916 individuals with DM (91.6% with oral antidiabetics or no medication [DM-O], and 8.4% with insulin [DM-I]) and 107,284 individuals without DM. A total of 20 419 (19.0%) non-DM subjects, 3921 (22.6%) DM-O patients and 485 (30.6%) DM-I patients had histories of falls. After adjustment for potential confounders, the odd ratio (OR) for falls in DM-O group and DM-I group were 1.09 (95% CI: 1.03-1.16) and 1.76 (95% CI: 1.52–2.04) compared with non-DM group. Corresponding results for recurrent falls (≥2 times per year) in DM-O group and DM-I group were 1.15 (95% CI: 1.05–1.25) and 2.15 (95% CI: 1.77–2.62).
Conclusions
The risk of falls was increased in diabetes patients, particularly among those using insulin.

The influence of adipose tissue and bone marrow fat on bone mineral density in short bowel syndrome

Luciana Parreiras-e-Silva[1], Iana de Araújo[1], Carlos Salmon[2], Julio Marchini[1], Vivian Suen[1], Marcello Nogueira-Barbosa[1], Jorge Elias Jr[1] & Francisco de Paula[1]
[1]Ribeirao Preto Medical School, USP, Ribeirao Preto, Brazil; [2]FFCLRP, USP, Ribeirao Preto, Brazil.

Short bowel syndrome (SBS) is a complex disease, occurring after extensive resection of the small intestine, leading to malabsorption of nutrients and fluids. Lipids storage significantly affects bone maintenance. Caloric restriction promotes bone and adipose tissue (AT) loss but marrow adipose tissue (MAT) expansion. SBS is a condition strongly associated with malnutrition; patient survival initially depends of caloric replacement through parenteral nutrition (PN). The present study was designed to prospectively evaluate the association of subcutaneous (SAT), visceral (VAT), intra-hepatic lipids (IHLs) and MAT on bone mineral density (BMD) in SBS patients. Also, it was investigated the relationship between adipose tissue and bone markers [osteocalcin (OC) and C-terminal telopeptide of type I collagen (CTX)]. The study comprised two groups matched by age, sex and height: a) control group (CG) (n=18; 9M, 9F) and b) SBS group that was evaluated two times, (SBS0; n=14; 7M,7F) at 6.5 years after enterectomy and 1 year latter (SBS1; n=11; 6M, 5F). Magnetic resonance was used to measure AT (^{1}H spectroscopy for MAT). SBS group showed a non-significant decrease in BMD throughout the study, but BMD was lower in SBSG0 and SBS1 than in CG. IHLs were higher in SBS0 and SBS1 than in CG. CTX was lower in SIC0 comparing to CG (CG=0.36±0.19×SIC0=0.81±0.57). Values of MAT, SAT, VAT and OC were similar between groups throughout the study. MAT was negatively correlated with L3 BMD in the CG (r=-0.6; P<0.05), but not in the SBS group (SBS0 r=0.45; P=0.13; and SBS1 r=0.45; P=0.17). After adjustments by body mass index (BMI) and age, the association disappeared (R^2=0.09; P=0.91). IHL was negatively and significantly associated with femoral neck BMD (R^2=0.16; P<0.05) and total hip BMD (R^2=0.27; P<0.05). Moreover, IHL was positively and significantly associated with CTX (R^2=0.46; P<0.05). There was no association between MAT and CTX. Osteoporosis is a frequent complication in SBS patients. MAT amount is not increased and there is no negative relationship between MAT and BMD in SBS. Access to calories seems to positively affect the relationship between MAT and bone mass in malnutrition. The accumulation of IHLs negatively affects bone mass in SBS patients.

Kinesiotherapy rehabilitation program to correct deep core stability muscle dysfunction in patients with osteoporotic vertebral fractures

Ekaterina Makarova, Larisa Marchenkova & Michail Eryomushkin
FSBI National Medical Research Center of Rehabilitation and Balneology of Ministry of Health of Russian Federation, Moscow, Russian Federation.

Objective
The study is aimed to estimate the effectiveness of kinesiotherapy based on deep core stability muscles training in the program of rehabilitation in patients with osteoporotic vertebral fractures (VF).
Material and methods
Fourty-five patients (M-4, F-41) aged 43-81 (average age 62.75±12.5) with primary osteoporosis and at least one non-traumatic VF were included in the study. The rehabilitation program focused on training of deep core stability back muscles and consisted of 4 kinesiotherapy methods (Dr Wolff and CBS simulators, kinesiohydrotherapy in the pool and complex physical exercises by Gorinevskaya-Dreving) was prescribed for 21 days to all patients. Isometric core strength test (Back-Check, Dr Wolff, Germany) was performed at baseline, at the end of the rehabilitation treatment and after 21 day past all training at follow-up visit.
Results
At baseline relative flexion strength (REL FS), relative extension strength (REL ES), left lateral flexion strength (LLAT FS), right lateral flexion strength (RLAT FS) were lower than recommended indexes: 113.01±34.03% of 150% (P=0.001), 75±12.78% of 100% (P=0.006), 85±12.78% (P=0.04) and 79.73±9.2% of 100% (P=0.003) accordingly. Ratio relative flexion/extension strength (FLE:EXT S) also was in imbalance in 38 of 45 patients. Lateral flexion ratio (LLAT:RLAT FS) showed imbalance only in 6 patients. The all isometric core strength test indexes improved significantly: REL FS up to 132.57±47.08% (P=0.0001), REL ES up to 86.45±9.4% (P=0.03), LLAT FS up to 90.7±9.55% (P=0.07), RLAT FS up to 89.4±2.5% (p=0.03) after the rehabilitation course. The muscle strengths stay better than the baseline indexes at the follow-up measurement: REL FS =121.5±39.9% (P=0.002), REL ES =79.78±10.5% (P=0.02), LLAT FS =87.1±11.07% (P=0.06), RLAT FS =80.14±8.62% (P=0.09).
Conclusions
The basic dysfunction of deep core muscles and disbalance flexion/extension strength in osteoporotic patients with VF were estimated. Rehabilitation program using kinesiotherapy in patients with VF showed the high prolong effect on improving back muscle strength.

Investigating glucocorticoids as mediators of increased bone marrow adiposity during caloric restriction

Andrea Lovdel[1], Karla Suchacki[1], Richard J Sulston[1], Robert J Wallace[2], Gavin Macpherson[3], Roland H Stimson[1], Natalie ZM Homer[1], Karen E Chapman[1] & William P Cawthorn[1]
[1]University/BHF Centre for Cardiovascular Science, The Queen's Medical Research Institute, University of Edinburgh, Edinburgh, UK; [2]Department of Orthopaedics, University of Edinburgh, Edinburgh, UK; [3]Department of Orthopaedic Surgery, Royal Infirmary of Edinburgh, Edinburgh, UK.

Background
Bone marrow adipose tissue (BMAT) comprises >10% of total adipose mass in healthy humans and further increases in diverse clinical conditions, including obesity/diabetes, osteoporosis and following caloric restriction (CR). However, why BMAT increases during CR remains unknown. One possibility is that this is mediated by glucocorticoid (GC) excess**.** GC action on target tissues depends on circulating and intracellular concentrations of the active hormone (cortisol in humans; corticosterone in rats/mice). Most effects of endogenous glucocorticoid excess are mediated by 11b-hydroxysteroid dehydrogenase type 1 (11b-HSD1), which catalyses intracellular regeneration of active glucocorticoids from inert 11-keto forms. CR increases circulating GCs, and GC therapy increases BMAT; thus, *we hypothesise that GC excess mediates BMAT expansion during CR.*
Objectives
Determine 1) if bone marrow expresses 11b-HSD1; 2) if CR increases GC activity within bones; and 3) if ablation of 11b-HSD1 blocks CR-induced BMAT expansion.

Methods
1) *HSD11B1* mRNA was measured in bone marrow from hip-replacement patients. 2&3) Male and female C57BL/6J mice lacking *11b-HSD1* ($Hsd11b1^{Del1/Del1}$) or littermate controls (WT) were fed *ad libitum* (AL) or 70% of AL intake (CR) from 9 to 15 weeks of age and skeletal GC target gene expression determined. Body mass, composition, and plasma were measured weekly. At 15 weeks mice were euthanised. Plasma corticosterone and 11-dehydrocorticosterone were measured by ELISA or LC–MS/MS. Bone loss (calcified bones) and BMAT (*decalcified, osmium-tetroxide-stained bones*) were measured by micro-computed tomography.
Results
1&2) 11b-HSD1 was expressed in bones and marrow of mice and humans. CR in mice increased expression of GC target genes in bone, suggesting increased GC action. 3) In WT and $Hsd11b1^{Del1/Del1}$ mice, CR decreased body and lean mass and increased circulating corticosterone. Consistent with previous studies, in both genotypes CR decreased fat mass only in male mice. Circulating 11-dehydrocorticosterone was significantly greater in AL and CR $Hsd11b1^{Del1/Del1}$ mice than WT controls. While CR-induced bone loss was negligible, CR-induced BMAT expansion occurred in females of both genotypes and in WT males, but not $Hsd11b1^{Del1/Del1}$ male mice.
Conclusions
CR increases GC action within bones; BMAT expansion is not sufficient for bone loss; and intracellular GC activation by 11b-HSD1 is required for CR-induced BMAT expansion in male, but not female mice. These findings highlight glucocorticoids as potential mediators of BMAT formation and identify novel sex-dependent differences in the skeletal and metabolic adaptations to caloric restriction.

Thirty-one men and women with145 spontaneous vertebral fractures after denosumab discontinuation: a single center observational study

Gonzalez Rodriguez Elena[1,2], Delphine St[2], Bérengère Aubry-Rozier[2] & Lamy Olivier[2,3]
[1]Service of Endocrinology, Diabetes and Metabolism, CHUV, Lausanne, Switzerland; [2]Center of Bone Diseases, CHUV, Lausanne, Switzerland; [3]Service of Internal Medicine, CHUV, Lausanne, Switzerland.

Denosumab discontinuation (DD) induces an increase of B-crosslaps above baseline values for two years, and a decrease of BMD values. This rebound effect is associated with spontaneous clinical vertebral fractures (SCVF) in close to 15% of patients considering a follow-up of 2 years without taking another osteoporosis treatment. We report the clinical characteristics of 31 patients evaluated at our center from July 2015 to January 2018.
Results
Thirty women and one man, 62.8 ± 10.1 years, experienced 145 SCVF (median 5) in the 11.7 ± 3.0 months (median 11; min 7, max 20) following the last denosumab injection. They received 6.4 ± 2.7 denosumab injection (min 2; max 11). Ten women had vertebroplasties with 22 new SCVF in the following days. Nine women received aromatase-inhibitors (AI) with denosumab. Eight women had prevalent VF, five received bisphosphonate before denosumab. The mean B-crosslaps value at the time of SCVF was 1511 ± 573 µg/l; B-crosslaps values increase with the number of denosumab doses ($P = 0.05$) and decrease with age ($P < 0.01$). The number of SCVF was inversely associated with age ($P < 0.004$). Before the vertebroplasty, the mean number of SCVF was 5.1 ± 3.0 vs 2.3 ± 1.5 in women <65 vs >65 years. The delay between DD and the occurrence of SCVF increases with age: 10.6 ± 1.6 vs 13.3 ± 3.8 months, before vs after 65 years ($P < 0.01$). The mean reasons for DD were: end of AI or no more osteoporosis (15), omission (7), patient's wish (5), AFF or dental intervention (4).
Conclusion
The SCVF are a very severe and frequent clinical complication occurring after DD. A close follow-up during 2 years post DD is necessary. Studies are urgently needed to better define the place of denosumab in osteoporosis treatment, and the strategies to avoid these side effects.

Effects of anti-osteoporotic medications on glucose metabolism and the incidence of type 2 diabetes mellitus: a systematic review

Panagiotis Anagnostis[1], Stavroula Paschou[2], Anastasia Dede[3], Andromachi Vryonidou[4], Daniel Morganstein[3] & Dimitrios Goulis[1]
[1]Unit of Reproductive Endocrinology, First Department of Obstetrics and Gynecology, Medical School, Aristotle University of Thessaloniki, Thessaloniki, Greece; [2]Division of Endocrinology and Diabetes, "Aghia Sophia" Hospital, Medical School, National and Kapodistrian University of Athens, Athens, Greece; [3]Department of Endocrinology and Diabetes, Chelsea and Westminster Hospital, London, UK; [4]Department of Endocrinology and Diabetes, Hellenic Red Cross Hospital, Athens, Greece.

Introduction
Type 2 diabetes mellitus (T2DM) and osteoporosis may co-exist in the same individual. However, the exact effect of anti-osteoporotic treatment on glucose metabolism is unknown. We aimed to systematically review the effects of anti-osteoporotic medications on glucose metabolism and the incidence of T2DM.
Methods/design
PubMed, Cochrane and EMBASE were systematically searched until the 31 of December, 2017.
Results
Bisphosphonates ($n = 2$): One retrospective cohort study ($n = 35\,998$, follow-up: 42 months) showed a significant reduction in T2DM risk in individuals exposed to bisphosphonates, compared with age-, sex- and body mass index (BMI)-matched controls. The other retrospective cohort study ($n = 23\,976$) did not show any significant effect (follow-up: 4.2 years).
Alendronate ($n = 3$): In one randomized placebo-controlled trial (RCT), no difference in fasting plasma glucose (FPG) concentrations or T2DM incidence was observed between postmenopausal women assigned to alendronate ($n = 3084$) or placebo ($n = 3067$), after four years. In one retrospective case-control ($n = 1011$) and one cohort study ($n = 55\,090$), patients exposed to alendronate showed a reduced incidence of T2DM, compared with no treatment (mean time of exposure: 3.8 years).
Zoledronic acid ($n = 2$): One RCT ($n = 3537$, follow-up: four years) and one prospective study ($n = 24$, follow-up: 1 year) did not show any effect on glucose metabolism in non-diabetic osteoporotic postmenopausal women.
Denosumab ($n = 3$): One RCT ($n = 3535$, follow-up: three years) and two prospective studies ($n = 38$ and $n = 14$, follow-up: 24 and 12 weeks, respectively) did not show any effect on FPG or T2DM incidence.
Teriparatide ($n = 3$): One study ($n = 23$) showed an increase in FPG and insulin resistance (IR), after six months of treatment. Two other prospective studies ($n = 14$ and $n = 25$) did not show any effect.
Strontium ranelate ($n = 1$): One study ($n = 40$, follow-up: 12 months) did not show any effect on FPG.
Raloxifene ($n = 17$). Only one prospective study in T2DM ($n = 37$, follow-up: six months) showed a decrease in HbA1c levels. Two RCTs in non-diabetic patients ($n = 44$ and $n = 30$, follow-up: two and six months, respectively) showed a decrease in FPG and IR.
Bazedoxifene ($n = 1$): One prospective study ($n = 20$) did not show any effect in T2DM patients, regarding FPG or IR after 12 weeks of treatment.
Conclusions
Bisphosphonates and raloxifene exert either neutral or beneficial effects on glucose metabolism. Neutral or detrimental effects have been reported for teriparatide. Neutral effects have been also observed with denosumab, basedoxifene and strontium ranelate, although these data derive mainly from small prospective studies of short duration. The reduction in T2DM risk with bisphosphonates warrants further investigation.

Bone structural components and lean mass assessed by 3D-DXA in hip fracture patients

Luis Del Rio[1], Silvana Di Gregorio[1], Ludovic Humbert[2], Patricia Sanchez Ortuño[1] & Renaud Winzenrieth[2]
[1]CETIR Centre Medic, Barcelona, Spain; [2]Galgo Medical, Barcelona, Spain.

Bone mass, macrostructure and lean mass are being identified as main contributors of strength of upper femur. The purpose of this study has been to assess the role of the cortical and trabecular bone as well as muscle mass in the hip fracture production. We used a new DXA application which allow 3D bone volume reconstruction from standard 2D DXA scans, providing a three dimensional approach of the femoral shape and bone density spatial distribution and measurement cortical thickness. The purpose of this study was to analyze these measurements in a cohort of elderly patients suffering a recent hip fracture.

Methods
A prospective study was carried out to collect scans from 96 patients of both sexes, older of 75 years, who have suffered a hip fracture indoor in a shorter interval of 2 weeks. None of the patients had osteoporotic fracture history at baseline. 3D-DXA technology in an early version (Galgo Medical S.L; Barcelona, Spain) was used to obtain patient-specific models from the 2D-DXA scans performed in the opposite femur (iDXA model GE Healthcare). The 3D-DXA algorithm made the registration of a 3D appearance model incorporating statistical information about the femoral shape and density onto the 2D DXA image. From the resulting patient-specific models the volumetric BMD can be automatically quantified as well as the volume (for trabecular and cortical regions) and cortical thickness distribution. Also, a total body scan was performed in these patients for body composition analysis purpose. The parameters were compared with reference values obtained on age and sex matched healthy volunteers and also on young people of same sex.
Results
A 47.1% of these patients were classified as osteoporotic using the WHO criteria. The femur of the patients suffering hip fracture show a significant less vBMD and BMC in cortical and trabecular bone ($P > 0{,}001$). The average cortical thickness was also lower for fracture group (1.49 mm) than for sex and age-matched references (1.63 mm, $P < 0.001$). This difference was bigger (26%) at the antero-superior radiant of femoral neck. The limb lean mass had a good correlation with all the bone parameters (r2: 0.218–0.375). Trabecular bone parameters (vBMD, BMC) were the most deviated from reference values.
Conclusion
Both trabecular as well as cortical bone assessed by 3D-DXA are decreased in patients suffering hip fracture.

Inflammatory profile in monocytes of patients with Addison's disease and Vitamin D effects

Anna Kraus, Marissa Penna-Martinez, Gesine Meyer & Klaus Badenhoop
Department of Internal Medicine I, Division of Endocrinology, Diabetes and Metabolism, University Hospital Frankfurt am Main, Frankfurt am Main, Germany.

Introduction
Vitamin D (VD) deficiency affects many autoimmune disorders requiring steroid therapy. In contrast to glucocorticoid immune suppressive doses for autoimmune diseases, patients with Addison's disease (AD) require physiological replacement. There is growing evidence of a cross-talk between glucocorticoids (GC) and VD. However, VD's interaction with the GC pathway remains poorly understood.
Methods
To explore this issue, $CD14^+$ monocytes were obtained from 15 Addison patients and 30 healthy controls (HC). Cells were stimulated with VD and/or IL1β as an inflammatory stimulant for 24 h. To address inflammatory responses, gene expression levels of anti-inflammatory interleukin 10 (IL-10), programmed cell death ligand 1 (PD-L1) and VD receptor (VDR) were analyzed by qPCR and normalized to endogenous reference 18sRNA.
Results
The mRNA expression of IL1β-induced VDR was reduced after VD addition in AD patients and HC ($AD_{IL1\beta/IL1\beta+VD}$ 343 vs 205, $P = 10^{-4}$; $HC_{IL1\beta/IL1\beta+VD}$ 307 vs 213, $P = 2\times10^{-4}$). IL-10 expression in AD patients showed a higher expression compared to HC in the culture conditions (untreated, IL1β, VD) and baseline $CD14^+$ monocytes (Baseline $P = 0.05$, untreated $P = 0.03$, IL1β $P = 0.0007$, VD $P = 0.007$). No difference of IL-10 expression between HC and AD was observed in IL1β + VD culture condition ($P = 0.4$). However, HC showed a strong activation of IL-10 expression after VD addition in IL1β-treated monocytes, whereas no activation of IL-10 could be observed after VD addition in IL1β-stimulated monocytes in AD patients ($AD_{IL1\beta/IL1\beta+VD}$ 134 vs 126, $P = 0.7$, $HC_{IL1\beta/IL1\beta+VD}$ 76 vs 126, $P = 2\times10^{-5}$). PD-L1 expression did not differ from HC, however, it increased after VD addition in IL1β-stimulated monocytes in HC, but only marginally in AD ($AD_{IL1\beta/IL1\beta+VD}$ 12 vs 14, $P = 0.06$, $HC_{IL1\beta/IL1\beta+VD}$ 16 vs 23, $P = 0.006$).
Conclusion
VD-induced downregulation of VDR implies a functional feedback mechanism of VDR, indicating a normal paracrine cellular regulation of VD in both AD patients and HC. Regarding anti-inflammatory parameters we showed an increased IL-10 expression in AD patients, which could be explained by their GC replacement therapy that may affect the immune response more than the endogenous cortisol of healthy individuals. Furthermore, the observation that anti-inflammatory cytokines IL-10 and PD-L1 do not respond to VD stimulation in AD patients may indicate a cross-inhibition of VD and GC potentially leading to an attenuation of the inflammatory response.

OCT1 gene variants are associated with cardiovascular characteristics in non-diabetic, prediabetic and diabetic patients

Natascha Schweighofer[1,2], Christoph Haudum[1,2], Albrecht Schmidt[3], Caterina Raffaela Colantonio[4], Ines Mursic[3], Thomas R Pieber[1,2] & Barbara Obermayer-Pietsch[1,2]
[1]Department of Internal Medicine, Division of Endocrinology and Diabetology, Medical University of Graz, Graz, Austria; [2]CBmed GmbH, Center for Biomarker Research in Medicine, Graz, Austria; [3]Department of Internal Medicine, Division of Cardiology, Medical University of Graz, Graz, Austria; [4]Department of Internal Medicine, Division of Cardiology, Graz, Austria.

Type 2 diabetes (T2DM) patients are at high risk for vascular complications. Some of them have even a higher risk during metformin therapy, as we have recently shown by associations of polymorphisms in the Oct1 gene with a therapy-dependent increased risk of cardiovascular death. In this study, we investigated whether Oct1 gene variants were associated with cardiovascular characteristics such as pulse wave velocity (PWV), echocardiographic parameters and intima/media thickness (IMT) in non-diabetic, prediabetic and T2DM patients at cardiovascular risk. Data from the BioPersMed cohort ($n = 1025$), a prospective cohort study of asymptomatic patients at cardiovascular risk, were analysed. T2DM, prediabetes and absence of diabetes (non-diabetics) were defined according to ADA criteria. Determination of Oct1 genotypes was done by GSA array (Illumina Inc., USA), pulse wave analysis by a SphygmoCor device (Atcor Medical, Australia), and carotid intima/media thickness as well as echocardiographic measurements were performed using the Vivid 9 device (GE Healthcare Austria GmbH & Co OG, Austria). In a preliminary analysis, we focused on associations with score systems for cardiovascular risk (PROCAM and Framingham), as well as PWV and IMT. An association with the Framingham score was found for SNPs rs35888596 ($P = 0.012$) and for rs112476023 ($P = 0.015$) in nondiabetics and for rs461473 ($P = 0.018$) and rs806383 ($P = 0.03$) in prediabetics. PROCAM score was associated in non-diabetics with rs112476023 ($P = 0.023$) and in T2DM with rs662138 ($P = 0.045$). A significant association with PWV was seen for rs12208357 ($P = 0.02$) in non-diabetics, for rs12208357 ($P = 0.009$) in prediabetics and for rs662138 ($P = 0.034$) in T2DM. Associations with IMT were documented in T2DM for rs806383 ($P = 0.034$), rs2197296 ($P = 0.027$), rs622342 ($P = 0.008$), as well as for rs662138 ($P = 0.030$), in prediabetics for rs34130495 ($P = 0.048$) and rs622342 ($P = 0.049$) and in T2DM for rs2282142 ($P = 0.008$), rs2282143 ($P = 0.009$) and rs112476023 ($P = 0.019$). According to these associations, several variants in the OCT1 gene might play a consistent role in the modulation of vascular properties and concomitant cardiovascular characteristics and thus contribute to an increased cardiovascular risk even beyond the occurrence of diabetes or therapy options.

Habitual dietary intake of n-3 polyunsaturated fatty acids and leptin gene expression in visceral and subcutaneous adipose tissues of non-diabetic adults

Emad Yuzbashian[1], Maryam Zarkesh[2], Golaleh Asghari[1], Parvin Mirmiran[1], Mehdi Hedayati[2] & Alireza Khalaj[3]
[1]Nutrition and Endocrine Research Center, Research Institute for Endocrine Sciences, Shahid Beheshti University of Medical Sciences, Tehran, Islamic Republic of Iran; [2]Cellular and Molecular Endocrine Research Center, Research Institute for Endocrine Sciences, Shahid Beheshti University of Medical Sciences, Tehran, Islamic Republic of Iran; [3]Tehran Obesity Treatment Center, Department of Surgery, Shahed University, Tehran, Islamic Republic of Iran.

Introduction and aim
Leptin is a hormone that mainly expressed and secreted in adipose tissues and has a number of important effects on regulation of body weight, energy expenditure, and thermogenesis. High intake of n-3 polyunsaturated fatty acids (PUFA) promotes reduced plasma concentration of triacylglycerol, glycerol, and free fatty acids, as well as metabolism of the epididymis. The aim of current study was to examine the association of n-3PUFA on leptin gene expression in visceral and subcutaneous adipose tissue of adults.
Methods
We gathered visceral and subcutaneous adipose tissues during an elective abdominal surgery which have minimal impact on dietary intake form 98 participants aged >19 who were free of diabetes and cancers and without using anti-lipid medication. Before the surgery, a reliable and validated semi-quantitative food frequency questionnaire was completed to assess habitual dietary intake of n-3 PUFA, α-linolenic acid ALA), eicosapentaenoic acid (EPA), and docosahexaenoic acid (DHA). Dietary exposures were adjusted for energy by using the residual method. The mRNA expressions of leptin gene in both adipose tissues measured by SYBER-Green real-time quantitative PCR. Multivariable linear regression was performed to assess the association of dietary n-3 PUFA with leptin gene expression. All models were adjusted for age, body mass index(BMI), insulin, and physical activity.
Results
The mean age of participants was 41.6 years and BMI was 33.6 kg/m^2. Median intake of n-3 PUFA in our study was 2.44 g/day which corresponded to 0.88% of total energy intakes. In visceral fat, leptin mRNA levels were significantly higher compared with subcutaneous adipose tissue. After controlling for confounders, usual intake of dietary n-3 PUFA was negatively associated with leptin gene expression in subcutaneous ($\beta=-0.523$, $P<0.001$) and visceral ($\beta=-0.780$, $P<0.001$) adipose tissues. Moreover, we found a significant inverse association of dietary intake of ALA ($\beta=-0.695$, $P<0.001$) and DHA ($\beta=-0.471$, $P=0.009$) with leptin gene expression in visceral adipose tissue. There was no significant association between leptin gene expression and EPA intake.
Conclusion
The current study illustrated that higher usual dietary n-3 PUFA were negatively associated with leptin gene expression in both adipose tissues independent of BMI, age, insulin, and physical activity. In addition, DHA and ALA had a relationship with leptin mRNA expression, especially in visceral adipose tissue. It seems that habitual intake of n-3 PUFA might affect adipose tissue metabolism through modifying leptin gene expression.

Decreased heart rate variability can predict future development of metabolic syndrome in Asian adults

Da Young Lee[1], Ji Hee Yu[1], Hyemi Kwon[2], Eun-Jung Rhee[2], Cheol-Young Park[2], Ki-Won Oh[2], Sung-Woo Park[2], Won-Young Lee[2] & Se Eun Park[2]
[1]Korea University College of Medicine, Seoul, Republic of Korea; [2]Kangbuk Samsung Hospital, Sungkyunkwan University School of Medicine, Seoul, Republic of Korea.

Introduction
This study aimed to examine whether altered Heart Rate Variability (HRV) could predict the risk of development of metabolic syndrome (MetSD) in Asians.
Methods
We investigated health checkup records of 33 752 adults aged 20–65 years old who did health checkups and HRV measurement between April 2011 and June 2014 at Kangbuk Samsung Hospital, without MetSD, anemia, thyroid disease, malignancy, and heart disease. A 3-minute HRV recording was performed while seating on a chair. We analyzed HRV in time domain (standard deviation of the normal-to-normal interval [SDNN, ms], root mean square difference [RMSSD, ms]), and frequency domain (total power [TP, 0–0.4 Hz, ms^2], very low-frequency [VLF, $\leq$0.04 Hz, ms^2], low-frequency [LF, 0.04–0.15 Hz, ms^2], high-frequency [HF, 0.15–0.4 Hz, ms^2] power, normalized LF, normalized HF, and LF : HF ratio). We compared the risk of incident MetSD between 2012 and 2016 using multivariate Cox analysis according to tertiles of HRV variables with tertile 1 as reference group. MetSD was determined by the presence of three or more of waist circumference $\geq$90 cm in men or $\geq$85 cm in women, fasting glucose $\geq$100 mg/dl or use of an anti-glycemic agent, triglyceride >150 mg/dl or use of an antihyperlipidemic agent, high-density lipoprotein-cholesterol <50 mg/dl in men, <40 mg/dl in women or use of an anti-hyperlipidemic agent, and blood pressure $\geq$130/85 mmHg or use of an antihypertensive drug.
Results
Mean age of subjects were 37.8$\pm$5.7 years. During 40 324 033 person-years, 4061 subjects were diagnosed with MetSD. Most of time and frequency domain variables were lower in MetSD group than nonMetSD group, whereas LF norm and LF/HF ratio were higher. In cox analysis, the risk of development of MetSD was significantly decreased as SDNN, RMSSD, TP, VLF, LF, HF, and HF norm tertiles increased. In case of LF norm and LF/HF ratio, positive relationship was observed. These tendencies were maintained in RMSSD, LF, and HF after adjustment for age, sex, body mass index, current smoking, systolic blood pressure, serum low-density lipoprotein-cholesterol, high sensitivity c-reactive protein, and glucose levels as confounders. Hazard ratios(95% confidence intervals) of tertile 3 were 0.83(0.76–0.91) for RMSSD, 0.92(0.85–0.99) for LF, and 0.90(0.82–0.98) for HF.
Conclusion
Decreased HRV can anticipate the risk of incident MetSD in young Asian adults.

Evaluation of irisin levels in chronic heart failure with preserved or reduced ejection fraction

Antonio Mancini[1], Andrea Silvestrini[2], Carmine Bruno[1], Edoardo Vergani[1], Alessandro Brunetti[1], Angela Maria Rita Favuzzi[3], Francesco Guidi[4], Elisabetta Meucci[2] & Alvaro Mordente[2]
[1]Internal Medicine Department, Division of Endocrinology, Catholic University of the Sacred Heart, Rome, Italy; [2]Institute of Biochemistry and Clinical Biochemistry, Catholic University of the Sacred Heart, Rome, Italy; [3]Internal Medicine Department, Division of Internal Medicine and Cardiovascular Diseases, Rome, Italy; [4]Institute of Obstetrics and Gynaecology, Catholic University of the Sacred Heart, Rome, Italy.

Background
The recently discovered myokin Irisin, a peptide originated by a proteolytic cleavage of the transmembrane protein fibronectin type III domain containing 5 (FNDC5) whose expression is induced by exercise and/or by increasing peroxisome proliferator-activated receptor (PPAR)-γ co-activator 1α (PGC-1α), has been considered a prognostic factor in Chronic Ischemic Cardiomyopathy and Acute Heart Failure. Nevertheless, no data are available on Irisin levels in Chronic Heart Failure, both with preserved (HFpEF) or reduced (HFrEF) ejection fraction, matched for age and NYHA classes.
Materials and methods
Therefore, we have evaluated basal plasma irisin levels, by immunoenzymatic method, in these two subtypes of Heart Failure ($n=22$ HFpEF, age range 59–88 years, mean$\pm$S.E.M. BMI 28.9$\pm$1.3 kg/m^2; $n=18$ HFrEF, 54–88 years, BMI 26.5$\pm$0.9) and correlated them with metabolic parameters (HOMA-index) and Total Antioxidant Capacity (TAC), as a parameter of Oxidative Stress, measured with a spectrophotometric method, using the system H_20_2-metmyoglobin and the chromogen ABTS.
Results
The two groups did not show significant differences in NT-proBNP levels (2548.8$\pm$551.1 ng/ml in HFpEF vs 6007.1$\pm$2297.2 in HFrEF). Fasting Irisin levels were significantly lower in HFrEF (mean$\pm$S.E.M. 2.77$\pm$0.77 ng/ml) in respect to HFpEF (mean$\pm$S.E.M. 7.72$\pm$0.76 ng/ml). Moreover, a significant inverse correlation between Irisin and LAG values in HFpEF was found ($r^2=0.145$, $P<0.05$). On the contrary, in HFrEF patients, Irisin and LAG presented a trend toward direct correlation although not significant. No others correlations was found between Irisin and BMI or HOMA-IR for both HFrEF and HFpEF groups.
Conclusions
These data may suggest a different pathophysiological mechanism in these two subtypes of CHF, and a possible role of Oxidative Stress in modulation of Irisin levels. They also strengthen the involvement of metabolic factors in HFpEF.

Liraglutide prevented the deposition of Collagen in the animal model of Bleomycin-induced lung fibrosis

Juan Fandiño Gómez, Laura Toba Estévez, Ana Álvarez Vaz, Lucas Carmelo González Matías, Yolanda Diz Cháves & Federico Mallo Ferrer
CINBIO, Biomedical Research Center, Vigo University, Vigo, Spain.

Idiopathic pulmonary fibrosis (IPF) is an excessive accumulation of fibrous filaments in the extracellular matrix (ECM), in response to an inflammatory reaction that disrupts normal lung architecture and physiology. Collagen is the most abundant fibrous protein in the ECM. The GLP-1 receptor is highly expressed on lung tissue, where his activation plays an essential role in the synthesis and secretion of surfactant proteins. The objective of this study was to elucidate the effect of Liraglutide treatment on collagen synthesis and deposition in the lungs of an animal model of IPF. IPF was induced in male rats by a single intra tracheal instillation of bleomycin (BLM, 2.5 mg/kg) on day 0. Animals were treated with Liraglutide at a dose of LIR, 100 μg/kg per 12 h subcutaneous, using two different protocols. 1-Preventive treatment: LIR treatment was given from day-1 to day 6 and animals were sacrificed in day 7 and day 21. 2-Therapeutic intervention: animals were treated from day 10 to day 20 after BLM; and animals were sacrificed on day 21. Lung lobes were isolated and frozen for mRNA expression analysis by Real time PCR, and for hydroxyproline quantification and Arginase-1 activity testing. We obtained Broncho alveolar lavage liquid for analysis of soluble collagen. The mRNA expression of Collagen type 1 and the enzymes Arginase-1 and prolyl hydroxylase, which are essential for collagen fibre synthesis, were increased at day 7 and day 21 in BLM instilled animals. Tissue levels of hydroxyproline were very increased just at day 21, in the fibrotic phase. LIR treatment normalized the mRNA expression levels of the two enzymes at the times studied. In addition, LIR administration decreased day 21 type I collagen mRNA expression and total collagen deposition on lung tissue, as well the soluble collagen in alveolar lavage liquid. In conclusion, incretins play an important role in the regulation of the synthesis and activity of key enzymes in the formation of collagen fibres and deposition. Since, incretins may be useful molecules in the treatment and prevention of the pulmonary tissue fibrotic processes.

Turner syndrome and cardiovascular risk

Bernardo Marques[1], Margarida Bastos[2], Diana Oliveira[2], Diana Martins[2], Adriana Lages[2], Mara Ventura[2], Nelson Cunha[2], Lúcia Fadiga[2], Diana Catarino[2] & Francisco Carrilho[2]
[1]Deparment of Endocrinology, Instituto Português de Oncologia de Coimbra Francisco Gentil, EPE, Coimbra, Portugal; [2]Department of Endocrinoloy, Diabetes and Metabolism, Centro Hospitalar e Universitário de Coimbra, EPE, Coimbra, Portugal.

Introduction
Turner Syndrome (TS) is associated with cardiovascular anomalies and account for a threefold higher mortality in these women. The most common findings are congenital malformations of the heart (CMH), aortic dissection, valvular heart disease (VHD), hypertension and ischemic heart disease. It has been suggested that the ocurrence of cardiovascular disease in TS women is related to their karyotype and possibly to growth hormone (GH) treatment. Our study aimed to assess cardiovascular risks in patients with TS.
Methods/design
This was a retrospective study of 64 patients with TS identified from our institutional database. They were categorized in three groups, according to their karyotype: group 1 included 24 patients with monosomy X, group 2 comprised 21 patients with mosaicism, and group 3 comprised 19 patients with structural aberrations of X chromossome. We assessed age, treatment with GH, pubertal development, lipid profile, diabetes mellitus, body mass index, blood pressure and cardiac and valvular abnormalties. The association between variables was evaluated using Fisher's exact test and paired samples *t* test.
Results
The patients evaluated were aged 23–69 years old (s.d. 36 ± 10.1), with median follow-up time of 20 ± 8.3 years. VHD was present in 19 patients (30%) and CMH were detected in 17 patients (27%), the most common being aortic coarctation ($n=11$). CMH were detected more frequently in group 1 patients ($P=0.001$), namely aortic coarctation (8 of the 11 cases detected, $P=0.001$). Group 2 patients presented a higher rate of spontaneous puberty than the others ($P=0.029$). There were no differences regarding other cardiovascular risk factors and anomalies among the 3 groups, as well as association between GH treatment and the development of CMH or VHD.
Conclusion
The pathophysiology of the cardiovascular anomalies in TS is still unclear. In our study, monossomy X was associated with CMH and spontaneous pubertal development was associated with VHD. Life-long surveillance is recommended, namely evaluation of cardiac function, aortic diameter and blood pressure, in order to provide early identification and management of potentially serious cardiovascular conditions.

Can monogenic severe hypertriglyceridemia be differentiated from polygenic forms through clinical features: data from APPROACH and COMPASS studies in FCS and non-FCS hypertriglyceridemic patients?

Louis O'Dea[1], James MacDougall[2], Andres Digenio[1], Brant Hubbard[1], Marcello Arca[3], Patrick Moriarty[4], John Kastelein[5], Eric Bruckert[6] & Joseph Witztum[7]
[1]AkceaTherapeutics™, Inc., Cambridge, Massachusetts, USA; [2]BioBridges, Wellsley, Massachusetts, USA; [3]La Sapienze University of Rome, Rome, Italy; [4]University of Kansas Medical Center, Kansas City, Missouri, USA; [5]Academic Medical Center (AMC), University of Amsterdam, Amsterdam, The Netherlands; [6]ICAN, Paris, France; [7]University of California, San Diego, California, USA.

Introduction
Differentiation between familial chylomicronemia syndrome (FCS), a rare hypertriglyceridemia, and severe hypertriglyceridemia (sHTG; non-FCS) is challenging due to overlap in triglyceride (TG) levels and symptomology but important in disease management. Clinical characteristics that allow for reliable differentiation may exist in the presenting clinical features and primary diagnostic testing. The objective of this analysis was to assess whether readily obtainable clinical information can effectively diagnose and differentiate patients with FCS from sHTG (non-FCS) based on 2 well-curated datasets arising from 2 clinical studies.
Methods
Patients from two Phase-III clinical trials of sHTG patients, one with molecularly-proven FCS and one with polygenic sHTG (non-FCS) were included in this analysis. Logistic regression analyses were performed to determine the ability of variables (individually or sets), including patient demographics, medical history and baseline lipids, to differentiate between FCS and sHTG (non-FCS) populations. For each of the logistic regression analyses, receiver operating characteristics (ROC) were employed to determine the highest accuracy (defined as the percentage of times the Actual and Predicted values match) using the predicted probability (Pr) of being in the FCS-population. Positive predictive-value (PPV), and negative predictive-value (NPV) are defined as follows: PPV is Pr (Predicted-FCS + True-FCS |Predicted-FCS); NPV is Pr(Predicted Non-FCS + True Non-FCS|Predicted Non-FCS). Optimal was defined as maximizing sensitivity + specificity.
Results
One hundred and fifty four patients ($n=49$ genetically confirmed FCS patients and $n=105$ sHTG (non-FCS) patients) were included in the analysis. Of the 154 patients, 45/49 of FCS patients and 99/105 of sHTG (non-FCS) patients were diagnosed correctly based on the model. Optimal sensitivity was 91.8%, optimal specificity was 94.3%, and accuracy was 93.5%. Fasting low-density lipoprotein-Cholesterol (LDL-C), apolipoprotein-A1 (apoA1), and apoB were determined to have the highest individual predictability with ROC area-under-the-curve values of 0.902, 0.8971, and 0.8852, respectively. FCS and sHTG (non-FCS) patients could be differentiated with an accuracy of 91.6% with a 3-variable set (apoB/LDL-C, BMI, and history of pancreatitis) and 93.5% with a 5-variable set (HDL-C and VLDL-C included). Individual variables and sets both had higher NPV than PPV.
Conclusions
Our results indicate that FCS and sHTG (non-FCS) patients can be diagnosed and differentiated with a high-degree of accuracy by analyzing readily obtainable clinical information. This suggests that where genetic testing is not available or among FCS patients who do not test positive for a known genotype, the diagnosis of FCS can be made clinically with a high-degree of certainty.

Changes in lipid profile 5 years after bariatric surgery: laparoscopic Roux-en-Y gastric bypass versus laparoscopic sleeve gastrectomy

Elisenda Climent, David Benaiges, Juana A Flores-Le Roux, Jose M Ramón, Helena Julià, Juan Pedro-Botet & Albert Goday
Hospital del Mar, Barcelona, Spain.

Importance
Few studies have compared mid-term results of laparoscopic Roux-en-Y gastric bypass versus laparoscopic sleeve gastrectomy and none have focussed on lipid profile.
Objectives
The main objective of this study was to compare laparoscopic Roux-en-Y gastric bypass versus laparoscopic sleeve gastrectomy with respect to 5-year remission rate of the different lipid disturbances. Secondary outcomes included relapse, late remission and incidence rates of the different lipid disorders and evaluation of factors associated with mid-term remission. Design, setting and participants: A retrospective analysis of a non-randomised prospective cohort was conducted on patients with severe obesity undergoing bariatric surgery at Hospital del Mar, Barcelona, from January 2005 to January 2012 with $\geq$ 5 years follow-up.
Exposure
Laparoscopic Roux-en-Y gastric bypass or laparoscopic sleeve gastrectomy. Main outcome: 5-year remission rate of lipid disorders after laparoscopic Roux-en-Y gastric bypass versus laparoscopic sleeve gastrectomy.
Results
87% of the patients were women, mean age of the total cohort was 46.1 ± 8.7 years and BMI 45.2 ± 4.8 kg/m^2. Of the 259 patients who underwent bariatric surgery between 2005 and January 2012, 151 completed 5 years follow-up. The 5-year remission rate of high low-density lipoprotein cholesterol was superior after laparoscopic Roux-en-Y gastric bypass with respect to laparoscopic sleeve gastrectomy [61.2% (30/49) versus 26.1% (6/23); $P=0.011$] being male sex, absence of statins treatment and type of bariatric surgery technique (laparoscopic Roux-en-Y gastric bypass) the associated factors with remission. Hypertriglyceridemia remission was also higher after laparoscopic Roux-en-Y gastric bypass [92.0% (23/25) versus 66.7% (10/15); $P=0.041$], although type of surgery was not an associated factor. No differences were found in remission rates of low high-density lipoprotein cholesterol between groups. Absence of fibrates treatment and 5-year percentage of excess weight loss were independently associated with hypertriglyceridemia remission and only the latter was independently associated with low high-density lipoprotein cholesterol remission 5 years after surgery.
Conclusions
Five-year outcome data showed that, among patients with severe obesity undergoing bariatric surgery, laparoscopic Roux-en-Y gastric bypass was more effective than laparoscopic sleeve gastrectomy in terms of total and low-density lipoprotein cholesterol reduction and remission, with no differences in hypertriglyceridemia and high-density lipoprotein cholesterol normalization.

Prevalence and risk factors of periodontitis in diabetic patients with or without metabolic syndrome

Soo Min Hong, Yang Im Hur & Ho Seok Koo
Seoul Paik Hospital, In Je University, Seoul, Republic of Korea.

Introduction
This study examined prevalence and risk factors of peri-odontitis in representative samples of Korean adults, with and without diabetes mellitus (DM). Additionally, we did subgroup analysis in diabetic patients with or without metabolic syndrome.
Methods
This study analyzed data from the 2010 to 2015 the Korea National Health and Nutrition Examination Survey (KNHANES) in South Korea which include periodontitis and the parameter of metabolic syndrome (MS). MS was defined according to the National Cholesterol Education Program Adult Treatment Panel III (NCEP-ATP III). Among data collected from 22,737 respondents, propensity score matching of sex and age was applied and the data were analyzed.
Results
A total of 4706 subjects after propensity score matching of sex and age, including 2060 with periodontitis and 2646 without periodontitis, were analyzed. Periodontitis was present in 43.7% of the total. When compared to the no periodontitis group, the periodontitis group was older (63 ± 10.4), had more males (58.8%), a lower number of subjects who had higher education (56.3%), low-income families (32.1%), higher fasting plasma glucose (122.3 ± 39.2), and higher waist circumference (86 ± 9). Moreover, systolic blood pressure, body mass index, and plasma triglycerides were higher in the periodontitis group whereas HDL cholesterol was lower ($P<0.001$). Many of those in the periodontitis group had hypertension (57.6%) and diabetes mellitus (55.5%), and metabolic syndrome (46.3%). It showed the same tendency more like in diabetes group. In multiple regression analysis of the risk factors of periodontitis, the risk increased when MS was present (OR 1.12, 95% CI 1.01–1.24), when diabetes mellitus was present (OR 1.19, 95% CI 1.02–1.38), and when there was history of smoking (OR 1.63, 95% CI 1.46–1.81). In particular, for MS in DM, the risk of periodontitis increased as the number of MS components became higher ($P<0.001$).
Conclusion
The risk of periodontitis was 1.19-fold higher when DM was present than when it was not. The risk was particularly higher when MS was also present and in those that smoke. Moreover, the risk of periodontitis also increased as number of the MS components became higher. Thus, diabetic patients with periodontitis may benefit when they control metabolic parameters.

GP72

Toe-brachial index is associated more strongly with progression of diabetic nephropathy than ankle-brachial index in type 2 diabetic patients

Dong-Hyeok Cho, Jin-Ook Chung, Dong-Jin Chung & Min-Young Chung
Chonnam National University Medical School, Gwangju, Republic of Korea.

Background and aims
Atherosclerosis is more prevalent among people with chronic kidney disease (CKD) than among those with normal renal function. Ankle-brachial index (ABI) and toe-brachial index (TBI) are a simple useful method for assessing peripheral atherosclerosis. The aim of our study was to investigate whether ABI or TBI were more strongly associated with progression of diabetic nephropathy such as change of urinary albumin/creatinine ratio (ACR), serum creatinine levels and estimated glomerular filtration rate (eGFR).
Materials and methods
We recruited a total of 149 type 2 diabetics: 62 men (mean age 62.4 ± 12.1 years) and 87 women (mean age 60.3 ± 10.9 years) with CKD ($\geq$ stage 2) by diabetic nephropathy and followed for 1.6 ± 1.2 years. Renal function was evaluated by serum creatinine levels, estimated eGFR (Cockcroft-Gault equation) and urinary ACR. Baseline-to-study end changes in eGFR were calculated, and yearly change of eGFR (ml/min/year) was computed. ABI and TBI measurements were performed with the subject in a supine position, and were determined as the ratio of ankle or toe systolic blood pressure to the brachial systolic blood pressure, with both determined using an automatic device.
Results
Overall, the mean age was 61.2 ± 11.0 years, duration of diabetes 13.8 ± 10.5 years, HbA_{1C} $7.9 \pm 2.2\%$, ACR $1{,}635.2 \pm 783.3$ mg/gCr, and serum creatinine 1.6 ± 1.1 mg/dL. Mean calculated GFR was 62.8 ± 27.1 ml/min/1.73m^2. ABI were 1.05 ± 0.24 (Rt.) and 1.01 ± 0.20 (Lt.). TBI were 0.73 ± 0.31 (Rt.) and 0.79 ± 0.22 (Lt.). Of the study population, 39 patients (26.1%) were smokers or ex-smokers, 135 patients (90.6%) were having hypertension, and 123 patients (82.6%) were taking ACEI or ARB. Age, duration of diabetes, serum creatinine, ACR and eGFR were significantly correlated with ABI or TBI. Mean yearly change of eGFR was 7.2 ± 10.4 ml/min per year. Yearly change in the eGFR was negatively correlated with TBI, but not with ABI. Changes of ACR or serum creatinine were not significantly correlated with ABI or TBI. By Univariate linear regression, TBI but not ABI showed a significant negative correlation with yearly change in the eGFR ($r=-0.309$, $P<0.05$).
Conclusion
This study demonstrated that TBI may be predictor of progression of diabetic nephropathy in patients with type 2 diabetes. We suggest that toe-brachial index may help to manage appropriately as early predictors on progression of diabetic nephropathy.

GP73

The BMI and skeletal muscle mass as a risk factor of carotid atherosclerosis in patients with type 2 diabetes

Se-Hwa Kim[1], Soo-Kyung Kim[2], Young-Ju Choi[3], Seok-Won Park[2], Eun-Jig Lee[4], Yong-Wook Cho[2] & Kap-Bum Huh[3]
[1]Catholic Kwandong University College of Medicine, International St. Mary's Hospital, Incheon, Republic of Korea; [2]CHA Bundang Medical Center, CHA University, Seongnam, Republic of Korea; [3]Huh's Diabetes Center and the 21st Century Diabetes and Vascular Research Institute, Seoul, Republic of Korea; [4]Yonsei University College of Medicine, Seoul, Republic of Korea.

Background
The body mass index (BMI) is the most widely used method of assessing fat accumulation, and is recognized as an independent risk factor for cardiometabolic diseases. However, there might be substantial variations in the fat or muscle amount among persons with a similar BMI. The aim of the present study was to investigate whether BMI and skeletal muscle mass (SMM) estimated from by bioelectrical impedance analysis (BIA) are associated with carotid atherosclerosis in patient with type 2 diabetes.
Methods
This was an observational study performed in 4437 patients with type 2 diabetes. Anthropometric measures and BIA were performed for each subject. Carotid atherosclerosis was defined by having a clearly isolated focal plaque or mean carotid intima-media thickness (CIMT) $\geq$ 1.1 mm.
Results
CIMT and the frequency of carotid atherosclerosis were higher with decreasing SMM quartiles rather than with increasing BMI quartiles in both genders. The SMM to BMI ratio was significantly related with CIMT and carotid atherosclerosis in both genders, even after adjusting for potential confounders (adjusted odds ratio of carotid atherosclerosis for the highest quartile of this ratio compared with the lowest quartile being 0.630 [95% CI, 0.440–0.901] and 0.582 [0.391–0.860] in men and women, respectively).
Conclusions
BMI alone could not assess the carotid atherosclerotic risk. An additionally estimation for skeletal muscle may provide a role in assessing atherosclerotic burden in patients with type 2 diabetes.

Is liver stiffness associated with diabetic complications in patients with type 2 diabetes and non-alcoholic fatty liver disease?

Carolina M Perdomo, Javier Gargallo, María Llavero, Marta García, Alejandro Bojórquez, Mercedes Iñarrairaegui, José I Herrero, Camilo Silva, Gema Frühbeck, Javier Salvador & Javier Escalada
University of Navarra Clinic, Pamplona, Spain.

Aim
Non-alcoholic fatty liver disease (NAFLD) and type 2 Diabetes (T2D) are common conditions that frequently co-exist. Studies have shown an increase likelihood of micro and macrovascular complications in this population, as well, as an increased risk of developing more severe forms of liver disease. The aim of this study was to identify diabetic complications in patients with both diseases and search for an association with liver stiffness assessed by Liver Elastography (LE).
Methods
We retrospectively reviewed patients with T2D and NAFLD (May 2016-December 2017) after excluding other causes of liver disease and in whom LE was performed (LE $\geq$8.2 kPa reflects fibrosis, LE $\geq$9.9 kPa reflects significant fibrosis).
Results
We reviewed 555 patients, 25% (139) had NAFLD. 33.8% (47) of the patients with NAFLD had T2D, and up to 73.4% (102) had T2D or Prediabetes. In the T2D population, 68.1% (32) were men between 39-81 years old (60.1$\pm$8.7) with 6.02$\pm$4.99 years of evolution. 85.1% had metabolic syndrome: 97% BMI $\geq$25 kg/m^2, 76.6% dyslipidemia, 70.2% high blood pressure, 21.3% OSAS and 17% hyperuricemia. 80.8% had ALT> AST, and 48.9% ALT $\geq$40 IU/L. Liver fibrosis assessed by LE was present in 29.8% of the patients, 20% had significant fibrosis. A positive correlation was found between kPa and glomerular filtration rate (CKD-EPI) (r=0.331, $P\leq$0.05), and liver stiffness increased as glomerular function worsened (P=0.008). However, we did not find an increased prevalence of diabetic retinopathy nor diabetic neuropathy in patients with fibrosis. Patients with fibrosis had a higher non-significant prevalence of peripheral artery disease, carotid obstruction and cardiovascular events in comparison with the group without fibrosis (P=0.595, P=0.154, P=0.241, respectively). No increased prevalence of cerebrovascular events was found in patients with liver fibrosis.
Conclusions
Liver fibrosis is highly prevalent in patients with NAFLD and T2D. Increased liver stiffness is significantly associated with renal dysfunction in T2D and a higher non-significant prevalence of cardiovascular events was found in this population. Thereby, our results support the value of LE and the assessment of individual cardiovascular risk in every patient with T2D and NAFLD.

Effects of post-transplant and pre-existing diabetes mellitus on graft function after kidney transplantation

Alparslan Ersoy[1], Ayşegül Oruç[1], Bahriye Güney[1], Suat Akgür[1], Abdülmecit Yıldız[1] & Canan Ersoy[2]
[1]Uludag University Medical Faculty, Department of Nephrology, Bursa, Turkey; [2]Department of Endocrinology and Metabolism, Uludağ University Medical Faculty, Bursa, Turkey.

Diabetes mellitus (DM) is one of the most serious comorbidities in kidney transplant recipients. New onset diabetes after kidney transplantation (NODAT) is a common and an important complication following solid organ transplantation. It is associated with poor graft function and increased cardiovascular complications. Therefore, management of hyperglycemia after transplantation is important to reduce diabetes-related risks. We aimed to compare the effects of pre-existing DM and NODAT on graft functions in kidney transplant recipients.
Methods
Fifty-nine kidney transplant recipients were divided into two groups: pre-existing diabetics (n=28, 52.7$\pm$10.2 years, 12 males) and NODAT (n=31, 49.9$\pm$11.8 years, 18 males). HbA1c and renal functions at the first year of transplantation and the last visit were obtained.
Results
The median post-transplant follow-up durations were 62.5 months in pre-existing DM group and 65 months in NODAT group. The median diagnosis time in NODAT group was 2.5 months (range: 1–159) after transplantation and thirteen recipients were diagnosed at the first month. There was no significant difference between gender, age, donor age, donor type and body mass index values in NODAT and pre-existing diabetics groups. Tacrolimus based immunosuppressive regimen ratios were significantly higher in NODAT group (61.3% vs. 29%, P=0.007). HbA1c levels (6.9$\pm$2 vs. 7.8$\pm$1.6%, P=0.036) at first year of transplantation were lower in NODAT group. HbA1c levels of both groups at the last visit were similar (7.49$\pm$1.7% in NODAT and 7.79$\pm$1.3% in pre-existing diabetics). Serum creatinine levels at the first year of transplantation (1.29$\pm$0.75 vs. 1.48$\pm$0.53 mg/dL) and at the last visit (1.67$\pm$1.58 vs. 2.14$\pm$1.63 mg/dL) were comparable in NODAT and pre-existing diabetics groups, respectively (P=0.056). Estimated glomerular filtration rate values at the first year of transplantation (69.5$\pm$27.2 vs. 56.0$\pm$29.7 mL/min/1.73 m^2, P=0.021) and at the last visit (61.0$\pm$27.7 vs. 42.7$\pm$21.2 mL/min/1.73 m^2, P=0.007) in NODAT group were significantly higher than those of pre-existing diabetics group. The ratio of graft lost in NODAT group was lower than that of the pre-existing diabetes group (6.5% vs. 14.3%, P=0.311).
Conclusion
Although glycemic control was achieved in both groups in our study, the presence of pre-existing diabetes was a risk factor for graft failure after kidney transplantation. Therefore, longer diabetes duration could negatively affect graft function in recipients with pre-existing diabetes.

Glucose variability and pregnancy outcomes in gestational diabetes mellitus: a prospective study

Rosa Márquez-Pardo[1], María-Gloria Baena-Nieto[1], Lourdes García-García-Doncel[1], Concepción Cruzado-Begines[1] & Isabel-María Torres-Barea[2]
[1]Jerez Hospital, Jerez de la Frontera, Spain; [2]Puerta del Mar Hospital, Cádiz, Spain.

Introduction
Gestational diabetes mellitus (GDM) is associated with an increase of maternal-fetal complications. Continuous glucose monitoring system (CGMS) detects parameters of glycemic variability through which it could be predicted the appearance of maternal-fetal complications.
Methods
Women with GDM at 26–32 gestational weeks were allocated a 6-day CGM system (Ipro^{TM}2) right after diagnosis in an observational prospective study. It was analysed:
CGMS: mean glucose and standard deviation (S.D.), mean amplitude of glycemic excursions (MAGE), mean of daily differences (MOOD), continuous overlapping net glycemic action (CONGA). Expressed: mg/dl.
Maternal and neonatal outcomes.
Results
$n=52$. Maternal age 30 ± 2.42 years (>35 years$=40.3\%$), family history of diabetes 57.7%, prepregnancy BMI 26.1 ± 4.62 kg/m^2 (>30 kg/m$^2=23.1\%$), weigh gain 7.6 ± 5.19 kg, HbA1c 4.9%, insulin treatment 32.7%.
CGMS: mean 98.02, DS 19.66, MAGE 44.22 ± 13.16, MODD 19.44 ± 5.74, CONGA 86.19 ± 8.56.
Maternal and neonatal outcomes
Caesarean 32.7%, gestational age at delivery 39 week, macrosomia 9.6%, large for gestational age (LGA) 21.2%, small for gestational age 5.8%, neonatal hypoglycaemia 25%, neonatal hyperbilirubinemia 7.7% and need for supplemental oxygen in the neonatal 5.8%.
Multivariable binary logistic regression
MAGE was an independent factor for LGA (Odds ratio 1.075; 95% confidence interval 1.007–1.148; *P* value 0.031). It was not found another independent risk factor for maternal or neonatal outcomes.
Conclusions
There is a correlation between MAGE at diagnosis of GDM and LGA. The use of CGMS could identify patients with more risk of maternal-fetal complications. These patients should have a close surveillance in order to prevent complications. However, further studies with a larger number of patients are required.

Patients with community acquired pneumonia are three times more likely to die if they have concomitant diabetes mellitus

Elsa Joy[1], Navjyot Singh[1] & Jubbin Jacob[2]
[1]Department of Medicine, Christian Medical College and Hospital, Ludhiana, India; [2]Endocrine and Diabetes Unit, Christian Medical College and Hospital, Ludhiana, India.

Objective
To compare the clinical features, mortality and morbidity outcomes in patients with diabetes mellitus and patients without diabetes mellitus, who are hospitalized with community acquired pneumonia (CAP).
Methods
This cross sectional study included 175 patients (49 patients with diabetes and 126 without diabetes) admitted with CAP to a tertiary care hospital. The study included both quantitative and qualitative variables, which were compared using Independent T test/Mann-Whitney Test (when the data sets were not normally distributed) and Chi-Square test/Fisher exact test respectively. Univariate regression was used to find the risk factors of mortality due to pneumonia in patients with diabetes and without diabetes. Multivariate analysis was used in the end to isolate the effect of diabetes for mortality in community acquired pneumonia (after excluding proven H1N1 cases) while controlling the effect of other variables.
Results
The mean age of presentation in patients with diabetes was 63.7 ± 10.9 years vs. 57.7 ± 16.6 years among patients without diabetes. (*P*-value-0.006). Comorbidities were present in 79.59% of patients with diabetes with heart disease as the most common comorbidity found in 53.06% of those with diabetes (*P* value-0.001). Other clinical features as well as outcome were not very much different in both the groups. On univariate analysis increasing capillary glucose at admission, a higher CURB 65 score, cigarette smoking, presence of type 1 respiratory failure, metabolic acidosis and requirement of invasive ventilation were associated with increased risk of mortality in patients with diabetes. On multivariate analysis diabetes mellitus was found to be a single independent predictor for mortality after controlling for age, COPD (by controlling respiratory acidosis and type 2 respiratory failure) and H1N1 infection with a *P* value of 0.045, an adjusted odds ratio of 2.344 with CI 1.02–5.382. Diabetes mellitus was an independent predictor for mortality in community acquired pneumonia (after excluding H1N1) with a *P* value of 0.008, adjusted odds ratio of 3.439 with a CI of 1.382–8.559.
Conclusion
Diabetes mellitus is an independent predictor of mortality in patients admitted with community acquired pneumonia.

DOI: 10.1530/endoabs.56.GP77

Diabetic patients are old as theirs feet are old:the strongest association of foot pathology with mortality in diabetes

Dragan Tesic[1], Edita Stokic[1], Milena Mitrovic[1], Milica Medic/Stojanoska[1], Ivana Bajkin[1], Tijana Icin[1], Dragica Tesic[2] & Mirjana Tomic[3]
[1]Clinic of Endocrinology, Diabetes and Metabolic Diseases, Clinical Centre of Vojvodina, Novi Sad, Serbia; [2]Institute for Cardiovascular Diseases of Vojvodina, Sremska Kamenica, Novi Sad, Serbia; [3]Emergenz Center, Cliunical Centre of Vojvodina, Novi Sad, Serbia.

Background and aims
Foot lesions (amputations, ulcerations) are the consequence of neuro-vascular complications. Cardiovascular risk factors are similar for both. Thus, we carried out a prospective 5-year study to examine the effects of established complications and classical risk factors on mortality in diabetic patients.
Materials and methods
During the previous 5 years we analyzed 244 patients attending a diabetes clinic. The International Working Group on Diabetic Foot (IWGDF) risk categorization was used to quantify the severity of foot pathology. Retinopathy was diagnosed by funduscopy. Peripheral neuropathy diagnosed by the Neuropathy Disability Score (NDS) and Neuropad time to color change were studied as well. Coronary artery disease (CAD) and lower extremity arterial disease (LEAD)] were evaluated. Cardiovascular risk factors were: hypertension, triglycerides, HDLc, LDLc, diabetes duration, fibrinogen, proteinuria, smoking. 53 patients (group A) had meanwhile died, and 191 (group B) are still alive.
Results
There were no differences between groups A and B in the following parameters: male gender [31(58.5%) vs. 94(49.2%), $P=0.23$], diabetic retinopathy [34 (64.15%) vs. 105(54.97%), $P=0.29$], proteinuria (385.2 ± 609.9 vs. 443.9 ± 1003, $P=0.23$), CAD [5(9.43%) vs. 16(8.38%), $P=0.81$], [triglycerides (1.9 ± 1.51 vs. 1.93 ± 1.7 mmol/l, $P=0.90$), HDLc (1.27 ± 0.51 vs 1.25 ± 0.28 mmol/l, $P=0.80$), LDLc (3.44 ± 0.81 vs 3.62 ± 0.89 mmol / l, $P=0.18$)], [type 1 diabetes [6 (11.3%)). 24 (12.6%), $P=0.80$], HbA1c ($8.9\%\pm2.04$ vs. $9.2\pm1.94\%$, $P=0.17$)], smoking [7 (13.2%) vs. 36(18.8%), $P=0.34$]. Patients in group A exhibited significant differences in the following parameters: IWGDF risk category 2/3 ($P=0.0002$), VPT (3.35 ± 3.2 vs. 4.8 ± 3.00 V, $P=0.004$), Neuropad response (13.8 ± 8.9 $P=0.03$), age at developing foot lesions (69.2 ± 8.77 vs 66.2 ± 9.7 years, $P=0.03$), ankle reflexes (AR) score (3.42 ± 1.06 vs. 3.04 ± 1.28, $P=0.036$); among classical risk factors: hypertension [42(79.2%) vs. 117 (61.3%), $P=0.015$], fibrinogen (4.3 ± 1.11 vs. 3.89 ± 0.88, $P=0.02$), DM duration (20.2 ± 10.45 vs. 16.96 ± 8.8, $P=0.026$). However, in multivariable logistic regression analysis it was only IWGDF category 2/3 that remained significantly associated with mortality (OR: 3.78, 95% CI: 1.72–8.28, $P=0.001$).
Conclusion
This finding underlines the importance of timely diagnosis and management of diabetic foot pathology, especially when we are talking about the intensity of lowering HbA1c. The severity of diabetic foot pathology was a stronger prognostic factor of mortality than cardiovascular risk factors.

Outcomes of hyperglycemia in patients with and without diabetes mellitus hospitalized for infectious diseases

Alexander Gorshtein[1,2], Ilan Shimon[1,2] & Amit Akirov[1,2]
[1]Institute of Endocrinology, Beilinson Hospital, Petach Tikva, Israel; [2]Sackler School of Medicine, Tel Aviv University, Tel Aviv, Israel.

Context
Hyperglycemia is common among patients with and without diabetes mellitus (DM) hospitalized for infectious diseases. The long-term outcomes of hyperglycemia have not been adequately studied in this population.

Objective
Examine the prognostic implications of hyperglycemia and the importance of glycemic control in patients with and without DM during hospitalization for infectious diseases.
Methods:
Historical prospectively collected data of patients hospitalized between 2011 and 2013. Infection-related hospitalizations were classified according to site of infection. Median follow-up was 4.5 years. Outcome measures included in-hospital and end-of-follow-up mortality.
Setting
Historical prospectively collected data of patients hospitalized between January 2011 and December 2013.
Patients
Patients $\geq$18 years.
Main outcome
Length of stay, in-hospital and end-of-follow-up mortality.
Results
The cohort included 8051 patients (50% female, mean age $\pm$ s.d., 68$\pm$20 years) with a primary diagnosis of an infectious disease. Of these, 2363 patients (29%) had type 2 DM. The most common infectious sites included respiratory tract (n=3285), genitourinary tract (n=1804), skin and soft tissue (n=934) and gastrointestinal tract (n=571). There was no difference in admission rates of patients with and without DM according to the site of infection, except for skin and soft tissue infection which were more common among patients with DM (16% vs. 10%). In-hospital mortality risk was greater in patients with DM (aOR= 1.3, 95% CI =1.1–1.7). In the entire cohort, adjusted mortality risk (aHR, 95% CI) at the end-of-follow-up was greater among patients with DM (1.2, 1.1–1.4), with increased mortality risk following hospitalization for respiratory (1.1, 1.0–1.4) and skin and soft tissue infections (1.7, 1.3–2.3). In-hospital and end-of-follow-up mortality risk were highest among patients with and without DM with median glucose >180 mg/dl during hospitalization.
Conclusions
In patients hospitalized for infectious diseases, DM is associated with increased long-term mortality risk, specifically following hospitalization for respiratory and skin and soft tissue infections. Poor glycemic control in patients with and without DM during hospitalization is associated with increased long-term mortality.

Self-reported low-energy fractures and associated risk factors in diabetic portuguese patients: a cross-sectional population-based study

Sofia Furtado[1], Ana Rodrigues[2,3], Sara Dias[3], Jaime C Branco[2,3,4,5] & Helena Canhão[2,3,5]
[1]Unidade Funcional Medicina 1.2, Hospital São José - Centro Hospitalar Lisboa Central, Lisboa, Portugal; [2]EpiReumaPt Study Group - Sociedade Portuguesa de Reumatologia, Lisboa, Portugal; [3]EpiDoc Unit - Unidade de Epidemiologia em Doenças Crónicas (CEDOC, NMS/UNL), Lisboa, Portugal; [4]Serviço de Reumatologia, Hospital Egas Moniz - Centro Hospitalar Lisboa Ocidental, Lisboa, Portugal; [5]Lisbon NOVA University: NOVA Medical School, National School of Public Health, Lisboa, Portugal.

Introduction
Patients with diabetes have an increased risk of low-energy bone fractures (LEF). Traditional clinical risk factors and bone mineral densitometry underestimate LEF risk in diabetics. We aim to evaluate the frequency of LEF and associated risk factors in the diabetic Portuguese population.
Methods
National, cross-sectional and population-based study to describe the prevalence of self-reported LEF in diabetic subjects over 40 years-old. Estimates were computed as weighted proportions/means, considering sample design. Multivariate logistic regression models were used to assess predictors of LEF in the diabetic.
Results
In a national cohort of 10 661 people, 7675 subjects were over 40 years-old, of which 1173 were diabetic. Compared to nondiabetic, diabetic patients were older (mean age 66.0$\pm$11.49 years-old; 55.8% female), more overweight or obese (81.1% vs. 61.3%) and more frequently reported osteoporosis (20.4% vs. 15.4%) and falls in the previous 12 months (32.4% vs. 22.9%). Estimated prevalence of self-reported LEF was 16.2% (95% CI: 13.68–19.13, n=203) among the diabetic, compared to 13.3% (95% CI: 12.14–14.57, n=931) in nondiabetic (crude OR for the association between diabetes and LEF: 1.26, 95% CI: 1.01–1.58, P=0.045; in women, adjusted OR: 1.41, 95% CI: 1.05–1.89; in men, adjusted OR: 0.86, 95% CI: 0.57–1.31, P=0.481; P-value for the interaction between diabetes and gender: 0.008). In the diabetic patients, LEF were more frequent among women and increased with age; LEF of distal forearm were the most prevalent (13.9%, 95% CI: 9.26–20.28), followed by hip (5.2%, 95% CI: 2.54–10.49) and vertebral fractures (3.2%, 95% CI: 1.35–7.59). A third of the diabetic (95% CI: 25.80–35.0) reported at least one major LEF (hip, vertebral or distal forearm) and 70% (95% CI: 65.39–74.36) in other sites. Self-reported LEF were associated with female gender (adjusted OR 1.66, 95% CI: 1.07–2.56, P=0.023) and the occurrence of falls in the previous 12 months (adjusted OR 1.72, 95% CI: 1.12–2.63, P=0.013) in the diabetic subjects.
Conclusion
Diabetics reported more falls and had a higher prevalence of self-reported LEF than nondiabetic. Female gender and falls were associated with LEF in the diabetic. Our findings emphasize the need for fracture and falls preventive measures in diabetic patients.

Impaired cortisol and growth hormone counterregulatory responses during severe hypoglycemia in type 2 diabetes mellitus

Young A Rhyu[1], Ju-Young Jang[1], Sooyoun Park[1], Yoonjung Kim[1], Jee Hyun An[2], Dong-Lim Kim[1], Suk Kyeong Kim[1] & Kee-Ho Song[1]
[1]Konkuk University School of Medicine, Seoul, Republic of Korea; [2]Korea University College of Medicine, Seoul, Republic of Korea.

Background
Cortisol and growth hormone elevations are critical counterregulatory responses to severe hypoglycemia. However, the proportion and clinical characteristics of type 2 diabetic patients who fail to show appropriate cortisol and/or growth hormone secretion in response to severe hypoglycemia have not been investigated.
Methods
We measured the plasma cortisol and growth hormone levels in type 2 diabetes with severe hypoglycemia (defined as blood glucose < 40 mg/dl with loss of consciousness) who visited the emergency department between 2006 and 2015.
Results
Of 187 hypoglycemic patients, 37 (19.8%) had impaired cortisol responses (<18 μg/dl) and 143 (76.5%) patients had impaired growth hormone responses (<5 ng/ml). There were 31 (16.6%) patients with impaired responses to both cortisol and growth hormone. The patients with impaired cortisol response, growth hormone response and both hormone response were significantly older (74.0, 76.0, 74.0 vs. 69.5 years) and had higher BMI (24.8, 23.7, 23.8 vs. 21.6 kg/m^2) compared with normal hormone response group. Individuals with impaired cortisol response group, impaired growth hormone response group and both hormone abnormal response group showed significantly higher admission rates (35.1%, 35.9%, 32.3% vs. 2.6%), lower growth hormone level (0.8, 0.8, 0.6 vs. 12.7 ng/ml), and lower adrenocorticotropic hormone (ACTH) level (20.0, 34.4, 19.5 vs 105.5 pg/ml) than individuals with normal hormone response group. Multivariate logistic regression analysis indicated that impaired cortisol response were significantly associated with growth hormone after adjusting for age, BMI, DM duration, and ACTH. Impaired growth hormone response were significantly associated with age, BMI, and ACTH after adjusting for eGFR.
Conclusion
A considerable number of type 2 diabetic patients have impaired cortisol and/or growth hormone responses to severe hypoglycemia. The type 2 diabetic patients likely to have abnormal GH response when they are older, have shorter DM duration, and have higher BMI.
Keywords: hypoglycemia, cortisol, growth hormone, type 2 diabetes mellitus, counterregulatory hormone response

Maternal exposure to air pollutants and risk of gestational diabetes mellitus in Taiwan

Hsiu-Nien Shen[1], Sheng-Yuan Hua[2], Chang-Ta Chiu[3] & Chung-Yi Li[2]
[1]Chi Mei Medical Center, Tainan, Taiwan; [2]National Cheng Kung University, Tainan, Taiwan; [3]Tainan Municipal An-Nan Hospital, Tainan, Taiwan.

Objective
Mounting evidence has shown an increased risk of gestational diabetes mellitus (GDM) in association with elevated exposure to air pollution. However, limited

evidence is available concerning the effect of specific air pollutant(s) on GDM incidence.
Methods
We conducted this case-control study on 6717 mothers with GDM diagnosed in 2006–2013 and 6717 age- and year of delivery-matched controls to further address the risk of GDM in relation to specific air pollutant. Both cases and controls were selected from a cohort of 1-million beneficiaries of Taiwan's National Health Insurance program registered in 2005. Maternal exposures to mean daily air pollutant concentration, derived from 76 fixed air quality monitoring stations, within the 12-week period prior to pregnancy and during the 1st and 2nd trimesters were assessed by the spatial analyst method (i.e., ordinary kriging) with the ArcGIS.
Results
After controlling for potential confounders and other air pollutants, an increase in pre-pregnancy exposure of 1 inter-quartile range (IQR) for $PM_{2.5}$ and SO_2 was found to associate with a significantly elevated odds ratio (OR) of GDM at 1.10 (95% confidence interval (CI) 1.03–1.18 and 1.37 (95% CI 1.30–1.45), respectively. Exposures to $PM_{2.5}$ and SO_2 during the 1st and 2nd trimesters were also associated with significantly increased ORs, which were 1.09 (95% CI 1.02–1.17) and 1.07 (95% CI 1.01–1.14) for PM2.5, and 1.37 (95% CI 1.30–1.45) and 1.38 (95% CI 1.31–1.46) for SO_2.
Conclusions
It was concluded that higher pre- and post-pregnancy exposures to $PM_{2.5}$ and SO_2 for mothers were associated with a significantly but modestly elevated risk of GDM.

Aim
Gestational diabetes mellitus (GDM) is an important public health issue associated with significant short- and long-term morbidity both for mother and offspring. Prevalence rates of GDM show considerable variation among different countries and regions of the world. The primary aim of this study was to determine the nationwide prevalence and predictors of GDM in Turkey.
Materials and methods
We conducted a prospective nationwide screening among pregnant women. Between August 2016 and November 2017, a total of 2643 pregnant women from 51 centers in 12 different regions were enrolled. Two step screening method was used. All participants were screened with a 50-g glucose challenge test between 24 and 28 weeks of gestation. Those with values exceeding 140 mg/dl at 1 h underwent a 100-g oral glucose tolerance test on a different day. Carpenter Coustan criteria were used for the diagnosis of GDM. Clinical and biochemical data were obtained by electronic database software.
Results
The national prevalence of GDM was found to be 16.2% without a significant difference between urban and rural regions. Mean age and body mass index (BMI) of the study population were 29 ± 5 years and 25.1 ± 4.8 kg/m^2 respectively. Women with GDM were older (mean age 32 ± 5y vs. 28 ± 5y, $P<0.001$) and heavier (mean BMI 27.2 ± 5.1 kg/m^2 vs. 24.7 ± 4.7 kg/m^2, $P<0.001$) than their healthy counterparts. Prevalence of GDM tended to increase with age (6.9% in age <25y, 15.6% in 26–35y, and 32.7% in 36–45y, $P<0.001$). Maternal age, maternal BMI, history of previous GDM and family history of diabetes mellitus were independent predictors of developing GDM ($P<0.05$ for all). Low risk women (age <25y, BMI <25 kg/m^2, no family history of diabetes) comprised 10.7% of the whole population and the prevalence of GDM in these women was 4.5%.
Conclusion
The results of first nationwide study in Turkey indicate that GDM is very common affecting 1 out of 7 pregnancies in the country. Implementation of international guidelines on screening and management of this public health problem is required.

Incretin hormones in pathogenesis of secondary hyperglycaemia in patients with Cushing's disease and acromegaly

Lubov Machekhina[1], Ekaterina Shestakova[1], Lyudmila Astafieva[2] & Marina Shestakova[1]
[1]Endocrinology Research Centre, Moscow, Russian Federation; [2]Burdenko Neurosurgery Institution, Moscow, Russian Federation.

Aim of the study
To analyze the dynamics and levels of incretins and neuropeptides secretion in patients with CD and acromegaly and therefore to specify the pathogenesis of carbohydrate metabolism disturbances.
Methods
Forty-two patients with Cushing disease and acromegaly were included into the study. All patients were newly diagnosed with Cushing disease and acromegaly. Oral glucose tolerance test (OGTT), during which glucose, glucagon, glucagon like peptide 1 and 2 (GLP1, GLP2), gastric inhibitory peptide (GIP) and ghrelin were measured at 0, 30 and 120 min respectively was performed.
Results
The presence of prediabetes was higher in CD patients (40% vs 23% in acromegaly). Insulin resistance (assesed by HOMA-IR) was extremely high in both groups (11–13). In CD patients glucagon levels were significantly higher at all cut off points compared to controls (p 0 min $=0.001$, 30 min $=0.016$, 120 min $=0.025$). GIP secretion was lower in CD patients. Acromegaly group was characterized by inverse rhythm of GIP secretion, with no peak level at 30′ $P=0.324$. Basal GLP-1 level was significantly higher in CD patients ($P=0.047$). Both groups were characterized by unusual GLP-1 secretion with no peak levels at 30 min. No significant differences were found while analysing GIP and GLP-1 secretion in subgroups, divided regarding the stage of carbohydrate metabolism disorders. GLP-2 levels were significantly higher in CD patients (0 min $P<0.001$, 30 min $P=0.007$, 120 min $P<0.001$). Ghrelin levels were significantly higher in CD (0 min $P=0.013$ 30 min $P=0.002$ 120 min $P=0.003$) and acromegaly patients (0 min $P=0.048$ 30 min $P=0.023$ 120 min $P=0.015$) at all cut off points.
Conclusion
GIP and GLP-1 secretion in CD and acromegaly patients are characterized by an atypical rhythm with no peak levels which might mean that incretins are not playing the crucial role in carbohydrate disturbances that is seen in these patients. GLP-2 and ghrelin seem to influence and potentially regulate glucose homeostasis in CD and acromegaly patients.

Association of glucagon-to-insulin ratio and nonalcoholic fatty liver disease in patients with type 2 diabetes mellitus

Ji Oh Mok[1], Chan Hee Jung[1] & Ki Young Lee[2]
[1]Soonchunhyang University Bucheon Hospital, Incheon, Republic of Korea; [2]Gachun University Gil Hospital, Incheon, Republic of Korea.

Objective
Although the importance of islet α-cell dysfunction in the pathogenesis of type 2 diabetes has been reappraised, data on whether increase or decrease of glucagon relative to insulin is related with glucose metabolism parameters or metabolic diseases such as nonalcoholic fatty liver disease(NAFLD) in clinical settings are

very limited. Therefore, we investigated the association between glucagon-to-insulin ratio(G/I ratio) and presence of NAFLD and metabolic parameters in T2DM.
Methods
This retrospective, cross-sectional study was performed with data obtained from 230 T2DM patients(mean age, duration of DM, and BMI:56 years, 8 years, and 25 kg/m^2, respectively). Participants were assessed for serum fasting and postprandial G/I ratio and divided into tertiles. NAFLD was defined as ultrasonographically detected fatty liver. Results: The patients in the lowest tertile of fasting G/I ratio had higher BMI, visceral and subcutaneous fat thickness(VFT, SFT), and HOMA-IR and shorter duration of DM. Fasting and postprandial G/I ratios were negatively correlated with BMI, VFT, SFT, fasting c-peptide, and HOMA-IR. In addition, postprandial G/I ratio was positively correlated with HbA1c levels, FBG, and HDL-C. Subjects with HbA1c $>8\%$ showed significantly higher mean G/I ratio than those with HbA1c $\leq 8\%$. Prevalence of NAFLD was significantly decreased across tertile of fasting and postprandial G/I ratio. Low G/I ratio was significantly associated with presence of NAFLD by both unadjusted analysis and after multivariate adjustment (OR, 95%[CI]:3.24[1.4–7.51], 2.59[1.03–6.55], respectively).
Conclusion
Our results suggest that the high glucagon relative to insulin may contribute to hyperglycemia, whereas low glucagon relative to insulin may contribute to NAFLD in T2DM.

DOI: 10.1530/endoabs.56.GP85

Heart rate variability is related to concomitant glucose fluctuation in longstanding type 1 diabetes

Anna Shalimova, Beata Graff, Anna Szyndler, Jacek Wolf, Magdalena Blaszkowska, Elzbieta Orlowska-Kunikowska, Bogumil Wolnik & Krzysztof Narkiewicz
Medical University of Gdansk, Gdansk, Poland.

The presence of type 1 diabetes (DM1) affects the heart rate variability (HRV). However, there are conflicting data on the impact of hyper- and hypoglycaemia on the parameters of cardiovascular autonomic regulation.
The aim
To investigate the possible association of glucose fluctuation with HRV in longstanding DM1.
Design and methods
We examined 49 patients with longstanding (>20 years) history of DM1 (without overt cardiovascular disease) and episodes of hyperglycaemia >160 mg/dl during 24-hour continuous glucose monitoring (CGM). In all patients, simultaneous 24-hour CGM and Holter electrocardiographic recording were performed. Time- and frequency HRV parameters were used as indicators of cardiovascular autonomic regulation. Patients were divided into two groups: with and without hypoglycaemia <50 mg/dl ($n=22$ and $n=27$, respectively).
Results
As compared to patients with hypoglycaemia, patients without hypoglycaemia had a significantly longer time of daily and early morning hyperglycemia >160 mg/dl ($P=0.001$ and $P=0.038$, respectively), as well as higher values of current and historical (mean values over the past 10 years) HbA1c levels ($P=0.019$ and $P=0.007$, respectively). Patients without hypoglycaemia had significantly lower values of time- and frequency domain HRV parameters. SDANN was positively related to duration of hypoglycemic episodes ($r=0.40$, $P=0.004$) and negatively correlated with total time of hyperglycemic episodes ($r=-0.41$, $P=0.003$). Furthermore, daily HF% was negatively linked to hyperglycaemia episodes ($r=-0.40$, $P=0.038$), but not to hypoglycaemia ($r=-0.08$, $P>0.05$). Presence of diurnal hypoglycaemia influenced the direction of HRV parasympathetic component response to episodes of daily and early morning hyperglycaemia. In patients without hypoglycemic episodes, hyperglycaemia was associated with decrease in daily HF% ($r=-0.40$, $P=0.038$), whereas in patients with hypoglycemic episodes, hyperglyceamia was linked to increase in HF% during both day and night ($r=0.45$, $P=0.034$ and $r=0.44$, $P=0.043$, respectively).
Conclusions
In patients with longstanding DM1, HRV is related to concomitant glucose fluctuation. Our findings suggest interactive effect of hypoglycaemia and hyperglycaemia on cardiovascular autonomic regulation.

Objective
Neuroinflammation is a common primary or secondary mediator of the neurodegenerative process accompanying Alzheimer's disease (AD). Impaired brain insulin signaling, defining brain insulin resistance may represent a link between AD and type 2 diabetes mellitus (T2DM) while neuronal apoptosis may also be involved in the inflammatory process. Peripheral cytokine levels of IL-1β, IL-6, TNFα along with high sensitivity C-reactive protein (hsCRP) and apoptotic marker Fas ligand (FasL) were investigated in AD patients and they were compared with T1DM, T2DM.
Methods
We studied 93 patients: 41 with AD, 20 T1DM, 21 patients with T2DM and 11 healthy subjects. The number of cytokine-secreting peripheral blood mononuclear cells (nPBMCs) before and after mitogenic stimulation was determined for interleukin-1β (nIL-1β), interleukin-6 (nIL-6) and tumor necrosis factor-α (nTNFα) by the Enzyme-Linked-Immuno-spot assay. Serum levels of hsCRP and Fas ligand (FasL) were determined by ELISA.
Results
The studied subgroups did not differ in gender but differed in age. hsCRP had higher levels in AD (statistically significant difference only compared to T1DM, $P=0.02$) and lower in controls. The nPBMCs was higher in AD patients after stimulation than in basal conditions. This increase showed a statistically significant increase in nTNFα ($P<0.001$ versus T2DM, $P<0.001$ vs. T1DM, $P=0.005$ vs. control) and nIL-6 ($P=0.039$ vs. T2DM, $P<0.001$ vs. T1DM, $P=0.003$ vs. control) after stimulation with PMA, in all studied groups, but in basal conditions only nTNFα was higher in AD ($P=0.011$ versus control, $P=0.02$ versus T1DM). FasL concentrations in AD subgroup displayed statistically higher levels compared to all the other subgroups ($P<0.001$ versus T2DM, $P<0.001$ versus T1DM, $P<0.001$ versus control), while T2DM and T1DM subgroups had statistically lower levels compared to controls ($P<0.001$ and $P=0.035$, respectively) and T2DM had statistically lower levels compared to T1DM ($P<0.001$) ($P=0.08$). The nPBMCs was positively correlated with plasma levels of Fas-L after correction with age and this correlation was seen in AD subgroup only.
Conclusion
Low-grade systemic inflammation is higher in patients with AD compared to diabetic patients particularly after mitogenic stimulation. The Fas-FasL pathway, displaying the highest levels in AD and the lower in diabetes compared to control subjects, may have a role in this process as it is extrapolated by the positive correlation of FasL concentration and the magnitude of inflammatory response particularly in AD. Further investigation in the inflammatory-apoptotic pathway will shed light to any druggable pathway of ill-controllable AD.

Gestational diabetes mellitus and continuous glucose monitoring system. A prospective study.

Rosa Márquez-Pardo[1], María-Gloria Baena-Nieto[1], Lourdes García-García-Doncel[1], Concepción Cruzado-Begines[1] & Isabel-María Torres-Barea[2]
[1]Jerez Hospital, Jerez de la Frontera, Spain; [2]Puerta del Mar Hospital, Cádiz, Spain.

Introduction
Gestational diabetes mellitus (GDM) is associated with an increase of maternal-fetal complications. Continuous glucose monitoring system (CGMS) detects postprandial hyperglycemia and hypoglycemia during 24h.
Methods
Women with GDM in gestational weeks 26–32 were allocated a CGMS (Ipro^{TM}2) after diagnosis in an observational prospective study. It was analysed: Mean glucose and standard deviation, area under the curve (AUC) with glucose >140 and <70. Percentage of glucose above or below the limit of normality before and after breakfast, lunch, dinner and night. (Target ranges: before meals 70–95, after meal 70–140 and night 70–120 (expressed: mg/dl)).
Results
$n=65$. Maternal age 33 ± 4.46 years (>35 years $=36.9\%$), family history of diabetes 65.3%, personal history of diabetes 21.3%, prepregnancy BMI 26.21 ± 4.74 kg/m^2 (>30 kg/m^2 $=23.1\%$), weigh gain 8.15 ± 5.47 kg, HbA1c 4.9%, insulin treatment 27.7%.
CGMS: Glucose before breakfast 87.63 ± 7.98, after breakfast 116.89 ± 19.57, before lunch 86.20 ± 10.08, after lunch 111.08 ± 18.19, before dinner 92.32 ± 11.79 and after dinner 109.22 ± 16.27 (mg/dl)
AUC $>140=0.62$ and $<70=0.64$.
Time glucose above or below range:

Table 1

Time (%)	Before breakfast (70–95)	After breakfast (70–140)	Before lunch (70–95)	After lunch (70–140)	Before dinner (70–95)	After dinner (70–140)	Night (70–120)
Above range	26.98%	19.35%	20.01%	11.30%	36.05%	7.41%	8.15%
In range	65.74%	79.94%	68.96%	85.67%	60.02%	89.27%	81.73%
Below range	7.28%	0.71%	11.03%	3.03%	3.03%	3.32%	10.12%

Conclusions
SMCG showed preprandial hyperglycemia, mainly before dinner. Few hypoglycemias were detected predominantly before lunch and night. Patients with GDM should have a narrow monitoring before and after every meal, especially before dinner, to prevent maternal-fetal complications.

Depression screening in adults with diabetes

İbrahim Demirci[1], Cem Haymana[1], Yusuf Alper Sonmez[1], Abdullah Bolu[2], Nazlı Gulsoy Kırnap[1], Orhan Demir[1], Mustafa Dinc[1], Coskun Meric[1], Aydogan Aydogdu[1] & Omer Azal[1]
[1]Gulhane Training and Research Hospital, Department of Endocrinology and Metabolism, Ankara, Turkey; [2]Gulhane Training and Research Hospital, department of Psychiatry, Ankara, Turkey.

Introduction
Elevated depressive symptoms and depressive disorders affect one in four patients with type 1 or type 2 diabetes (1). Thus, routine screening for depressive symptoms is indicated in this high-risk population. Current guidelines all recommend screening for depression in diabetic population(2). The Patient Health Questionnaire-9 (PHQ-9) is a valid screening tool for depression in individuals with diabetes (3). There is no specific data about the prevalence of depressive disorders diabetic population of Turkey. Therefore, we planned this study to investigate depressive disorder incidence in a small group of diabetic patient population.
Methods
The demographic and laboratory parameters including glycated hemoglobin (HbA1c), lipid levels and body-mass indexes (BMI) were measured and PHQ-9 questionnaire was applied to all the diabetic patients admitted our endocrinology department and accepted to participate in the study. We used a cut-off point of 10 and above as high risk for depression in PHQ-9 questionnaire.
Results
A total of 552 patients with diabetes (mean age 58.548 ± 12.13) were enrolled in the study. Based on the predefined PHQ-9 cut-off value, 87 (16%) participants had depressive disorders. The patients with depressive disorders had worse HbA1c (7.91 ± 2.05 vs. 8.52 ± 2.44 in depression negative and positive groups, respectively; $P=0.012$), BMI (31.54 ± 5.72 vs. 34.17 ± 7.96 in depression negative and positive groups, respectively; $P=0.005$). Although statistically unimportant, LDL-C, non-HDL-C and FBG levels were also higher in the depressive disorder positive group. Patients of whom HbA1c was above target (uncontrolled diabetes) had higher PHQ-9 scores and there was a positive correlation detected between PHQ-9 score and HbA1c values ($r=0.108$, $P=0.011$).
Conclusion
Depressive disorders prevalence is higher than expected in diabetic population. As recommended by guidelines every diabetic patient should be screened for depressive disorders periodically. PHQ-9 questionnaire is a practical and useful material for screening depressive disorders in diabetic patients.

Nutritional composition of carbohydrate-rich gluten free products and glycemic index calculation of commercially available gluten free pasta

Anastasia Koureta[1], Apostolia Boumpa[2], Christos Tzallas[3], Eleni Themeli[2] & Stelios Tigas[1]
[1]Department of Endocrinology, University of Ioannina, Ioannina, Greece; [2]Department of Nutrition, Ioannina University Hospital, Ioannina, Greece; [3]Laboratory of Clinical Chemistry, Ioannina University Hospital, Ioannina, Greece.

Background
Celiac disease (CD) is an autoimmune enteropathy triggered by gluten ingestion in genetically susceptible individuals. Its prevalence is $\sim$7 times higher in type 1 diabetes (T1D) patients compared to the general population; in addition to adherence to a gluten free (GF) diet, these patients use carbohydrate counting to estimate their pre-meal insulin dosages. We aimed to (a) compare the nutritional composition between some GF and non GF carbohydrate-rich products available in the Greek market, and (b) calculate the GI of one commercially available, GF pasta.
Methods
We recorded the nutritional composition of 35 commercially available products (toasted bread, pasta and breakfast cereals). The in vivo GI was calculated for one specific GF pasta by comparing the plasma glycemic responses (area under the curve) in 10 healthy subjects (6 females, 4 males), after ingestion of (a) 50 g of glucose and (b) pasta containing 50 g of carbohydrate.
Results
Nutritional differences were identified between GF foods and their gluten counterparts (expressed as mean $\pm$ S.E.). Specifically, GF bread had lower energy and protein content per 100 g (1038 ± 7 VS 1123 ± 2 KJ and 4.0 ± 0.1 vs 9.0 ± 0.1 g respectively, $P<0.05$). GF pasta was higher in total carbohydrates but lower in simple carbohydrates and protein per 100 g (76.3 ± 2.1 VS 68.3 ± 1.5 g, 1.4 ± 0.3 vs 3.3 ± 0.1 g and 7.3 ± 0.7 vs 12.3 ± 0.2 g respectively, $P<0.05$). GF breakfast cereals' were higher in energy, saturated fat and simple carbohydrates, but lower in total carbohydrates, fiber and protein per 100 g (1906 vs 1580 ± 25 KJ, 4.2 vs 0.4 ± 0.2 g, 25.0 vs 9.4 ± 1.4 g, 70.8 vs 79.4 ± 4.6 g, 2.1 vs 5.3 ± 2.3 g and 6.4 vs 8.2 ± 1.2 g respectively, $P<0.05$). The *in vivo* calculated GI of the studied GF pasta (80% corn and 20% rice flour) was 32 ± 7 and its nutrient composition per 100 g was as follows: 78.5 g total carbohydrate, 0.5 g simple sugars, 1.2 g fiber, 6.5 g protein.
Conclusions
The present study revealed significant nutritional differences between GF and non GF products. The GI of the studied GF pasta was surprisingly low, probably due to the lower content in simple carbohydrates. T1D patients with CD should be aware of the high content of GF foods in total carbohydrates. All consumers should be advised to carefully read the food labels of GF products, as nutritional composition may vary considerably.

Analysis of health-related quality of life in patients with type 2 diabetes mellitus: results of an epidemiological study FORSIGHT-T2DM

Marina Kalashnikova[1], Andrei Gerasimov[2], Dmitriy Belousov[3], Lizaveta Aboishava[4] & Ivan Dedov[1,5]
[1]Department of Endocrinology, I.M. Sechenov First Moscow State Medical University, Moscow, Russian Federation; [2]Department of Medical Statistics, I.M. Sechenov First Moscow State Medical University, Moscow, Russian Federation; [3]Center of Pharmacoeconomics and Outcomes Research, Moscow, Russian Federation; [4]I.M. Sechenov First Moscow State Medical University, Moscow, Russian Federation; [5]Endocrinology Research Centre, Moscow, Russian Federation.

Background
The aim of this study was to assess health-related quality of life (HRQoL) of patients living in cities and towns with different population in the Russian Federation (RF) using EQ-5D questionnaire, to calculate health utility index (QALY) and cost-utility ratio (CUR).
Methods
One of the goals of the multicenter, observational, epidemiologic study FORSIGHT-DM2 was to evaluate HRQoL using the EQ-5D Questionnaire. The study included more than 2000 patients with T2DM from 45 cities in the RF. We analysed the impact of different factors associated with the disease itself, specific features of its course, living conditions on the QoL. We performed a multivariable linear regression analysis to estimate the contribution of each independent variable to overall outcome.
Results
The proportion of patients with moderate or severe decrease in HRQoL status with respect to any parameter(s) was significantly higher among patients residing in small cities/towns with population less than 1 million inhabitants compared to patients residing in large cities (over 1 million inhabitants), including Moscow and Saint Petersburg ($P<0{,}001$). However, the self-reported health status was comparable in all groups. The assessment of HRQoL using a visual analogue scale (VAS) showed that mean score reflecting self-reported health status of patients with T2DM was 4.97 on a 10-point scale, $s=2.4$, (49.7 for on a 100-point VAS), after converting this measure of health status into QALY-weights the value was 0.503. The cost of one quality-adjusted life year (CUR) of T2DM patient in RF in 2014 was 209 417 rubles ($3722.4). It was estimated according to the QALY index calculations made in the FORSIGHT-DM2 study using the following equation: CUR = COI / QALY, COI being the total direct medical costs of treating DM2 and its complications and comorbidities amounting 105 337 rubles per patient ($ 2742). Diabetic foot syndrome, depression, diabetic osteoarthropathy, myocardial infarction in anamnesis, and age had the biggest negative impact on HRQoL. Our prognoses showed moderate correlations.
Conclusion
Patients with T2DM have lower HRQoL (49,7) compared to the general population of the Russian Federation in similar age groups (60,1 according to the ESSE-RF study). Health utility index and cost-utility ratio calculated within the study can be used as a criterion for the assessment of medical care quality for patients with T2DM in the RF.

Gestational Diabetes Mellitus is associated with increased risk of Non-Alcoholic Fatty Liver Disease: A population-based cohort study

Aikaterini Lavrentaki[1,2], Anuradhaa Subramanian[3], G Neil Thomas[3], George Valsamakis[2], Konstantinos Toulis[3,4], Barbara Daly[5], George Mastorakos[2], Abd Tahrani[1,6] & Krishnarajah Nirantharakumar[3]
[1]Institute of Metabolism and Systems Research, University of Birmingham, Birmingham, UK; [2]Endocrine Unit, Aretaieion University Hospital, Athens Medical School, National and Kapodistrian University of Athens, Athens, Greece; [3]Institute of Applied Health Research, University of Birmingham, Birmingham, UK; [4]Department of Endocrinology, 424 General Military Hospital, Thessaloniki, Greece; [5]School of Nursing, Faculty of Medical and Health Sciences, University of Auckland, Auckland, New Zealand; [6]Birmingham Health Partners, Birmingham, UK.

Background
Gestational diabetes mellitus (GDM) is associated with adverse perinatal outcomes, and increased risk of post-natal type 2 diabetes and cardiovascular disease. However, whether GDM increases the risk of developing incident Non-alcoholic Fatty Liver Disease (NAFLD) is unclear and has not been well examined in previous studies. This is important considering the significant health burden of NAFLD and the opportunity to interfere in high risk population in order to reduce the risk of developing end-stage liver disease.
Methods and results
We conducted a retrospective cohort study after extracting data from a large primary care database (The Health Improvement Network databse) in the United Kingdom. The cohort consisted of 9640 women with GDM diagnosis and 31 296 control women, matched for age, body mass index (BMI) and time of pregnancy. All study participants were free from NAFLD diagnosis at study entry. Mean (standard deviation) age of the whole cohort was 32.62 (S.D.: 5.34) years and BMI 28.62 (S.D.: 6.10) kg/m^2. There were 44 (0.46%) and 41 (0.13%) NAFLD incident diagnosis in the GDM and control population respectively over a median follow-up of 2.87 (IQR 1.16–5.81) years. Unadjusted incidence rate ratio (IRR) for NAFLD development was 3.28 (95% CI 2.14–5.02). After adjusting for age, Townsend (deprivation) quintile, smoking, BMI and Metformin usage; women with GDM remained at increased risk of developing NAFLD compared to women without GDM (IRR 2.95; 95%CI 1.91–4.55). Further adjustment for the diagnosis of polycystic ovarian syndrome, hypertension, hypothyroidism, and lipids lowering treatment did not change our findings (IRR 2.83; 95%CI 1.83–4.38).
Conclusions
Women diagnosed with GDM were at significantly increased risk of NAFLD development in their post-delivery life compared to women without GDM. Clinicians should have a low threshold to investigate women with history of GDM for the presence of NAFLD. Future studies need to examine whether lifestyle or pharmacological interventions could reduce the risk of developing NAFLD in women with history of GDM.

Proinflammatory cytokines and endotoxemia level change in patients with type 2 diabetes and nonalcoholic fatty liver disease after hepatoprotective and probiotic therapy usage

Kateryna Kondratiuk[1], Mykola Lysianyj[2], Kondratiuk Valentyna[3] & Galyna Myhalchyshyn[4]
[1]O.O. Bogomolest National Medical University, Kyiv, Ukraine; [2]A.P. Romodanov Institute of Neurosurgery of NAMS of Ukraine, Kyiv, Ukraine; [3]P.L. Shupyk National Medical Academy of Postgraduate Education, Kyiv, Ukraine; [4]O.O. Bogomolest National Medical University, Kyiv, Ukraine.

Association of type 2 diabetes, NAFLD, intestinal dysbiosis and endotoxemia is a trigger factor of cytokine cascade which manifest in proinflammatory state development, insulin resistance, hyperglycemia and dyslipidemia progression. The aim of this study is to reveal the effect of multiprobiotic Symbiter (symbiotic association of 14–24 strains of Bifidobacterium Lactobacillus, Propionibacterium, Lactococcus lactis, Streptococcus, Acetobacter aceti) and hepatoprotector Glutargin (arginine and glutamic acid salt) on proinflammatory cytokine levels and endotoxemia in patients with type 2 diabetes and NAFLD. Materials and methods. We observed 64 patients with type 2 diabetes and NAFLD who received oral hypoglycaemic agents, hepatoprotector Glutargin (0.75 g three times a day) together with multiprobiotic Symbiter (10 g twice daily) during 30 days. The control group consisted of 25 apparently healthy individuals. The concentration of the cytokines (IL 6, 8, TNF-α) in both blood serum and coprofiltrates and levels of antibodies to LPS in blood serum were determined by enzyme-linked immunosorbent assay (ELISA). The state of intestine microbiota was evaluated based on the results of bacteriological examination of faeces. Results and discussion. Before treatment patients with type 2 diabetes and NAFLD had significant increased blood proinflammatory cytokines concentrations indicating severe inflammatory and immunopathological reactions. We also revealed increased levels of IgG antibodies to LPS and proinflammatory cytokines in coprofiltrates which had strong correlation with dysbiotic disorders rate, reflecting the inductive role of Gram-negative flora endotoxin in inflammation progression in these patients. Conclusions. The use of Glutargin and multiprobiotic Symbiter complex reduced systemic inflammation by statistically significant decrease of serum proinflammatory cytokines and endotoxemia levels in patients with type 2 diabetes with NAFLD, which directly correlated with intestinal microbiota improvement. Due to this we consider that dysbiosis correction improve immunological status in this patients.

Telemonitoring and Telemedicine for Type 2 Diabetes Care: Multi-center Randomized Controlled Trial

Jae-Han Jeon[1], In-Kyu Lee[1] & Ji-Yun Jeong[2]
[1]Kyungpook National University, Daegu, Republic of Korea; [2]Sun Chun Hyang University Hospital Gumi, Gumi, Republic of Korea.

The advent of Web-based patient management technologies, including Web-based messaging, video conferencing, remote monitoring of vital signs, and Web-based educational programs, has resulted in the recognition that telemedicine may benefit diabetic patients with limited access to healthcare providers and/or a high burden of disease. In this regard, 24-week prospective multi-center randomized controlled trial involved 338 adult patients with type 2 diabetes at four university hospitals in South Korea was performed to determine the effectiveness of the Smart Care service on glucose control based on telemedicine and telemonitoring compared with conventional treatment in patients with type 2 diabetes. The patients were randomly assigned to a control group (group A, $n=113$), a telemonitoring group (group B, $n=113$), or a telemedicine group (group C, $n=112$). Patients in the telemonitoring group visited the outpatient clinic regularly, accompanied by an additional telemonitoring service that included remote glucose monitoring with automated patient decision support by text. Remote glucose monitoring was identical in the telemedicine group, but assessment by outpatient visits was replaced by video conferencing with an endocrinologist. The adjusted net reductions in HbA1c concentration after 24 weeks were similar in the conventional, telemonitoring, and telemedicine groups ($-0.66\% \pm 1.03\%$ vs $-0.66\% \pm 1.09\%$ vs $-0.81\% \pm 1.05\%$; $P>0.05$ for each pairwise comparison). Fasting glucose concentrations were lower in the telemonitoring and telemedicine groups than in the conventional group. Rates of hypoglycemia were lower in the telemedicine group than in the other two groups, and compliance with medication was better in the telemonitoring and telemedicine than in the conventional group. No serious adverse events were associated with telemedicine. Telehealthcare was as effective as conventional care at improving glycemia in patients with type 2 diabetes without serious adverse effects.

Randomized control study to compare security and efficacy of the new long acting analogues degludec and glargina U300 in people with type 1 Diabetes. Preliminary results of the Ineox study

Marta Elena Domínguez-López, Rosario Vallejo, Virginia Morillas, Natalia Colomo, Mercedes Guerrero, Gema Rojo & Marisol Ruiz de Adana Navas
Endocrinology Department, Hospital Regional Universitario, Málaga, Spain.

Background
There aren't published randomized studies comparing the clinical impact of degludec and Glragina U300 in the treatment of type 1 diabetes patients. (T1DP)
Objective
To compare efficacy and safety of the new long acting analogues Glargine U 300 and Degludec in 300 Type1 diabetes patients treated with basal/bolus treatment.(BBT)
Material and methods
Randomized control study 1.1 in 300 T1DP treated with BBT with glargineU100 or Detemir who change to GlargineU300 or Degludec at 1500 h during 24 weeks, with telematic visit (using Emminens platform) 6 weeks after the change of the treatment. The efficacy is mainly measured by change of HbA1c, secundary measures evaluated where variabilitu (SD,CV), BMI, insulin doses and quality of life (DQol). Safety measure being number of hypoglycemias (<54 mg/dl, <7 mg/dl and at night) and severe hypoglycemias during the whole 6 months period. We present the results of the first 150 recruited patients, age: 39.3 ± 11.7 years, sex (male 54%/female 46%), duration of the diabetes $19{,}43 \pm 11$ years, previously treated with Glargina U100 one or two doses (63%) or detemir two doses (37%)
Results
Globally there is a significative improvement at 24 weeks in HbA1c (7.8 ± 0.9 vs 7.6 ± 1; P 0.002) and also in porcentaje of hypoglycemias in glucometer download (13.6, $6 \pm 12\%$ vs $10{,}4 \pm 7{,}7$; P 0.005). We found no significant differences in all the studied variables except except for the lower insulin dose needed in the degludec group vs glargineU300 (IBasal 6 m: 27.4 ± 14 vs 34 ± 14,$P=0.009$; IBasal 6 m/kg: 0.36 ± 0.16, vs 0.46 ± 0.17,$P=0.001$; TDD(total daily dose)6 m/kg: 0.67 ± 0.25 vs 0.79 ± 0.27, $P=0.011$.
Conclusions
In T1DP the change of the treatment to the new long acting analogues degludec or Glargine U300 leads to an improvement in metabolic control in 24 weeks with less percentage of hypoglycemia and a a dose 22% inferior for degludec. We found no differences in metabolic (HbA1c, CV, BMI, Dqol) or safety variables(mild or severe hipoglucemias in 6 months) evaluadas. A larger number of patients and a longer period of follow up will help to corroborate those results.

Long term results and determinants of outcomes in primary health care diabetes prevention. The DE-PLAN project

Aleksandra Gilis-Januszewska[1], Jaana Lindström[2], Noël C Barengo[3] & Jaakko Tuomilehto[4,5,6]
[1]Department of Endocrinology, Jagiellonian University, Medical College, Krakow, Poland; [2]Chronic Disease Prevention Unit, National Institute for Health and Welfare(THL), Helsinki, Finland; [3]Department of Medical and Population Health Science,Herbert Wertheim College of Medicine, Florida International University, Miami, Florida, USA; [4]Dasman Diabetes Institute, Dasman, Kuwait; [5]Department of Chronic Disease Prevention, National Institute for Health and Welfare, Helsinki, Finland; [6]Diabetes Research Group, King Abdulaziz University, Jeddah, Saudi Arabia.

Background
Real life implementation studies performed in different settings/populations proved that lifestyle interventions in prevention of DM2 can be effective. However, little is known about long term results of these translational studies and determinants of the outcomes.
Aim
The purpose of this study was to examine the maintenance of diabetes type 2 risk factor during 3 year follow-up and to examine determinants of long term outcomes.
Methods
Study participants ($n=263$), middle-aged, slightly obese with baseline increased DM2 risk (FINDRISC)>14), but no baseline diabetes were invited to receive 11 lifestyle counselling sessions, guided physical activity sessions and motivational support during 10-months. Examinations were performed baseline, after one/three years. Repeated measure analysis was used for comparison of the 3 measurements. Stepwise regression analysis was used to determine predictors of weight reduction maintenance.
Results
Mean weight decreased by 2.27 kg (S.D. $=5.25$) after 1 year ($P=<0.001$), the mean total weight loss at the end of the study was maintained by 1.14 kg (S.D. $=5.8$) (ns). 70% of participants showed weight loss during the intervention (mean weight loss 4.2 kg, S.D. $=5.1$), 37% maintained weight loss during the 3 year follow-up(mean weight loss 2.1 kg, S.D. $=2.3$) In repeated measures analysis significant changes were observed from baseline to year 1 and year 3 in: weight ($P=0.048$), BMI ($P=0.001$), total cholesterol ($P=0.013$), TG ($P=0.061$), fasting glucose level ($P=0.037$) and FINDRISC ($P=0.001$) parameters. The conversion rate to diabetes was 2% after 1 year and 7% after 3 years. In multivariate analysis baseline history of increased glucose (odds ratio (OR) $=3.7$; 95% confidence interval (CI) 1.0–13.6) and reduction of total fat in diet during follow-up (OR $=4.3$; 95% CI 1.5–12.2) were independent predictors of successful weight loss maintains during follow up.
Conclusions
Type 2 diabetes prevention in real life primary health care setting through lifestyle intervention delivered by trained nurses leads to long term modest weight reduction and decrease of diabetes risk. Further studies exploring predictors of success are needed to help health care providers to redesign interventions and improve long-term outcomes of real life interventions.

Comparison of insulin degludec with Insulin glargin 300 units/ml in insulin-naive patients with type 2 diabetes mellitus

Tomislav Bozek[1], Ines Bilic Curcic[2] & Lea Smircic Duvnjak[1]
[1]Clinical Hospital Merkur, University Clinic Vuk Vrhovac, Zagreb, Croatia; [2]Department of Endocrinology, Clinical Hospital Osijek, Osijek, Croatia.

Introduction:
Many type 2 diabetes patients continue to have poor glycaemic control and would benefit from insulin therapy. One of the risks that hinders insulin use is

hypoglycemia. Optimal insulin therapy should therefore minimize the risk of hypoglycemia while improving glycemic control. Newer insulin preparations degludec and glargin 300 units/ml show more even and prolonged pharmacokinetic profile, enabling an evenly distributed daytime glucose-lowering effect with high reproducibility of action.
Aims
The aim of the study was to compare efficacy and safety of the insulin degludec with glargin 300 units/ml in insulin-naive subjects with type 2 diabetes.
Patients and methods
In this 24-week, parallel-group, randomized, open-label, treat-to-target-trial, adults with type 2 diabetes with A1c >7% taking oral antidiabetic drugs (OADs) were randomized 1:1 to receive once daily degludec or glargin 300 units/ml, both with metformin. At randomisation, eligible participants discontinued all OADs (DPP-IV inhibitors, sulfonylureas, pioglitazone) with the exception of metformin. Degludec and glargin 300 units/ml were administered in the morning with breakfast. Insulin was titrated to achieve prebreakfast plasma glucose (PG) of 3.9–4.9 mmol/l. In order to control postprandial glycemia, DPP-IV inhibitors or repaglinide were introduced as needed.
Results
Study included 184 participants (mean age 68.5±8.5 years, mean duration of diabetes 12.0±4.7 years, mean BMI 27.2±2.6 kg/m^2, mean baseline A1c 9.5±1.4%) that were randomized (degludec 92, glargin 300 units/ml 92). Reduction in A1c with degludec was similar to that with glargin 300 units/ml (2.2% vs 2.3%, $P=0.7$). Overall rates of confirmed hypoglycemia (PG<3.9 mmol/l) were similar with degludec and glargine 300 units/ml (0.8 vs 0.9 episodes/patient-year). None of enrolled patients had severe or nocturnal hypoglycemia. End-of-trial mean daily insulin doses were 0.35 units/kg and 0.39 units/kg for degludec and glargine 300 units/ml, respectively, which was significant difference ($P=0.02$). Increase in body weight was observed: 1.8 kg and 1.5 kg for degludec and glargine 300 units/ml, respectively ($P=0.6$).
Conclusion
Despite the well-documented benefits of timely blood glucose control and the availability of consensus guidelines encouraging the earlier use of insulin replacement, a substantial delay remains with respect to the appropriate initiation of insulin treatment in routine clinical practice. BOT with both insulin degludec and glargine 300 units/ml are useful strategies that improve glycemic control in clinical practice without causing serious hypoglycemia.

Adult-onset autoimmune diabetes: comparative analysis of classical and latent presentation

Lúcia Fadiga[1], Joana Saraiva[1,2], Diana Oliveira[1], Adriana Lages[1], Mara Ventura[1], Nelson Cunha[1], Diana Catarino[1], Bernardo Marques[3], João Frade[4] & Francisco Carrilho[1]
[1]Endocrinology Department, Coimbra Hospital and Universitary Centre, Coimbra, Portugal; [2]Faculty of Medicine of the University of Coimbra, Coimbra, Portugal; [3]Endocrinology Department, Portuguese Institute of Oncology, Coimbra, Portugal; [4]Clinical Pathology Service, Coimbra Hospital and Universitary Centre, Coimbra, Portugal.

Introduction
Adult-onset autoimmune diabetes (AID) has two different phenotypes: classic type 1 diabetes mellitus (T1DM), with insulin requirement just after diagnosis, and latent autoimmune diabetes in adults (LADA). According to the Immunology of Diabetes Society, LADA diagnostic criteria are: age of onset of 30 years or more, any islet autoantibody, absence of insulin requirement for at least 6 months. The purpose of this study is to characterize patients with AID followed on a tertiary centre, comparing classic T1DM and LADA.
Methods
We collected data from patients with diabetes and positive islet autoantibodies, with at least 30 years at diagnosis. We classified patients who started insulin in the first 6 months as T1DM and patients with no insulin requirements in the first 6 months as LADA. Data regarding presentation, autoantibodies, A1C and C-peptide at diagnosis, therapeutics and complications were analysed with SPSS.
Results
Ninety-two patients included, 46 with T1DM and 46 with LADA. In T1DM group, 50% female, in LADA 52.1%. The median age at diagnosis was 38 years in T1DM group and 42 years in LADA group. The median follow-up time after diabetes diagnosis was 8 years in T1DM and 11 years in LADA ($P=0.023$). The median time between diagnosis of diabetes and diagnosis of autoimmune cause was 0 months in T1DM and 60 months in LADA ($P<0.001$). The mean BMI at diagnosis was 23.52 kg/m^2 in T1DM and 26.07 kg/m^2 in LADA ($P=0.023$). The median number of positive autoantibodies was 2 in T1DM and 1 in LADA ($P=0.013$). There was no statistical difference between both groups in what concerns to title of GAD autoantibodies, A1C and C-peptide at diagnosis of autoimmune aetiology. The presence of symptoms at diagnosis was associated with T1DM group ($P<0.001$). There was no difference between both groups in A1C, lipid profile, glomerular filtration rate and BMI at the last evaluation. LADA group was associated with macroalbuminuria ($P=0.042$). The median daily insulin dose was 40U for T1DM and 33.5U for LADA. Patients in LADA group used more often non insulin antidiabetic drugs ($P=0.001$). There were no differences on other diabetes complications.
Conclusion
Patients with classic T1DM presented more often with symptoms at diagnosis, lower BMI and higher number of autoantibodies, which may be related to a more aggressive autoimmune process. Patients with LADA were associated with macroalbuminuria and were more often under non insulin antidiabetic drugs. The ideal treatment of LADA is yet to be identified.

Optimal time for measuringglucose level to detect steroid induced hyperglycaemia

Guven Baris Cansu[1], Dondu Uskudar Cansu[2], Bengur Taskiran[1], Sule Yasar Bilge[2], Muzaffer Bilgin[2] & Cengiz Korkmaz[2]
[1]Yunus Emre State Hospital, Eskisehir, Turkey; [2]Osmangazi University, Eskisehir, Turkey.

Purpose
Steroid usage may cause hyperglycaemia in non-diabetic patients. We aimed to detect the onset of hyperglycaemia and the best time for glucose measuring over a short time span (1–5 days) in non-diabetic patients who commenced moderate or high dose steroid therapy.
Methods
Electronic data of patients, who were commenced moderate or high dose steroid therapy (15–60 mg prednisolone or equivalent dose methyl prednisolone) due to inflammatory rheumatologic diseases between January 2015 and December 2016, were retrospectively evaluated. The subjects who had confirmed diagnosis of DM were excluded. Seven point (morning fasting, pre-meal before breakfast, lunch, and dinner, and bedtime) capillary blood glucose measurements during the first 5 days of steroid therapy were evaluated. Results: 1750 premeal and postmeal glucose measurements were collected from 15 male (age 44±16 years) and 35 female (age 41±12) patients. Fasting blood glucose ≥126 mg/dl and random glucose ≥200 mg/dl were diagnosed with DM, while random glucose between 179 and 200 mg/dl was considered as hyperglycemia. 21 (%42) patients developed steroid induced overt hyperglycemia compatible with DM and 39 (% 78) developed hyperglycemia to a lesser extent. Mean fasting blood glucose was 88.04±9.9 mg/dl and hemoglobin A1c was 5.46±0.36% before steroid therapy. The highest glucose was detected postprandial on 3rd day of steroid therapy both in DM developers and non-DM developer hyperglycaemia group (234±29 vs 180±18 mg/dl, $P<0.0001$). DM developers and non-DM developers did not show significant difference in terms of steroid dose, age, BMI, baseline hemoglobin A1c, previous steroid therapy history, underlying rheumatologic disorder, or family history of DM.
Conclusions
Fasting blood glucose may be normal and postprandial hyperglycaemia may be present in endogenous steroid excess due to Cushing' syndrome and exogenous steroid usage. It is not recommended to monitor glucose levels during low dose steroid therapy, while moderate or high dose steroid therapy demands follow-up. It is especially important in outpatients to detect the best time for measurement. We showed that the highest values were postprandial levels on 3rd day of therapy in patients taking moderate-high dose of steroid. As a result we recommend measuring postprandial instead of fasting glucose levels during first 3 days of moderate-high dose of steroid therapy.

Effect of aerobic exercise training on serum malondialdehyde level and quality of life in type 2 diabetes

Nesrin Dogan Dede[1], Suleyman Ipekci[2], Levent Kebapcilar[2], Mihriban Arslan[1], Sevil Kurban[3], Mustafa Yildiz[4] & Mustafa Sait Gonen[1]

[1]Meram Medical Faculty, Department of Internal Medicine, Konya, Turkey; [2]Division of Endocrinology and Metabolism, Selcuk University Faculty of Medicine, Konya, Turkey; [3]Department of Biochemistry, Necmettin Erbakan University, Meram Medical Faculty, Konya, Turkey; [4]Karamanoğlu Mehmetbey University Faculty of Physical Education and Sport, Karaman, Turkey.

We planned to research the effect of the regular exercise of type 2 diabetes mellitus (DM) patients on metabolic control, malondialdehyde (MDA) as the oxidative stress marker and on the quality of life. The study has been carried out 64 patients diagnosed with Type 2 DM for at least 6 months, without any microvascular/macrovascular complication for diabetes, using oral anti-diabetic agent with a HbA1c value of less than 9%. The 31 patients were asked to carry out aerobic exercise under supervision based on the American Diabetes Association recommendations, in 3 non-successive days for 150 min a week in 12 weeks. Both groups were given a diet. Systolic and diastolic blood pressure (SBP, DBP), body mass index (BMI), waist/hip measurements were made in the beginning and in the end of the study. Venous blood samples were taken for HbA1c, insulin, lipid panel and MDA analysis and Short Form Health Survey (SF-36) quality life questionnaire form was applied. All parameters within and between the groups were compared as a result of the 3-month-period. In the exercise group, there have been statistically significant reductions in the BMI ($P=0.017$) and MDA ($P=0.046$) levels in the measurement of SBP ($P=0.027$), DBP ($P=0.042$), waist circumference ($P=0.01$). There has been an increase in the tendency of statistical significance in the mental health sub score ($P=0.06$) of the SF-36 questionnaire form as well as increases in other sub scores including physical and mental scoring. In the control group, there has been a statistically significant decrease in the general health scores ($P=0.006$). In the end of the study, there has been a statistical increase in favour of the exercise group compared with the control group in the sub scores of general health ($P=0.02$) and mental health ($P=0.03$) as compared with the initial values. Twelve weeks aerobic exercise program for the type 2 diabetic patients has been effective in reducing the MDA level, which is the oxidative stress indicator. In the exercise group, there has not been any significant change in the metabolic parameters after the twelve weeks long aerobic exercise, however, there has been increases in favour of the general health and mental health scores of the quality of life when compared to the control group. In order to observe improvements in metabolic parameters, there is need for studies to be conducted with more patients for longer periods and including combined exercise programs.

A healthier fat intake is associated with absence of diabetic retinopathy in patients with type 1 diabetes

Minerva Granado-Casas[1,2], Mariona Martín[3], Jordi Real[1,4,5], Anna Ramírez-Morros[1], Esmeralda Castelblanco[1,6], Núria Alonso[1,6], Alicia Traveset[2,7], Nuria Alcubierre[2], Manel Puig-Domingo[1,6], Marta Hernández[2,8] & Dídac Mauricio[1,2,6]
[1]Department of Endocrinology and Nutrition, Health Sciences Research Institute and University Hospital Germans Trias i Pujol, Badalona, Spain; [2]Biomedical Research Institute, University of Lleida, Lleida, Spain; [3]Department of Endocrinology and Nutrition, University Hospital Germans Trias i Pujol, Badalona, Spain; [4]Epidemiology and Public Health, International University of Catalonia, Barcelona, Spain; [5]Unit Support of Research, Institut d'Investigació en Atenció Primària Jordi Gol (IDIAP Jordi Gol), Barcelona, Spain; [6]Centre for Biomedical Research on Diabetes and Associated Metabolic Diseases (CIBERDEM), Instituto de Salud Carlos III, Madrid, Spain; [7]Department of Ophthalmology, University Hospital Arnau de Vilanova, Lleida, Spain; [8]Department of Endocrinology and Nutrition, University Hospital Arnau de Vilanova, Lleida, Spain.

Background
Medical nutrition therapy is an important part of the management of type 1 diabetes mellitus (T1DM). Proper adherence to a healthy diet may have a favorable impact on diabetic complications. Our aim was to assess differences in food and nutrient intake of type 1 diabetic patients with and without diabetic retinopathy (DR).
Subjects and methods
This was a two-center, cross-sectional study in patients diagnosed with T1DM with and without DR. Subjects were recruited through the DR screening program of the Departments of Ophthalmology. A validated food frequency questionnaire was administered. Clinical variables were collected. The analysis of data included comparison between groups and multivariable models.
Results
A sample of 103 T1DM with DR and 140 T1DM without DR were recruited. Subjects with DR showed a lower intake of total fat ($P=0.036$) than their non-DR counterparts. DR was associated with increasing age ($P=0.004$), hypertension ($P<0.001$) and diabetes duration ($P<0.001$), and there was a negative association with high educational level ($P=0.018$). The multivariable adjusted analysis showed that the intake of complex carbohydrates was positively related to the presence of DR ($P=0.018$). In contrast, the intakes of total fat ($P=0.004$), monounsaturated fatty acids (MUFA) ($P=0.005$), oleic acid ($P=0.005$), α-linolenic acid ($P=0.041$) and vitamin E ($P=0.004$) were associated with the absence of DR.
Conclusions
The intake of total MUFA, oleic acid, α-linolenic acid and vitamin E is associated with a lower frequency of DR in patients with T1DM. These results suggest a potential protective effect of these lipid components for DR.

Type 2 diabetes remission one year after bariatric surgery – a comparison between vertical sleeve gastrectomy and gastric bypass

Inês Ferreira Barros, Sílvia Paredes, Fernando Manso, José Manuel Maia da Costa, Aline Fernandes, Marta Alves & Maria Lopes Pereira
Hospital de Braga, Braga, Portugal.

Background
Gastric Bypass surgery (Bypass) is recognized as the ultimate metabolic surgery. The success in type 2 Diabetes (DM2) remission documented in patients submitted to Vertical Sleeve Gastrectomy (Sleeve) made questionable the hypothesis that this restrictive surgery has beneficial metabolic effects.
Main goal
Comparing the Bypass and Sleeve's efficacy in DM2 remission.
Methods
Retrospective study of 112 diabetic patients submitted to bariatric surgery in Hospital de Braga from January of 2011 to December of 2016. For each patient, the data was collected from the clinical process and Body Mass Index (BMI), fasting glucose and insulin, glycated haemoglobin (HbA1c) and diabetic therapy were compared at 0 and 12 months. The criteria used for the definition of DM2 remission was the American Diabetes Association's. The statistical analysis was made through the SPSSvs22 program, with T-test for correlated and independent samples (significance level of 0.05).
Results
From the 112 patients included in the study, 63 performed Sleeve, with 74.6% female ($n=47$) with a medium age of 47.63 ± 11.7 years. The remaining 49 performed Bypass, with 79.6% female ($n=39$) and a medium age of 50.29 ± 10.0 years. Twelve months later, with Sleeve, patients presented a medium reduction of the BMI of -13.40 ± 4.7 kg/m^2 and with Bypass of -13.55 ± 5.3 kg/m^2, statistically significant. Nevertheless there were no differences statistically significant in the magnitude of reduction of BMI between both surgeries. Concerning fasting glucose, Sleeve allowed a medium reduction of -29.69 ± 31.8 mg/dl and Bypass of -47.23 ± 53.0 mg/dl, without differences in the magnitude of reduction between both surgeries ($P=0.076$). Fasting insulin after Sleeve decreased a medium of -10.75 ± 10.5 uUI/ml and after Bypass -20.68 ± 12.9 uUI/ml. Regarding HbA1c, with Sleeve, patients obtained differences of -0.85 ± 0.9% and with Bypass a medium of -1.50$\pm$1.6%. Bypass showed a more significant reduction in insulinemia ($P=0.001$) and HbA1c ($P=0.039$). One year after Sleeve, 42.9% of the patients kept the DM2 therapy ($n=27$). Of the patients submitted to Bypass, 46,9% didn't suspend the medication ($n=23$). Twenty patients went on DM2 remission after Sleeve ($n=31.7$%) and 17 after Bypass (34.7%).
Conclusion
Both surgeries allowed DM2 remission after one year. Despite Sleeve and Bypass had equivalent reductions of BMI and fasting glucose, Bypass allowed a more significant reduction in fasting insulin and HbA1c values, independently of weight loss.

DOI: 10.1530/endoabs.56.GP102

GP103

Glycemic control and outcomes of patients admitted in the acute stroke unit

Tania Ramos Martínez, María Dolores Ballesteros Pomar, Sara García Arias, Javier Tejada García, David Barajas Galindo, Paula Fernández Martínez, Elena González Arnaiz & Isidoro Cano Rodríguez
Complejo Asistencial de León, León, Spain.

Introduction
Post-stroke hyperglycemia affects two-thirds of the patients during acute ischaemic stroke and it is associated with poorer outcomes. The aim of this study was to analyze the differences between the diabetic and non- diabetic patients that underwent an acute stroke.
Methods
Retrospective descriptive study of patients admitted to the Acute Stroke Unit from January to June 2017, including blood parameters, glycemic treatment and 3 months outcomes.
Results
From January to June 2017, 126 patients were admitted to the Acute Stroke Unit. 28,6% of them with a previous diagnosis of diabetes. More than half of the patients were men and the mean age was 73.2 (s.d. 9.0) in diabetics and 71.9 (s.d. 12.8) in non-diabetics. 17% ($n=6$) of the diabetic patients needed thrombolysis versus 11%($n=10$) of non diabetics. Mean HbA1C was 7.4% (s.d. 1.4) in diabetics against 5.6% (s.d. 0.39) in non-diabetics. Mean glucose level in diabetics at admission was 166.0 mg/dl (s.d. 67.6) and in the first 72 hours 159.2 mg/dl (s.d. 51.5) starting treatment with an average of 185.0 mg/dl (s.d. 53.6). The most common treatment used was IV insulin 41.7% ($n=15$), sliding-scale SC insulin 19.4% ($n=7$), sliding-scale with basal SC insulin 14% ($n=5$) and only one patient received metformin on the acute treatment. 22.2% ($n=8$) of the diabetic patients had no treatment during admission. In non-diabetic patients, the mean glucose level at admission was 108.0 mg/dl (s.d. 19.8) and in the first 72 hours 104.4 mg/dl (s.d. 16.0). Only one of them developed stress hyperglycemia and was treated with sliding-scale SC insulin. Regarding outcomes, 41.7% of diabetics had a total recovery, 50% developed sequels and 8.3% died versus 51.1%, 45.6%, 3.3% in non-diabetics. 16.7% of the diabetics were readmitted in less than 3 months versus 12% of the non-diabetics, not statistically significant. The outcomes were related with the glucose level when treatment was started, 173.5 mg/dl (s.d. 57.4) in those with a total recovery, 189.4 mg/dl (s.d. 50.9) the ones that developed sequels and 202.0 (s.d. 32.6) in those that died during the admission, although the differences were not statistically significant.
Conclusions
Diabetic patients seemed to have poorer outcomes after a stroke. The poorest outcomes seemed to be related to the highest glucose level when treatment was started, although our sample was not large enough to detect significant differences. Almost 20% of diabetics received sliding-scale SC insulin although studies had shown is not an appropriate treatment.

Validation of Friedewald formula for estimatinglow-density lipoprotein cholesterol in Korea: the Korea National Health and Nutrition Examination Survey, 2009–2011

Jongseok Lee[1], Sungok Jang[2], Haemin Jeong[1] & Ohk-Hyun Ryu[1]
[1]Hallym University, Chuncheon, Republic of Korea; [2]Korea Association of Health Promotion, Gangwon branch, Chuncheon, Republic of Korea.

Objectives
The aim of this study is to compare Friedewaldestimated and directly measured lowdensity lipoprotein cholesterol (LDLC) values and assess the concordance in guideline risk classification between the two methods.
Methods
The data were derived from the 2009 to 2011 Korea National Health and Nutrition Survey (KNHANES). Analysis was done for 6454 subjects with lipid panels – total cholesterol (TC), directly measured LDL-C, high-density lipoprotein cholesterol (HDL-C), and triglycerides (TG).
Results
For subjects with TG <400 mg/dl, overall concordance in guideline risk classification was 79.1%. The Friedewald formula tended to underestimate LDL-C more at higher TG or lower HDL-C levels. Especially, the percent of subjects who were misclassified into a lower risk category was 31% when TG were 200–299 mg/dl; and 45.6% when TG were 300–399 mg/dl. A greater under-estimation of LDL-C occurred at higher TG and lower Friedewaldestimated LDL-C levels. Of subjects with a Friedewaldestimated LDL-C <70 mg/dl, 55.4% had a directly measured LDL-C ≥ 70 mg/dl when TG were 200–399 mg/dl.
Conclusions
The Friedewald equation tends to underestimate LDL-C in highrisk subjects such as hypertriglyceridemia and hypo-HDLcholsterolemia. For these individuals accurate assessment of LDL-C is crucial, and therefore additional evaluation is warranted.

Acute insulin-induced hypoglycemia decreases systemic fibrinolytic balance in patients with type 1 diabetes

Karina Sarkisova[1,2], Iwona Renata Jarek-Martynowa[2], Marina Shestakova[2], Alexander Ilyin[2], Larisa Nikankina[2], Lydia Chirkova[2], Ekaterina Koksharova[2], Ekaterina Mishina[2] & Minara Shamkhalova[2]
[1]I.M. Sechenov First Moscow State Medical University, Moscow, Russian Federation; [2]Endocrinology Research Centre, Moscow, Russian Federation.

Background and aims
Hypoglycemia can be a risk factor for adverse cardiovascular and cerebrovascular events. However, changes in platelets and coagulation hemostasis during hypoglycemia have not been extensively studied. During hypoglycemia, a wide spectrum of physiologic responses are activated that could have potential vascular biological effects. To date, the role played by catecholamines, the sympathetic nervous system, and neuroendocrine hormones on activating adhesion molecules and influencing fibrinolytic balance is incompletely understood. The aim of this study was to assess the impact of insulin-induced hypoglycemia on the platelet activity, and fibrinolysis in patients with type 1 diabetes.
Research design and methods
We studied 15 patients with type 1 diabetes (9 male and 6 female, age 24.4 ± 5.6, A1C $9.07\pm2.3\%$) without microvascular complications during hyperinsulinemic (1 mU/kg per min) hypoglycemic clamp protocol. Induced platelet aggregation in whole blood using thrombin receptor activating peptide 6 (tRaP-6), collagen, arachidonic acid, adenosine-diphosphate, ristomycin was measured during hypoglycemia (plasma glucose(pg) 2.3 ± 0.1 mmol/l), euglycaemia (pg 4.4 ± 0.4 mmol/l), hyperglycemia (pg ≥ 12 mmol/l) and recovery phase by multiple electrode platelet aggregometry (Multiplate). Plasminogen activator inhibitor (PAI-1), tissue plasminogen activator (tPA) was determined by ELISA. Statistical analysis was performed with SPSS 22,0 for Windows, $P<0.05$.
Results
Platelets aggregation induced collagen ($P=0.001$), thrombin ($P=0.003$), adenosine- diphosphate ($P=0.016$), arachidonic acid ($P=0.05$) was significantly increased during 20-min of hypoglycemia compared with euglycemia. Plasma PAI-1 activity were significantly different during hypoglycemia as compared with euglycemia ($P=0.001$) and as compared with recovery phase ($P=0.018$). Plasma concentrations of tPA did not alter during either hypoglycemic clamp in individuals with type 1 diabetes.
Conclusions
The present study confirmed that platelet activation is promoted by hypoglycemia and that hypoglycemia decreases systemic fibrinolytic balance by increasing PAI-1 activity while maintaining tPA values. Thus, at least two separate mechanisms for increasing thrombosis are activated by hypoglycemia in individuals with type 1 diabetes.

Transcranial duplexsonography in patients with type 1 diabetes and diabetic nephropathy

Karina Sarkisova[1,2], Iwona Renata Jarek-Martynowa[1], Mikhail Martynow[3], Albina Tsagaeva[3], Ludmila Pyshkina[3], Marina Shestakova[1] & Minara Shamkhalova[1]
[1]Endocrinology Research Centre, Moscow, Russian Federation; [2]I.M. Sechenov First Moscow State Medical University, Moscow, Russian Federation; [3]N.I. Pirogov Russian National Research Medical University, Moscow, Russian Federation.

Background and aims
Cerebrovascular reactivity (CVR) impairment was reported as a marker of cerebral microangiopathy in long-term type 1 diabetes (DM1). Indices of cerebral

blood flow might serve as an indicator of early microangiopathic complications. The aim of this study was to evaluate CVR in patients with DM1 and diabetic nephropathy. Research design and methods: Study has been reviewed by the Local Ethics Committee. The study has been performed in accordance with ethical standards laid down in the Helsinki Declaration. Peak systolic blood flow velocity (S) in the middle cerebral artery (MCA) before (S1) and after (S2) compression of the ipsilateral common carotid artery (CCA) and the index of vasomotor reactivity (VMRr = (S2–S1) × 100/S1) were measured with transcranial duplex sonography in 41 patients (age 28.9 ± 6.2 years, duration of DM1 15 ± 4 years, HbA_1c 8.9 ± 1,8%) with DM1, without history of cerebrovascular events, and 22 healthy control subjects (age 26.3 ± 4.2 years). The study included patients with normoalbuminuria AER in the morning urine < 20 mg/l ($n = 22$); microalbuminuria AER < 199 mg/l ($n = 12$); macroalbuminuria AER ≥ 200 mg/l ($n = 7$). A decrease of glomerular filtration rate (GFR) of 45–59 ml/min per 1.73 m^2 was noted in 6 patients, in 35 patients with GFR ≥ 60 ml/min per 1.73 m^2. Statistical analysis was performed with SPSS 22,0 for Windows, $P < 0.05$.

Results

There was statistically significant decrease of VMRr in patients with DM1 compared with control group ($P = 0.01$) (*U*-test). S in the MCA before compression of the CCA was not different in the study groups. S had statistically significant decrease after compression in the group of patients with GFR 45–59 ml/min per 1.73 m^2 compared with the group of patients with GFR ≥ 60 ml/min per 1.73 m^2 ($P = 0.008$) (*U*-test). S after compression was higher in patients with macroalbuminuria compared with normoalbuminuria ($P = 0.019$)(*P*-test). There was not statistically significant difference depending on HbA_1c level, duration of DM1, age, hypertension, smoking, presence and severity of diabetic retinopathy.

Conclusion

The CVR was reduced in patients with DM1. In patients with diabetic nephropathy (macroalbuminuria or GFR < 60 ml/min per 1.73 m^2), the ability of the MCA to change diameter under the influence of mechanical factor is reduced that leads to a disruption in the ability of the cerebral circulation to compensate a hemodynamic deficit. Diabetic nephropathy can indicate the severity of cerebral microangiopathy in patients with DM1.

Cumulative effect of glucose regulation in Calbindin-D9k knockout mice

Eui-Bae Jeung, Changhwan Ahn, Bo Hui Jeon, Seon Young Park & Duc Viet Ly
Chungbuk National University, Cheongju, Republic of Korea.

Cellular Ca2+ signals have been proposed to activate signal for hormone secretion. In pancreatic β cell which produce insulin, Ca2+ signals have been known contributing insulin secretion. Prior to conduct this study, we confirmed calbindin-D9k (CaBP-9k) which responsible for regulation of the distribution offree calcium in the cytoplasm. Hypoxic condition induces endoplasmic reticulum(ER) stress, increase both insulin signaling and insulin resistance. Byexposing hypoxia, CaBP-9k KO mice showed more increased level of ER stressmarker protein than wild type mice. To examine the cumulative effacement of CaBP-9k molecule ablation, we did examined the glucose tolerant test for 6, 12, 18 24 months old mice. After 6 month, CaBP-9k KO mice showed delayedregulation of serum glucose after glucose administration. Serum insulin of CaBP-9k KO mice were decreased compare to wildtype mice. In addition, theinsulin transcription factors of CaBP-9k KO mice (Mafa, Pdx, NeuroD1) have been downregulated. It demonstrated that CaBP-9k is not only the part of the insulin-secreting calcium signaling but also insulin working mechanism which could link to pathology for exacerbating type 1diabetes to type 2 diabetes.

The effect of GLP-1 agonist treatment on serum betatrophin levels and comparison with insülin treatment in type 2 diabetes mellitus patients

İlhan Tarkun[1], Yağmur Çakmak[2], Zeynep Akyay[1], Alev Selek[1], Zeynep Cantürk[1] & Berrin Çetinarslan[1]
[1]Department of Endocrinology and Metabolism, Kocaeli University, Kocaeli, Turkey; [2]Department of Internal Medicine, Kocaeli University, Kocaeli, Turkey.

Objective

Insulin insufficiency which is the result of deficiency of β-cells is the common feature for all types of diabetes. Therefore protection of functional β-cell mass is the keystone of diabetes treatment. Betatrophin, a newly determined hormone, has been identified as a potent stimulator that increases the production and expansion of β-cells in mice. However, very little is known about the physiological role of betatrophin in human.Chronic treatment of rodents with GLP-1 agonists can result in an increase in β-cell mass due to increases in β-cell proliferation, neogenesis and decreases in β-cell apoptosis.The aim of this study is to show the effect of GLP-1 agonist treatment on betatrophin levels and comparison with insülin treatment in type 2 diabetic (T2DM) patients. This is the first human study in the literature with relation between betatrophin and GLP-1 treatment.

Methods

This prospective study included 27 patients with uncontrolled T2DM which were treated with metformin and sulfonylurea. 17 patients were enrolled in GLP-1 group and 10 patients were insulin group. Fasting betatrophin levels were evaluated before and at the 6.th month of treatment.

Results

Demographical features and BMI of two groups were similar. Betatrophin levels decreased in both groups after 6 months of treatment. But no statistical difference is observed between compared groups ($P = 0.473$). The reduction in betatrophin levels were only significant in insülin treated group ($P = 0.017$). There were no significant relation between betatrophin and c-peptid levels ($P = 0.903$). Also betatrophin levels were not correlated with age, sex, duration of diabetes, variables of glucose and lipid profiles.

Conclusion

Betatrophin levels were decreased significantly in insulin group but not in GLP-1 group. Incretin based treatments are known to increase β-cell mass and betarophin is a potent stimulator of β-cells. As betatrophin levels were still high in subjects on GLP-1 treatment it can be postulated that betatrophin would be a pathway on β-cell increment during GLP-1 treatment in long-term. However, in order to obtain more significant results further studies with higher number of patients and long-term follow-up is needed.

High glucose stimulates mineralocorticoid receptor activity of retinal Müller glia cell

Kennosuke Ohashi, Takeshi Hayashi & Kazunori Utsunomiya
Division of Diabetes, Metabolism and Endocrinology, Department of Internal Medicine, The Jikei University School of Medicine, Tokyo, Japan.

Activation of mineralocorticoid receptor (MR) is shown in diabetic pathophysiology. We have investigated the activation mechanism of MR protein in diabetic nephropathy and clarified one of the mechanisms of activation of MR protein by hyperglycemia. On the other hand, MR is abundantly expressed in the retina. Retinal Müller glial cells are known to be involved in the control of retina hydration and homeostasis of potassium through MR and it is reported that treatment of MR antagonist is effective in central serous chorioretinopathy that causes edema between retina and choroid. Therefore, it is suggested that MR may be involved in edematous diseases of the retina. In diabetic macular edema, the role of VEGF has been demonstrated in recent studies, but a detailed mechanism of edema remains largely unknown. In this study, we confirmed the MR pathway in human retinal Müller glial cells and observed the response by hyperglycemia stimulation. We examined the MR pathway with MIO-M1 cell line which is a naturally immortalized retinal Müller glial cell line derived from human retina. We confirmed that MR proteins and mRNA are expressed in MIO-M1 cells by Western blotting and real time RT-PCR. Furthermore, we confirmed SGK1 and αENaC which were a target gene of the MR. We treated MIO-M1 cells with aldosterone. Aldosterone induces a significant up-regulation of MR, αENaC and SGK1 mRNA expression in MIO-M1 cells. For the examination of the diabetic retina, we treated MIO-M1 cells with high glucose (HG) condition and examined the effect of HG on MR activities. As a control, normal glucose (NG) was treated. HG treatment increased the 2.2 times MR protein levels in MIO-M1 cells ($P < 0.01$). On the other hand, MR mRNA did not change. Regarding MR target genes, SGK1 mRNA was significantly increased in HG compared to NG (6 h: $P < 0.001$, 12 h $P < 0.01$) but αENaC did not change. In Müller cells of the retina, hyperglycemia stimulates MR signal activity and may be associated with aggravation of edema. In this study, MR protein was increased, but MR mRNA was not increased in hyperglycemic condition. Regarding the mechanism of increase in MR protein, it was suggested that stimulation of hyperglycemia may induce activation of the translational factor and suppression of MR protein degradation.

Knock-down of class 2a histone deacetylases (HDACs) in hepatocytes of healthy mice does not affect gluconeogenesis but is associated with increased hematopoiesis

Maximilian Bielohuby[1], Suryaprakash Raichur[2], Manuela Stolte[3], Ulrike Hemmann[3], Sven W Görgens[1], Paulus Wohlfart[1], Kerstin Jahn-Hofmann[4], Bodo Brunner[4] & Norbert Tennagels[1]
[1]R&D Diabetes Division, Sanofi-Aventis Deutschland GmbH, Frankfurt, Germany; [2]Evotec International GmbH, Goettingen, Germany; [3]Preclinical Safety, Sanofi-Aventis Deutschland GmbH, Frankfurt, Germany; [4]Biologics Research, Sanofi-Aventis Deutschland GmbH, Frankfurt, Germany.

Class 2a HDACs (i.e. HDAC 4, 5, 7 and 9) are involved in the regulation of gluconeogenesis and accordingly, their inhibition has been shown to result in lower blood glucose and improved pyruvate tolerance in diabetic mice. However, pan-inhibition of HDACs is not a viable approach for chronic treatment of type 2 diabetes (T2D) due to induction of severe side effects in various tissues. We now have investigated *in vitro* and *in vivo* efficacy and safety of a liver-selective HDAC knock-down via single or combinatorial siRNAs for HDAC 4, 5 or 7. In mouse and human hepatocytes, siRNAs directed against HDAC4, 5 or 7, as well as the combination of all three siRNAS, led to a selective knock-down of the respective HDAC mRNA(s) by about 80-90%. In parallel, genes involved in the regulation of gluconeogenesis, namely G6PC and PCK1, were significantly down-regulated by 70–80% in primary hepatocytes. Those siRNAs were used either alone or in dual or triple combinations (0.75 mg/kg) to treat healthy 9-week old C57BL/6J mice with five intravenous injections for 25 days, as control served either PBS, or a non-silencing control siRNA. After the 4th injection, data from an intraperitoneal pyruvate tolerance test (PTT) in 16 h fasted mice showed no significant differences in glucose excursion. Furthermore, no significant effects on fasting blood glucose and plasma insulin were observed between treatment groups. Quantitative real-time PCR demonstrated a significant hepatic down-regulation of the respective HDACs mRNA by 60–80%. However, no reduction of the gluconeogenic genes PCK1 and G6PC was detected in livers of mice. During microscopic examination of key tissues, adverse findings were increased hematopoiesis in spleens of 15/49 mice and chronic purulent pyelonephritis in individual animals (5/49) treated with the different targeting siRNAs. In contrast, spleens and kidneys of mice treated with the non-silencing control siRNA displayed no adverse findings. While the pyelonephritis may indicate an ascending bacterial infection after immunosuppression, the pathomechanism of increased hematopoiesis remains unclear. In summary, although active in cell culture, liver-targeted siRNA knockdown of class 2a HDACs did not translate in an inhibition of genes regulating gluconeogenesis in vivo. Lack of glucose lowering properties in vivo as well as the detection of increased hematopoiesis hamper a clear path forward for development of this approach for treatment of T2D.

Olfactory receptor OR51E1 mediates GLP-1 secretion in enteroendocrine L cells

Cheol Ryong Ku[1], Ye Eon Han[1], Daham Kim[1], Jae Won Hong[2], Sun Ho Kim[1] & Eun Jig Lee[1]
[1]Yonsei University College of Medicine, Seoul, Republic of Korea; [2]Ilsan-Paik Hospital, College of Medicine, Inje University, Koyang, Gyeonggi-do, Republic of Korea.

Few studies have investigated the intracellular signaling pathways mediating the effects of glucagon-like peptide-1 (GLP-1) secretagogues in enteroendocrine L cells. Specific receptors, channels, and intracellular signaling proteins expressed by the L cells have only begun to be characterized. The present study aimed to investigate the role of the olfactory receptor (OR) OR51E1 in GLP-1 secretion. We verified the expression of olfactory marker protein (OMP), an indicator of OR-mediated events in non-olfactory systems, in human intestinal L cells. Furthermore, we analyzed OMP and OR51E1 expression in the human L cell line NCI-H716. To investigate whether odorant-activated OR signaling stimulates GLP-1 secretion, we employed nonanoic acid, a known OR51E1 ligand. Treatment with 100 μM nonanoic acid increased GLP-1 secretion by 2.09 ± 0.39 folds; however, this effect was ameliorated on *OR51E1* knockdown. Oral administration of nonanoic acid to rats resulted in a 2.89 ± 0.53-fold increase in circulating GLP-1 levels and reductions in blood glucose levels compared to those in the control group. Our findings suggest that nonanoic acid stimulates GLP-1 secretion via OR51E1 signaling in intestinal L cells, thereby indicating an essential role of OR-mediated events and the corresponding odorants in GLP-1 secretion.

Study on antioxidant and hypoglycemic effects of natural polyphenols in the experimental diabetes model

Talat Saatov, Sanobar Irgasheva, Mukhammadjon Mustafakulov, Zafar Ibragimov, Tokhir Ishankhodjaev, Elvira Ibragimova, Nodira Abdulladjanova & Bakhodir Zainutdinov
Institute of Bioorganic Chemistry, Uzbekistan Academy of Sciences, Tashkent, Uzbekistan.

According to the findings from the recent studies, the oxidative stress can be a cause for type 2 diabetes mellitus onset. In that context, the development of drugs with antioxidant effect to be used for prevention and treatment of the disease is of vital importance. The work was initiated to study the oxidative stress in the experimental diabetes and methods of its correction by means of natural antioxidants. In our study we used polyphenols isolated from the seeds of common grape vine (*Vitis vinifera*) and the leaves of upland cotton (*Gossypium hirsutum*), as well as the safflower (*Carthamus tinctorius L.)* extract. The antioxidant activity of the agents was assessed *in vitro* by ability to inhibit the adrenalin autoxidation; in tissue homogenates it was assessed by measuring concentrations of oxidates and activity of enzymes in the antioxidant system. Intensity of antioxidant activity of the agents above was compared to the one observed in quercetin, a flavonoid used as a reference product. All the agents under study demonstrated antioxidant effects close to the one produced by quercetin. To assess the hypoglycemic effect of the agents, in white outbred rats weighing 230–280 g type 2 diabetes mellitus was induced by three-fold intraperitoneal administration of diabetogenic dose of alloxan. When blood serum glucose was higher than 9–11 mmol/l the agents under study were administered to the experimental animals intragastrically in the doses providing optimal concentrations. Polyphenols isolated from *Vitis vinifera* and *Gossypium hirsutum* as well as *Carthamus tinctorius L.* extract were found to reduce the blood serum glucose in the diabetic animals by 50.0, 45.9% and 41.7%, respectively. Of note, gliclazide (Servier, France), the second generation sulfonylurea derivative, used as an oral hypoglycemic agent, reduced the parameter by 45.9%. The agents under study demonstrated both antioxidant and hypoglycemic effect. The hypoglycemic effect of agents under study observed in the type 2 experimental model could be associated with the antioxidant effect they produced.

Diazoxide pretreatment improves pancreatic islet survival *in vitro* and functionality *in vivo*

Michiel Nijhoff, Francoise Carlotti, Marten Engelse & Eelco de Koning
Leiden University Medical Center, Leiden, The Netherlands.

The efficacy of human islet transplantation is reduced by loss of islets directly after transplantation. Ischemia is likely to be an important contributing factor to the observed islet loss. Diazoxide inhibits insulin secretion by beta cells and has been shown to exhibit anti-apoptotic and anti-ischemic effects. We hypothesized that preincubation of human islets with diazoxide leads to improved islet survival and graft function.

Methods

Isolated human pancreatic islets were incubated in CMRL1066 culture medium with or without diazoxide 260 μmol/l for 72 h. After incubation, a sample was taken to assess islet viability (FDA-PI staining) and function (glucose stimulated insulin secretion, GSIS). Islets (3000 IEQ) were transplanted under the kidney capsule of NOD-SCID mice which had been rendered diabetic by intraperitoneal injection with streptozotocin. Fourteen days after islet transplantation, the mice underwent an intraperitoneal glucose tolerance test (IPGTT) to assess endogenous human C-peptide production and glucose tolerance.

Results

83.2 ± 4.0% of islets pretreated with diazoxide were viable compared to 76.0 ± 4.2% of islet incubated without diazoxide ($P < 0.001$). Islet function *in vitro* did

not differ (GSIS ratio 2.2±0.8 for treated islets versus 1.8±0.8 for untreated islets, $P=0.2$). The IPGTT demonstrated a higher glucose excursion in untreated mice as compared to treated mice (AUC glucose: 1273 mmol/120min for treated mice versus 2804 mmol/120 min for untreated mice, $P=0.03$). Also, the IPGTT stimulated human C-peptide excursion was greater in mice who received islets treated with diazoxide than in mice who received islets without diazoxide exposure (0.34±0.23 nmol/l vs 0.056±0.10 nmol/l at 60 min, respectively, $P=0.03$).

Conclusion

Diazoxide pretreatment of isolated human islets improves pancreatic islet survival *in vitro* and leads to improved islet graft function in diabetic mice.

Benefits of the association of triiodothyronine (T3) to insulin treatment for the glycemic control of alloxan-induced diabetic rats

Armando Florido-Neto, Lucas Agostini, Ana Carolina Panveloski-Costa & Maria Tereza Nunes
University of São Paulo - Institute of Biomedical Sciences, São Paulo, Brazil.

Diabetes mellitus (DM) is a disease that results from impairment of insulin synthesis/secretion or signaling. The glycemia of type 1 DM (DM1) patients is controlled by insulin replacement therapy, which chronically results in insulin resistance. We have shown that alloxan-induced diabetic rats present hypothyroidism, and that T3 treatment reduced the inflammatory state and hepatic glucose production and increased insulin sensitivity, improving glycemia control. Considering that insulin replacement is the unique treatment for DM1 and that T3 was shown to increase insulin sensitivity in DM1 rats, this study aimed at investigating whether T3 could act as an adjuvant of insulin for DM1 treatment. Male Wistar rats (250 g) were made diabetic with alloxan injection (150 mg/kg, ip), and assorted in different groups that were subjected to insulin treatment (3 or 6 U) associated or not with T3 (1.5 µg/100 g de PC), for 4 weeks. Non-diabetic rats were subjected to the same procedures, but treated with saline instead of T3 and/or insulin. They were weekly weighted, and subjected to the evaluation of fasting glycemia. The insulin sensitivity was evaluated by the constant rate for the Insulin Tolerance Test (kITT). It was shown that DM rats treated or not with T3 presented lower body weight (BW) than control group and insulin treated group. kITT returned to control levels when DM rats were treated with 3 or 6U of insulin or with 3U of insulin plus T3. However, the kITT was reduced when DM rats were treated with 6U of insulin plus T3. The fasting glycemia of DM rats was higher than those observed in all groups studied. The fasting glycemia of DM rats treated with insulin (both doses) and/or T3, was lower than non-treated DM rats. Our findings reinforce that T3 treatment improves insulin sensitivity and fasting glycemia of DM rats, and show that the association of T3 with insulin in the lower dose (3U) ameliorates glucose homeostasis, since it reduces the fasting glycemia and increases the kITT to the levels of the control group, restoring the insulin sensitivity. We conclude that T3 could act as an adjuvant of insulin (3U) in the DM treatment. The implication of this data is that with this association lower doses of insulin could be used for the DM treatment, which would postpone the development of insulin resistance that classically occurs in patients under insulin chronic treatment.

Male AKR1D1 (5β-reductase) knockout mice have altered pancreatic islet morphology and hormone secretion

Shelley Harris[1], Laura Gathercole[1,2], Reshma Ramracheya[1], Alison Forhead[2,3] & Jeremy Tomlinson[1]
[1]University of Oxford, Oxford, UK; [2]Oxford Brookes University, Oxford, UK; [3]University of Cambridge, Cambridge, UK.

The enzyme 5β-reductase (AKR1D1) catalyses an essential step in bile acid (BA) synthesis, but in addition, controls intra-cellular steroid hormone availability by inactivation. Steroid hormones and BA are regulators of global lipid and carbohydrate metabolism. As disturbances in steroid hormone and BA metabolism have potent effects on metabolic health, we hypothesize that AKR1D1 may play a role in metabolic homeostasis. The role of AKR1D1 in regulating glucose homeostasis and pancreatic function remains unexplored. We generated a global AKR1D1 knockout (KO) mouse and using immunohistochemical and stereological techniques, defined whole pancreas and islet morphology in mice at 12 weeks of age (12w) compared against wild-type (WT) controls. Additionally, pancreatic islets were isolated from male WT and KO mice at 30w. Insulin and glucagon secretion were assessed in static incubations. At 12w, relative pancreas mass was decreased in AKR1D1 KO mice compared to WT controls, in both males (g/kg: WT: 12.7±1.3, KO: 7.5±1.0) and females (g/kg: WT: 9.2±0.7, KO: 6.3±0.2, $P<0.05$). Pancreatic islet volume and relative beta-cell mass were decreased in male KO mice only. At 30w, insulin secretion was increased in isolated KO islets upon treatment with 1mM (basal) glucose (mean as % islet content: WT: 0.07±0.01, KO: 0.12±0.01, $P<0.05$), without any change in total islet insulin content. However, in response to 20 mM glucose, the increase in insulin secretion was lower in KO islets when expressed relative to basal (WT: 3.5-fold change, KO: 2.6-fold change, $P=0.08$). Compared to WT controls, the KO islets failed to suppress glucagon release in the presence of 20 mM glucose (mean as % change in glucagon secretion: WT: −29±20, KO: 61±14). Indeed, we observed a paradoxical increase in glucagon secretion with increasing glucose concentration (1 mM glucose; WT: 5.8±1.1, KO: 7.4±3.9 pg/islet per hour. 20 mM glucose; WT: 4.0±0.7, KO: 8.7±3.0 pg/islet per hour). Whilst endogenous expression of AKR1D1 in the murine pancreatic islet is very low, alterations in steroid hormone and BA exposure modifies pancreatic islet cell function. AKR1D1 KO male mice have a dysregulation of insulin and glucagon secretion, which may have profound effects on normal glucose homeostasis. The mechanisms underpinning the changes observed remain to be determined. Further characterization is warranted to define the role of AKR1D1 and to determine whether it has potential as a therapeutic target in metabolic disease.

The role of oncostatin m in the development of type 2 diabetes associated with obesity

Siri Taxeras[1], Irene Piquer-Garcia[1], Silvia Pellitero[2], Rocío Puig[2], Eva Martínez[2], Jordi Tarascó[2], Pau Moreno[2], Ernest Bombuy[2], Carmen Higueras[2], Paloma Malagón[2], Carles Lerin[3], Manel Puig-Domingo[1] & David Sanchez-Infantes[1]
[1]Institut d'Investigació en Ciències de la Salut Germans Trias i Pujol, Barcelona, Spain; [2]Hospital Germans Trias i Pujol, Barcelona, Spain; [3]Hospital Sant Joan de Déu, Barcelona, Spain.

Background

Obesity can lead type 2 diabetes (T2D), however there are patients with obesity who present euglycemia. The mechanisms by which T2D appears have not been fully elucidated. Oncostatin m (OSM) is a proinflammatory cytokine, member of the IL-6 family, which is increased in obesity in mice and humans, and impairs browning in mice. Here, we aim at evaluating the potential role of OSM in the development of T2D in patients with obesity.

Material and methods

A cohort of 25 patients across a range of BMI (24–60 kg/m^2) were recruited for this study. Patients were classified in 3 groups according to clinical data: 1) Healthy normal-weight controls; 2) Normoglycemic obesity (fasting glycemia <100 mg/dl); 3) Hyperglycemic obesity (fasting glycemia >100 mg/dl). Subcutaneous white adipose tissue (sWAT) was collected for RNA analysis.

Results

As expected, we found that OSM mRNA levels increased in sWAT from patients with obesity compared to healthy controls. Moreover, we observed for the first time that OSM mRNA expression was elevated in patients with obesity who had hyperglycemia compared to those who had obesity but normal glucose values ($P=0.04$). In addition, a direct correlation was found between OSM gene expression and insulin and triglyceride levels.

Conclusions

Low-grade chronic inflammation during obesity may lead to the development of T2D. OSM is a cytokine with an important role in several inflammatory diseases. Here, we propose that this cytokine could also be involved in the development of insulin resistance. Therefore, OSM might be a novel target molecule for the prevention/treatment of T2D associated to obesity.

A rare case report of Graves disease with coexisting TSH producing pituitary adenoma

Rujuta Katkar, Thinzar Lin & Antoine Makdissi
University at Buffalo, Buffalo, New York, USA.

Background
Only 10 cases of Grave's disease coexistencing with a TSH-secreting pituitary adenoma (TSHoma) have been reported to date. We present a patient with a TSHoma identified based on the biochemical pattern developing while on treatment with anti-thyroid medications initiated after establishing the diagnosis Grave's disease.
Case report
A 44-year-old Caucasian lady presented with unintentional weight loss. Physical examination revealed diffuse goiter without bruit. TSH was 0.158 (0.4–4.5, free T4 (FT4) 3.5 mg/dl (0.8–1.8) with TSI antibodies elevated 345%. I^{123} thyroid uptake and scan showed a diffuse uptake of 84% at 24 h. While on treatment with Methimazole(MMI), thyroid function tests (TFTs) normalized initially, however, a pattern of elevated FT4 with inappropriately normal TSH was noted. Assay interference and thyroid hormone resistance were ruled out by negative HAMA antibodies and negative RTH mutation analysis. Alpha subunit was1.2 ng/ml (normal <1.02) with elevated α-TSH/TSH molar ratio at 5 (normal range <1). MRI revealed a $1.7\times1.4\times1.6$ cm pituitary macroadenoma. Transsphenoidal resection of the pituitary adenoma was done. TFTs normalized postoperatively without medications. However, four months after surgery, FT4 was found to be elevated at 6.5 with suppressed TSH <0.005. Patient was treated again with MMI with successful achievement of biochemical and clinical euthyroid state. Discussion: Hyperthyroidism caused by excess TSH is uncommon. TSH-secreting pituitary adenoma accounts for less than 2% of pituitary adenomas. The association of TSHoma with Graves' disease is exceedingly rare.. It is recommended that surgery as primary therapy for TSHoma but there is no established management guideline for coexisting condition of Grave's disease and TSHoma at this time. In our case, it is possible that the coexistance of the two conditions is incidental. However, the interruption of normal negative feedback mechanism caused by antithyroid medications leading to the progression of preexisting TSHoma has been postulated. Similarly, it has been postulated that a rapid decrease TSH level after pituitary tumor removal may induce autoimmune activation against the thyroid gland
Conclusion
We emphasize the importance of re-evaluation of the primary diagnosis and consideration of coexisting diagnoses including rare entities if there is any deviation of clinical and laboratory findings from the primary diagnosis.

Non-syndromic multiple insulinomas with atypical clinico-biological presentation in two adult patients: a specific entity?

Fidéline Bonnet-Serrano[1,2], Gaëlle Lethielleux[3], Sébastien Gaujoux[4], Marie-Odile North[5], Benoît Terris[6], Jean Guibourdenche[1] & Jérôme Bertherat[3,7]
[1]Hôpital Cochin-UF d'Hormonologie, Paris, France; [2]INSERM UMR_S1016 CNRS UMR 8104-Institut Cochin, Paris, France; [3]Hôpital Cochin-Service d'Endocrinologie, Paris, France; [4]Hôpital Cochin-Service de chirurgie viscérale, Paris, France; [5]Hôpital Cochin-Service de Génétique, Paris, France; [6]Hôpital Cochin-Service d'anatomopathologie, Paris, France; [7]INSERM UMR_S1016 CNRS UMR 8104 Institut Cochin, Paris, France.

Introduction
Insulinoma is the most frequent functional endocrine tumor of the pancreas but remains rare with an incidence of less than 5 cases by million and by year. It is often sporadic but can occur in the context of MEN1 in about 5% of cases, being then readily multiple. Clinically, it is typically responsible for fasting hypoglycemic episodes. Only one case of multiple insulinomas, with no obvious argument for MEN1 context, has previously been reported (Babic an al., *JCEM*, 2016).
Methods
We report two cases of multiple insulinomas with atypical clinical and biological presentation, occurring outside the context of MEN1. The first case was a man, 51 years old and the second case, a woman, 69 years old. Both patients reported post-prandial hypoglycemic episodes and experienced severe hypoglycemia following glucose charge, respectively 0.8 mmol/l after intravenous glucose load in the first case and 2 mmol/l after oral glucose charge in the second case, with concomitant elevated insulin, respectively 157.6 mUI/l and 28.2 mUI/l. More expectedly, both cases also displayed at least one hypoglycemic episode during fasting trial, always associated with inadequate insulin and C-peptide levels, confirming the existence of an endogenous hyperinsulinism. Pancreatic imaging (MRI or CT) identified 4 lesions in the caudal region of the pancreas in both patients, ranging from 3.5 to 12 mm in the first case -2 of them being confirmed by octreoscan- and ranging from 8 to 30 mm in the second case-all harboring intense signal on TEP-DOTATOC (negative octreoscan). Histology confirmed the presence of 4 neuroendocrine benign tumors in both cases, respectively all and three of them being positive for insulin staining. No mutation in MEN1 gene or in genes involved in hyperinsulinism including ABCC8, KCNJ11, GCK, HNF4A and HNF1A was identified in the first case while MEN1 gene analysis is still in progress for the second case (very unlikely diagnosis).
Conclusion
We describe here a new entity of non-syndromic multiple insulinomas. Symptoms begin after the age of 50 years old, consisting in hypoglycemic seizures, unusually post-prandial. Glucose charge, stimulating inadequate insulin secretion, reproduces severe hypoglycemia. Organic substratum consists in lesions, localized in pancreas tail and positive in molecular imaging based on somatostatin receptors expression. The search for a molecular alteration might give clue to this new entity.

Langerhans cell histiocytosis (LCH) is a disease with monoclonal proliferation and infiltration of organs by Langerhans cell. LCH is commonly seen in the skeletal system and skin, but it may also involve paranchymal organs. Thyroid involvement in LCH is unusual, and coexistence of thyroid with lung involvement is seen very rare. Here we present a patient with LCH, who has thyroid and lung involvement.
Case
A 26-old woman, who had LCH of the lung was referred to our clinic for thyroid nodules detected on Thorax computerized tomography. She had no symptoms at admission. On physical examination no pathological findings were detected. No goitre was seen on the examination of the neck. Thyroid function showed subclinical hypothyroidism based on the following hormone levels: free triiodothyronine (FT3): 2.4 pg/ml; free thyroxine (FT4):0.97 ng/dl and TSH: 12.30 mIU/l; antithyroid antibodies were negative. Levothyroxine was prescribed, and the thyroid function returned to normal. On thyroid ultrasound, the right lobe measured $11\times10\times40$ mm and the left lobe measured $10.7\times13\times40$ mm. On the left lobe a $5\times6\times14$ mm hypoechoic area was detected (Figure 1). Fine needle aspiration and biopsy was performed from this area. On pathological analysis proliferation of Langerhans histiocytes with nuclear grooves in a background of scattered eosinophils was detected. Immunohistochemical staining for S-100, CD68 and CD1a were positive. Chemotherapy was administered to the patient.
Discussion
LCH is a rare neoplastic disease of the langerhans cells, which may involve various organs and systems. Thyroid involvement of LCH is rare with only a slow

number of patients reported in the literature. The frequency of thyroid involvement was reported as 0.4% among all LCH patients. Diagnosis of thyroid LCH is quite challenging, but thyroid involvement of LCH should be kept in mind in patients suffering from LCH.

Coexistence of papillary thyroid cancer and malignancies of other organs in patients carrying CHEK2 gene mutations – case series.

Anhelli Syrenicz, Monika Koziołek, Anna Sieradzka, Marta Rudnicka, Bartek Kiedrowicz & Agnieszka Kaźmierczyk-Puchalska
Department of Endocrinology, Metabolic Diseases and Internal Diseases, Pomeranian Medical University, Szczecin, Poland.

Introduction
CHEK2 mutations are associated with increased risk of having neoplasms of various organs, including thyroid, breast, colon, renal and ovarian cancers. Coexistence of thyroid and breast cancers was observed in female carriers of CHEK2 gene mutations. In polish population the most common mutations are those truncating CHEK2 protein (1100delC, IVS2+1G>A, del5395) and a missense I157T CHEK2 mutation. Carrying missense I157T mutation is connected with having twice the risk of getting papillary thyroid cancer in polish population whereas mutations truncating CHEK2 protein increase the risk by five times.
Case series
1) 63-year-old female patient after total thyroidectomy because of multifocal papillary thyroid cancer in 2014, after surgery in 2002 and subsequent hormonal therapy because of left-sided breast cancer and after surgery because of sigmoid colon cancer in 2013. In family history – mother suffered from breast cancer. Molecular testing revealed missense I157T mutation of CHEK2 gene.
2) Female patient, operated in 2013 at the age of 44 for multifocal papillary thyroid cancer with metastases to the left-sided cervical lymph nodes. In October 2013 the patient was diagnosed with invasive ductal left-sided breast cancer with metastasis to the left axillary lymph node. She was treated with breast amputation, radiotherapy and hormonal therapy. Molecular testing revealed missense I157T mutation of CHEK2 gene.
3) 60-year-old female patient after total thyroidectomy in 2017 because of papillary thyroid cancer, after right-sided mastectomy in 2010 because of breast cancer and after surgery because of endometrial cancer in 2011. Molecular testing revealed CHEK2 protein truncating mutation.
4) 49-year-old female patient after total thyroidectomy in 2017 because of papillary thyroid microcarcinoma, after left-sided mastectomy in 2015 because of breast cancer. Molecular testing revealed CHEK2 protein truncating mutation.

Conclusions
1) In consideration of possible coexistence of thyroid and breast cancers, in case of diagnosing one of them, it is advised to perform diagnostics and observation to identify possible development of the other neoplasm.
2) In patients with CHEK2 gene mutation we need to remember about higher risk of papillary thyroid cancer and possibility of concomitant malignancies especially breast cancer.

GP122

A case of nivolumab induced fulminant type 1 diabetes

Simona Frunza-Stefan & Hillary Whitlatch
University of Maryland Medical Center, Baltimore, Maryland, USA.

Introduction
Immunotherapy has revolutionized the treatment of cancer. Nivolumab, an anti-programmed cell death 1(PD-1) antibody, is used to treat several malignancies refractory to standard chemotherapy. While highly effective at prolonging patient survival, these agents can induce a wide range of endocrine immune-related adverse events (irAEs), including hypophysitis, thyroid dysfunction, and, uncommonly, type 1 diabetes (T1DM). Here we describe a rare case of PD-1 inhibitor induced fulminant type 1 diabetes (FD).Case Report:A 55-year-old African American female was diagnosed with stage III B squamous cell carcinoma of the lung in 2013. She was not a surgical candidate and received 6 cycles of carboplatin and gemcitabine as well as salvage radiation. One year later, there was disease progression with involvement of the brain, adrenal glands, and gluteal muscle. In 2015 she began treatment with nivolumab. Cycle 4 was delayed, as she developed autoimmune hepatitis, for which she received high dose steroids. After normalization of liver function tests, nivolumab was restarted. After 8 months, she presented for cycle 13 reporting extreme fatigue, dry mouth, nausea, polyuria and polydipsia. Laboratory tests at the time of hospitalization revealed a blood glucose of 467 mg/dl (70–105). She had ketonuria without ketoacidosis. Unexpectedly, her glycosylated hemoglobin (HbA1c) was only 7.1%, suggesting rapid onset of hyperglycemia. Serum anti-glutamic acid decarboxylase antibody and anti-islet-cell antibody were negative, and C-peptide was 0.42 ng/ml (0.8–3.85), consistent with a diagnosis of FD. HLA-typing was not performed. Insulin therapy was initiated, and she was discharged on a basal/bolus insulin regimen. Given wide glycemic excursions, the patient was eventually transitioned to insulin pump therapy with a continuous glucose monitor. Nivolumab was not restarted.
Discussion
FD is a severe subtype of T1DM, characterized by the complete loss of pancreatic beta cells at disease onset. Initially described in Japan in 2000, cases have been reported primarily in East Asia. FD is characterized by rapid onset of hyperglycemia combined with ketoacidosis or ketonuria and the absence of islet-cell autoantibodies. Out of the 24 cases of diabetes thus far reported as a side effect of anti-PD-1 treatment, 10 (42%) are consistent with FD, with unusually low HbA1c at diagnosis (under 8.7%) and low or undetectable c-peptide. Given increasing oncologic indications for anti-PD1, it is important that physicians be made aware of this rare, but potentially life-threatening, adverse reaction. Frequent biochemical monitoring and early recognition of hyperglycemia are critical in optimizing treatment outcomes.

GP123

A rare case of type-2 familial partial lipodystrophy (FLD type 2) non-Dunnigan type with laminin A/C gene (LMNA) mutation causing multi-organ failure and diabetes mellitus

Simona Frunza-Stefan[1], Raafia Memon[2], Rana Malek[2], Elizabeth Streeten[2], Toni Pollin[2] & Kristi Silver[2]
[1]University of Maryland, Baltimore, Maryland, USA; [2]University of Maryland Medical Center, Baltimore, Maryland, USA.

Introduction
Mutations of the LMNA gene cause a wide range of diseases including lipodystrophy, myopathy [including dilated cardiomyopathy (DCM)], neuropathy and progeroid syndrome, and are collectively known as A-type laminopathies.
Case report
A 51-year-old Caucasian male with history of heart, liver and kidney transplants was referred for evaluation and treatment of post-transplant diabetes. He was diagnosed with hypertriglyceridemia at age 38. At 43, he was diagnosed with idiopathic cardiomyopathy. Subsequently, he developed liver failure that was presumed to be secondary to passive congestion from heart failure. He underwent simultaneous heart and liver transplants at 44. By age 51, he developed end stage renal disease, treated with hemodialysis prior to recent renal transplant. He developed post-transplant diabetes and endocrine consult was requested. He was noted to be extremely thin with BMI 17.4 kg/m^2 (weight = 130 lbs, height = 6′1″), with generalized lipodystrophy including face, trunk and extremities. Diabetes was managed with a basal/bolus insulin regimen requiring approximately 1.8 units of insulin/kg to control hyperglycemia suggesting severe insulin resistance. Laboratory evaluation was notable for leptin of 2.5 ng/ml (0.3–13.4). Genetic testing revealed a heterozygous *LMNA* gene missense mutation (c.1045 C>T; p. Arg349Trp). Since identification of the mutation, metformin was added to the insulin with the goal of improving insulin resistance.
Discussion
To date, 19 additional patients have been reported with the c.1045C>T *LMNA* mutation identified in our patient, including a family with 16 affected members, of whom 4 had renal disease. Patients with c.1045C>T mutations have partial lipodystrophy of the non-Dunnigan type (affecting face and extremities), with the exception of one with Dunnigan-type. In the 19 patients, DCM was noted in less than half and elevated creatine kinase, with or without clinical signs of myopathy, was also noted. Less than half had overt diabetes and at least one had euglycemic insulin resistance. The c.1045 C>T variant was not observed in the NHLBI Exome sequencing project, 1000 Genomes Project or Exome Aggregation

Consortium database; however the p.Arg349Trp substitution has been identified in patients with skeletal, cardiac and metabolic phenotypes. Collective evidence supports c.1045 C>T as a likely pathogenic variant for an A-type laminopathy and the multiorgan failure seen in our patient. Multiorgan failure should alert endocrinologists of the possibility of *LMNA* mutation.

MODY – a diagnosis to be considered in diabetes

Claudia Matta-Coelho[1], Marta Alves[1], Olinda Marques[1], Ana Antunes[2] & Sofia Martins[2]
[1]Endocrinology Department, Hospital de Braga, Braga, Portugal; [2]Endocrinology Pediatric Unit, Hospital de Braga, Braga, Portugal.

Introduction
Maturity-Onset Diabetes of the Young (MODY) is a form of monogenic diabetes caused by mutations in islet-related genes characterized by early-onset and inheritance in an autosomal dominant manner. MODY accounts for 2 to 5% of all cases of diabetes. The clinical presentation is heterogenous. Our aim was to characterize clinical features of patients with MODY in our department.
Methods
We retrospectively analysed MODY diabetes cases diagnosed at the Endocrinology Pediatric Unit (EPU) and at the adult Endocrinology Department (ED) of our hospital, from 2000 to 2017.
Results
We found 8 patients diagnosed at the EPU and 4 at the ED adult. Two pairs of them are sisters. The majority are female ($n=10$), with an average age at diagnosis of 12 years-old (IQR 7-16). All had family history of diabetes. Genetic confirmation of MODY was obtained 48 months after clinical diagnosis of diabetes (IQR 19-77). None presented diabetic ketoacidosis at diagnosis. Negative islet autoantibodies were observed in all. The median HbA1c at diagnosis was 7.5% (IQR 6.4–8.3). Regarding the type of MODY, 8 presented GCK mutation (MODY 2), 3 HNF1A mutation (MODY 3) and 1 HNF1B mutation (MODY 5). In patients with MODY 2, one is not currently under oral antidiabetic drugs, one is treated with insulin and the remaining with metformin and/or dipeptidyl peptidase-4 inhibitor. The 3 patients with MODY 3 are under a sulfonylurea and the patient with MODY 5 is treated with insulin in a basal bolus scheme.
Discussion
The diagnosis of MODY requires a high index of suspicion. Therefore, in a patient with family history of diabetes, negative islet autoantibodies and diabetes onset <25 years, a diagnosis of MODY should be suspected. Our series revealed a considerable delay until the confirmation of MODY, which supports the increased awareness warranted for this entity.

Hyperinsulinaemic hypoglycaemia in the three generations of a family with GCK, c.295T>C (p.Trp99Arg) mutation

Aleksandra Gilis-Januszewska, Anna Skalniak, Malgorzata Wilusz, Grzegorz Sokołowski, Joanna Walczyk, Jacek Pantoflíński, Dorota Pach, Elwira Przybylik-Mazurek & Alicja Hubalewska-Dydejczyk
Department of Endocrinology, Medical College, Jagiellonian University, Krakow, Poland.

Background
Familial Hyperinsulinaemic hypoglycaemia (FHH) is a very rare disease with heterogeneous clinical manifestation causing risk of late diagnosis or even misdiagnosis. In infants and children, it can lead to serious and permanent damage to the central nervous system. FHH has been correlated with mono-gene mutations in approximately 48% of cases. Clinical manifestation may vary even in the same affected GCK mutation family.
Objective
To describe the clinical presentation and metabolic profiles of affected family members with GCKc.295T>C(p.Trp99Arg) mutation.
Design
Clinical, biochemical and metabolic assessment, and GCK sequencing in affected family members.
Results
Family G: four family members from three generations affected (father, 2/3 children, grandson). A father of three children, age 54 (birth weight 3800g, current BMI-32), diagnosed at the age of 20 years. Symptoms of hypoglycaemia (HS) present from postnatal period, with an increased intensity in early childhood. Learning and behaviour problems during childhood. Hypoglycaemias:mild/severe, fasting/after the meal, no relation with physical activity/diet. Epilepsy diagnosed at age 10. Diazoxide: from the age of 20/some improvements/poor compliance. MRI/GLP-1 imaging not significant. Normal lipids/no liver steatosis. A son, age 25 (birth weight 4400 g, current BMI-25.9), diagnosed at the age of 4 years. HS from postnatal period, increased intensity in early childhood. School difficulties/problems with concentration. HS: mild/severe, fasting/overnight hypoglycaemias/after the meal/improvement after carbohydrate rich diet, no relation to physical activity/diet. Diazoxide: from age of 4, partial improvement/poor compliance. MRI not significant. Normal lipids/no liver steatosis. A daughter, age 23 (birth weight 3650 g, current BMI-23), diagnosed during postnatal period. HS: mild/severe, increased in early childhood. School difficulties/problems with concentration. HS: fasting/ after the meal, no relation with physical activity/diet. Diazoxide from postnatal period, some response/poor compliance. MRI not significant. Normal lipids/no liver steatosis. During early pregnancy (2014) severe hypoglycaemias, with response to steroid therapy, in the second/third trimester improvement. A grandson, age 3 (birth weight–3850 g, glucose after delivery 15 mg%). Immediate treatment with Diazoxide, no HS. Physical/psychological development is normal.
Conclusions
The clinical presentation of the disease is similar in the family members with GCK c.295T>C (p.Trp99Arg). Early diagnosis, diazoxide implementation/compliance are important in the course of the disease.

Acromegaly and acromegaloidism, two rare insulin-resistance conditions in one patient: reason for GH-IGF-1 discrepancy?

Paula Freitas[1,2,3], Vanessa Guerreiro[1,2], Irene Bernardes[4], Josue Pereira[5], Roberto Pestana Silva[6], Susana Fernandes[7] & David Carvalho[1,2,3]
[1]Departamento endocrinologia CHSJ, Porto, Portugal; [2]Faculdade de medicina Porto, Porto, Portugal; [3]Instituto de investigação e inovação em saude, Universidade do Porto, Porto, Portugal; [4]Departamento Neurologia CHSJ, Porto, Portugal; [5]Departamento Neurocirurgia CHSJ, Porto, Portugal; [6]Departamento Anatomia Patologica CHSJ, Porto, Portugal; [7]Departamento genetica Faculdade Medicina Porto, Porto, Portugal.

Introduction
Lipodystrophies are a group of genetic or acquired diseases characterized by abnormal adipose tissue deposition, frequently associated with insulin resistance, diabetes mellitus, dyslipidaemia, hypertension and hepatic steatosis. Congenital generalized lipodystrophy (LCG) is a well-defined syndrome with autosomal recessive heredity, prevalence <1:10million, with about 400 cases being described. Extreme shortage of subcutaneous adipose tissue, muscle hypertrophy and other adipose tissues, confer an acromegaloid-like appearance in patients with LCG, however no case of SBS and acromegaly has been reported.
Clinical case
63-year-old man appealed to endocrinology clinic for suspected lipodystrophy. He had lipoatrophy of upper and lower limbs, muscular prominence, acromegaly facies with thick lips, widening of the wings of the nose, creased nasolabial grooves, dental diastema, prominence of supraciliary arches, large hands and feet and soft tissue tumescence. No acanthosis nigricans. None of the parents had changes in body composition or diabetes. His 59-year-old sister has similar phenotype. He had dyslipidaemia (total-cholesterol: 192 mg/dl, HDL:31 mg/dl, LDL1: 41 mg/dl, triglycerides: 440 mg/dl); increased IGF-1: 379–481–410 ng/mL (NL<269); HOMA-IR: 11.93, A1c:6.4%. 1st OGTT: Impaired glucose tolerance (0 h:101; 2 h:186 mg/dl) and GH-0h:1.5; nadir:0.92 ng/ml; second OGTT 10 months after-diabetes (glucose 0 h:120; 2 h: 204 mg/dl) and GH-0h:0.98; nadir: 0.64 ng/ml). Thyroid function, gonadal, metabolism calcium phosphate, prolactin, ACTH, and cortisol are normal. There was a ratio of fat mass trunk/limbs to 1.02 by densitometry and without osteoporosis. Colonoscopy and upper digestive endoscopy were normal. A 17 cm hepatomegaly with mild steatosis was detected on abdominal ultrasound. Left ventricular hypertrophy was observed in the ECG. In the pituitary MRI was found an area of hypocaptation contrast product with rounded aspect in right half of pituitary gland, passing

midline to opposite side and prophesying to sphenoid sinus in relation to the pituitary adenoma. No deviation of the pituitary stalk. Subjected to transphenoidal pituitary surgery pathological evaluation showed pituitary adenoma, with extensive expression of GH and ACTH and rare expression of FSH and PRL. Genetic study revealed a intron3/exon3 deletion of the AGPAT2 gene in homozygosity. A GH/IGF-1 discrepancy, IGF-1 increased with normal GH variant was present. The role of insulin resistance or hepatic steatosis isn't clear and could disturb the diagnosis.

Conclusion

GCL is a rare disease that occurs with acromegaly; however, no case of genetic lipodystrophy associated with acromegaly has been described in the literature.

Cardiovascular disease in a nationwide population of Danish women with polycystic ovary syndrome

Dorte Glintborg[1,2], Katrine Hass Rubin[3], Mads Nybo[4], Bo Abrahamsen[3,5] & Marianne Skovsager Andersen[1]
[1]Department of Endocrinology, Odense University Hospital, Odense C, Denmark; [2]University of Southern Denmark, Odense C, Denmark; [3]OPEN – Odense Patient Data Explorative Network, Institute of Clinical Research, University of Southern Denmark, Odense C, Denmark; [4]Department of Clinical Biochemistry and Pharmacology, Odense University Hospital, Odense C, Denmark; [5]Department of Medicine, Holbæk Hospital, Holbæk. Denmark, Holbæk, Denmark.

Background

Polycystic ovary syndrome (PCOS) is associated with obesity and low grade inflammation, factors linked to cardiovascular disease (CVD).

Methods

National Register-based study including women with PCOS and no previous diagnosis of CVD or hypertension. PCOS OUH ($n=1165$) included premenopausal women with PCOS and clinical and biochemical examination. PCOS Denmark ($n=18\,112$) included women with PCOS in the Danish National Patient Register. Three age-matched controls were included per patient ($n=52\,769$). The main study outcome was CVD events including hypertension defined according to nationwide in- and outpatient hospital contact diagnosis codes and/or inferred from filled medicine prescriptions.

Results

The age at inclusion was median (quartiles) 29 (23–35) years and follow up was 11.1 (6.9–16.0) years. The Hazard ratio (95% CI) for development of CVD including hypertension in PCOS Denmark was 1.7 (1.6; 1.8) ($P<0.001$) and the total event rate of CVD was 19.2 per 1000 patient years in PCOS Denmark vs 11.6 per 1000 patient years in controls ($P<0.001$). The median age at diagnosis of CVD was 35 (29–42) years in PCOS Denmark vs 36 (30–44) years in controls ($P=0.02$). Obesity, diabetes, and infertility, and previous use of oral contraceptives were associated with increased risk of development of CVD in PCOS Denmark ($P<0.001$). Also, age, BMI, blood pressure, lipid status, and glycemic status predicted development of CVD in PCOS OUH.

Conclusion

The event rate of CVD and hypertension was higher in PCOS compared to controls. The risk of developing CVD must be considered even in young women with PCOS.

DOI: 10.1530/endoabs.56.GP127

GP128

Low-dose SKA Progesterone and Interleukin-10 modulate the inflammatory pathway in endometriotic cell lines

Francesca Mancini[1], Domenico Milardi[2], Piero Carfagna[3], Giuseppe Grande[1], Vincenzo Miranda[4], Alessandra De Cicco Nardone[3], Domenico Ricciardi[3], Alfredo Pontecorvi[1,2], Riccardo Marana[1] & Fiorenzo De Cicco Nardone[3]
[1]International Scientific Institute "Paul VI", Rome, Italy; [2]Division of Endocrinology, Fondazione Policlinico "A. Gemelli", Rome, Italy; [3]Department of Obstetrics and Gynecology, Fondazione Policlinico "A. Gemelli", Rome, Italy; [4]Clinical Research Unit, GUNA S.p.a., Milan, Italy.

Endometriosis is a chronic gynecological inflammatory disease characterized by the presence of functional endometrial glands and stroma outside of the uterine cavity. It affects 7–10% of women of reproductive age, up to 50% of women with infertility and up to 60% of women with dysmenorrhea. The aim of this preclinical study was evaluate the efficacy of low-dose SKA Progesterone (GUNA) and low-dose SKA IL-10 (GUNA) in the modulation of the inflammatory response in endometriotic cell lines. Immortalized human endometriotic epithelial cells (12Z) derived from active red peritoneal lesions, immortalized human endometriotic stromal cells (22B) derived from active red peritoneal lesions and immortalized human endometrial cell line T-Hesc (ATCC collection) have been used for this study. Cells were treated with SKA-Progesterone and SKA-IL10 at low doses (10 pg/ml and 10 fg/ml respectively). Medroxyprogesterone 17-acetate (MPA) was used at a dose of 10 μM as reference treatment. We analyzed the modulation of HSD17B1 levels by WB analysis after low-dose SKA Progesterone and MPA and the modulation of IKBα protein levels and NF-kB p65 nuclear levels by WB analysis after low-dose SKA-Progesterone, low-dose SKA-IL10, low-dose SKA-Progesterone and low-dose SKA-IL10 (combined treatment), MPA. Low-dose SKA Progesterone was effective in the inhibition of HSD17B1 expression in endometriotic epithelial (12Z) and stromal (22B) cell lines. Low-dose of SKA Progesterone and low-dose of SKA-IL10 inhibit NF-kB p65 nuclear localization and DNA binding in endometriotic epithelial (12Z) cells, stromal (22B) cells line and in endometrial cell line T-Hesc. The combined treatment showed an additive effect, namely increasing the inhibition of nuclear localization of NF-kB p65 and DNA binding as result of single treatments. Our data suggest that the use of a combination of low-dose SKA Progesterone and IL-10 may represent an opportunity for the development of new therapies in the clinical management of endometriosis.

GP129

Impaired GLP-1 response predicts prediabetes in obese PCOS with adverse metabolic phenotype independent of BMI

Mojca Jensterle, Simona Ferjan & Andrej Janez
Department of Endocrinology, Diabetes and Metabolic Diseases, University Medical Centre Ljubljana, Ljubljana, Slovenia.

Objective

Impaired glucose homeostasis in PCOS is closely linked to obesity, age and disease phenotype. The potential separate role of reduced GLP-1 response in the development of prediabetes in this population is unclear.

Aim

To compare the GLP-1 response after OGTT in a cohort of obese PCOS with normal glucose tolerance (NGT) and prediabetes.

Design/participants/methods

Case control study recruited 26 obese Caucasian women with PCOS phenotype A. Thirteen of them had normal glucose tolerance (NGT) and 13 had prediabetes defined as having impaired fasting glucose, impaired glucose tolerance or both. They were matched for BMI (37.0 ± 5.5 kg/m^2, mean ± S.D.) and age (37.2 ± 6.9 years, mean ± S.D.). Serum glucose, insulin, C-peptide, total GLP-1 and total GIP were sampled during 2 h OGTT. Model derived static and dynamic parameters for the assessment of beta cell function and insulin resistance were determined. All patients underwent measurement of androgen profile and whole-body composition by DXA.

Results

Women with prediabetes had significantly reduced total GLP-1 after glucose load (GLP-1 in 120 min 3.3 ± 2.1 vs 5.5 ± 2.7 pM in NGT, $P=0.014$) and decreased incremental area under the curve of GLP-1 ($\Delta AUC_{GLP\text{-}1}$) when compared to NGT group ($P=0.016$). Values of GLP-1 at 120 min below 3.02 pM predicted prediabetes (sensitivity 0.615 and specificity 0.923). In addition, women with prediabetes had lower insulin and C-peptide values with significant difference at 90 and 120 min of OGTT ($P=0.01$) and lower insulin sensitivity index (OGIS) (387 ± 69.5 vs 326.6 ± 59.7 in NGT, $P=0.04$). Despite same BMI, group with prediabetes had higher visceral adipose tissue (VAT) mass, volume and area as measured by DXA ($P=0.001$ for all). Plasma GLP-1 levels at 120 min was negatively correlated with VAT mass and volume and positively correlated with OGIS. Furthermore, the correlation between the $\Delta AUC_{GLP\text{-}1}$ and the family history of at least one first-degree relative affected with type 2 diabetes was confirmed. The two groups did not differ in total GIP, HOMA-B, MBCI, QUICKI, HOMA-IR and IAI and androgen profile.

Conclusion

GLP-1 response to oral glucose was reduced in obese PCOS with prediabetes independent of age, BMI and disease phenotype. Our findings identify a new separate risk factor for prediabetes in obese PCOS, in particular with predominant visceral obesity.

DOI: 10.1530/endoabs.56.GP129

Alterations in gonadotropin receptors and signal activation in granulosa lutein cells from women with polycystic ovary syndrome

Lisa Owens[1], Georgios Christopolous[1], Shirin Khanjani[1], Kate Hardy[1], Stuart Lavery[2], Stephen Franks[1] & Aylin Hanyaloglu[1]
[1]Imperial College London, London, UK; [2]Wolfson Fertility Centre, Hammersmith Hospital, London, UK.

Background
Polycystic ovary syndrome (PCOS) is a common endocrine disorder, affecting 5–10% of women of reproductive age. The underlying pathogenesis is complex and incompletely understood. There is evidence that gonadotropin and gonadotropin receptor action play a role in the pathogenesis of PCOS with genome wide association studies in PCOS also implicating altered gonadotropin action in the aetiology of PCOS. Furthermore, our recent studies have demonstrated that gonadotrophin receptor signaling is tightly regulated by the endocytic pathway. However, the precise mechanisms resulting in altered gonadotropin receptor activity in PCOS are unclear.
Objectives
1. To measure gene and protein expression of LH/hCG and FSH receptors in granulosa lutein cells (GLC) from women with and without PCOS. 2. To measure in-vitro second messenger cAMP generation in GLC from women with and without PCOS after treatment with FSH and LH. 3. To assess the role of receptor internalization on signalling in GLC from women with and without PCOS.
Materials and methods
GLC were isolated from follicular fluid collected at the time of oocyte retrieval. RNA was extracted from the cells and gene expression analysed by RT-qPCR. Protein was extracted and expression analysed by immunohistochemistry. GLC were cultured and treated with LH or FSH with or without pre treatment with Dyngo-4a, a dynamin inhibitor, and cAMP assay performed.
Results
Gene and protein expression of LH/hCG receptor and it's known splice variants were similar in GLC from women with and without PCOS. Gene expression of FSHR was higher in GLC from women with PCOS than controls (4-fold, $P<0.05$). LH-dependent cAMP levels were significantly higher (2.5 fold, $P<0.05$) in GLC from women with PCOS compared to control. Pre-treatment of GLCs with Dyngo4a, which inhibits dynamin dependent receptor internalisation, inhibited both LHR and FSHR cAMP generation (70–80%) equally in both control and PCOS.
Conclusion
There is higher FSH receptor expression in GLC from women with PCOS. Although gene and protein expression are similar in normal and PCOS GLC, LH/hCG receptor signal activation in GLC from women with polycystic ovary syndrome is amplified. Receptor internalisation is required for normal cAMP generation in both normal and PCOS GLCs.

Prevalence of mutations in the insulin receptor gene and lamin A/C gene in functional ovarian hyperandrogenism with insulin resistance

Eider Pascual-Corrales, Jose Luis Sanmillán, María Ángeles Martínez, Manuel Luque-Ramírez & Héctor Escobar-Morreale
Hospital Ramón y Cajal, Madrid, Spain.

Introduction
Extreme insulin resistance monogenic syndromes, including type A insulin resistance syndrome and congenital lipodystrophies, share some phenotypic characteristics with polycystic ovary syndrome (PCOS). These conditions have an increased risk for developing cardiovascular disease and diabetes mellitus. Thus, both an early diagnosis and a personalized management are required at clinical realm.
Objective
To assess the prevalence of mutations in the insulin receptor (*INSR*) and lamin A/C (*LMNA*) genes in women with functional ovarian hyperandrogenism and insulin resistance.
Material and methods
n: 242 women with functional ovarian hyperandrogenism (PCOS or idiopathic hyperandrogenism) and insulin resistance defined by a Matsuda-index (ISI) <3.5 and/or HOMA-IR$>$ 3.2 were studied. Genetic analysis was performed with genomic DNA from total blood samples using the real-time polymerase chain reaction (PCR) technique with fluorescence TaqMan probes or by sequencing. Mutations described in the literature in *INSR* and *LMNA* genes were screened in all patients. In 49 extreme-insulin resistant patients, exons and adjacent intronic regions of *INSR* and *LMNA* genes were also studied by Denaturing High-Performance Liquid Chromatography (DHPLC), and positive results were confirmed by sequencing.
Results
Sequencing of amplified DNA revealed that found variants in exons 2, 8, 9, 12, 13 and 17 in *INSR* gene, and variants in exons 3, 5, 7 and 10 in *LMNA* gene were benign polymorphisms within the coding region. *LMNA* promoter −1030 C/T polymorphism, described as a putative genetic responsible for arterial stiffness in Japanese population, was detected in 17 subjects with CT genotype and in 4 with TT genotype. Two sister were found to have a patogenic heterozygous mutation in exon 8 (c.1444C$>$T, p.Arg482Trp) in *LMNA* gene, and the final diagnosis of Dunningan familial partial lipodystrophy was established. One proband with extreme insulin resistance was found to have a heterozygous mutation in exon 5 (c.1246C$>$T, p.Arg416*) in *INSR* gene. Currently, exons 19-22 of *INSR* gene are being processed.
Conclusions
The identification of monogenic insulin resistance syndromes is essential in patients with apparent functional ovarian hyperandrogenism. Molecular-genetic studies allow an early diagnosis and genetic counseling, and likely, improving their prognosis. Since most available treatments are not fully satisfactory, molecular studies may provide potential novel therapeutic targets.

Women with PCOS display reduced cardiac vagal activity which is dependent on metabolic abnormalities

Meri-Maija Ollila[1], Antti M Kiviniemi[2], Elisabet Stener-Victorin[3], Katri Puukka[4], Aimo Ruokonen[4], Juha S Tapanainen[1,5], Stephen Franks[6], Laure Morin-Papunen[1] & Terhi Piltonen[1]
[1]Department of Obstetrics and Gynaecology, University of Oulu and Oulu University Hospital, Medical Research Center, PEDEGO Research Unit, Oulu, Finland; [2]Research Unit of Internal Medicine, University of Oulu, Oulu, Finland; [3]Department Physiology and Pharmacology, Karolinska Institutet, Stockholm, Sweden; [4]NordLab Oulu, Department of Clinical Chemistry, University of Oulu and Oulu University Hospital, Medical Research Center, Oulu, Finland; [5]Department of Obstetrics and Gynaecology, University of Helsinki and Helsinki University Hospital, Helsinki, Finland; [6]Institute of Reproductive and Developmental Biology, Imperial College London, London, UK.

It has been reported that women with polycystic ovary syndrome (PCOS) show cardiovascular autonomic dysfunction, with reduced parasympathetic (vagal) and increased sympathetic activity, which are known to be independent risk factors for cardiovascular morbidity and mortality. However, it is not yet clear if PCOS *per se* leads to cardiovascular autonomic dysfunction independently of metabolic abnormalities. In a prospective, general population-based follow-up birth cohort ($n=5889$ females), postal questionnaires were sent at ages 14 (95% answered), 31 (81% answered) and 46 (72% answered). Women who reported both oligo/amenorrhea and hirsutism at age 31 and/or diagnosis of PCOS by age 46 were considered as PCOS cases ($n=279$) and were compared with women without PCOS symptoms or diagnosis ($n=1577$). Clinical examinations were performed at age 31 in 3115 women, and at age 46 in 3280 women. The cardiovascular autonomic function was evaluated at age 46 by vagal-mediated heart rate variability (rMSSD) from R-R intervals, spectral power densities (LF: low frequency and HF: high frequency) and spontaneous baroreflex sensitivity (BRS). Both rMSSD and HF describe the vagal activity. The effects of body-mass-index (BMI), hyperandrogenism and metabolic status were assessed by analysis of covariance (ANCOVA) and linear regression analysis. At baseline, vagal activity was significantly lower in women with PCOS compared with controls (rMSSD: 19.5 [12.4; 31.9] vs 24.3 [16.1; 34.8], $P=0.004$ and HF: 172 [75; 399] vs 261 [112; 565], $P=0.002$), and these differences remained significant after adjustment for BMI by ANCOVA. BRS was comparable in PCOS and control women after adjustment for BMI. In the linear regression model, PCOS and BMI both modified rMSSD (for PCOS: $B=-0.108$, 95%CI: -0.207 to -0.008, $P=0.033$ and for BMI: $B=-0.026$, 95%CI: -0.033 to -0.020,

$P<0.001$), but PCOS lost its significance after adjustment for diastolic blood pressure. Then, in the linear regression model for HF, PCOS remained significant after adjustment for diastolic BP (for PCOS: $B=-0.217$, 95%CI: -0.415 to -0.018, $P=0.033$), but then lost its significance after further adjustment for HOMA-IR. Of note, testosterone or free-androgen-index did not modify rMSSD or HF in the linear regression analysis. Women with PCOS display altered cardiovascular autonomic function manifested as decreased vagal activity. However, metabolic status, but not hyperandrogenism, seems to be the strongest contributing factors. These findings indicate that metabolic abnormalities should be screened and efficiently treated in women with PCOS, already early in life, to prevent the development of cardiovascular autonomic dysfunction and cardiovascular diseases.

Favorable prognosis of pregnancies in 28 hypopituitary women: Retrospective multicentric study on 39 pregnancies

Eve Melloul[1], Olivier Chabre[1], Philippe Caron[2], Jacques Young[3], Helène Bry[3], Gerald Raverot[4], Francoise Borson Chazot[4], Aurélie Brosse[5], Thierry Brue[6], Frederic Castinetti[6], Pascale Hoffmann[7] & Laure Villaret[7]
[1]Endocrinologie, Centre Hospitalier Universitaire Albert Michallon, Grenoble, France; [2]Endocrinologie, Centre Hospitalier Universitaire Larrey, Toulouse, France; [3]Endocrinologie, Centre Hospitalier Universitaire Kremlin-Bicêtre, Paris, France; [4]Endocrinologie, Groupement Hospitalier Est, Bron, France; [5]Médecine de la Reproduction Gynécologie Obstétrique, Groupement Hospitalier Est, Bron, France; [6]Endocrinologie, Assistance publique hôpitaux de Marseille, Marseille, France; [7]Médecine de la Reproduction Gynécologie Obstétrique, Centre Hospitalier Universitaire Albert Michallon, GRENOBLE, France.

Background
Pregnancy in women with hypopituitarism has been described as presenting high risks of maternal and fetal complications but this is only based on 2 small size series.
Objective
To reassess the prognosis of pregnancy in women with hypopituitarism.
Methods
Multicentric, observational, retrospective study including 39 pregnancies in 28 women with gonadotropic insufficiency and at least one other pituitary hormone deficiency followed in the last 22 years in five French tertiary centers. Due to the a multi-disciplinary approach, the substitutive treatment of corticotroph and thyrotropin insufficiencies were followed by endocrinologists. We collected the data regarding infertility management, pregnancy outcome, obstetrical or endocrine complications and new born children characteristics.
Results
28 women with a median age of 30 years (25–41) were included. Pituitary insufficiency was linked to the following lesions and their medical, surgical or radiotherapic treatments: Craniopharyngioma ($n=8$); different adenomas ($n=8$); Sheehan Syndrome ($n=4$); Hypophysitis ($n=3$); Congenital ($n=3$); Rathke cyst (1); Pinealoma (1). Pituitary deficiences were gonadotropic (100%) Thyrotropic (92%) Somatotropic (81%) Corticotropic (64%) Diabetes inspidus (39%). 26 patients with thyrotropin insufficiency were treated by L-thyroxine adjusted during all the pregnancy. 18 were treated by hydrocortisone for corticotroph insufficiency. Pregnancy was obtained by ovarian stimulation by FSH and ovulation stimulation by hCG in all but 4 cases but *in vitro* fertilization was required in only 6 cases (19%). Among 39 pregnancies, 36 live births (92%) (25 singletons and 11 twins) occured, and 3 ectopic pregnancies, 5 miscarriages and 1 intra uterine fetal death were observed. For all births, the rate of caesarean section was 42%: 36% for singletons and 66% for twins. The new-borns were healthy with a median weight of 3120 g (570–4250) and a median length of 50 cm (31–53), 22% were preterm babies (4% for singletons and 58% for twins) and 27% had a low birth weight (12% for singletons and 58% for twins). No maternal complications related to pituitary insufficiency occurred. The pregnancies outcomes were comparable to those in the French population for singleton pregnancies but there were less favorable for twin pregnancies. Five out of six twin pregnancies had at least one perinatal complication with one intrauterine fetal death.
Conclusion
In this study we found a good prognosis of pregnancies in women with hypopituitarism followed in tertiary centers by a multi-disciplinary team. However because twin pregnancies showed more perinatal complications than in the general population ovarian stimulation should be carefully monitored to favor singleton pregnancies.

Liquid chromatography-tandem mass spectrometry characterization of a broad serum and salivary steroid profile in classical form of polycystic ovary syndrome

Marco Mezzullo, Flaminia Fanelli, Laura Zanotti, Uberto Pagotto & Alessandra Gambineri
Endocrinology Unit, Department of Medical and Surgical Sciences, Centre for Applied Biomedical Research (C.R.B.A.), S. Orsola-Malpighi Hospital, Alma Mater University of Bologna, Bologna, Italy.

Polycystic ovary syndrome (PCOS) is a common endocrine disorder among premenopausal women affecting up to 20% of the population. Even though androgen excess is the main diagnostic criterion for PCOS, the evaluation of hyperandrogenemia relies on methods with low accuracy and mainly able to measure total androgen amounts. Liquid chromatography-tandem mass spectrometry (LC–MS/MS) allows high accuracy steroids measurement and if applied to saliva, it also allows the measurement of free or biovalable fractions. We performed seventeen-hours circadian salivary androgens analysis and serum steroids circadian profile in 9 classic PCOS (oligomenorrhea + hirsutism/high testosterone + polycystic ovary morphology) and 7 fertile controls. Subjects woke-up at 0700 h and collected saliva by direct spitting in fasting condition. At 0800 h subjects went to hospital for blood withdrawal, second saliva collection and anthropometric data recording. The blood collection was repeated at 1000 h and 1600 h. Saliva was collected every hour until 2300 h. Daily food intake and menstrual phase were standardized. Steroids were measured by validated LC–MS/MS methods and area under curve (AUCg) was computed. Compared to controls, PCOS girls were younger ($P=0.023$) and displayed higher BMI ($P=0.017$) and waist circumference ($P=0.011$). Both baseline levels and circulating hormones daily exposure were higher in PCOS: testosterone ($P=0.001$; $P=0.006$) androstenedione ($P<0.001$ for both) DHEA ($P=0.004$; $P=0.001$) and 17OHProgesterone ($P<0.001$ for both). Moreover, PCOS group showed higher estrone ($P=0.002$; $P=0.006$) and 17OHpregnenolone ($P=0.013$; $P=0.001$) levels compared to controls. No differences were found for serum cortisol, cortisone, corticosterone, 11-deoxycortisol, progesterone, estradiol and dihydrotestosterone. PCOS displayed higher salivary androgens both at basal levels and in daily exposure: testosterone (4.41 ± 0.96 vs 13.5 ± 6.9 pg/ml, $P<0.001$; 3314.9 ± 1029.7 vs 8328.9 ± 2984.7 AUCg, $P<0.001$) androstenedione (69.6 ± 18.7 vs 162.3 ± 49.9 pg/ml, $P<0.001$; 51829.7 ± 14968.3 vs 125592.7 ± 36501.2 AUCg, $P<0.0001$), DHEA (169.2 ± 100.4 vs 349.1 ± 152.1 pg/ml, $P=0.007$; 113272.3 ± 47145.4 vs 185457.8 ± 67046.8 AUCg, $P=0.018$) and 17OHProgesterone (10.5 ± 4.9 vs. 25.1 ± 10.2 pg/ml, $P=0.010$; below sensitivity limit vs 14643.0 ± 2790.0 AUCg) compared to controls. PCOS subjects displayed high serum testosterone, androstenedione, DHEA, 17OHProgesterone, 17OHpregnenolone and estrone, both at baseline and in daily exposure. Increased serum androgens resulted in high salivary androgens too, showing the salivary androgens profiling as promising tool for non-invasive diagnostic work-up of PCOS patients.

Novel mechanisms and genes involved in the pathogenesis of primary ovarian insufficiency (POI) by whole-exome sequencing approach

Raffaella Rossetti[1], Ilaria Ferrari[1], Davide Gentilini[2,3] & Luca Persani[4,5]
[1]Laboratory of Endocrine and Metabolic Research, IRCCS Istituto Auxologico Italiano, Cusano Milanino, Italy; [2]Department of Brain and Behavioral Sciences, University of Pavia, Pavia, Italy; [3]Bioinformatics and Statistical Genomics Unit, IRCCS Istituto Auxologico Italiano, Cusano Milanino, Italy; [4]Division of Endocrine and Metabolic Diseases and Laboratory of Endocrine and Metabolic Research, IRCCS Istituto Auxologico Italiano, Milan, Italy; [5]Department of Clinical Sciences and Community Health, University of Milan, Milan, Italy.

The ovarian reserve naturally declines with age, however, 1–2% of women before 40 years experiences a premature exhaustion of the ovarian function and suffers from a fertility defect named Primary Ovarian Insufficiency (POI). The genetic origin of POI is well established and strongly supported by multiple reports of familial cases. To date, thanks to the candidate gene-discovery approach, few X-linked and autosomal genes have been associated to POI onset, but most of 46,XX cases still remain idiopathic suggesting the involvement of new genetic mechanisms. Whole-Exome Sequencing (WES) has been performed in ten POI patients with the extreme phenotype of absent pubertal development (primary amenorrhea), of which 6 familial and 4 sporadic, to reveal rare variants affecting genes implicated in ovarian function. Their relatives have been similarly analyzed as control population, for a total of 24 exomes. Genomic DNA was first extracted by patients and their relatives, then sheared into random fragments of roughly 300 base pairs and those fragments falling in exome regions were enriched by capturing, and finally sequenced. Data analysis consisted of image recognition, base calling, demultiplexing and trimming of adapter sequences, quality control of generated reads and estimation of coverage, alignment of the clean reads to the reference genome. In order to prioritize variants with potentially pathogenetic role in POI, first we focused on rarity and assessed the frequency of each variant in the general population by using the information provided by ongoing large genome projects (such as ExAC, Exome Variant Server, dbSNP browsers). Variants' frequencies $>1\%$ have been considered not rare and filtered out. A total of 18 570 rare variants (including: missense, 86%; nonsense, 3.5%; small indels, 5.6%) have been identified in our selected cohort of patients. The pathogenic level of each identified variant has been predicted *in silico*. A pathway-based analysis was performed through the Reactome software on 1916 genetic identifiers occurring mutated at least once. The overrepresentation analysis revealed enrichment among altered genes in: the Chromatin organization pathway and, consequently, the cell cycle and meiosis pathways; the Extracellular matrix organization and cell-cell communication pathways. Further, one hundred fifty-two coding variants in 117 genes participating in key biological processes within the ovary were identified by WES and therefore result potentially related to the POI onset in our patients. Finally, we observed the presence of at least two variants in distinct genes in all the patients in agreement with the oligogenic nature of POI.

Hypothalamo-pituitary-adrenal axis sensitivity in women with polycystic ovary syndrome

Djuro Macut[1], Ivana Bozic-Antic[1], Dusan Ilic[1], Tamara Bogavac[1], Jelica Bjekic-Macut[2], Danijela Vojnovic-Milutinovic[3], Olivera Stanojlovic[4], Bojana Popovic[1], Tatjana Isailovic[1], Valentina Elezovic-Kovacevic[1] & Sanja Ognjanovic[1]
[1]Clinic of Endocrinology, Diabetes and Metabolic Diseases, Clinial Center of Serbia, Belgrade, Serbia; [2]CHC Bezanijska kosa, Belgrade, Serbia; [3]IBISS, University of Belgrade, Belgrade, Serbia; [4]Institute of Physiology, Faculty of Medicine, University of Belgrade, Belgrade, Serbia.

Introduction
Hypothalamo-pituitary-adrenal (HPA) axis dysregulation could be a link between polycystic ovary syndrome (PCOS) and cardiometabolic and psychological complications associated with disease.
Methods
We analyzed 50 women with PCOS according to ESHRE/ASRM criteria [age 28.66 ± 5.61, body mass index (BMI) 21.94 ± 3.38 kg/m^2] and 50 BMI- and age-matched healthy women (control group, CG), (age 28.66 ± 5.63, BMI 22.09 ± 3.70 kg/m^2). In follicular phase of menstrual cycle we analyzed body composition (BC) by bioelectrical impedance, serum fasting glucose, insulin, lipids, morning cortisol levels, ACTH, androgens and cortisol after overnight $Dex_{0.5mg}$ and Dex_{1mg} tests. HOMA-IR and FAI were calculated. Repeated measures ANOVA was used for analysis of HPA axis fuctionality after Dex tests.
Results
PCOS and CG didn't differ in BC parameters, HOMA-IR and lipids. Morning cortisol was significantly higher in PCOS (476.12 ± 168.68 nmol/l vs 401.1 ± 143.5 nmol/l, $P=0.019$), while ACTH didn't show any difference (29.0 ± 21.9 ng/ml vs 23.8 ± 14.0, $P=0.236$). After $Dex_{0.5mg}$ there was no significant difference in cortisol suppression ($86.8\pm16.2\%$ vs $86.5\pm16.9\%$, $P=0.931$) in contrast to Dex_{1mg} where PCOS showed significantly better cortisol suppression ($94.9\pm2.4\%$ vs $92.7\pm5.8\%$, $P=0.020$). During dexametasone tests, HPA axis showed higher level of functionality in PCOS group in comparison to CG ($Dex_{0.5mg}$: $F_{1,98}=5.97$, $P=0.016$; Dex_{1mg}: $F_{1,98}=4.88$, $P=0.029$).
Conclusion
Women with PCOS have the same body composition and insulin resistance, but at the same time higher level of HPA axis functionality and better HPA axis sensitivity in comparison to respective controls. HPA axis hyperactivity in PCOS could be possible link towards cardiometabolic and psychological outcomes of the syndrome.

Hypermethylation of tumour suppressor genes in pituitary adenomas: contribution to oncogenesis and tumour behaviour

Araceli García-Martínez[1], Johana Sottile[1], Carmen Fajardo[2], Rosa Cámara[3], Cristina Lamas[4] & Antonio Picó[5]
[1]General University Hospital of Alicante-ISABIAL, Alicante, Spain; [2]Endocrinology Service, University Hospital La Ribera, Alzira, Spain; [3]Endocrinology Service, University and Polytechnic Hospital La Fe, Valencia, Spain; [4]Endocrinology Service, General University Hospital of Albacete, Albacete, Spain; [5]Endocrinology Service, General University Hospital of Alicante-ISABIAL, Alicante, Spain.

Introduction
Epigenetic and genetic alterations contribute to cancer initiation and progression. These alterations may be playing a determinant role in the development of pituitary adenomas (PAs). One of these epigenetic processes is the DNA methylation and, specifically, methylation of Tumour Suppressor Genes (TSG). TSG are key elements that allow the maintenance of cellular homeostasis. Due to epigenetic changes are reversible, a better understanding of the underlying epigenetic alterations during tumourogenesis and the discovery of epigenetic biomarkers are essential aspects to develop new therapies in these tumours. The aim of the present study was to analyse the methylation status of 36 TSG in a series of 105 PAs using the MS-MLPA technique and quantify the gene expression of methylated genes by qRT-PCR.
Methods
The study was performed in 105 PAs (35 silent gonadotroph adenomas (SGT), 15 silent corticotroph adenomas (SCT), 15 functioning corticotroph adenomas (CT) and 40 functioning somatotroph adenomas (ST)). Clinical, pathological, and radiological data were collected anonymously for each sample from the Spanish Molecular Registry of Pituitary Adenomas (REMAH) database. Tumours were classified as aggressive (invasive or ki67$\geq$3%) or non-aggressive (non-invasive and ki67$<$3%). MS-MLPA was used to analyse the promoter TSG hypermethylation. Gene expression was performed by qRT-PCR.
Results
Between the 36 TSG studied we chose the five genes with higher frequency of methylation in the overall series and in the different subtypes: *TP73*, *CADM1*, *CASP8*, *MGMT* and *RASSF1*. The expression of *CADM1* was significant lower in SCT and in CT than in SGT ($P=0.018$ and $P<0.001$, respectively). Moreover, the expression of CADM1 was also lower in CT than in ST ($P<0.001$). The expression of *RASSF1* was lower in ST than in SGT ($P=0.014$). There were no differences between subtypes in the expression of the other genes studied. *TP73* was the only TSG studied whose expression correlated negatively with the aggressiveness of PAs although only in SCT subtype ($P=0.037$). Regrettably, methylation was associated with a decrease in the expression of *TP73* only in the global series ($P=0.049$) but not in the SCT subtype.
Conclusions
In this series, we identified for the first time a reduction in the expression of *CADM1* in the pituitary tumours derived from Tpit lineage, a subset of PAs known by its special aggressiveness compared with other subtypes. Although a larger number of SCT should be studied, it is possible that the methylation of *TP73* could also contribute to the aggressiveness of this subtype of PAs.

Why don't corticotroph tumours always produce Cushing disease?

Araceli García-Martínez[1], David Cano[2], Joan Gil[3], Carmen Fajardo[4], Rosa Cámara[5], Cristina Lamas[6], Alfonso Soto[2], Manel Puig[3] & Susan M Webb[7]
[1]General University Hospital of Alicante-ISABIAL, Alicante, Spain; [2]Endocrinology Service, University Hospital Rocío, Sevilla, Spain; [3]IGTP, Endocrinology Service, Badalona, Spain; [4]Endocrinology Service, University Hospital La Ribera, Alzira, Spain; [5]Endocrinology Service, University and Polytechnic Hospital La Fe, Valencia, Spain; [6]Endocrinology Service, General University Hospital of Albacete, Albacete, Spain; [7]Endocrinology Service, Sant Pau Hospital, IIB-S Pau, UAB, Barcelona, Spain.

Introduction
Silent corticotroph tumours (SCT) are a pituitary tumours (PT) subtype of corticotroph lineage that do not clinically express Cushing disease. Inmunohistochemical (IHC) studies reveal no differences between SCT and functioning corticotroph tumours with Cushing Syndrome (FCT). However, the silencing mechanisms of this type of tumours are not fully understood.
Aim
In an important series of SCT, to sequence the *POMC* gene and quantify the expression of transcription factors of corticotroph lineage (*TBX19* (Tpit), *NEUROD1*) and convertases involved in the processing of *POMC* (*PC1/3*) and in the degradation of ACTH (*PC2, CPE* and *PAM*).
Material and methods
From our collection of 248 PT we chose 22 SCT, 22 FCT and 26 silent gonadotroph tumours (SGT) (control group). All the adenomas had previously been IHC and molecularly characterized. The molecular identification of SCT was based on an overexpression of *POMC, AVPR1b* and *CRHR1* genes similar to FCT and significantly higher than other subtypes of PT. The molecular study allowed to identify a subtype of SCT IHC negative for ACTH (IHC-ACTH(−)). The gene expression of *TBX19, NEUROD1, PC1/3, PC2, CPE* and *PAM* was studied by qRT-PCR with TaqMan probes. Moreover, in 18/22 SCT we performed a Sanger sequencing of the *POMC* gene.
Results
Preliminary sequencing of *POMC* in SCT identified some SNPs that are associated with *POMC* deficiency. Besides, compared with FCT, SCT showed an overall lower expression of *PC1/3* ($P=0.031$), only significant in microadenomas ($P=0.05$) but not in the FCT macroadenomas. There were no differences in the expression of the other genes studied. Molecularly identified IHC-ACTH (+) SCTs showed a higher *PC2* and *CPE* gene expression than IHC-ACTH (−) ones ($P=0.042$ and $P=0.052$, respectively). There were no differences in the expression of the other genes studied. Moreover, and in comparison to FCT, there were no differences in the expression of *PC1/3* and *PAM* between SCT and the control group of GT.
Conclusions
SCT have lower *POMC* expression and processing than FCT, especially in functioning microadenomas, while ACTH degradation is similar in both subtypes. Indeed, the expression of the genes involved in the degradation of ACTH seems to be related to the amount of this hormone in the tumour. Moreover, SCT share some similarity with SGT in the processing of *POMC* and in the degradation of ACTH, suggesting the possible existence of silent corticogonadotroph tumours.

New horizons in medical treatment of Bronchial Carcinoids: evidence from *in vitro* models

Giulia Bresciani, Chiara Di Tullio, Patricia Borges De Souza & Maria Chiara Zatelli
Section of Endocrinology and Internal Medicine, Department of Medical Sciences, University of Ferrara, Ferrara, Italy.

Introduction
Bronchial Carcinoids are rare neoplasms originating from the diffuse neuroendrocrine system. Surgery is the only effective therapy but may not be feasible due to metastases. Available therapy may control symptoms but not tumor bulk. Everolimus has shown promising results, however patients may develop resistance. Previous studies demonstrated that Everolimus reduces viability of NCI-H720 (Atypical Carcinoid) but not of NCI-H727 cells (Typical Carcinoid). In order to find molecular targets different from mTOR, we previously assessed CDKs and cyclins protein levels in both NCI-H720 and NCI-H727 cells and found a differential expression pattern.
Aim
This study is aimed to test the efficacy of a CDK inhibitor, Dinaciclib, alone and in combination with Everolimus on NCI-H720 and NCI-H727 cells. We also investigated the involvement of autophagy in mediating the effects of Dinaciclib on cell viability and LC3B expression (autophagosome protein) by using a well-established autophagy inhibitor, Chloroquine.
Methods
Cell viability was tested by a luminescent assay and protein levels by Western blot analysis.
Results
Treatment with Everolimus (100 nM) reduced viability in NCI-H720 (−26% vs control; $P<0.01$) and in NCI-H727 cells (−19% vs control; $P<0.01$). Dinaciclib (100 nM) significantly reduced viability in both NCI-H720 (−39% vs control; $P<0.01$) and NCI-H727 cells (−62% vs control; $P<0.01$). Dinaciclib potentiated the inhibitory affects of Everolimus on NCI-H720 viability (−24% vs Everolimus; $P<0.01$), while in NCI-H727 cells the combination did not modify the inhibitory effects of Dinaciclib. Co-treatment with Chloroquine 1 mM did not modify these results. In addition, we assessed autophagosome protein LC3B by Western blot analysis. We found that LC3B levels were not influenced by the employed drugs in NCI-H727 cells. In NCI-H720 Dinaciclib reduced LC3B levels independently of the combination with Everolimus (−37% and −48% respectively vs. control); Everolimus alone did not influence LC3B levels. Chloroquine determined a reduction in LC3B levels (−40% vs control), and this effect was not influenced by Everolimus. On the contrary, Dinaciclib potentiated Chloroquine effects on LC3B reduction (−44.5% vs Chloroquine) independently of the combination with Everolimus.
Conclusions
Our results indicate that Everolimus effects are not mediated by autophagy. On the contrary, Dinaciclib inhibits autophagy in NCI-H720 but not in NCI-H727, indicating that in the latter cells the antiproliferative effects of Dinaciclib are mediated by mechanisms different from autophagy. At the same time, Dinaciclib could represent a good candidate for medical treatment of Bronchial Carcinoids, especially for those patients resistant to Everolimus.

[1]Department of Cell Biology, Physiology and Immunology, University of Córdoba, Cordoba, Spain; [2]Instituto Maimónides de Investigación Biomédica de Córdoba (IMIBIC)/Hospital Universitario Reina Sofía, Cordoba, Spain; [3]CIBER Fisiopatología de la Obesidad y Nutrición, Cordoba, Spain; [4]Univeristy of Liège, Liège, Belgium; [5]CIBER Fisiopatología de la Obesidad y Nutrición, Galicia, Spain; [6]Department of Physiology, University of Santiago de Compostela, Galicia, Spain.

GnRH neurons are the final output of the brain controlling reproduction. These neurons receive information from multiple central and peripheral signals, ranging from gonadal steroids to metabolic cues and brain neuropeptides, to regulate their activity. AMP-activated protein kinase (AMPK) is an intracellular sensor, activated by energy deficiency, involved in the regulation of the cellular and whole-body energy homeostasis. Previous *in vitro* studies suggested the participation of AMPK in the negative regulation of GnRH neuronal excitability in response to glucose deprivation. Nonetheless, the physiological relevance of AMPK signaling in GnRH neurons for the metabolic control of the reproductive function remains unknown. In this work, we aimed to explore the roles of AMPK signaling in GnRH neurons by generating a transgenic mouse, named GAMKO, with congenital elimination of the catalytic AMPK alpha-1 subunit specifically in this neuronal population. Ablation of AMPK in GnRH neurons resulted in advanced puberty onset in female, but not male mice. Moreover, acyclic GAMKO females, due to chronic caloric restriction, had a faster recovery of the estrous cyclicity after re-feeding, compared to control mice. Both features are compatible with unrestrained GnRH secretion in the absence of AMPK, which would drive a negative valence when become active (e.g., in conditions of negative energy balance). In addition, GAMKO females showed enhanced responsiveness to GnRH administration, in terms of LH secretion. On the other hand, adult GAMKO mice had increased fat mass and body weight, being already evident in

males at the time of puberty. All in all, our data are the first in describing the potential role of AMPK in GnRH neurons for the regulation of reproduction and metabolism. Further characterization of the reproductive (LH pulsatility, ovarian histology) and metabolic (insulin resistance, energy consumption) phenotype of GAMKO mice is currently ongoing in order to fully disclose the physiological function of this key energy sensor in the dynamic regulation of GnRH neurons and the bodily functions controlled thereby.

Preoperative SSA treatment positively affects the outcome of pituitary neurosurgery in acromegaly patients

Agata Baldys-Waligorska[1], Michal Koziara[1], Andrzej Nowak[2] & Andrzej Sokolowski[3]
[1]Department of Endocrinology, Jagiellonian University Medical College, Krakow, Poland; [2]Student, Faculty of Medicne, Jagiellonian University Medical College, Krakow, Poland; [3]Department of Statistics, University of Economics, Krakow, Poland.

Introduction
Treatment with somatostatin analogues (SSA) leads to shrinkage of pituitary adenoma in acromegaly naïve patients, as shown by the PRIMARYS study. Therefore the effect of this treatment on surgery was investigated.
Aim
To evaluate the efficacy of pre-treatment with SSA in acromegaly patients qualified for neurosurgery.
Material and methods
Group A (46 patients: 36 female, 10 male) were pre-treated with SSA. Group B (49 patients: 30 female, 19 male) were not treated, their mean ages at diagnosis: 49.2 ± 13.9 years and 41.2 yrs ± 13.1, respectively ($P = 0.005$). Group A- patients were treated with SSA (octreotide 30 mg and lanreotide autogel 120 mg every 4 weeks) for 3–6 months before surgery.The percentage of microadenomas/ macroadenomas in group A and group B was 21.7/78.3% and 6.3/93.7%, respectively ($P = 0.026$).
Results
In groups A and B, GH concentration at 120 min in OGTT and IGF-1 ULN concentration before surgery did not differ. Median values of IGF-1 before surgery in groups A and B were 748.0 (range 113.0–1872.9) ng/ml and 1026.5 (447.0–1998.9) ng/ml, respectively, $P = 0.031$. Three months after surgery, significant difference of median GH concentrations at 120 min was observed between group A: 0.58 (0.20–24.30) ng/ml and group B: 1.10 (0.15–58.40) ng/ml, $P = 0.035$, as well as between median of IGF-1 concentrations: group A: 240.5 (62-912) ng/ml and group: B 352.4 (88–1150) ng/ml, $P = 0.05$. In group A 73.3% of patients were considered cured, and 26.7% required further SSA treatment. In group B 32.6% of patients were considered cured, and 67.4% required further SSA treatment, $P = 0.0001$.Of those patients who required further SSA treatment 75% in group A and 64.5% in group B were well controlled. According to our most recent evaluation, in group A the levels of GH, IGF-1and ULN were: 1.57 (0.35–10.00) ng/m; 174.5 (51–558) ng/ml and 0.48 (0.16–1.87), respectively, while these levels in group B were: 1.40 (0.20–7.70) ng/ml; 226.5 (79-559) ng/ml and 0.60 (0.25-2.73), respectively. Only the difference in IGF-1 levels between groups A and B was statistically significant, $P = 0.0489$.Following multi-dimentional step-wise regression, pituitary microadenoma, IGF-1ULN after surgery, and SSA pre-treatment, were positive predictors of the final outcome, with respective odds ratios: 32.02 (±95% CL 2.17–472.0, $P = 0.0104$), 0.11 (± 95% CL 0.02–0.53, $P = 0.0054$) and 34.97 (±95% CL 7.63-160.38, $P = 0.0000$).
Conclusion
SSA pre-treatment improves the final outcome of pituitary surgery in acromegaly patients.

Characterization and functional rescue of a nephrogenic diabetes insipidus causing S127F substitution in V2 vasopressin receptor

László Erdélyi[1,2], Laura Szalai[1], András Sziráki[1], András Balla[1,2] & László Hunyady[1,2]
[1]Department of Physiology, Semmelweis University, Budapest, Hungary; [2]MTA-SE Laboratory of Molecular Physiology, Budapest, Hungary.

The concentrating function of the kidney is important to maintain the water homeostasis of the body. It is regulated by the arginine-vasopressin system through the type 2 vasopressin receptor (V2R). Loss-of-function mutations of V2R in kidney can lead to nephrogenic diabetes insipidus (NDI) which results several symptoms such as polyuria, polydipsia, and hyposthenuria. In this study, we functionally characterized and investigated the potential rescue of a missense mutation (S127F) of the V2R. We monitored the cellular localization of the S127F mutant V2 receptor using HA-tagged receptors in confocal microscopy experiments. The S127F V2 receptor was detected only in the endoplasmic reticulum but not in the plasma membrane. We also measured the cAMP signaling capability of the mutant receptor with BRET measurements. The S127F receptor was not able to increase the intracellular cAMP levels in response to vasopressin stimulation. Certain ER retention mutations can be rescued by pharmacological chaperones, which cause misfolded mutant receptors to present in the plasma membrane. We examined the effect of tolvaptan (a V2R antagonist) on the S127F V2 receptor. HEK293 cells were transiently transfected with the plasmid of the mutant receptor and after one day the cells were incubated for 18 h with tolvaptan. After the pretreatment, the cells were exposed to vasopressin, and we were able to detect significant cAMP signal generation of the mutant receptor. We also checked whether the result after tolvaptan pretreatment was due to restored plasma membrane location of the receptor. We were able to demonstrate significant increase of the mutant receptors in the plasma membrane using flow cytometry. We also investigated the effect of pharmacochaperone MCF14 compound (a cell permeable high-affinity agonist for the V2R) on the mutant receptor and we found that the MCF14 was also capable to restore the cAMP signaling function of the receptor. According to our data, pharmacochaperones could be the treatment for patients carrying the S127F mutation.

Genetics of binge-eating disorder (BED): a pilot study

Chiara Cacciatore[1,2], Valeria Vezzoli[2], Paolo Duminuco[2], Massimo Scacchi[3], Stefania Mai[3], Nicoletta Polli[1] & Luca Persani[1,2]
[1]U.O. Centro Day-Hospital-MAC di Medicina Endocrino-Metabolica, Ospedale San Luca, Istituto Auxologico Italiano, Milano, Italy; [2]Laboratorio di Ricerche Endocrino-Metaboliche, Istituto Auxologico Italiano, Milano, Italy; [3]U.O. di Medicina Generale a indirizzo Endocrino-Metabolico, Ospedale San Giuseppe di Piancavallo, Istituto Auxologico Italiano, Milano, Italy.

Binge-eating disorder (BED) is characterized by recurrent (≥1 per week for 3 months), brief (≤2 h), psychologically distressing binge-eating episodes during which patients sense a lack of control and consume larger amounts of food than most people would under similar circumstances. The prevalence of BED is estimated to be between 2% and 3.5% and majority of individuals with BED are either overweight or obese. Most of the genetic research about eating disorders (ED) has focused on Anorexia Nervosa and Bulimia Nervosa; less data are available for BED due to its status as a newly recognized ED diagnosis. Although family and twin studies suggest the role of genetic factors in BED, candidate gene studies have not clearly confirmed the involvement of any one gene or genetic pathway. The aim of our study was to examine the existence of genetic variants associated with the onset of BED, using the Next-Generation (NGS) technology. We analyzed 42 genes involved in neuro-regulation of hunger/satiety associated with BMI and/or obesity and/or eating disorders in 50 obese patients (BMI $>40\ kg/m^2$) affected by BED and in a control population (72 normal weight subjects overlapping with our cases by sex and age without a diagnosis of eating disorders). Twenty-eight obese patients with BED are mutated in 19 of the genes analyzed; of these, 12% vs 4% of controls carries more than one variant in different genes. Within the control population, fewer mutations were found (33%) compared to the case population, in which the percentage of the changes (56%) was higher than the percentage of the Wild-Type (44%). These differences indicate a statistically significant enrichment of rare variants in BED patients compared to controls according to the Exact Fisher Test ($P = 0.0159$). Several genes tested positive are known to be involved in the reward system and in the hedonic hunger (FTO, OPRM1, GHRL and LEPR), but we discovered new loci with a novel possible involvement in hedonic hunger. To date, our study is the first NGS study in a series of obese patients with BED and suggests for the first time some mechanisms potentially involved in conferring a genetic susceptibility to development of a BED.

Hyponatremia-associated mortality and volemia in patients on parenteral nutrition: a prospective multicenter study

Ana Ortolá Buigues[1], Emilia Gómez Hoyos[1], María Dolores Del Olmo García[2], Ana Herrero Ruiz[3], Julia Álvarez Hernández[4], Cristina Tejera Pérez[5], Sandra Herranz Antolín[6], Irene Bretón Lesmes[7], Miguel Angel Martínez Olmos[8] & Daniel De Luis Román[1]
[1]Hospital Clínico Universitario de Valladolid, Valladolid, Spain; [2]Hospital Universitario Severo Ochoa, Leganés, Spain; [3]Hospital Universitario de Salamanca, Salamanca, Spain; [4]Hospital Universitario Príncipe de Asturias, Alcalá de Henares, Spain; [5]Complejo Hospitalario Universitario de Ferrol, Ferrol, Spain; [6]Hospital General Universitario de Guadalajara, Guadalajara, Spain; [7]Hospital General Universitario Gregorio Marañón, Madrid, Spain; [8]Complejo Hospitalario Universitario de Santiago de Compostela, Santiago de Compostela, Spain.

Introduction
In patients receiving Parenteral Nutritcion (PN), hyponatremia is associated with increased in-hospital mortality. Our objective was to evaluate the influence of volemic classification (hypovolemia, euvolemia or hypervolemia) on in-hospital mortality in patients receiving PN presenting hyponatremia.
Methods
Prospective, non-interventional, multicenter study in 19 Spanish hospitals. 543 non-critical patients receiving PN were recruited. Hyponatremia was defined as a Serum sodium level (SNa) $<$ 135 mmol/l. Patient data collected included gender, age, prior comorbidity, body mass index-BMI-, nutritional assessment by subjective global assessment (SGA), SNa at start of and during PN, in-hospital mortality, and type (volemic classification) of hyponatremia. Duration of PN, metabolic and infectious complications related to PN were also registered. Statistics: univariate and multivariate logistic regression.
Results
60.2% were men. Median age 67 [IQR 57–76]. 162 patients (29.8%) presented hyponatremia. Clinical volemia was evaluated in 137/162: 14.6% were hypovolemic, 67.9% euvolemic, 17.5% hypervolemic. In-hospital mortality was: 13.6% (22.5% of hyponatremic patients vs 9.8% of normonatremic patients; $P<0.001$). In-hospital mortality according to hyponatremia type was: 20.0% in hypovolemic patients, 20.9% in euvolemic patients, 41.7% in hypervolemic patients ($P=0.096$). In multivariate logistic regression, hyponatremia was independently associated with increased in-hospital mortality (OR 1.83 [95% CI 1.03–3.24]; $P=0.039$), following correction for age, gender, SGA, BMI, prior comorbidity, duration of PN and metabolic /infectious complications related to PN. In the same multivariate analysis model, the Odds Ratios for in-hospital mortality by type of hyponatremia as compared with patients with eunatremia were: 1.95 (95% CI 0.54–7.07, $P=0.307$) in hypovolemia, 1.44 (95% CI 0.69–3.00, $P=0.337$) in euvolemia, and 3.36 (95% CI 1.17–9.63, $P=0.024$) in hypervolemia.
Conclusion
Hyponatremia is independently associated with increased in-hospital mortality in patients receiving parenteral nutrition. Patients with hypervolemic hyponatremia present a marked increase in mortality risk as compared with patients presenting eunatremia.

Hyperglycemia causes a reduction in FSH levels following aberrant epigenetic regulation in the gonadotropes due to the increased glucose metabolism

Philippa Melamed, Alona Feldman, Ayah Saleh & Lilach Pnueli
Technion-Israel Institute of Technology, Haifa, Israel.

The connection between metabolic state and fertility is well-recognized, and the hypothalamus clearly plays a central role in translating metabolic signals into altered GnRH release which affects the reproductive axis. We hypothesized that the gonadotropes might also directly impart some of the effects of hyperglycemia on reproductive function. Gonadotropes were shown to express predominantly the insulin-independent Glut-1 transporter, and their incubation in high glucose increases expression of the glucose responsive *Txnip* gene while altering levels of various glucose metabolites. The drop in NAD+ and increase in α-ketoglutarate affect the activity of Sirtuin histone deacetylases, JmjD histone demethylases and Tet DNA hydroxymethylases/demethylases, all of which use these metabolites as cofactors. Accordingly, gonadotropes in high glucose showed elevated histone acetylation and H3K4 trimethylation, reduced DNA methylation and increased hydroxymethylation, all of which are associated with elevated gene expression. Transcriptome analysis revealed that expression of many genes increased after incubation in high glucose. Notably however, *Fshb* expression was repressed in high glucose conditions, both in cultured cells and in two hyperglycemic mouse models *in vivo*. In one of these, circulating FSH levels were also significantly reduced. Increased expression and secretion of inhibin appears partly responsible for this repressive effect on *Fshb*. Although return of cells to normal glucose restored expression of some of the genes, *Fshb* levels remained low and the affected chromatin modification were not reversed. Our findings suggest that hyperglycemia aberrantly affects the gonadotrope epigenome with potentially long-term effects on gene expression and thus also reproductive function.

Macrophages involvement in neuroendocrine tumor behaviour and progression

Ilena Boemi[1], Eleonora Vitali[1], Giulia Veronesi[2], Alessandro Zerbi[3] & Andrea Lania[1,4]
[1]Cellular and Molecular Endocrinology Laboratory, IRCCS Clinical Research Institute Humanitas, Rozzano, Italy; [2]Division of Thoracic and General Surgery, IRCCS Clinical Research Institute Humanitas, Rozzano, Italy; [3]Pancreas Surgery Unit, IRCCS Clinical Research Institute Humanitas, Rozzano, Italy; [4]Department of Biomedical Sciences, Humanitas University, Rozzano, Italy.

Neuroendocrine tumors (NETs) are rare neoplasms showing a wide spectrum of clinical behaviors. The therapeutic options available for NET treatment are rarely curative and most are palliative, as NETs frequently show resistance to pharmacological therapy. Cancers develop in complex tissue environments, which they depend upon for sustained growth, invasion and metastasis. A major characteristic of the tumor microenvironment is inflammatory cell infiltration, where tumor-associated macrophages (TAMs) are a major cellular component. The polarized state of macrophages is classified into two subsets: classically activated M1 (anti-tumor promoting effects) and alternatively activated M2 (pro-tumor promoting effects). Thus the restoration of an M1 phenotype may provide therapeutic value by promoting anti-tumor behavior. The importance of immune microenvironment and the role of macrophages in NET are poorly understood. Aims of the study are: to investigate the effects of the different macrophages subtypes (M1, M2) on biological behavior of primary NET cells and QGP1 (pancreatic-NET) and H727 (pulmonary-NET) cell lines. We found that M1 macrophages significantly decreased the viability of QGP1 cell line ($-40\pm14\%$ $P<0.01$ vs basal) and H727 cell line (-43 ± 8 $P<0.01$ vs basal). Moreover, CM (conditioned medium) of M1 macrophages strongly decreased colony formation, colony average area and cell number (QGP1: $-42\pm17\%$ $P<0.05$ vs basal; H727: $-60\pm15\%$ $P<0{,}001$ vs basal) after 7 days of incubation. As shown by flow cytometry analysis, after CM of M1 macrophages treatment, G0/G1 phase was increased in H727 cells ($+18\pm7\%$ $P<0.05$), whereas G2/M phase was decreased in QGP1 cell ($-44\pm4\%$ $P<0.05$). Interestingly, as shown by real time analysis, the CM of NET cell lines promoted the differentiation of macrophages into an M2 phenotype, after 24 h of culture. Moreover, as shown in preliminary data of primary pancreatic NET cells, CM of M1 macrophages strongly decreased cell proliferation, whereas CM of M2 macrophages promoted it. In conclusion, M1 macrophages have a potent anti-tumor effect, able to affect the proliferation and the tumorigenicity of NET cell lines. Interestingly, NET cell lines contribute to promote a M2 phenotype of macrophages, suggesting a potential involvement of tumor microenvironment in the behaviour of pulmonary and pancreatic NETs.

Mountain cycling ultramarathon effects on neuromuscular, immune and stress biomarkers

Isanete Alonso[1,2,3], Andreia Matos[1,4,5,6], Ricardo Ribeiro[1,5,6,7], Ângela Gil[1,4], Carlos Cardoso[8] & Manuel Bicho[1,4]

[1]Laboratory of Genetics and Environmental Health Institute, Faculty of Medicine, University of Lisbon, Lisbon, Portugal; [2]Department of Nutritional Science, Atlântica University, Barcarena, Portugal; [3]CESOB – Center for Studies in Social Sciences, Business, Health and Welfare, Atlântica University, Barcarena, Portugal; [4]Institute of Scientific Research Bento of Rocha Cabral, Lisbon, Portugal; [5]i3S, Institute for Research and Innovation in Health, University of Porto, Porto, Portugal; [6]INEB, Institute of Biomedical Engineering, University of Porto, Porto, Portugal; [7]Departmentof Clinical Pathology, The Coimbra Hospital and Universitary Centre, Coimbra, Portugal; [8]Clinical Chemistry Laboratory, Joaquim Chaves Group, Miraflores, Portugal.

Introduction
The long-term mountain cycling effects on cognitive development for better performance, are still not fully elucidated. Notwithstanding, this type of exercise may induce a link with energy metabolism and sympathetic nervous system. We previously observed that a mountain cycling ultramarathon, induced a comodulatory influence of genetic- and exercise-associated factors on inflammatory and haemoglobin catabolic marker haptoglobin. We hypothesised that inflammatory process may induce hypothalamic-pituitary-adrenal (HPA) activation with consequent neuromuscular functional changes in long-term mountain cycling.
Methods
Fifty-five non-professional athletes (mean age 44.8 ± 7.1 years) participating in a 9-day mountain cycling ultramarathon (TransPortugal) were evaluated. Before and immediately after race were determined the following parameters: insulin, glucose, uric acid, creatinine and platelets by standard methods; IL-6-plasma, BDNF-serum, cortisol-salivary and irisin-serum by ELISAs. Δ% represents values adjusted for plasma volume. Body composition was evaluated by BIA-Quantum-X. Participants were also categorized according to the number of courses completed (<9 or 9 courses).
Results
After race, IL-6 and platelets increased by 1129.7% ($P<0.0001$) and 13.3% ($P<0.0001$), respectively, while BDNF and cortisol levels didn't change ($P>0.05$). At post-race, BDNF was directly correlated with % fat mass ($r=0.286$, $P<0.05$), glucose ($r=0.294$, $P<0.05$), platelets ($r=0.462$, $P<0.01$) and inversely correlated with skeletal muscle mass (kg) ($r=-0.469$, $P<0.01$). Post-race IL-6 was directly correlated with Δ% uric acid ($r=0.341$, $P<0.01$), Δ% insulin ($P=0.287$, $P<0.05$), Δ% HOMA-IR ($r=0.289$, $P<0.05$), Δ% HOMA- β ($r=0.315$, $P<0.05$) and post-race cortisol ($r=0.368$, $P<0.01$). The Δ% cortisol was directly correlated with Δ% creatinine ($r=0.319$, $P<0.05$), Δ% uric acid ($r=0.439$, $P<0.01$), Δ% glucose ($r=0.332$, $P<0.05$), Δ% insulin ($r=0.293$, $P<0.05$) and Δ% HOMA-IR ($r=0.373$, $P<0.05$). The completers of 9 courses, presented higher values of the Δ% IL-6 ($P=0.043$), Δ% cortisol ($P=0.008$), and post-race BDNF levels ($P=0.053$). Only for completers, the fastest (≤3715 min) presented lower values of BDNF in relation to the athletes of intermediate group (3715–4030 min) ($P=0.013$). Irisin levels were lower for athlets with better performance/fastest ($P=0.033$).
Conclusion
The HPA-axis hyperactivity may decrease BDNF production via IL-6 inflammatory response activation. The increased BDNF levels for 9 courses completers could reflect an management capacity, throughout multiple mediators of HPA axis, autonomic nervous system, and components of the immune system. Cerebral blood flow may decrease during very high intensity exercise, compromising the production of BDNF and, as such, consumption of foods rich in nitric oxide precursors may improve the flow, decreasing the inflammatory process.

Sex hormone-binding globulin is more than a sex steroid carrier: a New therapeutic target against obesity and non-alcoholic fatty liver disease

Cristina Saez-Lopez, Cristina Hernandez, Rafael Simo & David M Selva
Diabetes and Metabolism Research Unit, Vall Hebron Institut de Recerca (VHIR), Universitat Autònoma de Barcelona and CIBERDEM (ISCIII), Barcelona, Spain.

Low plasma SHBG levels are present in patients suffering chronic metabolic diseases, including obesity and non-alcoholic fatty liver disease (NAFLD). In overweight individuals, low plasma SHBG levels are a biomarker for the metabolic syndrome and predict a higher risk of suffering type 2 diabetes and cardiovascular disease. Our recent results demonstrate that SHBG is more than sex hormone carrier and its reduction in obese subjects play an active role in obesity and NAFLD development independently of sex steroids. We have demonstrated these new SHBG actions using different approaches including an *in vitro* approach, developing different transgenic mouse models and using human samples. Regarding the *in vitro* approach, we have used HepG2 cells underexpressing and overexpressing SHBG. We have developed a genetically-induced model of obesity and expressing human SHBG (crossing human *SHBG* transgenic mouse with C57BL/ksJ-db/db mouse), a diet-induced NAFLD model (by feeding human *SHBG* transgenic mice and their wild-type littermates with high fructose diet (HFrD) during 8 weeks and a diet-induced obesity model by feeding human *SHBG* transgenic mice and their wild-type littermates with high fat diet (HFD) during 8 weeks. We have elucidated the molecular mechanisms associated by which SHBG protected against NAFLD development and HFD-induced obesity. Moreover, human liver biopsies were used to corroborate the *in vivo* and *in vitro* findings. Overall, our results point out to SHBG as a protective factor against obesity and NAFLD. Therefore, SHBG could be a new therapeutic target whereby increased expression may reduce obesity and NAFLD.

Use of ultrasonography as a simple diagnostic method to measure different abdominal fat layers and metabolic syndromeprediction

Guillem Cuatrecasas[1,2], Francisco De Cabo[1], Ioana Patrascioiu[1], Maria Jose Coves[1], Gabriel Cuatrecasas[1], Gloria Aranda[1], Gerardo Aguilar-Soler[1], Sonia March[1], Marta Calbo[1], Clara Bretxa[1] & Mariona Balfego[1]
[1]Endocrinology and Nutrition Department, Fundació CPEN, Clínica Sagrada Familia, Barcelona, Spain; [2]Universitat Oberta Catalunya (UOC), Barcelona, Spain.

Introduction
Waist circumference is a validated tool to measure obesity-associated cardiovascular risk factor. However it does not differentiate between superficial and visceral abdominal fat. Ultrasonography has many advantages over TC/DEXA in abdominal fat assessment, specially imaging pre-peritoneal, omental and retroperitoneal fat. Our aims were to validate the diagnostic technique and to observe correlations between different abdominal fat layers with clinical and analytical parameters related to obesity comorbidities.
Methods
$n=274$ patients, mean age 53, 82 (30%) males, 192 (70%) females (59% menopause), mean BMI 31 kg/m^2 (19.2% normal weight, 28,8% overweight, 52.2% Obesity), came for conventional abdominal US. Thickness of 6 different consecutive layers of abdominal fat at the L4 level were assessed using a 12 MHz linear and 3–6 MHz convex probes (GE logic E): Superficial and deep subcutaneous fat; Pre-peritoneal fat; Peri-aortic (omental) fat; Hepatic steatosis area (cm^2) and hepatic US noise (dB) (visceral fat); Pre-renal fat (Left and Right) (retroperitoneal fat). We also obtain: Waist circumference (WC), Glucose, insulinaemia, HOMA index, leptin, Total cholesterol, LDL, HDL, Triglycerides, DM2 diagnosis, Hypothyroidism and Metabolic Syndrome according to ATPIII criteria.
Results
We found a different sex distribution pattern at the SC (mean range 23.28 mm F and 20.16 mm M), pre-peritoneal (10.47 mm F and 11.34 mm M) and peri-aortic fat layers (44.33 mm F and 66.63 mm M) ($P<0.05$). Only peri-aortic fat correlates with BMI ($r=0.446$; $P<0.001$) and WC ($r=0.456$; $P<0.001$). Peri-aortic, Right pre-renal, but specially Pre-peritoneal fat ($P<0.001$, CI 8–20 mm) correlate with steatohepatitis. Menopause predisposes to greater peri-aortic fat ($P<0.001$, CI 6–18 mm) as well as Metabolic Syndrome ($P<0.001$, IC 16–27 mm). In a multi-variant analysis, only peri-aortic fat layer thickness and Waist Circumference may predict metabolic syndrome. Peri-aortic fat >34.5 mm in F (AUC=0.761; $P<0,001$; 74% sensibility and 60% specificity) and >56.5 mm in M (AUC=0.763; $P<0,03$; 75% S and 70% E), are predictive for metabolic syndrome (ROC curves).
Conclusions
US is an easy method for the stratification of different abdominal fat layers. More than global visceral fat, US highlights the clinical importance of strict peri-aortic (omental) fat layer, with good correlations with BMI, WC and steatohepatitis. We suggest a cut-off point of 34 mm in F and 56 mm in M to consider the thickness of the omental layer as pathological and predictive of metabolic comorbidities. Pre-peritoneal fat thickness with a linear probe may also be an easy way to estimate Steatohepatitis.

Improvement in insulin-mediated suppression of branched-chain amino acid flux is responsible for the post-bariatric surgery decrease in plasma branched-chain amino acid levels

Jie Yao[1], Jean-Paul Kovalik[2], Kwang Wei Tham[3], Yong Mong Bee[3], Phong Ching Lee[3], Alvin Eng[4], Weng Hoong Chan[4], Eugene Lim[4], Jeremy Lim[4] & Hong Chang Tan[3]
[1]Duke-NUS Medical School, Singapore, Singapore; [2]Cardiovascular Metabolic Program, Duke-NUS Medical School, Singapore, Singapore; [3]Department of Endocrinology, Singapore General Hospital, Singapore, Singapore; [4]Department of Upper Gastrointestinal and Bariatric Surgery, Singapore General Hospital, Singapore, Singapore.

Background
Branched-chain amino acids (BCAA) are elevated in morbid obesity and decreases significantly following bariatric surgery. This decrease is associated with the post-surgical improvement in insulin resistance (IR) and may be secondary to the reduction in BCAA flux from proteolysis or an increase in BCAA catabolism. Presently, the underlying mechanism is unclear.
Aim
To investigate the changes in BCAA metabolism in morbidly obese individuals following bariatric surgery.
Hypothesis
The decrease in plasma BCAA after bariatric surgery is due to the improved ability of insulin to suppress BCAA flux from proteolysis.
Methods
11 morbidly obese non-diabetic subjects scheduled for sleeve gastrectomy and 9 healthy non-obese controls were recruited. Metabolic assessments were performed for all subjects at baseline and at 6 months for the surgical subjects. IR was quantified as the insulin sensitivity index (ISI) obtained using the hyperinsulinemic-euglycemic clamp method and plasma BCAA and short-chain acyl-carnitines (ACs) were measured using mass spectrometry during fasting and insulin clamp.
Results
Morbidly obese subjects were significantly more insulin resistant than controls at baseline with a lower ISI (4.39 ± 1.95 vs 17.27 ± 7.31 mg/kgFFM per min per μU/ml·100). Following surgery, there were significant reductions in weight (114.80 ± 22.64 to 91.90 ± 16.65 kg), BMI (39.09 ± 4.68 to 31.29 ± 2.91 kg/m^2) and increase in ISI (4.39 ± 1.95 to 13.68 ± 3.36 mg/kgFFM per min per μU/ml·100). Plasma BCAA in morbidly obese subjects were similar to controls during fasting, but decreased to a greater extent in the control group following insulin infusion such that BCAA levels measured during the insulin clamp were significantly higher in the morbidly obese (332.47 ± 88.77 vs 235.32 ± 33.00 μM). However, no difference in short-chain ACs between the two groups was found. Interestingly, plasma BCAA during fasting and insulin clamp both decreased significantly (fasting BCAA 445.37 ± 75.21 to 326.19 ± 54.88 μM; insulin clamp BCAA 332.47 ± 88.77 to 211.56 ± 44.16 μM) following bariatric surgery but also without any changes in short-chain ACs levels.
Conclusion
The impaired ability of insulin to suppress BCAA flux is responsible for the higher plasma BCAA level in morbidly obese individuals during insulin clamp at baseline while the decrease in BCAA following bariatric surgery can be attributed to the improvement in insulin-mediated suppression of branched-chain amino acid flux. BCAA catabolism by contrast did not play an important role.

Cell-derived extracellular vesicles as important intercellular messengers in obesity

Justyna Witczak[1,2], Dev Datta[3], Philip James[2] & Aled Rees[1]
[1]Centre for Endocrine and Diabetes Sciences, University Hospital of Wales, Cardiff, UK; [2]Department of Biomedical Sciences, Cardiff Metropolitan University, Cardiff, UK; [3]Deprtment of Biochemistry, University Hospital Llandough, Cardiff, UK.

Introduction
Extracellular vesicles (EVs) are submicron vesicles released by most cells. They contain protein, enzymes and microRNA of the donor cells and are believed to play a role in paracrine communication. Circulating EVs might reflect heightened immune/inflammatory status in obese individuals and play a role in initiation/modulation of chronic low grade inflammation associated with obesity.
Aims
To compare circulating plasma EVs between healthy volunteers and morbidly obese individuals attending a multidisciplinary weight loss clinic, and to assess the effects of lifestyle changes on the circulating EV profile.
Methods
EVs were isolated by differential centrifugation and measured by Nanoparticle Tracking Analysis (NTA). EV cellular origin (platelets CD41, monocytes/macrophages CD11b, erythrocytes CD235a, endothelial cells CD144) and adipocytokine expression (IL6, TNFα, interferon γ, adiponectin, FABP4, PPARγ) were evaluated by TRF immunoassay.
Results
Circulating EV profile and concentration in metabolically healthy volunteers was unaffected by BMI (all P=ns). However, the EV profile in healthy men appears to be more pro-inflammatory compared to women, with higher EV-expressed CD41, CD144, EV-IL6, interferon γ and FABP4 (all $P<0.05$). This was also reflected by lower plasma adiponectin concentration in males (128 μg/ml vs 272.3 μg/ml, $P<0.005$). Plasma FABP4 correlated strongly with BMI ($r=0.91$, $P<0.005$) and was lower in healthy lean versus obese individuals (13.5(6.4) vs 23.8(6.4) ng/ml, respectively ($P<0.05$)) despite fasting glucose and HOMA-IR being within the normal range (P=ns). Dietary and lifestyle management affected the EV profile, with lower signals observed from platelet- and endothelial cell-derived EVs ($P<0.05$) as well as FABP4-, TNFα- and Interferon γ-expressing EVs at 6 months' follow-up ($P<0.05$, $P=0.05$, $P=0.06$, respectively). The exosomal marker CD9 correlated with FABP4, interferon γ, adiponectin and TNFα ($r=0.49$, $r=0.41$, $r=0.59$, $r=0.53$, all $P<0.05$), suggesting that exosomes are the main carrier of these adipokines.
Conclusion
EVs can be regarded as diverse biological vectors playing an important role in regulation of adipose tissue homeostasis and inflammatory processes. Their concentration, cellular origin and content do not directly correlate with BMI but are affected by gender and the presence of obesity-driven comorbidities.

Introduction
Obesity and its comorbidities, specially type 2 diabetes (T2D), are a major public health problem. The disappointing result of dietary treatment and the scarce of drugs have led to increased bariatric surgery (BS) as the most efficient therapeutic option. However, not all obese patients with T2D who undergo BS achieve diabetes remission.
Objective
To develop a genetic scoring system for predicting T2D remission following BS. 2) To compare our results with the current clinical based prediction score (DiaRem).
Material and methods
We used a retrospective Spanish cohort (n=820) that included 169 individuals with T2D followed at least 18 months after BS (109 gastric bypass and 60 sleeve gastrectomy). DNA was extracted from saliva samples and processed using Nutri inCode test (NiC, Ferrer inCode) based on 6 genetic predisposition risk scores (GPS). Each GPS consists of several SNPs which were shown to be implicated in

appetite regulation, response to exercise, response to hypocaloric diet, response to lyfe style intervention, response to BS, and SNPs related to the presence of metabolic syndrome or T2D. Multivariate logistic regression was used for adding several GPS to DiaRem score creating new scores, to predicting the event of interest (T2D remission). The calibration of the adequacy of the different models was determined by Hosmer-Lemeshow test and the area under the receiver operating characteristic curve (AUC) was used for evaluating the prediction performance for each score.
Results
In patients underwent BS, the genetic test significantly predicted not only an excess weight loss higher than 50% [gastric bypass: 0.610 (0.503–0.717), $P=0.044$; sleeve gastrectomy: 0.693 (0.594–0.791), $P<0.001$)] but also T2D remission. In addition, this new test improved the AUC compared with DiaRem alone in patients underwent gastric bypass [0.816 (0.701–0.932) vs 0.718 (0.576–0.861), $P=0.024$] and sleeve gastrectomy gastrectomy [0.816 (95% IC: 0.701–0.932) vs 0.718 (0.576–0.861), $P=0.024$]. Notably the GPS for diabetes remision were not the same that for weight loss.
Conclusion
To identify subjects with an inadequate response before BS is a challenge for all healthcare systems. Our results suggest that genetic testing is a useful tool for this issue and could be incorporated to the current clinical practice. Clinical data helps to better predict diabetes remission following BS.

Eating and substance-related disorders after bariatric surgery
Eva Sanz, Guila-Fidel Kinori, Gemma Parramon, Enzamaria Fidilio, Mayra-Alejandra Velasquez, Mireia Guerrero, Marta Comas, Jordi Mesa & Andreea Ciudin
Hospital Vall D'Hebron, Barcelona, Spain.

Introduction
Obesity is a chronic condition with great morbidity, mortality and significant economic and psychosocial impact. Bariatric surgery has proven to be an effective therapy for sustained weight loss and has allowed a reduction in medical comorbidity and an improvement in self-esteem and life quality. However, recent evidence reports an increase in eating and substance-related disorders that are diagnosed in the postoperative period worsening the prognosis.
Objectives
To evaluate the development of eating and substance-related disorders in patients undergoing bariatric surgery.
Material and methods
A retrospective review of patients undergoing bariatric surgery was performed between January 2006 and December 2014 in our center. As per protocol, all the patients underwent a complete psychiatric and psychological evaluation before the surgery. Patients with previous mental disorders were excluded.
Results
Of 500 patients that underwent bariatric surgery in this period of time, 9 cases (4 women and 5 men) presented with new psychiatric disorders 3.67 ± 1.87 years after the surgery (1.8% of patients). The baseline characteristics of the patients were: age 41.89 ± 8.71 years, pre-surgery BMI 43.61 ± 6.82 kg/m^2. The patients underwent: Y-Roux gastric bypass (6), sleeve gastrectomy (2) and duodenum-ileal bypass over sleeve gastrectomy (1) and presented with BMI 31.20 ± 8.53 kg/m^2 after three years follow-up ($P<0.001$). A total of 66.67% developed eating disorders (6/9 patients): 1 case met criteria for restrictive food intake disorder, 2 for atypical anorexia nervosa, 1 for binge eating disorder, and the other 2 had problems in the self-control emotions and behaviors and anxiety disorders with a loss of control over feeding. The rest of patients 33.33% developed substance-related disorders (3/9 patients): 2 cases of alcohol and 1 of alcohol + cocaine use disorders. A weight regain 17.6 ± 7.44% during follow-up was seen in patients with binge eating disorders, problems in self-control or anxiety disorders and alcohol use disorder.
Conclusions
In our study, new mental disorders in the form of eating and substance-related disorders were higher than in general population (1.8% versus 1.01%) in patients without mental disorder before bariatric surgery. The development of eating and substance-related disorders influences the evolution of body weight after bariatric surgery. More studies are needed in order to evaluate the risk of new mental disorders in patients underwent bariatric surgery. A rigorous postoperative follow-up is needed to reinforce permanent changes with the new lifestyle, such as diet and exercise, and to detect abnormal behaviors.

We aimed to assess the effect of sleeve gastrectomy (SG) on the metabolic and gut microbiota profiles in non-diabetic obese patients with different grade of insulin resistance (IR).
Methods
Prospective study of 22 morbid non-diabetic obese patients (77.2% women, age 47.13 ± 9.51 years, basal BMI 45.59 ± 4.99 kg/m^2, 11 IR and 11 non-IR) undergoing SG. A fasting blood sample was collected at baseline and at 6 months post-SG for the determination of glycaemia, HbA1c, insulin, C-peptide, complete lipid profile. Gut microbiota study and body composition analysis by dual-energy X-ray absorptiometry (DEXA) were performed at the same time-points.
Results
At baseline insulin and C-peptide were higher in IR group (19.10 ± 4.47 vs 11.83 ± 4.80 m.u.int/l, $P=0.001$ and 3.59 ± 0.98 vs 2.33 ± 0.49 ng/ml, $P=0.016$, respectively) with no differences in lipid profile. At 6 months after SG, a significant decrease in BMI, waist circumference, blood pressure was observed, as well as a fat mass similar decrease in both groups, although fat free mass only decreased in non-IR group (52.17 ± 7.47 vs 46.86 ± 6.73 kg, $P=0.04$). After SG, in IR-group: Phylum and family diversity increased (0.7 ± 0.10 vs 0.79 ± 0.11 and 1.58 ± 0.39 vs 2.1 ± 0.18, $P<0.005$, respectively); bacteroidetes decreased (71.16 ± 9.43 vs 51.48 ± 17.4, $P>005$) and firmicutes increased (25.07 ± 10.3 vs 43.96 ± 19.09, $P>0.005$). Prevotellaceae diminished and odoribacteraceae rose ($P<0.05$). In non IR-group: family and genus richness decreased (186 ± 43.71 vs 159.4 ± 43.75, $P<0.005$ and 592 ± 187.03 vs 487 ± 171.01, $P<005$, respectively), Prevotellaceae diminished but not significantly (20.92 ± 30.09 vs 13.02 ± 21.69), and odoribacteraceae increased (0.63 ± 0.41 vs 2.32 ± 2.53, $P<0.005$) but there were no changes in bacteroidetes or firmicutes.
Conclusions
SG produces different effects on gut microbiota composition in non-diabetic patients with different grade of insulin resistance despite similar changes in BMI, waist circumference and fat mass. The decrease in Prevotellaceae and the increase in Odoribacteraceae after SG could be related with the enhancement of inflammation and metabolic dysfunction observed in patients undergoing bariatric surgery.

Pharmacological stimulation of p53 with low-dose doxorubicin ameliorates diet-induced nonalcoholic steatosis and steatohepatitis
María Jesús González Rellán[1,2], Begoña Porteiro Couto[1,2], Marcos Fernandez Fondevila[1,2], Xabier Buque[3,4], Uxía Fernández[1,2], Alfonso Mora[5], Daniel Beiroa[1,2], Miguel López[1,2], Guadalupe Sabioc[5], Carlos Dieguez[1,2], Patricia Aspichueta[3,4] & Rubén Nogueiras[1,2]

Introduction
p53 is a transcription factor involved in many biological functions such as stress, ageing, and metabolism. Although there is a large body of evidence showing that p53 promotes fatty acid catabolism while it inhibits anabolism through the regulation of gene expression, the possible contribution of p53 to the pathogenesis of nonalcoholic fatty liver disease (NAFLD) remains to be elucidated. Also, the anthracycline doxorubicin is an important chemotherapeutic agent, which therapeutic actions depends on p53, since p53 mutations are associated with resistance to this drug.
Objective
We hypothesized that the pharmacological activation of p53 with low-dose doxorubicin may have beneficial effects on nonalcoholic fatty liver disease (NAFLD) and nonalcoholic steatohepatitis (NASH).
Methods
We used long-term pharmacological activation of p53 by intraperitoneal injection or oral administration of low-dose doxorubicin in different animal models of NAFLD (high fat diet containing 45% and 60% kcal fat) and NASH (methionine- and choline-deficient diet and choline deficiency combined with high fat diet). We also administered doxorubicin in mice lacking p53 specifically in the liver.
Results
We demonstrate that chronic pharmacological stimulation of p53 with a low dose of doxorubicin (administered intraperitoneally and orally) improves liver injury in different models of diet-induced steatosis and NASH through stimulation of fatty acid oxidation and decrease of lipogenesis, inflammation, and ER stress. These effects did not occur when the drug was administered to mice with liver-specific ablation of p53.
Conclusion
Our results show that long-term pharmacological activation of p53 using intraperitoneal injection or oral administration of doxorubicin at much lower doses than those used in oncology ameliorates liver injury. The attenuation of liver injury was correlated with increased fatty acid oxidation, decreased *de novo* fatty acid synthesis, reduced inflammation, and lowered ER stress. We provide mechanistic insight evidence that these doxorubicin-mediated effects were dependent of p53, since they were not observed in mice where hepatic p53 expression was missing or reduced. These data provide new evidence for targeting p53 as a strategy to treat liver disease.

Obesity is associated with a dysregulation in the splicing machinery components at the hepatic level: influence of metformin

Fernando L-Lopez[1,2,3,4], Emilia Alors-Perez[1,2,3,4], Mercedes del Rio-Moreno[1,2,3,4], Andre Sarmento-Cabral[1,2,3,4], Justo P Castaño[1,2,3,4], Raul M Luque[1,2,3,4] & Manuel D Gahete[1,2,3,4]
[1]Maimonides Institute of Biomedical Research of Cordoba (IMIBIC), Cordoba, Spain; [2]Department of Cell Biology, Physiology and Immunology, University of Cordoba, Cordoba, Spain; [3]Reina Sofia University Hospital, Cordoba, Spain; [4]CIBER Physiopathology of Obesity and Nutrition, Cordoba, Spain.

Obesity, a multifactorial chronic endocrine-metabolic disease, represents one of the most serious and complex global health threats, as it is commonly associated with multiple and severe comorbidities (e.g. diabetes type-2). Indeed, as a source of severe metabolic-dysregulation, obesity alters physiological, homeostatic gene expression patters in multiple metabolic-tissues, including the central metabolic hub, i.e. the liver. However, the precise molecular mechanisms underlying this pathological association are still unknown. There is emerging evidence that alternative mRNA splicing, the key mechanism providing transcript/protein-diversity from a single gene, is dysregulated in many tissues under adverse metabolic-conditions, such as obesity, and can influence the development and progression of several pathologies. Here, we hypothesized that an alteration in the splicing machinery could occur in key metabolic tissues, such as the liver, during obesity, which might ultimately be associated with the progression of hepatic disease. To ascertain this question, an array of selected components of the major- ($n=13$) and minor-spliceosome ($n=4$), and associated splicing-factors ($n=28$) was developed, and their expression levels were evaluated using a Fluidigm methodology, in the liver of obese mice (fed a high-fat diet) compared with control-lean mice (fed a low-fat diet). Additionally, we analysed whether the splicing processes are regulated by metformin (an agent used to treat type-2-diabetes) in livers of obese vs. control-lean mice. Results revealed that expression of some splicing-machinery factors was altered in the liver of obese vs. control-lean mice (e.g. up-regulation: RNU1, RNU2, RBM22, SRSF3; down-regulation: RNU11). Interestingly, we found that metformin similarly altered the hepatic expression of two splicing-machinery factors (i.e. up-regulation of SRSF10 and PSF) in obese- and lean-mice. However, many other components of the splicing machinery-associated factors (i.e. RNU1, U2AF1, PRPF40A, PRPF8, RBM22, RNU6atac, CELF1, SRSF5, SRSF6, SRSF9, SNW1, SND1, SFPQ, KHDRBS1) were exclusively up-regulated by metformin under normal-lean, but not obese, conditions which might suggest that the liver of obese-mice (which had fatty-liver and were hyperglycemic and hyperinsulinemic) might be partially resistant to alterations in the splicing machinery in response to metformin. Altogether, our results suggest that the alteration of the some components of the cellular splicing machinery in hepatocytes could be responsible for the dysregulated expression of multiple splice variants produced in the liver under obesity conditions. Ongoing studies would clarify the potential physiological implications of these findings, which may provide novel diagnostic biomarkers and therapeutic tools to treat hepatic-diseases.

Dietary intake of fat and oil are associated with expression of miR-143 and miR-34a in visceral and subcutaneous adipose tissues of adults: a nutriepigenetic study

Emad Yuzbashian[1], Golaleh Asghari[1], Maryam Zarkesh[2], Azita Zadeh-Vakili[2], Parvin Mirmiran[1], Mehdi Hedayati[2] & Alireza Khalaj[3]
[1]Nutrition and Endocrine Research Center, Research Institute for Endocrine Sciences, Shahid Beheshti University of Medical Sciences, Tehran, Islamic Republic of Iran; [2]Cellular and Molecular Endocrine Research Center, Research Institute for Endocrine Sciences, Shahid Beheshti University of Medical Sciences, Tehran, Islamic Republic of Iran; [3]Department of Surgery, Tehran Obesity Treatment Center, Shahed University, Tehran, Islamic Republic of Iran.

Background and objective
Adipose tissue where energy homeostasis is regulated is now considered an endocrine organ. miRNAs may contribute to the regulation of energy balance and metabolic homeostasis, by controlling a wide range of metabolic pathways. miR-143 and miR-34a are the best studied among the miRNAs linked to adipose tissue regulation. Dietary intake, among many other environmental factors, is a key player that can induce epigenetic changes. The aim of the study was to investigate the association of the miR-143 and miR-34a expression in visceral and subcutaneous adipose tissues with habitual fat and oil intakes.
Materials and methods
Visceral and subcutaneous adipose tissues were obtained from 97 adults (41 non-obese, 18 obese, and 38 morbid obese), who underwent open abdominal surgery with minimal impact on dietary intake. Intake of hydrogenated and non-hydrogenated vegetable oils and butter were collected by using a valid and reliable food frequency questionnaire. The expressions of miR-143 and miR-34a in visceral and subcutaneous adipose tissues were measured by Real-Time PCR. Linear regression models were used to estimate association of dietary hydrogenated and non-hydrogenated vegetable oils and butter intake with miR-143 and miR-34a expression after adjustment for potential confounding variables.
Findings
Expression of miR-34a was more increased in morbid obese than obese subjects in both subcutaneous (13.3 vs 11.3, $P<0.002$) and visceral (13.4 vs 9.2, $P<0.001$) adipocytes. After adjustment for total energy intake, insulin, triglycerides, and age, visceral adipose tissue miR-143 expression was positively associated with total intakes of fats and oils ($\beta=0.334$, $P=0.024$) in the total population. The miR-143expression in visceral adiposity among morbid obese was negatively associated with non-hydrogenated vegetable oils ($\beta=-0.317$, $P=0.036$), and directly associated with butter ($\beta=0.503$, $P=0.002$) intake. The miR-34a expression among morbid obese participants was associated with total fats and oils ($r=0.534$, $P<0.001$) and non-hydrogenated oil ($\beta=0.443$, $P=0.008$) in visceral adipose tissue. Moreover, we found a significant association of miR-143 expression in subcutaneous adipose tissue with butter in both morbidly obese and non-obese participants.

Conclusions
A increase in miR-143 and miR-34a expression by total fats and oils, may explain the development of obesity through high-fat diet. A decrease in expression of miR-143 by non-hydrogenated oils would justify a lower adipogenic capacity and, would, therefore, contribute to the decrease of fat stores observed in adipose tissue with higher intake of fatty acids contains non-hydrogenated oils.

Role of Elovl6 in the thermogenic action of brown and beige adipocyte during β3-adrenergic receptor activation

Rahul Sharma[1], Takashi Matsuzaka[1], Kaori Motomura[1], Zao Hui[1], Hiroshi Ohno[1], Yoshinori Takeuchi[1], Naoya Yahagi[1], Motohiro Sekiya[1], Yoshimi Nakagawa[1], Masafumi Muratani[2] & Hitoshi Shimano[1]
[1]Department of Internal Medicine (Endocrinology and Metabolism), Faculty of Medicine, University of Tsukuba, Tsukuba, Japan; [2]Department of Genome Biology, Faculty of Medicine, University of Tsukuba, Tsukuba, Japan.

Recent studies suggest that adult humans have active brown or beige adipocytes, the activation of which might be a therapeutic strategy for the treatment of metabolic diseases. Treatment of CL-316243, a β3-adrenergic receptor agonist, activates brown/beige adipocytes and can cause significant reductions in adiposity. Many transcriptional pathways regulating brown/beige adipose tissue have been identified, the role of lipid biosynthetic enzymes in brown/beige adipose tissue has been less investigated. In this study, we investigated the role of Elovl6, the enzyme responsible for converting C16 non-essential fatty acids into C18 species, in the thermogenic action of brown/beige adipose tissue. We have observed upregulation of Elovl6 in brown adipose tissue (BAT) and inguinal white adipose tissue (iWAT) of mice treated with CL-316243 as well as cold-expose. It was reported that Elovl6 KO mice have impaired mitochondrial function and hence impaired thermogenic capacity of BAT when exposed to cold temperature (*Cell Rep.* 13:2039, 2015). When exposed to chronic CL-316243 treatment we observed that Elovl6 KO mice compensate its impaired BAT function by increased development of functional beige fat contributing to its increased energy expenditure. CL-316243 induces the expression of genes involved in creatine metabolism and mitochondrial biogenesis in the iWAT of Elovl6 deficient mice. Pharmacological reduction of creatine levels by the treatment of β-guanidinopropionic acid (β-GPA) to Elovl6 KO mice decreases whole-body energy expenditure after administration of CL-316243. Our data suggest that Elovl6-regulated FA chain length is important for brown/beige adipose tissue function and creatine metabolism has an important compensatory role in adipose tissue energy expenditure and thermogenesis during impaired BAT function.

GP160

Physiological regulation of brown adipose tissue in obesity by mild-cold exposure, a B3-agonist and exercise training at thermoneutrality

Peter Aldiss, Jo Lewis, Fran Ebling, Helen Budge & Michael Symonds
University of Nottingham, Nottingham, UK.

Background
Therapeutic activation of thermogenic brown adipose tissue (BAT) is a potential strategy to prevent obesity and metabolic disease in humans. However, it is now recognised that rodent studies examining BAT physiology are carried out at sub-thermoneutral temperatures (e.g. ~20°C), and are not translationally relevant to humans as BAT is 'hyperactive'. Therefore, the aim of this study was to determine the effect of common regulators of BAT metabolism when animals were raised at thermoneutrality (28°C).
Methods
Thirty weanling Sprague-Dawley rats were housed at thermoneutrality (28°C) and randomised to either chow (C, $n=6$) or a high-fat diet (HFD, $n=24$) from 3-weeks of age. At 12 weeks, subgroups ($n=6$) of HFD were randomised to either mild-cold exposure (20°C), Mirabegron, a selective β3-agonist (0.75 mk/kg per day) or exercise training (1 h/d, 5 d/week). Metabolic assessment was undertaken in CLAMS during the last 48 h to assess energy intake (EI), expenditure (EE) and physical activity (PA) in addition to the acute response to administration of Mirabegron. Key thermogenic and metabolic genes were analysed in interscapular BAT by qPCR in addition to targeted insulin resistance PCR Arrays (86 key genes, $n=3$).
Results
No interventions reduced body weight or fat mass. There was no difference in 24 h EE, EI or PA between groups. Key thermogenic genes in BAT were unchanged by the interventions. CITED1 expression was upregulated by HFD and reduced by all interventions whilst PRDM16 expression was reduced by HFD and increased by exercise. Similarly, expression of PPARA, mTOR and the 'beige' marker TBX1 were upregulated by exercise only. Targeted PCR arrays demonstrated an upregulation of inflammatory markers e.g. TLR4, EMR1, CASP1 and IL18R1 and a downregulation of metabolic genes e.g. SCD1, FASN, ACACB, HK2 with HFD. Only FASN, SCD1 and ACACA were upregulated in Cold whilst IL18R1, TLR4 and EMR1 were downregulated. Similarly, β3 increased FASN whilst downregulating IL18R1, IL6 and STAT3. Finally, Exercise upregulated FASN, SCD1, HK, ACACA, ACACB and PDK2 whilst downregulating NLRP3, IL1β and PYCARD.
Conclusion
Whilst there is an intervention specific effect on immune genes in BAT we show there is no consistent upregulation of thermogenic genes in response to common stimuli when animals are raised at thermoneutrality. Effects of interventions to activate BAT carried out at sub-thermoneutrality are most likely to be a consequence of chronic mild-cold stress and are unlikely to be translated to humans.

Cold induced thermogenesis is influenced by seasonal changes in outdoor temperature

Jael Rut Senn[1], Claudia Irene Maushart[1], Gani Gashi[1], Anton S Becker[2], Julian Müller[2], Irene A Burger[2] & Matthias Johannes Betz[1]
[1]Department of Endocrinology, Diabetes and Metabolism, University Hospital Basel and University of Basel, Basel, Switzerland; [2]Institute of Diagnostic and Interventional Radiology, University Hospital of Zurich, Zurich, Switzerland.

Background
Humans and other mammals need to maintain a stable core body temperature. Energy expenditure increases in response to a mild cold stimulus, this is called cold induced thermogenesis (CIT). Recently, thermogenic brown adipose tissue (BAT) has been found to play an important role for CIT in human adults. It is known that energy expenditure and CIT are acutely influenced by ambient temperature. In the present study, we investigated the effect of seasonal temperature variation on CIT in human adults.
Methods
We collected data from two prospective observational studies and the screening data from an interventional trial. The analysed 89 participants all underwent measurement of CIT. Of these, 56 participants were healthy volunteers and 33 were hypothyroid patients at the time of the measurement sufficiently substituted with thyroxin. CIT was measured by indirect calorimetry during warm conditions and after a mild cold stimulus of 90 min. CIT was determined as the difference between energy expenditure (EE) during warm (EE_{warm}) and cold (EE_{cold}) conditions. Skin temperature was measured in the supraclavicular region (TempSC) adjacent to the major human BAT depot and compared with parasternal temperatures (TempPS); the difference between TempSC and TempPS was calculated as an indicator of BAT activity. We analysed the relation ofEE, CIT and skin temperatures to the outdoor temperatures, which were recorded by the Institute for Meteorology, Climatology and Remote Sensing at the University of Basel. Daily temperatures were averaged over a period of 7 (TempMax7d) or 30 days (TempMax30d) prior to the corresponding study visit.
Results
CIT was inversely associated with the average maximum outdoor temperature during the week ($R^2=0.1737$, $P<0.0001$) and the month ($R^2=0.1424$, $P=0.0003$) before the visit date. EE_{warm} and EE_{cold} were not significantly related to outdoor temperatures, EE_{warm}; $R^2=0.0074$, $P=0.4218$ (TempMax7d), $R^2=0.0168$, $P=0.2252$ (TempMax30d) and EE_{cold}; $R^2=0.0132$, $P=0.2840$ (TempMax7d), $R^2=0.0035$, $P=0.5831$ (TempMax30d). The difference between

TempSC and TempPS was also inversely related to TempMax7d, $R^2=0.07575$, $P=0.0221$, indicating increased activation of BAT in response to longer periods of cold temperatures.
Conclusion
CIT is strongly and inversely correlated to outdoor temperatures indicating dynamic adaption of thermogenesis and BAT activity to environmental stimuli in adult humans.

Biomonitoring infantile urinary sexual hormone profiles for investigation of the endocrine disruptors associated mini-puberty effects

Shen Heqing[1], Liu Liangpo[1] & Wang Heng[1,2]
[1]Institute of Urban Environment, Xiamen, China; [2]Zhoushan Municipal Center for Disease Control and Prevention, Zhoushan, China.

Many surveys have shown that children are ubiquitously exposed to endocrine disruptors (EDs) like bisphenol A (BPA) and phthalates, and many laboratory studies have shown these EDs have adverse effects related to hormone secretion, while the evidence on infants' mini-puberty has not been observed yet. A prospective cohort was recruited at the early maternal pregnancy stage by the Maternal and Child Health and Family Planning Service Center, Daishan, China, from March 2012 to December 2014. After delivery, the mothers offered their baby (0–6 months old) urine samples collected by the disposable diapers. Urinary BPA, phthalate metabolites, estradiol (E_2), testosterone (T), follicle-stimulating hormone (FSH), luteinizing hormone (LH) and creatinine were analyzed, respectively. The partial correlation and multivariable linear regression were applied to assess the associations of endocrine disruptors with E_2, T, FSH and LH for each of the development stages, i.e., the newborn, 14-days, 28-days, 42-days, 3-months and 6-months, respectively. Firstly, urinary hormones showed the clear surge profiles for the selected hormones during mini-puberty; in addition, the endogenous creatinine releasing was increased with the growth of baby. After adjusted by creatinine, maternal age, end-of-pregnancy weight, parity, smoking, delivery mode and infant body mass index (BMI), BPA was positively associated with E_2 both in male (for 14-, 28- and 42-days stages) and female (for 14-, 28-, 42-days and 3-months stages) infants, positively associated with E_2/T ratio both in male (for 14- and 28-days stages) and female (for 14-days stage) infants, positively associated with T in female (for 3-months stage). To phthalates, their metabolism also changed, in which the di-ester phthalates' hydrolysis may be decreased but the 2nd β-oxidation of the middle and long side chains of the mono-ester phthalates was increased. After adjusted by maternal age, end-of-pregnancy weight, parity, smoking, delivery mode, gender and BMI of infants, some interesting associations were also observed between the phthalate exposure and mini-puberty hormone surges. By using a time-series sampling strategy, this study investigated the early infantile life-stage associated endocrine disrupting of phthalates and BPA to some selected hormones by using urine from diapers. The results showed that the phthalate metabolism in infantile body is changed along with the growth. In addition, the infants' first show of steroids' surge after leaving the maternal uterus steroidogenic environment (i.e., mini-puberty) may be affected by EDs, which disrupt the premature gonad function at some special development windows.

Global DNA methylation since early infancy to adulthood in the offspring of women with polycystic ovary syndrome (PCOS)

Teresa Sir-Petermann[1], Bárbara Echiburú[1], Manuel Maliqueo[1], Francisco Pérez-Bravo[2], Nicolás Crisosto[1], Cristian Flores[1], Daniel Sandoval[3] & Sergio E Recabarren[3]
[1]Endocrinology and Metabolism Laboratory, West Division, School of Medicine, University of Chile, Santiago, Chile; [2]Laboratory of Nutritional Genomics, Department of Nutrition, Faculty of Medicine, University of Chile, Santiago, Chile; [3]Laboratory of Animal Physiology and Endocrinology, Faculty of Veterinary Sciences, University of Concepcion, Chillán, Chile.

DNA methylation is an epigenetic mechanism of gene regulation that can be modified during intrauterine and postnatal life. Pregnant women with polycystic ovary syndrome (PCOS) present elevated androgen and insulin levels, which can affect the DNA methylation pattern of their offspring. Then, we studied the global DNA methylation pattern (GDNAm) in daughters and sons born to PCOS women compared to controls. Daughters (99 born to PCOS and 87 born to control women) and sons (74 born to PCOS and 93 born to control women) were studied at early infancy (2–3 months), puberty (7–17 years) and adulthood (18–35 years). In all of them, a clinical-anthropometric examination was performed and a blood sample was obtained for DNA isolation from peripheral leukocytes. The absolute percentage (%) of GDNAm was quantified using a colorimetric kit (Epigentek). PCOS and control sons showed a different methylation pattern from early infancy to adulthood. Interestingly, sons born to PCOS mothers presented lower GDNAm compared to controls in early infancy (3.0% vs 7.4%, $P=0.043$) and at the beginning of sexual maturation (2.9% vs 7.1%, $P=0.010$). In daughters, there were no differences in the GDNAm pattern from early infancy to adulthood between both groups. Our data indicate that sons seem to be more susceptible than daughters to changes of the GDNAm, mainly in periods of activation of the gonadal axis, such as early infancy and the beginning of puberty.

Utilisation of dental services and dental pathologies identified in children and adolescents with osteogenesis imperfecta in the south west of England

Robert Clark[1], Christine Burren[2] & Rebecca John[3]
[1]University of Bristol, Bristol, UK; [2]University Hospital Bristol, Bristol, UK; [3]Bristol Dental Hospital, Bristol, UK.

Background
50% of patients with osteogenesis imperfecta (OI) will have dental involvement of some degree including dentinogenesis imperfecta and a severe malocclusion. OI is the most common inherited disorder of bone fragility in children, increasing fracture risk 100-fold.
Aim
To assess the utilisation of tertiary dental services by children and young people with OI attending a supra-regional multidisciplinary OI service and review of the pathology identified and interventions undertaken.
Design
Case notes review of the current caseload of children and young people (0–18 years) with OI at an OI specialist centre. Primary outcome was if an initial dental assessment was arranged in a tertiary dental centre and the corresponding attendance.
Results
Only 49% received a dental assessment. 82% attended the appointment, 18% failed to attend multiple appointments. Those travelling >100 miles had a DNA rate of 47%. Greater the OI severity, the higher the incidence of DI; 7% incidence in Type I OI and 50% in Type III. 48% received bisphosphonate therapy. 33% required GA for extraction of carious teeth.
Conclusion
Due to the prevalence of DI, severe malocclusion and the increased incidence of dental caries necessitating extraction under GA, coupled with the increased use of bisphosphonates, all patients with OI should receive a formal dental assessment in tertiary care.

[7]Computational Medicine, Faculty of Medicine, University of Oulu, Oulu, Finland; [8]Department of Obstetrics and Gynaecology, University of Helsinki and Helsinki University Hospital, Helsinki, Finland; [9]Institute of Reproductive and Developmental Biology, Imperial College London, London, UK; [10]Department of Children, Young People and Families, National Institute for Health and Welfare, Oulu, Finland; [11]Department of Epidemiology and Biostatistics, MRC-PHE Centre for Environment and Health, School of Public Health, Imperial College London, London, UK; [12]Department of genomic of complex diseases, School of Public Health, Imperial College London, London, UK.

Background
The age at adiposity rebound (AR), at which BMI begins to rise after infancy around the age of 5 years, is associated with obesity and metabolic alteration in later life. Given that polycystic ovary syndrome (PCOS) has strong metabolic components, early growth patterns could reveal predisposition for PCOS. Thus, we aimed to investigate the associations of growth trajectories from birth to puberty with PCOS diagnosis,vbody composition and hyperandrogenism later in adulthood.
Materials and methods
In this prospective, population-based longitudinal Northern Finland Birth Cohort 1966 study, women reporting isolated PCOS symptoms at age 31 ($n=651$), or PCOS diagnosis by age 46 ($n=280$) were compared with asymptomatic women ($n=1573$). Growth data from birth to 13 years, weight, height, serum testosterone levels at menarche, 14, 31 and/or 46 years were analyzed. Findings: Women with PCOS had lower birth weight (3406 vs. 3507 g, $P<0.001$), earlier AR (5.19 vs 5.60 years, $P<0.001$) and higher BMI at menarche compared with controls. Early timing of AR associated with PCOS-diagnosis independently from BMI (OR:1.62, Cl: 1.37–1.92). Women with PCOS with early AR had an adverse body composition at age 31 and 46 compared with controls with early AR or PCOS with normal/late AR. Early AR was not associated with serum testosterone levels either at 31 years or 46 years.
Conclusions
Early AR is a risk factor for PCOS and high BMI later in life, thus, children with early AR should be considered at risk for adulthood obesity but also for PCOS. Thus, adolescents with early AR and persisting high BMI at menarche should be screened for PCOS symptoms, such as persisting irregular cycles and hirsutism.

Endemic goiter and breasts diseases in adolescent girls

Olga Gumeniuk & Yuriy Chernenkov
Saratov State Medical University, Saratov, Russian Federation.

Research indicates the relationship between beast and thyroid gland. Breast tissue contains the highest concentrations of iodine, so shortfalls in this essential mineral needs have a highly negative impact on breast tissue (R. Thompson, 2015).
Purpose
The study was undertaken to estimate the frequency of the breasts diseases in adolescent girls with endemic goiter.
Patients and methods
The study included 2371 girls (aged 10–18 years). Endemic goiter was diagnosed on the basis of the typical picture of examination and thyroid ultrasound, hormonal analysis. Breast diseases were diagnosed on the basis of clinical signs and typical picture of breast ultrasound. From the girls without thyroid pathology a control group were formed ($n=30$). Statistical analysis was performed using Mann-Whitney Test. This study has been carried out in accordance with the Helsinki Declaration.
Results
The endemic goiter was diagnosed in 685 (29%) girls. Thyroid function was normal in all girls; however, in comparison group the average TSH levels were 2.8 ± 0.7 and in control group – 1.7 ± 0.5 mIU/l ($P=0.033$). The investigation shows that in adolescent girls with endemic goiter were diagnosed breast cysts (in 29% cases); fibroadenoma was revealed in 2 patients. All second girls with endemic goiter had cyclic (premenstrual) mastalgia, only 2 girls without thyroid pathology had predmenstrual mastalgia and 1 girls had breast cysts (<0.001). All girls with breast dysplasia and fibroadenoma complained of mastalgia too.
Conclusions
This study has shown a high frequency of the breast diseases among the adolescent girls with endemic goiter. Endemic goiter is risk factor for breast diseases and shows the necessity of for observation and examination of breast.

Impact of fetal exposure to testosterone on fetal insulin sensitivity tissues in female sheep: a morphological and molecular approach

Daniel Sandoval[1], Mónica P Recabarren[1], José Montalbán[1], Sofia Bellalta[1], Albert Carrasco[1], Mabel Castillo-Blanco[1], Pedro P Rojas-García[1], Teresa Sir-Petermann[2] & Sergio E Recabarren[1]
[1]Laboratory of Animal Physiology and Endocrinology, Faculty of Veterinary Sciences, University of Concepción, Chillán, Chile; [2]Laboratory of Endocrinology and Metabolism, Western School of Medicine, University of Chile, Santiago, Chile.

PCOS is one of the most common cause of infertility in women during their reproductive years. High proportion of women with PCOS develop IR in peripheral tissues like skeletal muscle and adipose tissue, which may begin at the adolescent years when young women exhibit an increase in circulanting androgens. Studies in women with PCOS and animal models of PCOS have suggested alterations in insulin signaling pathways in skeletal muscle and adipose tissue. However, at the present time, it does not exist evidence between alteration on insulin signaling in endocrine pancreas and its correlative effect on peripheral insulin sensitivity tissues. Previous results from our group have demonstrated that female sheep born to mothers receiving T between days 30 to 120 of gestation exhibit features of insulin resistance from early postnatal stage to adulthood. In the present work, the reprogramming effect of prenatal T on adipose tissue morphology and the insulin signaling in adipose tissue was studied in postpubertal females born to untreated mothers (C-females) and born to T treated mothers (T-females), subjected to a further T administration at the pubertal age. Our aim was to identify if a further T treatment during pubertal development could affect pancreas and adipose tissue. Postpubertal C-females and T-females (38 weeks of age) were sacrificed after an eight week chronic T administration and samples of pancreas, SAT (subcutaneous adipose tissue) and VAT (visceral adipose tissue) were collected. The morphological analysis of the adipose tissue included measurements of area, perimeter, diameter and adipocyte number/mm^2. Results showed no difference ($P\geq0,05$) in morphological parameters between C- and T-females in SAT. However in VAT, the adipocyte area, perimeter, diameter was higher in T-females than in C-females. Gene expression of IR, IRS-1, PI3K, PKC in pancreas showed similar expression in T-females ($P\geq0.05$) compared to that of C-females, while, on the contrary, the Akt and GLUT4 RNAm was lower in T-females ($P<0.05$). Interesting, IRS-2 transcript showed a tendency to a higher expression ($P\geq0.05$) in T-females. qPCR assays of SAT showed a transcriptional repression of IRS-1, PKC, Akt and GLUT4 ($P<0.05$) in T-females. In VAT, insulin signaling did not show effect on expression of pathways elements, except higher Akt levels of RNAm in T-females ($P<0.05$). Results suggest that prenatal and postnatal exposure to T affects the insulin signaling on beta cells during post pubertal development and induced a dual effect in adipose tissue at the transcriptional and morphological levels.

Self-esteem, emotional stability, social anxiety disorder and suicidal behaviours among transgender youth before gender-affirmative treatment in spain

Ines Modrego Pardo[1], Marcelino Gomez Balaguer[1,2], Felipe Hurtado Murillo[2,3], Eva Maria Riera Sabater[1], Victor Atienza Moya[1], Santiago Garcia Torres[1], Juan Diego Salazar Leon[1] & Antonio Hernandez-Mijares[1,4]
[1]Department of Endocrinology of 'Hospital Doctor Peset', Valencia, Spain; [2]Identity and Sex Differentiation Group of the Spanish Society of Endocrinology and Nutrition, Valencia, Spain; [3]Sexual and reproductive health center of 'Fuente de San Luis', Valencia, Spain; [4]Department of Medicine of the University of Valencia, Valencia, Spain.

Introduction
The demand of health care for people with gender incongruence (IG) has grown exponentially especially in young population. Due to this, there is a growing number of studies that show psychological conflicts and social functioning in those individuals who have not received gender-affirming treatment with medical intervention (pubertal block, hormone or surgical treatment) and social intervention. However, the data published so far do not represent the European countries, they are an adult population and without a control group.
Aims
To assess the prevalence of psychomorbidity among transgender youth before gender-affirmative treatment.
Methods
Prospective observational study comparing young people between 13–21 years of age cared by GI, evaluated before starting hormonal treatment and at puberal stage at least 2–3 Tanner tested by levels of E2, testosterone, FSH and LH. Direct clinical interview and standardized tests were carried out: low self-esteem, social phobia, emotional inestability, suicidal ideation, suicide attempts and self-harm. The results were compared with those obtained in a population subjected to stress due to sexual orientation (cisgenders): 'homosexuals, lesbians and bisexuals' (LGTB) between 15 and 21 years. The follow-up was in the 'Gender Identity Unit of the Doctor Peset University Hospital' between 2014 and 2016. Those in prepubertal stage and/or who did not meet criteria for treatment initiation were excluded from the study.
Results
A total of 82 interviews were evaluated: 41 in each comparable age group. 51% of individuals with IG developed low self-esteem compared to 34% in the LGTB group ($P=0.118$); 83% moderate-high emotional instability and 44% LGTB group ($P<0.001$); 17% in the IG group developed social anxiety and 34% in LGBT individuals ($P=0.077$. The prevalence of suicidal ideation was 46% and 20% ($P<0.001$), with suicide attempt of 20% compared to 5% ($P=0.043$) and/or self-injury in 29% compared to 5% ($P=0.003$) in the group of individuals with IG with respect to the LGTB group, respectively. The risk of presenting psychomorbidities in the GI group regarding the LGTB group was evaluated through an odds ratio with a result of 2.26 times more risk.
Conclusions
– Low self-esteem and emotional instability are the most prevalent psychomorbidity in both groups; the latter is more frequent in the group with IG.
– Serious conflicts: attempts, suicidal ideation and self-harm are more prevalent in the group with IG.
– The group of individuals with GI present 2.26 times more risk of developing psychomorbidity than the LGTB group.

Glucose transporters in human placenta and its relation to birth weight

Juan García-Santillán[1], Martha Isabel González-Domínguez[2], María Luisa Lazo de la Vega-Monroy[1], Héctor Manuel Gómez-Zapata[3], Juan Manuel Malacara[1] & Gloria Barbosa-Sabanero[1]
[1]Universidad de Guanajuato, León, Mexico; [2]Universidad de la Ciénega del Estado de Michoacán de Ocampo, Sahuayo de Morelos, Mexico; [3]UMAE No. 48, León, Mexico.

Background
Birth weight is a marker and predictor of metabolic diseases in adult life. Fetal growth depends on the availability of nutrients, in turn cross the placental barrier by means of special cells called syncytiotrophoblasts, which express specific transporters for each type of nutrient. Glucose, the main energetic substrate for fetal development, is transported via facilitated diffusion, through glucose transporter proteins (GLUTs). Several investigations have focused on the study of GLUT-1 and GLUT-3 transporters in placental samples from women with complications during pregnancy. Therefore, our study objective was to determine the role of glucose transporters in palcental tissue of clinically healthy women, as well as its relationship with alterations in birth weight.
Methods
Placental samples from clinically healthy women were included in the study, SGA ($n=20$), AGA ($n=20$) and SGA ($n=20$). Placental homogenates were prepared for the evaluation of the expression of glucose transporters (GLUT-1 and GLUT-3) in the 3 study groups by Western Blot. Anti-GLUT1 and anti-GLUT-3 antibodies were used to detect GLUT1 and GLUT-3 (1 : 1500 and 1 : 500 respectively) and were incubated by 20 h. As secondary antibodies were used Anti-Rabbit (1 : 125 000) and anti-Mouse (1 : 5000) antibodies to detect anti-GLUT1 and anti-GLUT-3 respectively, with an incubation time of 2 h. Glucose transporters expression was normalized with the expression of the α Tubulin protein.
Results
Expression of GLUT-1 transporter in placentas of LGA group was 50% higher in comparison to SGA group ($P=0.018$). There were no significant differences in expression between LGA groups vs AGA ($P=0.087$) and SGA vs. AGA ($P=0.492$).
Conclusion
In placentas of infants small and large for gestational age (SGA and LGA) who do not have an adequate weight at birth, there is a differential expression of GLUT-1 transporter. This suggests that this transporter may be important in determining birth weight and, consequently, in the risk of diseases of adult life.

Association of glucocorticoid receptor gene (*NR3C1*) expression in HUVECs with glycemic targets during gestational diabetes treatment: a pilot randomized controlled study

Polina Popova[1,2], Lyudmila Vasilieva[1], Alexandra Tkachuck[1], Maxim Puzanov[1], Alexey Golovkin[1], Yana Bolotko[1], Evgenii Pustozerov[1], Irina Zazerskaya[1], Renata Dmitrieva[1] & Elena Grineva[1]
[1]Almazov National Medical Research Centre, Saint Petersburg, Russian Federation; [2]Saint Petersburg Pavlov State Medical University, Saint Petersburg, Russian Federation.

Background
Gestational diabetes mellitus (GDM) is known to predispose offspring to metabolic diseases. However, the underlying mechanisms has not been thoroughly studied yet. The glucocorticoid receptor gene or nuclear receptor sub-family 3, group C, member 1 (*NR3C1*) may predispose to type 2 diabetes mellitus, metabolic syndrome and depression. *NR3C1 gene* showed significantly decreased methylation levels in cord blood and placenta from GDM women compared with controls. Our aim was to study the level of expression of *NR3C1 gene* in human umbilical vein endothelial cells (HUVECs) of newborns from women with GDM depending on glycemic targets.
Materials and methods
The study included 52 women with GDM and 25 women without GDM (control group). GDM patients were randomized to 2 groups per target glycemic levels: GDM1 (more tight glycemic targets, fasting blood glucose <5.1 mmol/l and <7.0 mmol/l postprandial, $n=28$) and GDM2 (less tight glycemic targets, <5.3 mmol/l and <7.8 mmol/l, respectively, $n=24$). The diagnosis of GDM was based on IADPSG criteria. HUVECs were isolated, expanded *in vitro* up to passage 2 and tested for viability and replicative senescence. The level of genes expression was determined by RT-PCR. Women with GDM kept electronic nutrition and glycemic control diaries with the help of a specially developed mobile application and sent data to the doctor. According to the personal diaries automatic calculations of integral indicators characterizing self-control of glycaemia (mean fasting and postprandial glycaemia) and food intake (amount of carbohydrates, proteins, fat and kalories) were accomplished. Statistical analysis included Kruskal-Wallace test, Mann-Whitney test and Spearman correlations.
Results
The level of *NR3C1* gene expression was significantly lower in GDM1 and GDM2 group compared to controls (2.3 ± 0.8, 2.4 ± 1.2, and 3.1 ± 1.2, respectively, $P=0.005$), with no difference between GDM1 and GDM2. Age and pregestational BMI did not differ among the three groups. Some negative correlations have been observed between the level of *NR3C1* gene expression and the following parameters: fasting plasma glucose (PG) level ($r=$-0.331, $P=0.004$) and 2 h PG in OGTT ($r=-0.253$, $P=0.033$), fasting blood glucose (BG) ($r=-0.397$, $P=0.003$), and postprandial BG ($r=-0.276$, $P=0.046$) measured by participants during the study.
Conclusion
NR3C1 gene expression was down regulated in HUVECs of newborns from GDM mothers and was associated with fasting and postprandial levels of BG during GDM treatment. However, it was not associated with prespecified glycemic targets.

Autoimmunity markers in turner syndrome patients

Aneta Gawlik[1], Elzbieta Berdej-Szczot[1], Ewa Blaszczyk[1], Magdalena Hankus[1], Tomasz Gawlik[2] & Ewa Malecka-Tendera[1]
[1]Department of Paediatrics and Paediatric Endocrinology, School of Medicine in Katowice, Medical University of Silesia, Katowice, Poland; [2]Nuclear Medicine and Endocrine Oncology Department, Maria Skłodowska-Curie Memorial Institute and Cancer Center, Gliwice Branch, Gliwice, Poland.

Background
Turner syndrome (TS) predisposes to autoimmune diseases such as thyroiditis, coeliac disease, diabetes mellitus type 1, inflammatory bowel diseases, alopecia and vitiligo. The prevalence of autoimmunity increases with age and more than one autoimmune disease can coexist together in one patient. The possible factors leading increased autoimmunity in TS are not clear.
Aim
To compare the panel of autoimmunity markers in 37 TS girls (40.5% with 45,X) with the control group of 11 short healthy girls.
Method
Morning blood tests were performed to analyze total lymphocytes, CD3, CD4, CD8 CD4/CD8. CD19, NK, Treg, IgA, IgM, IgG, TGFβ, IL10, anti-TPO, anti-TG and anti-GAD.
Results
The mean ± s.d. age and BMI values in both, study and control, groups were comparable (11.9 ± 4.1 vs 12.5 ± 4.0 years; 19.2 ± 3.3 vs 19.7 ± 4.6 kg/m^2, $P > 0.05$). TS girls presented lower IgG concentration, CD4% and lower CD4/CD8 ratio comparing to healthy controls (9.1 vs 11.5, $P = 0.02$; 32.6% vs 40.4%, $P = 0.0004$; 1.2 vs 1.8, $P = 0.0005$). Further analysis showed that CD4% was the lowest ($P = 0.001$) in girls with isoXq who showed also the highest incidence of elevated thyroid antibodies. Although without statistical significance but girls with three copies of genes from Xq presented also the lowest Treg and the highest CD8. The remaining laboratory markers were comparable between study and control group and did not show any difference when girls with 45,X, 45,X/46,XX and other TS karyotypes were analyzed separately.
Conclusions
We confirm in TS the lower ratio of CD4/CD8 but in contrast to previous studies, besides girls with isoXq, it was not the result of higher number of CD8. IsoXq was found a risk factor for higher incidence of autoimmunity in TS.

A pilot study of the differences in miRNA expression profile in the blood serum between patients with malignant and benign parathyroid tumors

Julia Krupinova, Natalia Mokrysheva Vasiliy Petrov, Ekaterina Pigarova, Larisa Dzeranova & Anatoliy Tiulpakov
Endocrinology Research Centre, Moscow, Russian Federation.

Background
MiRNAs are small non-coding RNAs, which regulate biological and pathological processes, including organogenesis, apoptosis, cell proliferation and differentiation. Considering the complexity of the parathyroid cancer (PC) diagnosis, discovering of new markers of the disease, which may help to evaluate the prognosis before surgical treatment, becomes an important problem. We studied the differences in miRNA expression profile in the blood serum between patients with malignant and benign parathyroid tumors for better understanding of the molecular processes, which may play a role in parathyroid tumorigenesis and may serve as diagnostic markers for PC.
Aims
To develop a specific miRNA panel for the differential diagnosis of the carcinoma of the parathyroid glands (PG).
Materials and methods
Serum samples were taken from persons with clinically and laboratory confirmed primary hyperparathyroidism (PHPT) and stored frozen at −20°C. After the morphological analysis of postoperative material, the patients were divided into 2 groups: patients with adenomas of the PG ($n = 6$) and patients with cancer of the PG with metastasis ($n = 6$). To perform a simultaneous comparative expression analysis of 760 microRNAs, the «TaqMan OpenArray Human MicroRNA Panel» (Thermo Fiher) was used in conducting of real-time PCR reaction on «QuantStudio 12K Flex» station.
Results
We detected 14 miRNAs which level was significantly lower in patients with parathyroid carcinoma in compare to miRNAs in patients with parathyroid adenoma: miRNA-186 ($P = 0.006$), miRNA let-7e ($P = 0.019$), miRNA-195 ($P = 0.009$), miRNA 16 ($P = 0.005$), miRNA-15b ($P = 0.037$), miRNA-146b ($P = 0.037$), miRNA-19b ($P = 0.004$), miRNA-106b ($P = 0.018$), miRNA-126 ($P = 0.043$), miRNA 342-3p ($P = 0.005$), miRNA-17 ($P = 0.017$), miRNA-320 ($P = 0.039$), miRNA-25 ($P = 0.005$), miRNA-93 ($P = 0.037$).
Conclusions
The pilot study showed that 14 miRNAs could help to differentiate benign tumors from malignant tumors before a surgery and predict metastases. The next step of this study would be the analysis of the sensitivity and specifity of the result on a bigger sample of patients.

Excess of parathyroid hyperplasia incidence in subjects exposed to ionizing radiation after the CHNPP accident

Oleksii Kaminskyi, Olga Kopilova, Dmitryi Afanasyev, Kontantin Loganovskyi, Viktoria Talko, Olga Mazurenko, Katerina Grishcenko, Larisa Tsvet & Dmitrii Bazyka
State Institution 'National Research Center for Radiation Medicine of the National Academy of Medical Sciences of Ukraine', Kyiv, Ukraine.

Parathyroid glands are critical not only for regulation of the phosphorous-calcium metabolism, but also have a key role in the function of nervous, cardiovascular, digestive and other human body systems. Parathyroids are capable of accumulating the isotopes of cesium, strontium and radioactive iodine, which can lead to parathyroid cell damage and emergence of glandular dysfunction. Significant radioactive environmental releases and fallout after the Chernobyl NPP accident in 1986 were followed by incorporation of the, first and foremost, isotopes of iodine, cesium and strontium, which on top of that were accumulated in parathyroids. Since radioactive iodine is both alpha- and beta-emitter the accumulation of it in large amounts by the thyroid results in the secondary irradiation of parathyroids. Just similar situation is characteristic for the Fukushima NPP accident. Radiation exposure of parathyroids leads to the onset of related disorders of other systems. Unfortunately, we have started such a long-term research for the first time only now, i.e. about 30 years after the exposure of the survived people. We have now the very first important results here. Namely the 686 adults and 54 of their first-generation descendants were examined, and the obtained data testify to an increase in the incidence (28.64%) of clinically important parathyroid hyperplasia (more than 9 mm in adults, and more than 5 mm in children) among subjects irradiated after the Chornobyl accident, especially in the clean-up workers for a long time involved in recovery operations in the Chornobyl zone, and in their descendants (23.8–70.6%). Those adult subjects who live in areas contaminated by radioactive strontium and cesium are of especial concern when compared with the control group of unexposed subjects (24.15% incidence). The evacuees from the 30-km Chornobyl exclusion zone are the another group of risk as they were exposed from the incorporated iodine isotopes in the early days of the Chornobyl accident. Some detected abnormalities were not linked to the functional state parathyroids or lack of vitamin D. Continuation of the research will clarify the causative relationships here.

The design and preliminary results of a phase 1 TransCon PTH trial in healthy volunteers

David Karpf[1], Eva Mortensen[1], Kennett Sprogøe[2], Susanne Pihl[2] & Jonathan Leff[1]
[1]Ascendis Pharma, Inc., Palo Alto, California, USA; [2]Ascendis Pharma A/S, Copenhagen, Denmark.

Background
Hypoparathyroidism (HP), a condition of parathyroid hormone (PTH) deficiency, leads to abnormal calcium metabolism. Standard of care (SOC), ie, large amounts of calcium and active vitamin D, leads to hypercalciuria and increased calcium x phosphate. Daily Natpara, PTH(1-84), injections reduced calcium and active

vitamin D doses but not 24-hour urinary calcium (uCa) excretion or incidence of hypo- and hypercalcemia due to its 3-hour half-life (Natpara label). NIH studies of PTH(1-34) in children and adults with HP have shown that a single subcutaneous (SC) injection is superior to SOC, twice daily injections are superior to once daily, and continuous SC infusion normalizes serum calcium (sCa), serum phosphate (sP), and uCa. Ascendis Pharma is developing TransCon PTH, an inactive prodrug of PTH(1-34) for the treatment of HP. In its prodrug form, PTH(1-34) is transiently bound to the TransCon carrier via the TransCon linker. Through autohydrolysis at physiological temperature and pH, unmodified PTH(1-34) is released, providing free PTH at steady state with an infusion-like profile in the physiological range over 24 h.

Methods

This phase 1, randomized, placebo-controlled, single and multiple ascending dose (SAD and MAD) trial evaluated safety, tolerability, pharmacodynamics (PD), and pharmacokinetics (PK) of TransCon PTH in up to 170 healthy adults. Cohorts consisted of 10 subjects (8 active, 2 placebo) and received 7 SAD (3.5, 12, 32, 48, 72, 100, or 124 μg) or up to 9 MAD (3.5, 7.0, 12, 16, 20, 24, 32, 40, and 48 μg) for 10 days. The primary PD endpoints included sCa, uCa, sP, and PTH(1-84). The primary PK endpoint was free PTH.

Results

The completed SAD and MAD cohorts showed TransCon PTH was well-tolerated without DLTs. The PK showed dose-dependent increases in exposure, with $T_{1/2}$ of approximately 60 h. Single injections up to 100 μg showed dose-dependent increases in albumin-adjusted sCa (up to 11.0 mg/dl at 100 μg) sustained for $\geq$72 h and associated with reductions in PTH(1-84) but without change in fractional excretion of Ca (FECa). The trial is ongoing; 7 SAD cohorts and several MAD cohorts, including relevant phase 3 doses, will be presented.

Conclusion

TransCon PTH is being developed for HP as a once-daily SC injection. Interim data supports a normal range infusion-like PTH profile, with a PTH $T_{1/2}$ of approximately 60 h and sustained increases in sCa without change in FECa, potentially addressing limitations of available HP therapies.

Pseudohypoparathyroidism (PHP) and related disorders lead to a wide spectrum of abnormal physical characteristics, neurocognitive and endocrine abnormalities that share a common PTH/PTHrP signaling pathway. The clinical and molecular overlap of PHP and related disorders lead to difficulties in clinical and molecular diagnosis which prompt to the possibility of incorrect management of these patients. PHP (including all subtypes), pseudoPHP, acrodysostosis and progressive osseous heteroplasia refer to heterogeneous disorders characterized by physical findings, differently associated in each subtype, including short bones, short stature, a stocky build, subcutaneous ectopic ossifications (features associated to Albright Hereditary Osteodystrophy, AHO), as well as laboratory abnormalities such as hypocalcemia, hyperphosphatemia, and elevated PTH and TSH levels. Other features have been attributed to these disorders, such as intra uterine growth failure, early-onset obesity, hypogonadism, hypothyroidism, elevated calcitonin levels, growth hormone deficiency and neurocognitive deficiency. The main subtypes of PHP and related disorders are caused by *de novo* or autosomal dominantly inherited inactivating genetic mutations, and/or epigenetic, sporadic or genetic-based alterations within or upstream of GNAS, PRKAR1A, and *PDE4D* and PDE3A. Over the past 30 years, incredible progress has been made on the pathophysiology of these disorders throughout the world by physicians and research networks. However, caregivers and patients are lacking guidelines for the daily life management of patients. Our aim was to help them from the clinical diagnosis, to the molecular confirmation of the genetic or the epigenetic defect, up to the management of the most frequent manifestations of these rare diseases. Therefore, a consensus statement was prepared for 2 years to produce recommendations for clinical and molecular diagnosis and management of patients with PHP and related disorders. The approach comprised 2 pre-consensus meetings, an expert consensus meeting, and a Delphi-like methodology, adjusted to rare diseases. This consensus meeting was supported by several patients' associations and scientific societies, including the ESE. After a comprehensive literature search using PubMed, >800 papers published since 1 January 1990 to 18 December 2016 have been reviewed and recommendations on

clinical and diagnosis and management on PHP and related disorders have been voted and approved with different levels of evidence: 14 recommendations on clinical diagnosis, 11 on molecular diagnosis and 39 on management and treatment.

Symptom burden and HRQoL reported among patients with chronic hypoparathyroidism: impact of treatment with rhPTH (1-84) and with standard therapy

Kristina Chen[1], Nandini Hadker[2], Irana Abibova[2], Lachlan Hanbury-Brown[2], Montserrat Vera-Llonch[1] & Bart Clarke[3]
[1]Shire Human Genetic Therapies, Inc., Lexington, Kentucky, USA; [2]Trinity Partners LLC, Waltham, Massachusetts, USA; [3]Mayo Clinic Division of Endocrinology, Diabetes, Metabolism, and Nutrition, Rochester, New York, USA.

Chronic hypoparathyroidism (HypoPT) is a rare disease associated with a variety of symptoms and diminished health-related quality of life (HRQoL). This study aimed to characterise and quantify the symptom burden, HRQoL, and overall disease impact in patients receiving recombinant human parathyroid hormone (rhPTH1-84, Natpar®) for inadequately controlled HypoPT and in symptomatic patients receiving standard therapy (ST; calcium and/or vitamin D supplements). A web-based patient survey was developed with input from members of the US Hypoparathyroidism Association and from physician experts. Eligibility criteria included receiving rhPTH1-84 or having symptoms of HypoPT while on ST. All respondents were $\geq$18 years old, US residents, diagnosed with HypoPT, and currently taking prescription and/or over-the-counter therapies to manage their condition. The surveys were completed at one point in time and focused on patient characteristics, recall of symptom burden from prior to and while taking their current treatment, impact of HypoPT on life and work, and HRQoL evaluated by SF-36 v2. 90 patients (mean age, 54 years; women, 83%) with HypoPT (mean duration, 8.8 years) currently on rhPTH1-84 (mean duration of therapy, 19 months) and 47 patients (mean age, 50 years; women, 93%) with HypoPT (mean duration, 16.3 years) currently symptomatic on ST completed the survey. Patients on rhPTH1-84 experienced an average of 9.1 symptoms (range, 0–34) and patients on ST experienced an average of 20.2 symptoms (range, 1-39) over a recall period of up to 12 months. Patients currently on rhPTH1-84 recalled experiencing an average of 17.0 symptoms (range, 3–40) prior to rhPTH1-84 therapy. A numerically greater proportion of patients on ST reported significant disease-associated interference with their lives (49%) and impact on work responsibilities (31%) versus patients on rhPTH1-84 (27% and 15%, respectively). rhPTH1-84 patients scored numerically higher on HRQoL (SF-36v2 domain scores range, 44.8-49.8) compared with ST patients (range, 33.9–40.9). HypoPT is associated with significant symptom burden. Patients on rhPTH1-84 recalled a reduction in symptoms after starting therapy, while most patients on ST reported minimal improvement of their HypoPT-related symptoms. Patients on rhPTH1-84 reported numerically higher physical and mental domain scores as measured by SF-36v2 (higher score indicating better HRQoL) compared with ST patients. This cross-sectional real-world non-interventional study does not control for unobserved treatment selection bias and underlying clinical differences that may impact treatment effectiveness between treatment groups. Retrospective reporting of baseline symptoms and other questions, which depend on patient recall represents an additional limitation.

Maintenance of key biochemical parameters with recombinant human parathyroid hormone (1-84) in patients with hypoparathyroidism: an analysis of a long-term, open-label, single-centre study

Alan Krasner[1], Natalie E Cusano[2], Mishaela R Rubin[3], Rebecca Piccolo[1] & John P Bilezikian[3]
[1]Shire Human Genetic Therapies, Inc., Lexington, Kentucky, USA; [2]Lenox Hill Hospital Department of Medicine, New York, USA; [3]College of Physicians and Surgeons, Columbia University, New York, USA.

Hypoparathyroidism is a rare disorder characterised by hypocalcaemia and insufficient or undetectable parathyroid hormone (PTH). Recombinant human PTH, rhPTH(1-84), has been approved in the United States and Europe as an adjunctive treatment for adult patients with hypoparathyroidism. When hypoparathyroidism is established, long-term administration of rhPTH(1-84) is a treatment option. Thus, long-term safety and efficacy data for rhPTH(1-84) are needed. To this end, we evaluated data from adults with hypoparathyroidism who previously participated in a single-arm, single-centre study known as HEXT (NCT00473265) and are now enrolled in a new phase 4 study (NCT02910466). Uninterrupted rhPTH(1-84) therapy has been maintained for 4.0 to 11.4 years. Baseline was the last assessment before starting rhPTH(1-84). Visit windows, defined as once every 6 ± 3 months from baseline, were used for summary of assessments collected over time from medical records. If multiple measurements were recorded within a visit window, the value closest to the target day was used. Data are presented as mean $\pm$ SD.. This cohort comprises 33 patients (53.4 ± 12.4 years; 76% women; duration of hypoparathyroidism, 19.4 ± 12.1 years). Mean duration of rhPTH(1-84) treatment was 7.5 ± 2.3 years. Albumin-corrected serum calcium remained relatively stable during the treatment period and was near or within the target range for patients with hypoparathyroidism at most time points. Urinary calcium, serum phosphate, and serum creatinine were maintained within the target or normal ranges at all time points during rhPTH(1-84) treatment. Estimated glomerular filtration rate was between 60 and 89 ml/min per 1.73 m^2 at baseline and at most time points over the course of rhPTH(1-84) treatment. Calcium-phosphate product was 3.06 ± 0.55 $mmol^2/l^2$ at baseline and remained <4.4 $mmol^2/l^2$ at all time points. This analysis includes the longest reported experience with rhPTH(1-84) for the treatment of hypoparathyroidism. The results document that rhPTH(1-84) treatment is characterised by maintenance of biochemical parameters, including stable renal function, within normal or target ranges for this disease. These data provide strong support for the efficacy of rhPTH(1-84) in the long-term management of hypoparathyroidism.

The global, prospective, observational PARADIGHM™ registry for patients with chronic hypoparathyroidism was expanded to capture recombinant human parathyroid hormone, rhPTH(1-84), use under routine clinical care

Bart L Clarke[1], Lars Rejnmark[2], Maria Luisa Brandi[3], John Germak[4], Stefanie Hahner[5], Pascal Houillier[6], Olle Kampe[7], Christian Kasperk[8], Aliya Khan[9], Michael A Levine[10], Michael Mannstadt[11], Rebecca Piccolo[12], Dolores M Shoback[13], Tamara J Vokes[14] & Neil Gittoes[15]
[1]Mayo Clinic, Rochester, Minnesota, USA; [2]Aarhus University Hospital, Aarhus, Denmark; [3]University Hospital of Careggi, Florence, Italy; [4]Shire International GmbH, Zug, Switzerland; [5]University of Würzburg, Würzburg, Germany; [6]Georges Pompidou Hospital and Paris Descartes University, Paris, France; [7]Karolinska Institutet, Stockholm, Sweden; [8]Medical University, Heidelberg, Germany; [9]McMaster University, Hamilton, Ontario, Canada; [10]Children's Hospital of Philadelphia, Philadelphia, Pennsylvania, USA; [11]Massachusetts General Hospital and Harvard Medical School, Boston, Massachusetts, USA; [12]Shire Human Genetic Therapies, Inc., Lexington, Massachusetts, USA; [13]SF Department of Veterans Affairs Medical Center, University of California, San Francisco, California, USA; [14]University of Chicago Medicine, Chicago, Illinois, USA; [15]University of Birmingham, Birmingham, UK.

PARADIGHM™, a global, prospective, observational registry of patients with chronic hypoparathyroidism (HPT), began enrolment in 2013 to collect data on the natural history of chronic HPT (ClinicalTrials.gov NCT01922440). Since initiation, recombinant human PTH, rhPTH(1-84), has been approved in the United States and Europe as an adjunctive treatment for adult patients with HPT. The protocol for the registry (now a European Medicines Agency–designated postmarketing commitment) was amended to capture rhPTH(1-84) use in HPT patients under routine clinical care (EUPAS16927). Patient recruitment continues with a global enrolment goal of $\geq$900 patients, including $\geq$300 receiving rhPTH(1-84). Follow-up data collection on each patient is planned for $\geq$10 years. Patients with a diagnosis of HPT of $\geq$6 months are eligible for inclusion; exclusions include inability to provide informed consent, enrolment in any interventional study, or active PTH(1-34) therapy. Treatment regimens are determined by the patients' physician, per usual clinical practice, and can be conventional calcium/vitamin D supplements and/or rhPTH(1-84). Primary outcome variables are HPT lab tests, including renal function; renal and cardiovascular events; soft tissue calcification or bone fractures; presence of cataracts; and adverse events, including those considered to be related to rhPTH(1-84) treatment. Secondary outcome variables include health-related quality of life, disease-specific patient-reported measures, and hospitalisations

and emergency room visits. Additional data to be collected include demographics, medical history, HPT management, and concomitant medications. Data are collected every 6 months, and the database uploads are via electronic data capture. A steering committee reviews scientific reports and evaluates requests for analyses. Prior to starting the new protocol, a registry data cut on December 1, 2016, was completed. Forty-one investigator sites and 492 patients (49 ± 17 years of age; 30 ± 9 kg/m^2 body mass index) had been enrolled. Notably, 93% of patients reported ≥ 1 symptom within the previous 6 months despite prescribed conventional therapy of calcium (91%) and vitamin D (84%). Only 7% were recorded as receiving rhPTH(1-84) in a clinical trial setting (ie, data capture was prior to US Food and Drug Administration approval). Data from PARADIGHM will provide physicians with needed information on the natural history of HPT in patients prescribed conventional treatment and in those prescribed rhPTH(1-84).

Stone risk profile analysis in patients with asymptomatic primary hyperparathyroidism

Federica Saponaro[1,2], Filomena Cetani[1], Marina Di Giulio[1], Laura Mazoni[1], Matteo Apicella[1], Elena Pardi[1], Simona Borsari[1] & Claudio Marcocci[1]
[1]Endocrine Unit 2, University of Pisa, Pisa, Italy; [2]Dipartimento di Patologia Chirurgica, Medica, Molecolare e dell'Area Critica, Pisa, Italy.

The kidney is an important target of primary hyperparathyroidism (PHPT). The 4th International Workshop for the management of Asymptomatic PHPT included the presence of hypercalciuria (24-h urinary calcium > 400 mg/day) and increased stone risk by biochemical stone risk profile as criteria for surgery. Increased stone risk profile was defined as at least one between ßCaOx > 4 and ßHPO4 > 2, as defined in literature in a different study population. The aim of the present study was to evaluate the stone risk profile in 102 consecutive patients with asymptomatic PHPT, enrolled from October 2016-June 2017. We recorded clinical and biochemical data, kidney ultrasound and urinary stone risk profile by LithoRisk software, that calculates urine state of saturation for calcium oxalate (ßCaOx) and calcium hydrogen phosphate or brushite (ßHPO4). The group included 81 females and 21 males, mean age 55 ± 15 years. In 93 (91%) patients were sporadic and in 9 (9%) had MEN1 syndrome. We found clearance of creatine < 60 ml/min in 4.9% (n = 5) and nephrolithiasis/nephrocalcinosis ultrasound detected in 18.3% (n = 19). Hypercalciuria (24 h urinary calcium > 400 mg/24 h) was detected in 29.4% (n = 30). It was present in 57.9% (11 out of 19) patients with kidney stones detected at ultrasound (stone carriers) and in 22.9% (19 out of 83) of those patients without ultrasound detected stones. Either in the former and in the latter group all patients with hypercalciuria had also an increased stone risk profile. Moreover, we evaluated the stone risk profile also in those patients "stone carriers" without hypercalciuria (n = 8) and we found that in 5 patients it was increased. In the whole group we found a positive correlation between ßCaOx and PTH (P = 0.029, r = 0.25) and between ßHPO4 and PTH (P = 0.015, r = 0.27). Our data suggest that hypercalciuria alone can identify all patients with positive stone risk profile. However, in the group of patients with stones detected at ultrasound and 24-h- urinary calcium < 400 mg/24 h there is a proportion of patients in which Lithotest® can detect an increased stone forming risk.

Hypoparathyroidism is a disorder of mineral homoeostasis due to parathyroid hormone (PTH) deficiency. Conventional treatment with oral Ca and calcitriol may maintain serum Ca levels but does not replace other physiologic PTH effects. RACE is an ongoing open-label study of recombinant human PTH1-84 (rhPTH1-84) for hypoparathyroidism treatment in adults (ClinicalTrials.gov NCT01297309). Patients initially received rhPTH1-84 25 or 50 µg/day subcutaneously, with 25-µg increases to 100 µg/day maximum. rhPTH(1-84) could be titrated and oral Ca/calcitriol doses adjusted at any time during the study to maintain serum Ca levels within the optimised target (2.0–2.2 mmol/l). Primary objective was to demonstrate the long-term safety and tolerability of rhPTH1-84. Composite efficacy endpoint was the proportion of patients who achieved a ≥50% reduction from baseline (BL) in oral Ca dose (or Ca ≤500 mg/day) and a ≥50% reduction from BL in calcitriol dose (or calcitriol ≤0.25 µg/day) while maintaining albumin-adjusted serum Ca between 1.87 mmol/l and the ULN for the central laboratory. Five-year, open-label efficacy and safety data presented with descriptive summary statistics (mean(s.d.)). Study cohort included 49 adult patients enrolled at 12 US centres (age 48.1[9.78] years; 81.6% female); 40 patients (81.6%) completed 60 months (M60) of rhPTH(1-84) as of 8 May 2017. Oral Ca and calcitriol doses were reduced by 53.4% and 75.7%, respectively; albumin-adjusted serum Ca levels were maintained within the target range (M60, 2.1[0.20] mmol/l; BL, 2.1[0.17] mmol/l). At M60, the efficacy composite endpoint was achieved by 28/40 patients. Urinary Ca excretion showed a numerical reduction (M60, 6.2[3.30] mmol/24 h; BL, 8.9[5.01] mmol/24 h, n = 48), as did serum P levels (M60, 1.3[0.21] mmol/l; BL, 1.6[0.19] mmol/l,) and Ca-P product levels (M60, 2.8[0.45] mmol^2/l^2; BL, 3.4[0.51] mmol^2/l^2). Serum creatinine levels remained stable (M60, 81.7[19.85] µmol/l; BL, 84.7 ± 18.16 µmol/l), as did estimated glomerular filtration rate (M60, 108.1[42.32] ml/min; BL, 108.2[36.36] ml/min, n = 41). Treatment-emergent adverse events (TEAEs) were reported in 48/49 patients. Common TEAEs (>25% of patients) reported included symptoms of the underlying disease (ie, hypocalcaemia [36.7%], muscle spasms [32.7%], paraesthesia [30.6%]), sinusitis (30.6%), and nausea (30.6%). Serious TEAEs occurred in 13 patients. Continuous use of rhPTH1-84 over 5 years has an acceptable safety profile, was well tolerated, efficacious, and improved key measurements of mineral homoeostasis.

GP181

Is there HIV-associated hypoparathyroidism?

Sebastian Noe[1], Silke Heldwein[1], Celia Oldenbüttel[1], Hans Jäger[1] & Eva Wolf[2]
[1]MVZ Karlsplatz, Munich, Germany; [2]MUC Research, Munich, Germany.

Background
Parathyroid hormone (PTH) secretion in response to hypocalcemia was found to be altered in people living with HIV (PLWH) and HIV infection has therefore been acknowledged as a potential reason for hypoparathyroidism (HPO).
Aim
To describe the prevalence of HPO in a population of PLWH.
Methods
Monocentric, retrospective sub-study of the Munich ArcHIV cohort.
Results
579 patients (461 men (79.6%)) were included in the study with a median age of 48 (40–54) years. In 496 patients, albumin concentration was available in and the prevalence of HPO was 15.3% (n = 76) and 8.3% (n = 41) in 2016 and 2017, respectively. In 14 patients (1.4%) HPO was found in both years. One of these patients presented with a medical history of cervical irradiation due to Hodgkin's lymphoma. Of 14 patients with HPO in both years, 10 (71.4%) were on tenofovir disoproxil fumarate (TDF) at the time of PTH measurement in both years (P = 0.008). Therefore, exposure to TDF was associated with a risk ratio of 4.2 (1.3–13.1).

Discussion
The prevalence of HPO in our cohort of PLWH was unexpectedly high at 1.4%. Except for one patient, no "traditional" explanation for hypoparathyroidism could be found. Different from findings in "classical" hypoparathyroidism, phosphate levels were not higher in patients with HPO compared to controls; contrary, we even found a trend towards a higher frequency of at least one episode of hypophosphatemia. This might however be attributable to the more frequent use of TDF in patients with HPO, as TDF has been associated with increased phosphate excretion and lower phosphate levels before.
Conclusion
HIV-infection and antiretroviral therapy seem to be associated with a higher prevalence of HPO. The limitations of a retrospective study warrant further investigations on this topic.

Use of a Disease-Characteristic Questionnaire identified pain and cramps and neuro-vegetative symptoms as significantly elevated and affected by Medication in mainly well-controlled hypoparathyroid patients

Deborah Wilde[1], Lara Wilken[1], Bettina Stamm[2], Christina Heppner[3], Andreas Leha[4], Christoph Herrmann-Lingen[5] & Heide Siggelkow[1,3]
[1]Clinic of Gastroenterology and Gastrointestinal Oncology, University Medical Center, Goettingen, Germany; [2]ENDOKRINOLOGIKUM Saarbruecken, Saarbruecken, Germany; [3]MVZ endokrinologikum, Goettingen, Germany; [4]Institute for Medical Statistics, University Medical Center, Goettingen, Germany; [5]Clinic for Psychosomatic Medicine and Psychotherapy, University Medical Center, Goettingen, Germany.

Introduction
Hypoparathyroidism (hypoPT) is characterized by inadequately low circulating concentrations of parathyroid hormone (PTH) followed by low calcium and increased phosphate levels in the blood. Patients with hypoPT suffer from a number of complications and complaints including infections, neuro-psychiatric diseases, abnormal bone architecture impaired muscle function and reduced quality of life. Due to the complexity of the various clinical manifestations there is a demand for a disease-sensitive control instrument to be able to monitor symptoms beside biochemical values. We used a new disease-characteristic questionnaire to investigate hypoPT patients' complaints and contributing factors.
Methods
This prospective study was conducted in two endocrinological centers in Germany over one year. Patients with postsurgical hypoPT ($n=49$) were matched for sex and age ± 3 years and compared to patients with thyroid surgery without hypoPT (ThySu, $n=39$)) and patients with (former) primary hyperparathyroidism (pHPT, $n=35$). The Hypoparathyroid Patient Questionnaire (HPQ 40) was filled in during the patient's visit at the center. Information was completed by clinical background information (e.g. disease complications), blood tests and current medication. The influence of these clinical data on patients' complaints represented as subscales of the HPQ 40 (pain and cramps, depression and anxiety, gastrointestinal symptoms, vitality, neuro-vegetative symptoms) was analyzed.
Results
In hypoPT patients 87% had serum calcium-levels within the target range. Serum-phosphate-levels and calcium-phosphate-product were within reference range in 95.7% of patients, or 100% respectively. The scores for pain and cramps and neuro-vegetative symptoms were significantly elevated in comparison with one (neuro-vegetative symptoms; $P=0.002$) or both (pain and cramps; $P=0.001$) control groups. No laboratory parameter correlated with patients' complaints after Bonferroni correction. In contrast, treatment with alfacalcidol or calcitriol significantly influenced results on different subscales ($P=0.002$ and $P=0.021$, respectively).
Conclusions
This study identified pain and cramps and neuro-vegetative symptoms as relevant areas of complaints in predominantly well controlled patients with hypoPT. Our data suggest that different active vitamin D agents may influence certain disease manifestations. The impact of different treatment regimen on clinical manifestations of hypoPT patients should be more intensively investigated.

A novel mutation in the calcium sensing receptor GENE IN AN Italian family affected by autosomal dominant hypocalcemia

Laura Mazoni[1], Simona Borsari[2], Elena Pardi[2], Federica Saponaro[1], Chiara Banti[2], Giulia Marconcini[2], Claudio Marcocci[2] & Filomena Cetani[3]
[1]Department of Clinical and Experimental Medicine, University of Pisa, Pisa, Italy; [2]Department of Clinical and Experimental Medicine, University of Pisa, Pisa, Italy; [3]Universital Hospital of Pisa, Endocrine Unit 2, Pisa, Italy.

The G protein-coupled calcium sensing receptor (CaSR), widely expressed on the surface of parathyroid chief cells and in the kidney, plays a central role in calcium homeostasis. Activating mutations of *CaSR* gene are responsible for autosomal dominant hypocalcemia (ADH), a rare disorder caused by hypocalcemia, hyperphosphatemia, hypercalciuria and inadequately low concentration of parathyroid hormone (PTH). In this study, we report a family affected by ADH. The proband, a 26 year-old Italian woman, was referred to our Department in 2011 for a mild asymptomatic hypocalcemia detected in 2009 during routine blood tests. Biochemical evaluation confirmed a mild hypocalcemia (mean value: 8 ± 0.26 mg/dl, normal range: 8.6–10.2), normal serum PTH (mean value 22 ± 5.57 pg/ml, normal range 8–40) and relative 24 h urinary calcium excretion (mean value: 171 ± 30.3 mg/24 h, normal range: <250). Instrumental evaluation excluded intracranic calcifications, kidney stones and nephrocalcinosis. Serum calcium of first-degree relatives showed hypocalcemia in her father (8.1 mg/dl) and brother (8.2 mg/dl), and normocalcemia in her mother (9.6 mg/dl). Genomic DNA of the proband and her family members was isolated from peripheral blood leukocytes and the entire coding region and exon-intron boundaries of the *CaSR* gene were directly sequenced. Mutational analysis revealed a novel heterozygous variant of the *CaSR* gene in the proband, leading to the substitution of serine to proline at codon 591 in exon 7 (S591P), localized in the *CaSR* extracellular domain where $>85\%$ of activating mutations occurs. All affected relatives carried the same alteration that was absent in her mother and in 100 chromosomes of unrelated healthy subjects. *In silico* tests, using Mutation Taster software that integrates data from different databases, predicted a probably deleterious effect of the detected variant. In conclusion, we identified a novel missense variant in the *CaSR* gene co-segregating with hypocalcemia.

Adrenal insufficiency induced by anti-PD-1/anti-PD-L1 therapy in patients with cancer: a series of cases

I Peiró[1], P Iglesias[2], A Simó-Servat[3], M Taberna[4,5], JC Ruffineli[4,5], F Guerrero[3], JJ Díez[2] & C Villabona[3]
[1]Clinical Nutrition Unit, Institut Català d'Oncologia (ICO), L'Hospitalet de Llobregat, Barcelona, Spain; [2]Department of Endocrinology. Hospital Ramón y Cajal, Madrid, Spain; [3]Department of Endocrinology, Hospital Universitari de Bellvitge, L'Hospitalet de Llobregat, Barcelona, Spain; [4]Department of Medical Oncology. Institut Català d'Oncologia (ICO), L'Hospitalet de Llobregat, Barcelona, Spain; [5]ONCOBELL; IDIBELL, L'Hospitalet de Llobregat, Barcelona, Spain.

Background
Immune checkpoint inhibitors like monoclonal antibodies targeting programmed death 1 receptor (PD1) or its ligand (PD-L1) have shown antitumor activity in many malignancies by enhancing immune response against cancer cells resulting in significant long-lasting responses. However, this therapy can induce endocrine immune-related adverse events (EirAEs). Thyroid dysfunction is a common EirAE, while adrenal insufficiency (AI) is very uncommon.
Objective
To report our experience on anti-PD1/anti-PD-L1-induced impairment of the hypothalamic-pituitary-adrenal (HPA) axis in cancer patients.
Results
Four patients (two males; mean age 55.5 (±7.6) years) with advanced cancer (3 non-small cell lung cancer (2 locally advanced and 1 metastatic) and one metastatic head and neck squamous cell carcinoma) were included. Three patients received anti-PD1 treatment (one combined with chemotherapy) and the other one was treated with anti-PD-L1 therapy plus chemotherapy. No one was under

steroid therapy. The clinical features of AI were: fatigue (all patients), nausea/vomiting (25%), low blood pressure (25%), hyperkalemia (25%), and hyponatremia (50%). All cases had low baseline serum cortisol levels at diagnosis [mean: 23.5(±34) nmol/l; range: 5–80; normal range (NR): 172–497)] with absence of response to cosyntropin stimulation test. Three out of 4 patients developed secondary AI due to isolated adrenocorticotropic hormone (ACTH) deficiency (ACTH <1.1 pmol/l; NR: 2–12), whereas 1 patient developed primary AI due to autoimmune adrenalitis (positive anti-adrenal antibodies, ACTH: 237 pmol/l). All patients had a normal pituitary MRI and abdominal CT scan. Baseline serum concentrations of the rest of pituitary hormones (TSH, LH, FSH, GH, and PRL) as well as fT4 and IGF-1 were within the normal range in all cases. Patients were treated with replacement doses of hydrocortisone. All patients had to stop immunotherapy temporarily, but in 3 of them, it was reintroduced after a median of 41(±13.5) days. After 7.5±6.4 months (range: 3–18) of follow up, all patients remained with steroid hormone replacement therapy. Interestingly, 2 patients had a complete tumor response despite the advanced stage of the disease; one remained with stable disease after 12 months of follow-up and only one patient progressed 8 months after starting immunotherapy.

Conclusion

Cancer patients treated with anti-PD1 or anti-PD-L1 therapy can develop a persistent immune-related primary or secondary adrenal insufficiency. Isolated ACTH deficiency is the most frequent alteration in our series. In the primary failure, an autoimmune mechanism is suggested. Interestingly, half of these patients achieved a complete response.

Long-term treatment with metyrapone in four patients with Cushing's disease

Natacha Driessens[1], Dominique Maiter[2], Pascale Borensztein[3], Amélie Jaspart[3], Martine Bostnavaron[3] & Albert Beckers[4]
[1]Hôpital Erasme, ULB, Brussels, Belgium; [2]University Hospital Saint Luc, Brussels, Belgium; [3]HRA-Pharma, Paris, France; [4]CHU de Liège, Liége, Belgium.

Introduction

Cushing's disease (CD) is a severe disease, associated with an increased rate of comorbidities and mortality. Remission rate after surgery of pituitary tumor, is around 78%. Relapse occurs in 13% of patients within 10-years after surgery. According to guidelines, patients with unfeasible or non-curative surgery, require additional treatment, including medical therapies. Metyrapone, inhibits 11ß-hydroxylase enzyme, blocking the final step of cortisol synthesis in adrenal cortex. Daily dosage ranges from 250 to 6000 mg. An international European phase III/IV study (PROMPT) started in 2015 to evaluate efficacy and safety of metyrapone in endogenous Cushing's syndrome. Metyrapone was individually titrated during the first 3 months. An extension period of 6 months was proposed to patients who normalized mean urinary free cortisol (mUFC) or did not exceed 2-fold the normal upper limit (ULN =165 nmol/24 h). In Belgium, four patients were treated during 9 months in PROMPT study and benefited from further therapy with metyrapone through a medical need program. Results: Three women and one man with CD, previously treated by pituitary surgery for 3 of them and/or medical treatment, were controlled during the trial with daily doses between 500 and 5750 mg. Centralized UFC measurements (LC–MS/MS method) showed a baseline mUFC value of 768 nmol/24 h [range: 291–1244] reduced under ULN after 3 and/or 9 months of treatment in 3 of them. Baseline mUFC of last patient decreased by more than 50% after 9 months therapy to 235 nmol/24 h. ACTH remained unchanged after the first 3 months of therapy, except for the patient who needed 5750 mg/day of metyrapone (3.2-fold ACTH increase). The baseline mUFC was also the highest in this last patient. Despite a controlled disease with metyrapone, the fourth patient decided after 21 months of treatment to undergo bilateral adrenalectomy. The three others were still controlled after 24 months. Clinically, fatty deposits disappeared in 3 patients out of 4 (75%) and bruising disappeared in 2 patients out of 2 (100%). Regarding safety, patients experienced each 1 to 4 mild to moderate AEs during the 9 months of PROMPT study: nausea, fatigue, tiredness, dizziness, migraine, loss of appetite and arthralgia. Tolerance was still good during extension period after the 9 months study. No hirsutism or acne was observed in women. Conclusion: Metyrapone showed good efficacy and tolerance in long term management (up to 24 months) of 4 patients with CD.

Primary posterior pituitary tumors: a unique neoplasm with hight morbidity

Fernando Guerrero[1], Noemi Vidal[1], Carlos Del Pozo[2], Concepción Blanco[3], David Rivero-Celada[4], Juan José Díez[5], Pedro Iglesias[5], Antonio Picó[6] & Carles Villabona[1]
[1]Hospital Universitari de Bellvitge, L'Hospitalet de Llobregat, Spain; [2]Hospital Universitari Mutua Terrassa, Terrassa, Spain; [3]Hospital Universitario Príncipe de Asturias, Madrid, Spain; [4]Hospital Universitario Miguel Servet, Zaragoza, Spain; [5]Hospital Universitario Ramón y Cajal, Madrid, Spain; [6]Hospital General Universitario de Alicante, Alicante, Spain.

Background

The 2017 World Health Organization classification of pituitary tumors established that, pituicytoma, granular cell tumor of the sella (GCT) and spindle cell oncocytoma (SCO) are posterior pituitary tumors (PPT). These lesions are non-neuroendocrine and low-grade neoplasms of the sellar region presenting with mass effect symptoms. Their clinical manifestation, hormonal profile and radiological findings are indistinguishable from non-functioning pituitary adenomas (NFPA). Recent data suggests that these three tumors could have a common origin from the pituicytes.

Aim

To evaluate a retrospective multicenter study of 15 patients with histological diagnosis of PPT.

Results

Our series included 6 pituicytomas, 3 GCT and 6 SCO. Mean age at diagnosis was 54.2 years old (range 30–74) and 11 patients were female. The most common symptoms of clinical presentation were visual defects (40%), amenorrhea (20%) and sever hyponatraemia (20%). One case had hypercortisolism symptoms. Hormonal assessment showed hyperprolactinemia (40%), hypopituitarism (33%) and ACTH dependent hypercortisolism in one patient. No patient had diabetes insipidus (DI). MRI showed sellar/suprasellar masses with median size of 24.5 mm (±10.3), chiasmatic compression in 46% and cavernous sinuses infiltration in 13% of the patients. Fourteen patients underwent surgery (one patient died before intervention and diagnosis was made by previously biopsy). In 10 patients transphenoidal approach was performed while craniotomy was chosen in 4 cases. Serious bleeding during surgical procedure occurred in 3 cases (20%) and one of them died due to hemorrhage in the early postsurgical period. After surgery 8 patients had hypopituitarism (61%) and 5 patients (38%) developed DI. Complete resection was achieved in 8 cases and residual tumor persisted in the remaining 5 patients. A second intervention was performed in 3 cases (20%). The pathological evaluation of pituitary specimen in the patient with *Cushing's disease*, revealed a concomitant corticotropes hyperplasia and a GCT. *Cushing's disease* persisted after three interventions in this patient, radiotherapy and adrenolytic agent were also prescribed.

Conclusion

PPT are usually misdiagnosed as NFPA because of their clinical and imaging characteristics. However, the behave more aggressive than NFPA and the perioperative complications such as intra-operative bleeding, hypopituitarism, DI and incomplete resection are common.

GP187

Erdheim-chester disease presenting with hypopituitarism and diabetes insipidus

Hisashi Sugano[1], Wataru Kitamura[2], Tomoyuki Urata[3], Taku Okamoto[4], Kunihiko Numoto[5] & Natsue Maruyoshi[6]
[1]Department of Diabetes and Endocrinology, Kochi Health Sciences Center, Kochi, Japan; [2]Department of Internal Medicine, Yusuhara Hospital, Kochi, Japan; [3]Department of Respiratory Medicinees, Kochi Health Sciences Center, Kochi, Japan; [4]Department of Thoracic Surgery, Kochi Health Sciences Center, Kochi, Japan; [5]Department of Orthopedic Surgery, Kochi Health Sciences Center, Kochi, Japan; [6]Department of Neurology, Kochi Health Sciences Center, Kochi, Japan.

Introduction

Erdheim-Chester disease (ECD) is a rare and aggressive form of non-Langerhans cell histiocytosis (n-LCH). Its etiology is unknown, but recently, BRAFV600E (a

proto-oncogene) has been found in more than 50% of cases. This may play a part in chronic uncontrolled inflammation, which is an important aspect of disease pathogenesis.
Case report
A 42-year-old woman complained of generalized weakness, polyuria, and secondary amenorrhea. Biochemistry results revealed elevated plasma osmolality (309 mOsm/l), relatively low urinary osmolality (131 mOsm/l), and no serum AVP. Further results showed that both cortisol (4.3 μg/dl) and ACTH (9.1 pg/ml) were at the lower limit of the normal range. The patient's free T4 level was low (0.60 ng/dl), while her TSH level was within the normal limits. The prolactin level was increased (92.33 ng/ml), and estradiol was not detected. LH and FSH were low (<0.10 and 0.71 mIU/ml, respectively). The IGF-1 level was also low (62 ng/ml). A hormonal provocation test (CRH, TRH, GRH, and LH-RH) revealed hypothalamic panhypopituitarism. We performed cranial magnetic resonance imaging, which showed signal loss in the posterior pituitary region on T1-weighted images. Furthermore, space-occupying lesions were found in the hypothalamus, brainstem, and temporal lobes when Gad-enhancement was used. Positron emission tomography revealed slightly increased uptake activity in both peripheral lung fields. Video-assisted thoracoscopic surgery was performed for diagnostic purposes to obtain a tissue biopsy. Immunohistochemistry of the lung lesion demonstrated the presence of n-LCH markers, positivity for CD68, and negativity for S-100 protein and CD1a. Bone scintigraphy revealed symmetrically increased osteoblastic activity in the lower limbs. We reached a diagnosis of ECD with pan-hypopituitarism and central diabetes insipidus. BRAF mutation was negative in Sanger sequencing. The patient was treated with 12.5 μg of 1-desamino-8-D-arginine vasopressin (DDAVP) per day for diabetes insipidus. We started regular hydrocortisone 10 mg per day, followed by levothyroxine. For the ECD itself, she was first treated with 40 mg of prednisolone per day, and the tumors slightly decreased in size. However, the dose was tapered rapidly because of worsening of diabetes. The treatment was then commenced with interferon α, but the tumors did not decrease in size. We discontinued the treatment because it induced liver damage.
Conclusion
We present a rare case of ECD that presented with hypopituitarism and diabetes insipidus and involved several organs, including the cerebrum, bones, and both lungs.

Growth disorders in paediatric survivors of hematopoietic stem cell transplantation after chemotherapy-only conditioning- the experience of a single center
Luminita-Nicoleta Cima[1], Ioana Maria Lambrescu[1,2], Lavinia Nedelea[1], Elisabeta Sava[1], Bianca Leca[2], Elena-Alexandra Vadana[2], Anca Colita[1,3], Carmen Gabriela Barbu[1,2] & Simona Fica[1,2]
[1]Carol Davila University of Medicine and Pharmacy, Bucharest, Romania; [2]Elias University Hospital, Bucharest, Romania; [3]Fundeni Hospital, Bucharest, Romania.

Objective
The reported incidence of growth disorders in hematopoietic stem cell transplantation (HSCT) recipients ranges from 20 to 80% and it was usually described in patients that were given total body irradiation (TBI) in the conditioning regimen. Because the effect of chemotherapy-only conditioning is less clear, we investigated the frequency of growth failure in our series of children treated with HSCT for different disorders without TBI as part of the conditioning protocol.
Material and method
We compared height and IGF-I *z*-scores in 22 HSCT survivors and 16 healthy subjects matched for age and sex. Short stature was defined as height *z*-score < -2 S.D.
Results
We identified 4 patients with short stature. HSCT recipients had a higher frequency of short stature (18.83% vs 0%, $P=0.027$) compared to the control group. Patients transplanted for beta-thalassemia major were more likely to have short stature compared to patients with non-malignant hematologic diseases and malignant hematologic/non-hematologic disorders (100% vs 16.66% and 7.69%, respectively, $P=0.04$). The longer time elapsed from HSCT ($P=0.012$) and allogeneic compared to autologous grafting ($P=0.019$) were associated with a higher prevalence of growth failure in our study. HSCT survivors had lower mean height *z*-score ($P=0.029$) and lower body mass index *z*-score ($P=0.027$) compared to controls. Multivariate analysis revealed that allogeneic HSCT recipients had lower mean height *z*-score ($P=0.002$) and lower mean IGF-I *z*-score ($P=0.006$) compared to auto-HSCT recipients and controls.
Conclusion
Almost 20% of the patients in our cohort presented short stature despite the fact that they received chemotherapy-only conditioning, emphasizing the need for long-term surveillance of growth even in this group of patients that were not exposed to TBI.

Association of IGF1 receptor autoantibodies with height and body size
Christoph Haudum[1,2], Waldemar Minich[3], Julia Münzker[2], Andrea Groselj-Strele[4], Ewald Kolesnik[5], Ines Mursic[5], Christian Schwiebert[3], Tim Welsink[3], Albrecht Schmidt[5], Thomas Pieber[1,2], Lutz Schomburg[3] & Barbara Obermayer-Pietsch[1,2]
[1]CBmed GmbH – Center for Biomarker Research in Medicine, Graz, Austria; [2]Division of Endocrinology and Diabetology, Department of Internal Medicine, Graz, Austria; [3]Institut für Experimentelle Endokrinologie, Charité-Universitätsmedizin Berlin, Berlin, Germany; [4]Center for Medical Research, Core Facility Computational Bioanalytics, Medical University of Graz, Graz, Austria; [5]Division of Cardiology, Department of Internal Medicine, Medical University of Graz, Graz, Austria.

Objective
Insulin-like growth factor 1 (IGF1) has a crucial role in growth and metabolism. A specifically designed autoantibody (aAb) assay against the IGF1 receptor (IGF1R-aAb) is able to detect IGF1R-aAb in serum. As the IGF1R has shown involvement in many functional pathologies (e.g. in the Laron syndrome), we aimed to investigate the role of IGF1R-aAb in a large population-based cohort of middle-aged volunteers and their potential effects on anthropometric, osteological and metabolic characteristics.
Methods
Clinical and biochemical parameters of 966 volunteers (531 female and 435 male) of the BioPersMed cohort (*Bio*markers in *Pers*onalized *Med*icine, Medical University Graz) were analysed to identify putative differences between IGF1R-aAb positive (binding index >3 – times above background) and control subjects. Laboratory data in combination with DXA-derived measurements of bone density, dimensions and body composition allowed a detailed insight into the relation of IGF1R-aAb with biomarkers (body height and composition, hormones and metabolic factors). Unpaired 2 tailed *T*-test was used to test for statistical significance.
Results
Mean age of the cohort was 57.7 years ± 8.1 years for women and 58.4 years ± 9.0 years for men. IGF1R-aAbs were identified in 6.0% of all volunteers (7.6% female and 5.2% male). IGF1R-aAb positive volunteers showed significantly different bone density ($P=0.001$), body composition ($P=0.012$) and a significant increase in body height [+4.1 cm in men ($P=0.002$) and +1.6 cm in women ($P=0.1$)], with a more pronounced effect in men. There was no difference in age or BMI between the groups.
Summary and conclusions
IGF1R-aAbs are relatively prevalent in healthy adult humans and may affect body height by modulating bone growth. However, their origin, regulation, and relation to hormonal and metabolic pathways have not yet been fully clarified. Therefore, research and monitoring of IGF1R-aAb prevalence before puberty and during lifetime of women and men is a compelling approach but the mechanisms around IGF1R- aAbs and their potential effects remains to be elucidated.

GP190

Insulin sensitivity improves after disease control in acromegaly irrespective of treatment modality and despite an increase in intrahepatic lipid content: data from an investigator-initiated prospective trial

Mai C Arlien-Søborg[1], Jakob Dal[2], Michael Madsen[1], Morten Høgild[1], Niels Jessen[1] & Jens Otto Lunde Jørgensen[1]
[1]Aarhus University Hospital, Aarhus, Denmark; [2]Aalborg University Hospital, Aalborg, Denmark.

Background
Active acromegaly induces insulin resistance despite a lean phenotype, both of which reverse by curative surgery. The impact of somatostatin analogue treatment on insulin sensitivity is less certain and may be offset by its anti-lipogenic effects.
Aim
To study insulin sensitivity, body composition and extopic lipid content in newly diagnosed patients with acromegaly before and $\geq$6 months after successful surgical or medical treatment.
Patients and methods
21 patients with acromegaly underwent a hyperinsulinemic, euglycemic glucose clamp (HEC), dual x-ray absorptiometry (DXA) scan, and MR spectroscopy to quantify lipid content in liver (IHL) and muscle (IMCL).
Results
10 patients were controlled by surgery alone and 11 patients were controlled by a somatostatin analog (SA). Mean $\pm$ s.e. serum IGF-I levels (μg/l) before and after treatment were 696 $\pm$ 90 and 221 $\pm$ 33 with no treatment-specific difference either before ($P=0.75$) or after treatment ($P=0.11$). Insulin sensitivity assessed by mean $\pm$ SE glucose infusion rate (GIR) during the HEC (mg/kg per min) increased after treatment ($P=0.001$) regardless of modality ($P=0.505$) [GIR: 3.3 $\pm$ 0.4 (before) vs. 4.7 $\pm$ 0.5 (after)]. Disease control induced a 17% increase in total body fat ($P=0.001$) and 8% decrease in lean body mass ($P<0.000$). IHL (% CH2/water) increased after disease control, regardless of modality: 2.8 $\pm$ 0.6 (before) vs. 6.7 $\pm$ 2.2 (after) ($P=0.04$). IMCL did not change in either group.
Conclusions
1) The improvement in insulin sensitivity and change in body composition after disease control of acromegaly appear independently of treatment modality, 2) Our data extend and support the notion that IHL is a GH target, 3) Acromegaly and its treatment exemplifies that insulin sensitivity and body composition do not always walk hand in hand.

Ectopic Cushing's syndrome secondary to medullary thyroid carcinoma with apparent signs of hypercortisolism: a case report

M Masum Canat, Sezin Dogan Cakir, Duygu Yıldız, Feyza Yener Ozturk, Rumeysa Selvinaz Erol, Esra Cil Sen, Emre Sedar Saygili, Seda Erem Basmaz, Adnan Batman & Yuksel Altuntas
University of Health Sciences, Sisli Hamidiye Etfal Training and Research Hospital, Istanbul, Turkey.

Introduction
Ectopic ACTH syndrome (EAS) is a rare cause of Cushing's syndrome. EAS is most frequently caused by bronchial carcinoid tumor or small cell lung cancer. Medullary thyroid carcinoma (MTC) is a rare source of EAS, as reported in this case.
Case report
A 65-years-old-female with back pain and weight gain referred to our outpatient clinic with determined signs and symptoms of hypercortisolism. She had arterial hypertension, her sister had operated for thyroid malignancy. The significant findings were; centripedal obesity, plethora, muscle weakness, hypertension, overt diabetes and osteopenia. Laboratory tests were as follows: repeated 24-hour urinary free cortisol (UFC) excretions:900 and 978 μg/dl (n 36–137 /24h); midnight salivary cortisol:1.82 and 2.71 μg/dl (n <0.2 μg/dl); midnight plasma cortisol: 17.73 and 27.24 μg/dl (n <7,5 μg/dl), 1 mg dexamethasone supression test (DST): 17.56 μg/dl, 2 day 2 mg DST: 13.2 μg/dl.The high levels of ACTH (86.5 and 84.1 pg/ml), non-supressed 8 mg DST (18.03 μg/dl), insufficient increase serum cortisol and ACTH levels post CRH-stimulating testing and no mass on pitutiary MRI scanning confirmed ectopic ACTH syndrome. Imaging studies performed for tumor localization, showed a solid thyroid nodule, 20× 18 mm in diameter. Fine needle aspiration(FNA) of the thyroid nodule revealed MTC and calcitonin level in wash-out fluid from FNA was very high (12311 pg/ml), similar with plasma level (3068 pg/ml). Functional PET imaging with 68-Ga DOTATATE demonstrated pathological uptake at right thyroid lobe and right parapharyngeal area. A total thyroidectomy and bilateral, central neck dissection were performed, histology confirming MTC with immunohistochemistry-staining positive for calcitonin, CEA and ACTH. The carcinoma metastases were detected at lymph nodes localized at right level 2 and right parapharyngeal area. Postoperative 24-h UFC (368 μg/dl), 1 mg DST (4.8 μg/dl) and plasma ACTH (40.1 pg/ml) levels revealed uncontrolled hypercortisolism. The measurements of serum calcitonin and CEA were planned three months after surgery to detect the presence of residual disease.
Conclusion
Nearly 50 cases have been reported about EAS induced by MTC; however, to the best of our knowledge this is the first case in the literature from Turkey. Mortality in MTC with EAS due to complications of hypercortisolism is 50%. Therefore, management of Cushing's syndrome in MTC is very important. Surgical removal of MTC is recommended to control CS, but management is limited to debulking metastatic disease.

A case series of endocrine immune-related adverse effects of checkpoint inhibitors

Fotini Adamidou[1], Thomas Georgiou[1], Katerina Kafantari[2], Paraskevi Komzia[1], Anastasios Vagionas[3] & Marina Kita[1]
[1]Endocrinology Department, Ippokration General Hospital, Thessaloniki, Greece; [2]Second Internal Medicine Department, Thessaloniki, Greece; [3]Theagenio Anticancer Hospital of Thessaloniki, Thessaloniki, Greece.

Background
With the increasing use of cancer immunotherapies in advanced solid organ and hematologic malignancies, endocrinologists are beckoned to manage endocrine complications with unique presentations and natural history in the already challenged oncology patient. We describe four patients illustrating the multifarious endocrine adversities of checkpoint inhibitors.
Cases
Patient 1 is a 35-year old male with refractory Hodgkin's lymphoma, previously euthyroid and euglycemic. He was treated with nivolumab for three months before developing profound antibody-negative hypothyroidism (TSH 71.8 mIU/ml, fT4 <0.3 ng/dl), nephrotic syndrome (20 g proteinuria/d), insulin-requiring anti-GAD positive diabetes mellitus and positive tissue transglutaminase antibodies (pending duodenal biopsy), after six cycles of treatment. He presented a palpable hypoechoic goiter with increased vascularity. Patient 2 is a 76-year old male with metastatic melanoma with rapidly declining to suppressed TSH levels, fT4×3ULN and fT3×2ULN after the second infusion of nivolumab. He had a palpable hypoechoic thyroid gland, with increased vascularity. Thyroid-stimulating immunoglobulins were undetectable while anti-TPO were mildly positive. Within six weeks, he precipitously reverted to hypothyroidism (TSH 85 mIU/ml) and his thyroid gland regressed to marked atrophy. Patient 3 is a 59-year-old male with metastatic melanoma, who was switched to pembrolizumab after developing hypophysitis with ACTH (2 pg/ml) and prolactin (<1.0 ng/ml) deficiencies in addition to diabetes insipidus following four infusions of ipilimumab. He maintained intact thyroid, gonadal and GH axes while continuing pembrolizumab for two years, with stable disease. Patient 4 is a 49-year-old male with relapse of Hodgkin's lymphoma 4.5 years after autologous stem cell transplantation. He was previously euthyroid, but developed antibody-positive hypothyroidism after 4 cycles of pembrolizumab, demonstrating a hypoechoic 'honeycomb' gland. His TSH reached a peak of 37.88 mIU/ml, with corresponding levels of fT4 at 0.36 ng/dl (normal 0.7-2) and fT3 at 1.26 pg/ml (normal 2–4.4), indicating a possible central component to the hypothyroidism. The thyroid gland was barely discernible by ultrasound a year later.
Conclusion
The patterns of thyroid and pituitary dysfunction observed with checkpoint immunotherapy challenge our current understanding of 'thyroiditis' and 'hypophysitis'. Endocrinopathies resulting from these agents are common, mostly permanent and potentially life threatening, calling for regular monitoring, prompt management and coordination of care, so that cancer treatment may be safely continued.

Hypophysitis due to immune checkpoint blockade: rising numbers.

Gerrit van den Berg[1], Rob van den Brom[2], Melanie van der Klauw[1], Jeroen Hiltermann[3], Geke Hospers[2] & Thera Links[1]
[1]Department of Endocrinology, University of Groningen, University Medical Center Groningen, Groningen, The Netherlands; [2]Department of Medical Oncology,University of Groningen, University Medical Center Groningen, Groningen, The Netherlands; [3]Department of Pulmonology, University of Groningen, University Medical Center Groningen, Groningen, The Netherlands.

Hypophysitis is one of the immune-related adverse events of immune checkpoint blockade. This complication is potentially dangerous, mainly because of the insidious development of a life-threatening hypocortisolism. Unnecessary morbidity or mortality in an oncological responder may be the result. The number of patients treated with immune checkpoint inhibitors increases rapidly, due to the expansion of indications and trials. Moreover, the introduction of combination schedules leads to more adverse events.PD-1 inhibitors induce hypophysitis in an estimated 1%, the CTLA-4 inhibitor ipilimumab in approx. 5–10% and for the ipilimumab plus PD-1 inhibitor combination percentages up to more than 10% are reported. Caregivers need to be aware of this complication, and should coordinate their protocols accordingly. During the last 5 years we have encountered 26 patients with an immune checkpoint inhibitor-related hypophysitis, of which 11 patients in the last year alone. Ipilimumab is the main cause, but due to the large number of patients treated, monotherapy with PD-1 blockers is represented as well. The time of occurrence of a hypophysitis after starting immunotherapy was 5–18 weeks for Ipilimumab and 13–57 weeks for PD-1 inhibition (Pembrolizumab or Nivolumab). In 2 patients the hypophysitis occurred more than 1 year after the start of immunotherapy, and even after the discontinuation of immunotherapy, illustrating the need for long-term surveillance. The pattern of endocrine dysfunction was typical, failure of especially the adrenal axis (24 out of 26), accompanied by failure of the gonadal and thyroid axis (18 out of 26). The gonadal and thyroid axis showed recovery of function in about half of the cases. MRI abnormalities were minor, mostly in the form of a short-lived infiltrate in the sella without a large mass effect, and especially present in the Ipilimumab group (7 out of 12, as far as a simultaneous MRI is present). In 9 patients the hypophysitis was preceded by a thyroiditis, mostly during treatment with PD-1 inhibitors. Glucocorticoid substitution alone could suffice, without the need for high-dose steroid therapy, which was only applied in the first index patient in 2012, according to the guideline at that time. Based on our current experience the role for high-dose steroid therapy in immune checkpoint inhibitor-related hypophysitis is less prominent than recommended in the recent ESMO Clinical Practice Guidelines.

Olfactory marker protein regulates prolactin secretion and production by modulating Ca^{2+} and TRH signaling in lactotrophs

Cheol Ryong Ku[1], Chan Woo Kang[1], Daham Kim[1], Jae Won Hong[2], Sun Ho Kim[1] & Eun Jig Lee[1]
[1]Yonsei University College of Medicine, Seoul, Republic of Korea; [2]Ilsan-Paik Hospital, College of Medicine, Inje University, Koyang, Gyeonggido, Republic of Korea.

Olfactory marker protein (OMP) is a marker of olfactory receptor-mediated chemoreception, even outside the olfactory system. Here, we report that OMP expression in the pituitary gland plays a role in basal and thyrotropin-releasing hormone (TRH)-induced prolactin (PRL) production and secretion. We found that OMP was expressed in human and rodent pituitary glands, especially in PRL-secreting lactotrophs. OMP knockdown in GH4 rat pituitary cells increased PRL production and secretion via extracellular signal-regulated kinase (ERK)1/2 signaling. Real-time PCR analysis and the Ca^{2+} influx assay revealed that OMP was critical for TRH-induced PRL secretion. OMP-knockout mice showed lower fertility than control mice, which was associated with increased basal PRL production via activation of ERK1/2 signaling and reduced TRH-induced PRL secretion. However, both *in vitro* and *in vivo* results indicated that OMP was only required for hormone production and secretion because ERK1/2 activation failed to stimulate cell proliferation. Additionally, patients with prolactinoma lacked OMP expression in tumor tissues with hyperactivated ERK1/2 signaling. These findings indicated that OMP plays a role in PRL production and secretion in lactotrophs through the modulation of Ca^{2+} and TRH signaling.

Filamin A (FLNA) phosphorylation inhibits SSTR2 signal transduction in GH-secreting pituitary tumor cells

Erika Peverelli, Rosa Catalano, Elena Giardino, Federica Mangili, Donatella Treppiedi, Maura Arosio, Anna Spada & Giovanna Mantovani
Endocrinology Unit, Fondazione IRCCS Ca' Granda Ospedale Maggiore Policlinico; Department of Clinical Sciences and Community Health, University of Milan, Milan, Italy.

Despite the increasing evidence on the relevance of the actin binding protein filamin A (FLNA) in determining an efficient intracellular response to somatostatin analogs (SSA) in pituitary tumors, there is a gap in the knowledge on the mechanisms regulating FLNA itself. FLNA is phosphorylated by PKA on Ser^{2152} located in a FLNA region crucial for SST2 or partner proteins binding. Although cAMP/PKA pathway plays a crucial role in GH-secreting tumors pathogenesis, the biological relevance of FLNA phosphorylation is unknown. Aim of this study is to investigate in rat and human GH-secreting pituitary tumor cells ($N=3$) the impact of cAMP pathway activation and SSA stimulation on FLNA phosphorylation and the consequences on SST2 function. We found a PKA-mediated increase (about 2-fold) and SST2 agonist-induced decrease (-50%) of FLNA Ser^{2152} phosphorylation (P-FLNA) in GH3, GH4C1 and primary somatotroph tumor cells. By transfecting phosphomimetic (S2152D) and phosphodeficient (S2152A) FLNA mutants in GH3 cells, we found that S2152D FLNA abolished the antiproliferative effects exerted by BIM23120 in wild type or S2152A FLNA transfected cells ($-32\pm13\%$ and $-21\pm3\%$, respectively, $P<0.05$ vs basal). Moreover, BIM23120 increased caspase activity in wild-type and S2152A FLNA transfected cells ($+39\pm13\%+28\pm9\%$, respectively, $P<0.05$ vs basal), but not in S2152D FLNA transfected cells, suggesting a negative effect of FLNA phosphorylation on SST2 signal transduction. Co-immunoprecipitation and immunofluorescence analysis revealed that S2152D FLNA is able to bind SST2 on the plasma membrane both in basal conditions and after SST2 activation, whereas wild-type and S2152A FLNA are recruited to SST2 after 5 min of agonist stimulation. We can hypothesize that FLNA phosphorylation impair the ability of FLNA to bind proteins involved in SST2 signaling without affecting, or even increasing, its ability to bind SST2. In conclusion, our data suggest that cAMP pathway activation abolishes the ability of FLNA to function as scaffold for SST2 signal transduction by increasing FLNA phosphorylation, whereas SST2 activation induces FLNA dephosphorylation in a positive auto-regulatory loop. Since SST2 functions are regulated by FLNA, modulation of P-FLNA might suggest new pharmacological strategies for SSA resistant pituitary tumors as well as a new biomarker for tumor responsiveness to SSA.

Aim

To assess whether E-cadherin expression levels in somatotropinomas were associated with the response to somatostatin analogues (SSAs) therapy in patients with acromegaly.

Methods
In this retrospective study, 56 acromegaly patients that underwent transsphenoidal surgery were evaluated. All patients were treated preoperatively with SSAs (octreotide or lanreotide) for at least 6 months. Responsiveness to SSAs was evaluated by percent IGF-1 reduction after 3 and 6 months of treatment. Quantitative PCR was used to measure the expression of somatostatin receptors (SSTR1-SSTR5) and dopamine receptors (DRD1-DRD5). The expression of E-cadherin was evaluated by immunohistochemistry. Clinical and pathological variables were collected to evaluate potential associations between these variables and E-cadherin expression.
Results
28 of the somatotropinomas examined were found negative for E-cadherin. The remaining adenomas displayed moderate (10) or strong (18) immunoreactivity for E-cadherin and were analyzed as one single group. No statistically significant differences were observed between E-cadherin negative and positive adenomas regarding age, tumor invasion and GH and IGF1 levels at diagnosis. E-cadherin negative somatotropinomas were larger and more prevalent in women than in men. Almost all E-cadherin negative somatotropinomas were sparsely granulated adenomas. The IGF-1 per cent reduction after 3 and 6 months of SSAs treatment was significantly in E-cadherin negative adenomas compared with moderate/high E-cadherin adenomas. At 3 months of treatment, the median IGF-1 per cent reduction for adenomas negative for E-cadherin was 4.1 and 44.2 for adenomas positive por E-cadherin. At 6 months of treatment, the median IGF-1 per cent reduction for adenomas negative for E-cadherin was 8.9 and 49.8 for adenomas positive for E-cadherin. E-cadherin negative adenomas displayed lower SSTR1 and DRD4 expression levels.
Conclusions
In our series, a poor response to treatment with SSAs in patients with acromegaly is associated with absence of E-cadherin accumulation in somatotropinomas.

Efficacy of pharmacological USP8 inhibition in human Cushing's disease tumours *in vitro*

Marily Theodoropoulou[1], Luis Perez-Rivas[1], Adriana Albani[1,2], Günter Stalla[3], Michael Buchfelder[4], Joerg Flitsch[5], Juergen Honegger[6], Walter Rachinger[7] & Martin Reincke[1]
[1]Medizinische Klinik und Poliklinik IV, Ludwig Maximilians University Munich, Munich, Germany; [2]Department of Clinical and Experimental Medicine, University of Messina, Messina, Italy; [3]Clinical Neuroendocrinology, Max Planck Institute of Psychiatry, Munich, Germany; [4]Neurochirurgische Klinik, Klinikum der Universitat Erlangen, Erlangen, Germany; [5]Klinik für Neurochirurgie, Universitätskrankenhaus Hamburg-Eppendorf, Hamburg, Germany; [6]Department of Neurosurgery, Eberhard Karls University Tubingen, Tubingen, Germany; [7]Neurochirurgischen Klinik und Poliklinik, Klinikum der Universität München, Munich, Germany.

The tumorigenesis of Cushing's disease is characterized by somatic mutations in the USP8 gene in almost half of the cases. USP8 encodes for ubiquitin specific protease 8, a deubiquitinase that rescues proteins involved in the regulation of ACTH synthesis in corticotroph cells. In the present study we tested the antisecretory and antiproliferative efficacy of a commercially available specific USP8 inhibitor (IC50 3.1 μM USP8; >90 μM USP7) in immortalized murine corticotroph tumour AtT-20 cells and human corticotroph tumours in primary cell culture ($n=11$). The USP8 inhibitor decreased POMC transcription and promoter activity and ACTH secretion in a dose response manner starting from 10 nM (% suppression at 1 μM 58±2, 53±12 and 59±7 respectively). Knocking down USP8 abolished the inhibitory effect on POMC promoter activity, confirming the specificity of the targeted treatment. Treatment of the human corticotroph tumours *in vitro* decreased ACTH secretion beyond the arbitrarily set cut-off of 20%in all cases at 1.5–3 μM concentration (% suppression 33±15 and 44±17 respectively), 9 out of 11 cases at the 1 μM (% 34±15) and 7 out of 11 at the 0.1 μM (% 24±16). No toxicity was observed in any of these concentrations. In AtT-20 cells the USP8 inhibitor (1 μM) decreased cell number (% suppression 35%±1) without affecting cell volume and without cytotoxicity. The treatment decreased cell viability at 1 μM (but not at lower concentrations; % suppression 30±3). No changes in the apoptosis markers PARP and cleaved caspase 3 were observed under these conditions. All human corticotroph tumours responded to 3 μM by decreasing cell viability (% suppression 46±18) and 6 out of 11 to 1 μM treatment (% 30±24). Co-treatment with EGF, an ACTH secretagogue whose receptor is the best characterized target of USP8, in EGFR-overexpressing AtT-20 cells shifted the antiproliferative and antisecretory response to the USP8 inhibitor (% suppression 36±3 vs 27±2 and 64±6 vs 57±7 at 1 μM respectively), indicating that in part the effect of USP8 inhibition is mediated via its inhibitory crosstalk with the EGFR signalling. Altogether these data show that pharmacological USP8 inhibition can effectively suppress ACTH synthesis *in vitro* without accompanying cytotoxicity and indicate its potential for the management of ACTH hypersecretion in Cushing's disease.

Ubiquitin specific peptidase 8 (USP8) in human corticotroph pituitary tumors- possible targets and mode of action

Isabel Weigand[1], Lisanne Knobloch[1], Jens T Vanselow[2], Jörg Flitsch[3], Camelia Maria Monoranu[4], Wolfgang Saeger[5], Christian Hagel[5], Sabine Herterich[6], Cristina L Ronchi[1,7], Andreas Schosser[2], Martin Fassnacht[1], Timo Deutschbein[1] & Silviu Sbiera[1]
[1]Division of Endocrinology and Diabetes, University Hospital, University of Wuerzburg, Wuerzburg, Germany; [2]Rudolf Virchow Center for Experimental Biomedicine, University of Wuerzburg, Wuerzburg, Germany; [3]Neurosurgery, University Hospital of Hamburg-Eppendorf, Hamburg, Germany; [4]Institute of Pathology, University of Wuerzburg, Wuerzburg, Germany; [5]Institute of Neuropathology, University Hospital Hamburg-Eppendorf, Hamburg, Germany; [6]Central Laboratory, University Hospital, University of Wuerzburg, Wuerzburg, Germany; [7]Institute of Metabolism and Systems Research, University of Birmingham, Birmingham, UK.

Recently, somatic, heterozygous mutations in the gene encoding the deubiquitinase USP8 have been identified in 30–60% of corticotroph tumors. These mutations were found to hinder binding of 14-3-3 proteins, increasing its deubiquitinating activity. One substrate is Epidermal Growth Factor Receptor (EGFR), USP8 triggers EGFR recycling and increased EGFR signaling. However, tumors harboring mutations in USP8 are smaller than WT tumors, raising the debate if EGFR, as a potent growth factor, is the only substrate of USP8 in these tumors. We aimed to identify putative USP8 targets that might explain the tumorigenesis and increased ACTH secretion of these cells. We performed a literature search to identify putative USP8 targets, revealing several proteins with deregulated expression associated with corticotroph tumors that might be the result of increased USP8 deubiquitination (e.g. the transcription factors TR4 and CREB). Candidates were analyzed by IHC for their expression levels on FFPE tissue (pituitary tumors: corticotrophs ($n=85$), functionally inactive ($n=19$), somatotrophs ($n=12$) and normal pituitary glands ($n=5$)). We further metabolically labeled, transiently transfected the murine corticotroph cell line AtT-20 with USP8 WT or mutant plasmids and performed Tandem-Ubiquitin-Binding-Entity (TUBE)-assays, followed by nanoLC-MS/MS analysis to identify changes in poly-ubiquitinated protein abundance. Of the 10 proteins analyzed by IHC, 3 had an altered expression pattern between USP8 WT and mutated tumors, namely $p27/^{kip1}$ (mean expression: 1±0.7 vs 0.4±0.6 ($P=0.003$)), AVPR1b (mean expression: 0.8±0.6 vs 0.3±0.4 ($P=0.0045$)), phospho-CREB (mean expression: 0.7±0.7 vs 1.3±0.9 ($P=0.0165$)). TUBE assays revealed an increased de-ubiquitination of Small Ubiquitin-Like Modifier 3 (SUMO3) in $USP8^{mut}$ transfected cells, suggesting co-occurrence of another post-translational protein modification. In conclusion, these results suggest a much more complicated mechanism of action of the identified mutations in USP8, with sumoylation adding another dimension to the regulation of a USP8 mediated equilibrium between degradation and recycling.

Pituitary adenomas (PA), as well as pheochromocytomas and paragangliomas, are neuroendocrine tumors that arise from cells derived from the pituitary, adrenal and extra-adrenal nervous system, respectively. Recent studies have identified a growing series of susceptibility genes for these pathologies. Some genes may be associated with the development of both types of pathologies, as it is the case for succinate dehydrogenase complex genes, while, PAs have not been reported to date in patients harboring the most recently discovered pheochromocytomas and paraganglioma susceptibility genes, such as MAX, the MYC-associated factor X gene. Interestingly *MAX* is able to form heterodimers with MYC, an oncogene implicated in cell proliferation and apoptosis, which has been recently identified as a biomarker of aggressiveness in non-functioning Pas (NFPAs). Thus, to explore if *MAX* and/or *MEG3* (an imprinted gene located close to MAX, which arose as a marker of uniparental disomy in *MAX*-mutated patients) are associated with pituitary tumorigenesis, we analyzed *MAX* genomic sequence [by denaturing high-performance liquid chromatography (dHPLC)] in a cohort of 141 PA samples [71 NFPAs, 40 somatotropinomas, 19 corticotropinomas, 10 prolactinomas and 1 gonadotropinoma], together with the analysis of MAX and MEG3 expression (by qPCR) and/or methylation status (using bisulfite modification and methylation specific PCR). These analyses revealed that *MAX* and *MEG3* were substantially expressed in the different types of PA, wherein they displayed a tumor type-specific expression pattern: expression levels were significantly higher in somatotropinomas compared with NFPAs. Specifically, detectable MAX and MEG3 expression levels was present in 100% and 97% of somatotropinomas, 93% and 81% of NFPAs, 90% of corticotropinomas, and in 60% and 100% of prolactinomas, respectively and both were expressed in the gonadotropinoma. Interestingly, *MAX* and *MEG3* expression levels were directly correlated in this cohort of PAs, an observation that also tended to arise independently in somatotropinomas and NFPAs ($p=0.07$ and 0.08, respectively). Remarkably, none of the PA samples presented *MAX* mutations in dHPLC and sequencing analyses, nor displayed significant alterations in the methylation status of the CpG sites of *MAX* and *MEG3* genes examined. Altogether, our results show that mutations in *MAX* gene do not seem to play a relevant role in pituitary tumorigenesis in this cohort of patients. However, *MAX* and *MEG3* are significantly expressed, suggesting that the study of their functional role in pituitary pathophysiology could represent an interesting avenue for the identification of novel biomarkers and/or therapeutic targets in these pathologies.

Non-functioning pituitary adenomas (NFPAs) represent the most common type of pituitary adenomas. NFPAs are mostly macroadenomas (>1 cm) at diagnosis and, despite their lack of functional hormone hypersecretion, are associated to severe comorbidities related to mass effect (i.e. headaches, visual defects and hypopituitarism). Transsphenoidal surgery is the mainstay of NFPAs treatment, although it is often not definitive, mainly due to the invasion of neighboring intracranial structures precluding complete resection. Unfortunately, there are no medical treatments currently approved or recommended to manage NFPAs. Indeed, somatostatin analogs (SSAs), commonly used to treat functioning pituitary adenomas, have been largely ineffective in NFPAs, which might be explained by the limited expression of the main targets for these SSAs, i.e. somatostatin-receptor subtypes 2 (sst2) and 5 (sst5). However, since it has been previously demonstrated that NFPAs present a predominant expression of sst3, the main objectives of this study were: 1) to perform a comprehensive characterization of the expression pattern of sst3 in NFPA and normal-pituitary (NP) tissues (by qPCR and IHC); and, 2) to determine the functional role of sst3 in NFPA by analyzing different functional endpoints (i.e. cell-viability, apoptosis, chromogranin-A secretion, mRNA expression and intracellular signaling pathways) in primary NFPA cell-cultures in response to selective sst3 agonists and antagonists. Our results demonstrate that sst3 is the most abundantly expressed sst-subtype in NFPAs ($n=71$), being also significantly overexpressed in NFPAs compared to NPs ($n=12$) and functioning pituitary adenomas like GHomas ($n=63$) and ACTHomas ($n=17$). Treatment with sst3-agonists reduced cell viability and chromogranin-A secretion, while increasing apoptotic rate in primary NFPA cell-cultures. These inhibitory effects of sst3-agonists were completely reversed by specific sst3-antagonists, confirming the specificity of the effects observed. Interestingly, our data revealed the existence of two distinct subgroups of NFPAs that responded differentially (responsive vs. unresponsive) to treatment with sst3-agonists in terms of reduction in cell viability, being sst3 expression levels higher in responsive NFPAs. Further analysis revealed that the effects of sst3-agonists might be mediated by the inhibition of MAPK-pathways, as suggested by reduced phosphorylation levels of ERK1/2 and JNK. Altogether, our study provides novel data strongly supporting that sst3 plays a relevant functional role in the pathophysiology of NFPAs, and suggests that pharmacological treatments targeting this receptor could be a promising therapeutic alternative for these tumors.

Epigenetic and post-transcriptional regulation of the *SSTR5* gene in somatotropinomas

The somatostatin receptor 5 (sst5) and its truncated splicing variants (sst5TMD5, sst5TMD4) are considered putative biomarkers that can predict pharmacological response or aggressiveness in several endocrine-related pathologies, such as acromegaly. sst5 is encoded by a gene, *SSTR5*, that lacks introns within its coding sequence, and hence, the splicing variants identified are generated by non-

canonical splicing events. However, the mechanisms underlying their genesis and regulation are still to be fully elucidated. Recent analyses of *SSTR5* gene structure revealed the existence of a natural antisense transcript, named *SSTR5-AS1*, which overlaps with *SSTR5* and encodes an intergenic long non-coding RNA that may be involved in the regulation of *SSTR5* expression and processing. Likewise, recent studies indicate that DNA methylation within genic regions could influence exon inclusion and alternative splicing. Accordingly, in this study we have implemented pilot *in silico* analyses of the human *SSTR5* and *SSTR5-AS1* genes to explore the existence of CpG islands (high density CG regions susceptible to be methylated), located at their promoters, and, most interestingly, within their coding regions. Our ultimate goal was to ascertain if these processes could contribute to the regulation of the expression of *SSTR5* and the generation of its variants in somatotropinomas. Firstly, we measured the mRNA levels of sst5, sst5TMD4 and sst5TMD5 variants and the SSTR5-AS1 by qPCR in a cohort of 11 normal pituitary (NPs) and 27 somatotropinoma samples. In addition, we studied the methylation status in four CpG areas of *SSTR5* and *SSTR5-AS1* genes. Our results revealed that somatotropinomas expressed significantly more sst5 than NPs, whereas no significant differences were found in the expression of the antisense transcript. In addition, expression of sst5TMD4 and sst5TMD5 variants was numerically, although not significantly increased in this pilot cohort of patients. Methylation analysis revealed that CpG sites were differentially methylated on *SSTR5* and *SSTR5-AS1* genes in acromegaly compared with NPs, which might explain the differential expression of sst5. Interestingly, mRNA levels of *SSTR5* showed a direct correlation with *SSTR5-AS1* expression, but not with those of the sst5 splicing variants, both in acromegaly and NP samples, which could suggest that the antisense may regulate the expression of the full-length *sst5*, without affecting its splicing variants. Summarizing, results from this work supports the notion that epigenetic and post-transcriptional events might contribute to regulate the expression of *SSTR5* in acromegaly, while their precise involvement in *SSTR5* splicing dysregulation remain to be determined.

Endoscopic vs microscopic transsphenoidal surgery for Cushing's disease: a systematic review and meta-analysis

Leonie H A Broersen[1,2], Nienke R Biermasz[1,2], Wouter R van Furth[2,3], Friso de Vries[1,2], Marco J T Verstegen[2,3], Olaf M Dekkers[1,4] & Alberto M Pereira[1,2]
[1]Department of Medicine, Division of Endocrinology, Leiden University Medical Centre, Leiden, The Netherlands; [2]Center for Endocrine Tumors Leiden (CETL), Leiden University Medical Center, Leiden, The Netherlands; [3]Department of Neurosurgery, Leiden University Medical Centre, Leiden, The Netherlands; [4]Department of Clinical Epidemiology, Leiden University Medical Center, Leiden, The Netherlands.

Background
Cushing's disease is caused by an adrenocorticotropic hormone (ACTH)-secreting pituitary adenoma, resulting in glucocorticoid excess. First-choice treatment is transsphenoidal pituitary surgery, using either a microscopic or endoscopic technique. Convincing evidence supporting the choice for one of both techniques, either based on treatment results or complication rate, is lacking.
Objective
We aimed to compare endoscopic and microscopic transsphenoidal surgery for Cushing's disease regarding surgical outcomes (remission, recurrence, and mortality) and complication rates, and to stratify the results by tumor size.
Methods
Nine electronic databases were searched in February 2017 to identify potentially relevant articles. Cohort studies assessing surgical outcomes or complication rates after endoscopic or microscopic transsphenoidal surgery for Cushing's disease were eligible. Pooled proportions were reported including 95% confidence intervals.
Results
We included 97 articles with a total of 6695 patients (5711 microscopically and 984 endoscopically operated). Overall, remission was achieved in 5177 patients (80%), with no clear difference between the two techniques. Recurrence was around 10% and short term mortality $<0.5\%$ for both techniques. Cerebrospinal fluid leak occurred more often in endoscopic surgery (12.9% vs 4.0%), whereas transient diabetes insipidus occurred less often (10.4% vs 18.5%). For microadenomas, results were comparable between both techniques. For macroadenomas, the percentage of patients in remission was higher after endoscopic surgery (76.3% vs 59.9%), and the percentage recurrence was lower after endoscopic surgery (1.5% vs 17.0%).
Conclusion
This meta-analysis shows that for patients with Cushing's disease endoscopic surgery reaches comparable results for microadenomas, and probably better results for macroadenomas than microscopic surgery. These results are obvious despite the presumed learning curve of the newer endoscopic technique, although confounding cannot be excluded. Based on this study, the endoscopic technique may be considered the current standard of care, microscopic neurosurgical pituitary centers should at least consider referring Cushing's disease patients with a macroadenoma.

Factors predicting comorbidities in cured patients with Cushing's syndrome

Marie Helene Schernthaner-Reiter[1], Christina Siess[1], Alois Gessl[1], Christian Scheuba[2], Stefan Wolfsberger[3], Philipp Riss[2], Engelbert Knosp[3], Anton Luger[1] & Greisa Vila[1]
[1]Clinical Division of Endocrinology and Metabolism, Department of Internal Medicine III, Medical University of Vienna, Vienna, Austria; [2]Department of Surgery, Medical University of Vienna, Vienna, Austria; [3]Department of Neurosurgery, Medical University of Vienna, Vienna, Austria.

Introduction
In patients with cured Cushing's syndrome, comorbidities often persist after remission of glucocorticoid excess. Here we investigate long-term comorbidities in patients with Cushing's syndrome in remission, and their relationship to metabolic and hormonal markers at the initial diagnosis of the disease.
Methods/design
We evaluated 118 patients with cured Cushing's syndrome (55 Cushing's disease, 55 adrenal Cushing's syndrome and 8 ectopic Cushing's syndrome) 10 years (range 2–29) after the last surgery. Anthropometric, metabolic, hormonal parameters and comorbidities (obesity, diabetes, hyperlipidaemia, hypertension, osteoporosis, depression) at the last follow-up visit were obtained; baseline data on parameters at diagnosis of Cushing's syndrome were extracted from hospital records. Uni- and multivariate regression analysis was performed for testing the relationship between baseline factors and long-term comorbidities.
Results
Inpatients with manifest comorbidities at diagnosis, Cushing's remission resolved diabetes in 54% of cases, hypertension in 34% of cases, hyperlipidaemia in 28% and depression in 48% of cases. Ten (range 2-29) years after the last surgery the prevalences of comorbidities in cured patients were: obesity 16%, diabetes 12%, hypertension 58%, hyperlipidaemia 62%, depression 16% and osteoporosis 21%. In a multivariate regression analysis, age, fasting glucose and depression at Cushing's diagnosis, were positive predictors of the number of long-term comorbidities, while baseline urinary free cortisol secretion negatively correlated with the persistence of comorbidities in the long-term. The negative relationship between baseline 24-h urinary cortisol secretion and long-term comorbidities was also found when pituitary and adrenal Cushing's cases were analysed separately.
Conclusions
Long-term comorbidities after remission of Cushing's syndrome depend not only on the presence of classical cardiovascular risk factors such as age and hyperglycaemia at diagnosis, but also on the amount of glucocorticoid excess. Lower baseline urinary cortisol levels are associated with more long-term comorbidities, possibly due to the delayed diagnosis in milder Cushing's syndrome leading to a longer exposure to excess glucocorticoids.

Introduction
The 12-month results of a multicentre, double-blind, Phase III study showing the efficacy and safety of a monthly, long-acting formulation of pasireotide in Cushing's disease (CD) patients have been reported previously (Lacroix *et al. Lancet Diabetes Endocrinol* 2018). The results of the extension phase of this study are reported here.
Methods
Patients ($n=150$) with persistent/recurrent or *de novo* CD and mean urinary free cortisol (mUFC) 1.5–5× the upper limit of normal (ULN) were randomized to monthly pasireotide 10mg ($n=74$) or 30 mg ($n=76$). Up-titration was permitted at month (M) 4, M7, M9, or M12. Patients could enter an optional, open-ended extension if they had mUFC≤ULN at M12 and/or experienced significant clinical benefit in the investigator's opinion. Investigators and patients were unblinded after the M12 analyses were completed. Data from both dose groups were pooled for this analysis.
Results
Of 104 patients who completed the core study, 81 entered the extension. Median (range) exposure for patients who entered the extension was 23.9 (12.0–55.3) months. Of patients who entered the extension and had a valid mUFC assessment at the given time point, a controlled response (mUFC≤ULN) occurred in 42/81 (51.9%; 95%CI: 40.5,63.1) patients at M12, 38/58 (65.5%; 95%CI: 51.9,77.5) patients at M24, and 13/18 (72.2%; 95%CI: 46.5,90.3) patients at M36. Median (range) change from baseline in mUFC was −51.9% (−98.7,422.3) at M12, −64.1% (−97.8,356.0) at M24, and −68.3% (−99.2,−12.7) at M36. A ≥20% tumour-volume reduction from baseline was seen in 25/38 (65.8%) patients at M24 and 9/14 (64.3%) patients at M36; 10/14 (71.4%) and 4/4 (100%) patients with a pituitary macroadenoma (maximum diameter ≥10 mm) at baseline had a ≥20% reduction at M24 and M36, respectively. Improvements in clinical signs, including systolic/diastolic blood pressure and weight, were seen at M24 and M36. The safety profile of pasireotide was consistent with previous experience, with no new safety signals detected during the extension. Median (range) change from baseline in HbA_{1c} was 0.9% (0.8,1.2) at M24 and 0.8% (−0.2,2.2) at M36. After the M12 data cut-off, grade 3 adverse events (hyperglycaemia, hypertension, hypoglycaemia) were reported in three more patients; no grade 4 adverse events were reported.
Conclusion
Long-term treatment with long-acting pasireotide provided sustained biochemical and clinical improvements and reduced tumour volume, with no new safety signals emerging. These data support the use of long-acting pasireotide as an effective long-term treatment for some patients with CD.

Introduction
Long-acting pasireotide reduced urinary free cortisol (UFC) in most patients with Cushing's disease (CD) during a large Phase III study (Lacroix *et al. Lancet Diabetes Endocrinol* 2018). The analyses presented here explored the impact of baseline characteristics on response to long-acting pasireotide.
Methods
150 patients with persistent, recurrent or *de novo* CD and mean UFC (mUFC; from three 24-hour samples collected over 2 weeks) of 1.5–5xULN were randomized to monthly pasireotide 10 mg/30 mg. Dose up-titration was permitted at month (M) 4, M7, M9, and/or M12. Primary endpoint: mUFC≤ULN at M7. As response rates were similar between dose groups, data were pooled for the current analyses.
Results
41.3% ($n=62/150$) of patients achieved mUFC≤ULN at M7 (responders). Of patients with mUFC≤ULN at M3, 73.3% ($n=33/45$) were responders at M7, compared with 27.6% ($n=29/105$) of those with mUFC>ULN at M3. Baseline mean [S.D.] mUFC was numerically lower in responders than in non-responders (424.1 [308.8] vs 502.3 [284.1] nmol/24 h; $P=0.11$). Other baseline mean (S.D.) values in responders and non-responders were, respectively: serum cortisol, 571.3 (184.5) and 575.1 (207.5) pmol/l; late-night salivary cortisol, 12.2 (13.7) and 9.3 (6.6) nmol/l; maximum tumour diameter, 9.9 (4.5) and 9.8 (6.8) mm. Higher response rates were seen in patients with lower baseline mUFC; response rates were similar in other subgroups analysed (Table).
Response rate by baseline characteristic
Conclusion
Lower baseline mUFC and early control of mUFC after initiation of long-acting pasireotide were associated with higher response rates at M7.

Clinicopathological correlations in pituitary thyrotroph tumors from a cohort of 23 patients

Oana-Maria Capraru[1], Alexandre Vasiljevic[2,3,4], Céline Gaillard[5], Françoise Borson-Chazot[3,6], Véronique Raverot[7], Emmanuel Jouanneau[3,4,8], Jacqueline Trouillas[2,3] & Gérald Raverot[3,4,6]

[1]University of Medicine and Pharmacy Târgu Mureş, Târgu Mureş, Romania; [2]Centre de Pathologie, Groupement Hospitalier Est, Hospices Civils de Lyon, Lyon, France; [3]Université de Lyon, Lyon1, Lyon, France; [4]INSERM U1052, CNRS UMR5286, Cancer Research Center of Lyon, Lyon, France; [5]Centre Hospitalier, Bourg en Bresse, Bourg en Bresse, France; [6]Fédération d'Endocrinologie, Centre de référence maladies rares hypophysaire HYPO, Groupement Hospitalier Est, Hospices Civils de Lyon, Lyon, France; [7]Laboratoire d'hormonologie, Centre de Biologie, Groupement Hospitalier Est, Hospices Civils de Lyon, Lyon, France; [8]Service de Neurochirurgie, Groupement Hospitalier Est, Hospices Civils de Lyon, Lyon, France.

The thyrotroph tumors or pituitary neuroendocrine tumors (PitNET) classify as tumors of Pit-1 family. These tumors are rare and may be monohormonal, secreting only TSH, or plurihormonal, secreting TSH-GH ± PRL, with or without acromegaly. The objectives of this retrospective study were to confirm the frequency of the plurihormonal subtype and to compare the clinical, biological and pathological characteristics of these two pathological subtypes. We retrospectively studied the medical records of 23 patients with thyrotroph tumors treated by transphenoidal surgery. Routine staining and immunohistochemistry with the following antibodies against the hormones (PRL, GH, ACTH, βFSH, βLH, βTSH, and α-subunit), the somatostatin receptors ($SSTR_{2A}$, $SSTR_5$), and the transcription factor Pit-1 were performed. The proliferative rate (mitoses and Ki-67 index) and the p53 expression were also studied. The pituitary tumors were classified taking into account the invasion and the proliferation. All the tumors, except one with clinical and biological hyperthyroidism, expressed TSH. Half were monohormonal ($n=11$) and out of the 12 plurihomornal ones, 6 were positive for both TSH and GH. Two tumors expressed TSH, PRL and GH and 4 were positive for TSH and PRL. Only 3 patients with GH co-expression presented clinical and biological signs of acromegaly. Three TSH monohormonal tumors are silent. The symptoms of hyperthyroidism and goiter were more frequent in the plurihormonal tumors than in the monohormonal ones probably due to GH effect on thyroid facilitating the goitre occurrence. Almost all the thyrotroph tumors expressed Pit-1 and $SSTR_{2A}$ with a high score (>5). Monohormonal and plurihormonal TSH-PRL tumors were characterized by polymorphous cells, a high expression of $SSTR_{2A}$, but no or low expression of $SSTR_5$. The plurihormonal TSH-GH ± PRL subtype ($n=8$) had a higher expression of both $SSTR_{2A}$ and $SSTR_5$ and 4 of them exhibited cytological features of the somatotroph type. Fibrosis and calcifications were frequent in both tumor types. We did not observe differences regarding the proliferative rates and the grading of the tumors. In conclusion, this study confirms that these tumors, belonging to the Pit-1 family, are frequently plurihormonal, secreting mainly TSH-GH, and express SSTRs. The first line therapy is the transsphenoidal surgery, but complementary treatment by somatostatin analogues may be proposed, according to the expression of SSTRs by the tumor.

Molecular profiling of non-functioning pituitary adenomas does not support pharmacological therapeutic options

Joan Gil[1], Alberto Blanco[2], Guillermo Serra[3], Isabel Salinas[2], Susan M Webb[4], Cristina Hostalot[2], Gabriel Obiols[5], Elena Valassi[4], Olga Roig[4], Gemma Sesmilo[6], Carles Villabona[7], Mireia Jordà[1] & Manel Puig-Domingo[1]
[1]Institut Germans Trias, Badalona, Spain; [2]Hospital Germans Tries, Badalona, Spain; [3]Hospital Son Espases, Palma de Mallorca, Spain; [4]Hospital de Sant Pau, Barcelona, Spain; [5]Hospital Vall d'Hebron, Barcelona, Spain; [6]Hospital Quirón Dexeus, Barcelona, Spain; [7]Hospital de Bellvitge, Hospitalet de Llobregat, Spain.

Non-functioning pituitary adenomas (NFPA) are the most common pituitary tumours. They usually come to medical attention because of a mass effect and/or hypopituitarism. Tumour shrinkage during therapy with either dopamine agonists (DA) or somatostatin analogues (SSA) has been previously reported in some cases; however, response of NFPA to medical treatment is still poor and unpredictable. Our aim was to explore the molecular mechanisms underlying this lack of efficacy through evaluation of genes involved in therapeutic response to SSA and DA. Expression of 13 genes was analyzed in 105 acromegaly samples (ACRO), 20 NFA and 14 control pituitaries (CP) from autopsies and organ donors. The genes (*SSTR2*, *SSTR5*, *DRD2* long and short isoforms, *AIP, CDH1, Ki67, ARRB1, GHRL, IN1-GHRL, KLK10*, *PLAGL1* and *PEBP1*) were measured by RT-qPCR using TaqMan technology and the levels were normalized by three reference genes (*MRPL19*, *TBP* and *PGK1*).

Results

DDR2, SSTR2 and *SSTR5* showed significantly and absolute lower expression levels in NFA compared to ACRO ($P<0.01$ for all comparisons) and CP ($P<0.01$ for all comparisons). Moreover, *SSTR5* levels were extremely low in NFPA, pointing to a potential absolute negative therapeutic response to the second generation SSA Pasireotide compared to first generation SSA. Unsupervised clustering showed that NFPA were extremely different from CP and ACRO tumours according to the expression of these markers. Tumour size in NFPA significantly correlated with *AIP* and *IN1-GHRL* (Pearson's $r=0.48$ and $P=0.03$, Pearson's $=0.47$ and $P=0.04$, respectively); and showed a trend to correlation with *ARRB1* and *PLAGL1* levels (Pearson's $r=0.42$ and $P=0.07$, Pearson's $=-0.45$ and $P=0.05$, respectively). Moreover, *ARRB1* was significantly overexpressed in tumours that did not achieve complete remission after surgery (fold change $=1.81$, $P=0.01$). In addition, *RKIP* and *KLK10* showed a positive correlation trend with extrasellar extension (fold change $=1.39$ and $P=0.07$, fold change $=3.74$ and $P=0.07$, respectively). These preliminary results suggest that some molecular markers may identify NFPA with a higher potential for growth and invasiveness, thus contributing to therapeutic decisions regarding reoperation or radiotherapy but do not support the use of targeted drug according to the studied molecular profiling.

The role of clomiphene citrate in the resolution of hypogonadism in male patients with prolactinomas under cabergoline therapy

Lucio Vilar, Clarice Vilar, Ruy Lyra, Ana Carolina Thé, Erik Trovao, Patricia Gadelha, Izabela Cardozo, Thaize Borges, Icaro Sampaio, Liana Ferreira & Luciano Albuquerque
Division of Endocrinology, Hospital das Clinicas, Federal University of Pernambuco, Recife, Brazil.

Background

Dopamine agonists (DA) are the treatment of choice of prolactinomas. Cabergoline is preferable to bromocriptine due to its greater effectiveness and better tolerabilitiy. However, up to 30–50% of male patients may persist with low levels of testosterone despite prolactin (PRL) normalization under DA therapy or the use of the maximum tolerated dose of DA. The aim of this prospective open study was to evaluate the efficacy of the SERM clomiphene citrate (CC) in these cases.

Subjects and methods

The aim of this prospective study was to evaluate the efficacy of CC in normalizing total testosterone (TT) in prolactinomas patients with persistent hypogonadotropic hypogonadism (HH) despite the use of CAB in weekly doses of up to 3 mg/week. TT, estradiol (E2), LH, FSH, and PRL were measured before and 4, 8, and 12 weeks after CC. Erectile function and hypogonadism symptoms were evaluated before and after CC. Persistent HH was defined by TT levels <300 ng/dl, along with either normal/low LH and FSH levels after at least 6 months of DA therapy. Response to CC was defined as TT levels ≥ 300 ng/dl.

Results

Eighteen patients (72%), 10 hyperprolactinemic and 8 normoprolactinemic, responded to clomiphene (TT ≥ 300 ng/dl). Their mean TT levels were 234.1 ± 36.6 ng/dl before CC and 390.1 ± 38.9 ng/dl 12 weeks later ($P<0.01$). Significant increases were also observed in FSH and LH concentrations ($P<0.01$). PRL levels remained unchanged and E2 did not significantly differ when baseline and 12 weeks levels were compared. Erectile function improved in all responsive patients.

Conclusion

Clomiphene restored normal testosterone levels in most male patients with prolactinomas and persistent hypogonadism under CAB therapy. Recovery of gonadal function by clomiphene was independent of PRL levels.

Cabergoline - therapy for 121 giant invasive prolactinomas

Liudmila Astafyeva, Boris Kadashev, Pavel Kalinin, Maxim Kutin, Dmitriy Fomichev, Oleg Sharipov, Irina Klochkova & Yuliya Sidneva
N.N. Burdenko National Medical Research Center of Neurosurgery, Russian Federation, Moscow, Russia.

Objective
Prospective study of cabergoline effect in newly diagnosed patients with giant invasive prolactinomas.
Patients and methods
The study group included 121 patients with giant prolactinomas (tumors larger than 40 mm in size); among them 49 patients had tumors larger than 60 mm in size. 91 male and 30 female aged 16–67 years (median 37) were treated with 0.5–3.5 mg/week (mean 1.5 mg) cabergoline. The treatment period was 6–120 months (median 18).
Results
Before treatment 117 (97%) patients had hypogonadism, 99 (82%) - visual impairments, 71 (59%) - headaches, 29 (24%) - epileptic syndrome. Serum prolactin level before treatment ranged between 12990 and 2210000 mU/l (median 198000; normal 30–545 mU/l). Decrease of prolactin occurred in 114 (94%) patients; prolactin level was normalized during treatment in 49% of cases; 98/121 (81%) patients had significant adenoma shrinkage; 77/99 (78%) patients with pre-treatment visual abnormalities had visual improvement, 67/71 (95%) - headache regression. In 17 patients cerebrospinal fluid (CSF) leakage occurred within 3–6 weeks, in 1 case - in 76 months after initiation of treatment. In 15 patients endoscopic endonasal surgery for fistula repair was performed; in two patients the CSF leakage ceased after diuretic therapy and temporarily cabergoline dosage decrease; 7 (6%) patients had rapid progression cabergoline-resistant tumors. They had surgery followed by stereotactic radiotherapy. PRL-secreting pituitary carcinomas with intra- and extracranial metastases were diagnosed in three cases; 5 (4%) patients showed tumor enlargement due to intratumoral hemorrhage.
Conclusion
Cabergoline should be the first-line therapy for giant invasive prolactinomas. Use of cabergoline results in effective reduction of prolactin, improvement of visual defects and provides tumor shrinkage. However, patients with giant prolactinomas are at a risk of CSF leakage and tumor enlargement during primary cabergoline treatment.

Endocrine disorders in adults after allogenic hematopoietic stem cell transplant

Delia Bogdanet[1], Naoimh Herlihy[2], Catriona Reddin[1], Patrick Hayden[2] & Marie-Louise Healy[2]
[1]Galway University Hospital, Galway, Ireland; [2]St. James's Hospital, Dublin, Ireland.

Background
Over the last 20 years there have been significant advances in stem cell transplantation (SCT) in adults for haematological malignancies leading to improved survival. Endocrine disorders are among the most common complications in survivors after hematopoietic allogeneic stem cell transplant (HSCT), but data on adult transplant patients are still scarce.
Methods
This is a retrospective study which included 284 adult patients (94 females and 190 males) who underwent allogeneic HSCT between 2002 and 2014 in a University Irish Hospital. All patients were preconditioned with chemotherapy and total body irradiation (TBI). One hundred and thirty four patients received allogeneic HSCT from unrelated donors. The functions of the hypothalamic-pituitary-gonadal/thyroid/adrenal/somatotroph axis were evaluated at time of last review.
Results
The mean age of the patients at diagnosis was 33.3 (s.d. $\pm$10.6) years old with a mean age at transplant of 35.2 (s.d. $\pm$10.3) years old. 11.3% of the patients tested ($n=44$) had low morning cortisol levels at 16 months post-transplant and 25% of the patients tested ($n=12$) had hyperprolactinemia at 6 months post-transplant. Insulin-like growth factor-1 was tested in only 13 patients with below the normal range value in one patient (7.6%) and above normal range values in 2 patients (15.2%). Beyond one-year post - transplant, 39% of the patients had abnormal thyroid function tests of which 15% ($n=10$) displayed biochemical features of central hypothyroidism. Out of 54 women tested, 8 (14.8%) displayed biochemical features of hypogonadotropic hypogonadism and 33 (61.1%) had hypergonadotropic hypogonadism. In males, out of 108 tested, 2 (1.8%) had hypogonadotropic hypogonadism and 67 (62%) had hypergonadotropic hypogonadism. Out of 104 patients tested, 21.1%had a raised sex hormone binding globulin (SHBG). Men were more likely than women to develop hypergonadotropic hypogonadism ($P<0.01$). Patients with normal LH and FSH were more likely to be older compared to patients with a raised LH and FSH (35.9 Vs 31.5 years old, $P<0.01$). SHBG was more likely to be raised in patients with raised LH and FSH ($P<0.01$). Oestradiol levels but not testosterone levels were more likely to be influenced by age ($P=0.01$ vs $P=0.1$).
Conclusion
These data suggest that adults undergoing HSCT are at a high risk of endocrine dysfunction. These patients require early endocrinology input and long-term surveillance for the detection and treatment of endocrine disorders.

A systematic review and meta-analysis of endocrine-related adverse events associated with immune checkpoint inhibitors

Jeroen de Filette, Corina Andreescu, Filip Cools, Bert Bravenboer & Brigitte Velkeniers
University Hospital Brussels, Brussels, Belgium.

Background
Monoclonal antibodies targeting CTLA-4 and PD-1/PD-L1 are promising for a wide range of advanced malignacies. These immune checkpoint inhibitors (ICI) provoke endocrine adverse events including hypopituitarism and primary thyroid disease.
Methods
PubMed was searched through August 22nd, 2017, for relevant articles on endocrinopathies and ICI, by two reviewers independently (J.d.F. and C.A.). The weighted incidence and odds-ratio were estimated for hypophysitis, primary thyroid disease, primary adrenal insufficiency and diabetes mellitus. Their management is discussed in a systematic review.
Results
One hundred and one clinical studies (retrospective, prospective and randomized trials) involving 19.922 patients were included. Patients treated with ipilimumab experienced hypophysitis in 5.6% (95% CI, 3.9–8.1) which was higher than PD-1 treated patients (nivolumab, 0.5%; 95% CI, 0.2–1.2; pembrolizumab, 1.1%; 95% CI, 0.5–2.6). Tremelimumab (anti-CTLA-4) was also less likely to induce hypophysitis (1.8%; 95% CI, 1.1–2.9). Patients on PD-1/PD-L1 inhibitors had a higher incidence of primary thyroid dysfunction – particularly hypothyroidism (nivolumab, 8.0%; 95% CI, 6.4–9.8; pembrolizumab, 8.7%; 95% CI, 7.9–9.6; PD-L1, 5.5%; 95% CI, 4.4–6.8; versus ipilimumab, 3.8%; 95% CI, 2.6–5.5). Combination therapy was associated with a higher incidence for both hypothyroidism (10.2–16.4%) and hypophysitis (8.7–10.5%). Diabetes mellitus and primary adrenal insufficiency, rare findings on monotherapy, were substantially more frequent on combined therapy.
Conclusion
Our systematic review and meta-analysis demonstrates a high incidence of endocrine adverse events provoked by single agent checkpoint blockade which is further reinforced by combined treatment.

Predictors of failure to respond to fluid restriction and furosemide efficacy prediction in patients presenting Syndrome of Inappropriate Antidiuretic while receiving parenteral nutrition. Prospective Multicenter Study

Emilia Gomez-Hoyos[1], Ana Ortola-Buigues[1], Alfonso Vidal Casariego[2], Yaiza Garcia Delgado[3], Maria Julia Oncon Breton[4], Angel Luis Abad González[5], Luis Miguel Luengo Perez[6], Pilar Matia Martin[7], Maria Jose Tapia Guerrero[8] & Daniel De Luis Roman[1]
[1]Clinico de Valladolid Hospital-Ien, Valladolid, Spain; [2]Leon Hospital, Leon, Spain; [3]Insular de Gran Canaria Hospital, Gran Canaria, Spain; [4]Lozano Blesa Hospital, Zaragoza, Spain; [5]General de Alicante Hospital, Alicante, Spain; [6]Badajoz Hospital, Badajoz, Spain; [7]Clinico San Carlos Hospital, Madrid, Spain; [8]Regional de Malaga Hospital, Malaga, Spain.

Introduction
Syndrome of Inappropriate Antidiuretic (SIAD) is the most frequent cause of hyponatremia in parenteral nutrition (PN) patients. Yet studies concerning SIAD therapy are lacking. Our objective was to describe SIAD treatment and determine pre-treatment predictors of failure to respond to fluid restriction (FR) and furosemide efficacy prediction in a group of patients with SIAD while receiving PN.
Methods
Prospective, non-interventional, multicenter study in 19 Spanish hospitals. Forty-seven patients with SIAD-induced hyponatremia while receiving PN were recruited. Hyponatraemia was defined as a Serum Na level (SNa) <135 mmol/l. A positive response to therapy was defined as reaching SNa >135 mmol/l (eunatremia) following 72 hours of treatment. Urine osmolality-UOsm- $>$ 500 mOsm/kg, a Furst formula (ratio Urine Sodium + Urine Potassium/SNa) >1, or a 24-hour urine volume <1500 ml were all considered predictors of a negative response to FR. A UOsm >350 mOsm/kg was considered a predictor of a positive response to furosemide. The therapy used for the treatment of hyponatremia in these patients was also collected.
Results
59.6% were men. The average age was 66.9 (S.D. 11,5). All patients had diagnostic criteria for the diagnosis of SIAD. 20/47 received treatment: (80% FR, 10% FR and furosemide, 10% tolvaptan). No patient achieved FR to $\leq$ 1 liter/24 h. 26/47 (55.3%) patients had UOsm >500 mOsm/kg, 16/44 (36.4%) had a Furst formula>1 and 8/36 (22.2%) had a urinary volume <1500 ml/24 h. Thus, 68.1% had at least one criterion predicting a lack of response to FR. 69.6% had UOsm >350 mOsm/kg, and would be candidates for furosemide therapy. The percentage of patients achieving eunatraemia following 72 hours was: 40% with FR, 100% with furosemide, 100% with tolvaptan.
Conclusions
In parenteral nutrition patients with SIAD, fluid restriction is by definition difficult to achieve, and could compromise nutritional treatment. Furthermore, it is ineffective, with more than two-thirds of patients presenting predictors of non-response. Yet fluid restriction was the therapy most frequently used to treat SIAD-induced hyponatremia in this series of patients. Furosemide and tolvaptan should be considered first-line therapy for the treatment of SIAD in patients receiving parenteral nutrition.

Sperm DNA fragmentation index as a promising predictive tool for male infertility diagnosis and treatment management

Daniele Santi, Giorgia Spaggiari & Manuela Simoni
[1]Department of Biomedical, Metabolic and Neural Sciences, University of Modena and Reggio Emilia, Modena, Italy; [2]Unit of Endocrinology, Department of Medicine, Endocrinology, Metabolism and Geriatrics, Azienda Ospedaliero-Universitaria of Modena, Modena, Italy.

Background
Conventional parameters evaluated in semen analysis show several limits in the diagnostic setting of male infertility and do not provide any useful prognostic tool for assisted reproductive technique (ART). On the contrary, the assessment of sperm DNA fragmentation (sDF) was proposed to discriminate fertile from infertile men and to predict the follicle stimulating hormone (FSH) treatment response in infertile men. However, a comprehensive evaluation thereof is not available so far.
Purpose
This meta-analysis was designed to assess the sDF power in the diagnosis of male infertility and, in addition, to assess the sDF role in predicting FSH therapy response in infertile men.
Methods
Two literature searches were conducted. Firstly, both interventional and observational clinical trials comparing fertile to infertile/subfertile men were included. Secondly, interventional/observational clinical trials evaluating FSH-treated infertile men were assessed.
Results
Twenty-eight studies were included in the first analysis. sDF levels resulted significantly higher in infertile men ($P<0.001$), independently from the sDF method applied. ROC curves identified a sDF threshold of 20%, with a sensitivity of 79% and a specificity of 86%. Six studies were included in the second analysis, showing a significant sDF improvement ($P=0.04$) of 4.24% (C.I.: 0.23–826%) after 3 months of therapy. This sDF improvement was in line with the sperm number improvement ($P<0.001$), suggesting a similar efficacy in this setting.
Conclusion
This meta-analysis demonstrates the sDF relevance in male infertility assessment, showing a higher accuracy in detecting sperm function than conventional semen parameters. Although larger and properly designed prospective trials are needed before sDF may be adopted as an established diagnostic and prognostic test in male infertility, for the time it represents the most promising tool in clinical and research practice.

Alleviation of perfluorooctanesulfonate (PFOS)-induced disruption of blood-testis barrier by altering cell signaling molecule expression in human sertoli cells.

H Chen, CY Cheng & WM Lee
University of Hong Kong, Hong Kong, Hong Kong.

Perfluorooctanesulfonate (PFOS) and its related product perfluorooctanic acid (PFOA) are anthropogenic fluorosurfactants widely used in consumer products. In general, studies in rodents have supported the conception that PFOS perturbs testis function, such as by inducing Sertoli cell injury. It remains to be demonstrated if similar effects could be reproduced in humans. We sought to examine its effects on human spermatogenesis by using a human Sertoli cell primary culture system. Human Sertoli cells were cultured in chemically defined medium in the presence of 10% fetal bovine serum so that these cells remained mitotically active and could be re-used after multiple passes. They were used for *in vitro* cell junction formation studies and for the overexpression of cDNA constructs to identify the molecular mechanism that mediated toxicant- induced Sertoli cell injury. We also sought to examine possible FAK-mediated rescue function which could protect human Sertoli cell against PFOS-induced cell injury. Transfection of the human Sertoli cells for overexpression of target genes such as FAK and its mutants were performed. PFOS was found to induce human Sertoli cell injury through its disruptive effects on the actin microfilaments and microtubule (MT) organization across the Sertoli cell cytosol, making these cytokeletons failed to support cell adhesion at the Sertoli cell-cell interface that constituted the blood-testis barrier. However, an overexpression of a FAK phosphomimetic mutant p-FAK-Y407E (constitutively active) by converting amino acid residue Tyr-407 to Glu-407 was able to rescue the PFOS-induced Sertoli cell injury through proper organization of actin microfilaments and MTs across the Sertoli cell cytosol. Alternatively, since we have shown that the Sertoli cell BTB function is mediated by mTORC1 complex through rpS6, involving Akt1/2 (a family of serine/threonine kinase) downstream in a more recent study in rodents, overexpression of a constitutive active phosphor-mimetic mutant of p-Akt1-T308 (such as p-Akt1-T308E, by mutating Thr(T)-308 to Glu(E)-308) was also conducted. In short, PFOS is a toxicant which could induce Sertoli cell injury in humans, similar to its toxic effects in rodents. The PFOS-induced Sertoli cell adhesion function through changes in the organization of actin and MT

cytoskeletons could be rescued by overexpression of phosphorylated signaling molecules.

Sertoli cell-specific knockout of coxsackie and adenovirus receptor (Cxadr) disrupts the blood-testis barrier and causes impaired fertility

Kun Huang & Wing-Yee Lui
The University of Hong Kong, Hong Kong, Hong Kong.

Coxsackievirus and adenovirus receptor (CXADR) is localized at the blood-testis barrier (BTB) and at the interface between Sertoli cells (SC) and germ cells (GC). Earlier studies indicated that CXADR plays role in BTB function and germ cell migration. However, conventional knockout of CXADR leads to embryonic lethality, making the study of CXADR in the testis impossible. We aim to generate SC-specific CXADR knockout (KO) mice to evaluate the SC-specific function of CXADR on spermatogenesis in vivo. RNA sequencing and bioinformatics analyses were employed to identify and unravel the regulatory mechanisms that may involve in reproductive impairment. The SC-specific deletion of CXADR under the control of *Amh* promoter was confirmed by PCR and immunohistochemistry. Adult SC-$Cxadr^{-/-}$ mice exhibited significant reductions in fertility efficacy (>40% reduction) and testes/body weight ratio due to GC loss. Compromised BTB function coupled with down-regulation or mislocalization of the BTB components including occludin/ZO-1 complex and β-catenin have been observed in SC-$Cxadr^{-/-}$ testes. Transcriptomic and proteomic analyses of SC-$Cxadr^{-/-}$ testes revealed that the enriched gene ontology (GO) terms are highly related to male reproduction. Rap1/Wnt/Hippo signaling network and its core mediators such as β-catenin and Cdc42 were predicted in pertinent to fertility impairment in SC-$Cxadr^{-/-}$ testes via genome-wide data analyses. Besides, Wnt/Hippo targets including *Wnt5a*, *Wnt6*, *Wnt9a, Myc* and *Snai2* were also significantly altered in SC-$Cxadr^{-/-}$ testes. Activation of β-catenin and inhibition of Cdc42 with disorganized F-actin at the apical ES were observed in SC-$Cxadr^{-/-}$ testis and cultured $Cxadr^{-/-}$ SCs ($Cxadr^{-/-}$ MSC-1 cells). Overexpression of constitutively active Cdc42 in $Cxadr^{-/-}$ MSC-1 cells could partially recover the CXADR-mediated inhibition of non-phosphorylated β-catenin and F-actin filaments. Apparently, apart from being a structural protein at the BTB, CXADR functions as a crucial signaling mediator to trigger the downstream effects on junction disruption and actin reorganization via non-phosphorylation of β-catenin and Cdc42 inhibition. Taken together, CXADR in SCs affects the BTB function and F-actin organization via crosstalk of CXADR/β-catenin/Cdc42. SC-CXADR plays an indispensable role in spermatogenesis.

The first Belgian series of 56 patients with congenital hypogonadotropic hypogonadism (CHH): genetic and brain abnormalities

Hernan Valdes-Socin[1], Cécile Libioulle[1], Julie Harvengt[1], Axelle Pintiaux[2], Christelle Jonas[1], Anne Simone Parent[1], Vincent Geenen[1], Vincianne Corman[1], François Guillaume Debray[1], Vincianne Dideberg[1], Guy T'Sjoen[3], Anne De Leerner[2], Dominique Beckers[4], Anne Destree[5], Dominique Roland[4], Damien Lederer[6], Marina Boscolo[2], Vincent Bours[1], Dominique Maiter[7] & Albert Beckers[1]
[1]Centre Hospitalier Universitaire de Liège, Liège, Belgium; [2]Centre Hospitalier Universitaire Erasme, Bruxelles, Belgium; [3]Universiteit Gent, Gent, Belgium; [4]Université Catholique de Louvain, Louvain, Belgium; [5]Centre Hospitalier Saint Joseph, Liège, Belgium; [6]UZ Brussel, Bruxelles, Belgium; [7]Cliniques Universitaires Saint Luc, Bruxelles, Belgium.

Introduction
CHH is a genetic syndrome that combines reproductive and brain abnormalities. The brain phenotype has been incompletely characterized. We aimed to study neuroradiological and genetic features in this first Belgian series of patients with CHH.

Methods
A series of 56 adult patients (48 males, 8 females) presenting with CHH was investigated for a panel of 16 genes related to hypogonadotropic hypogonadism by next generation sequencing on a MiSeq® Instrument (Illumina) and by using a validated targeted approach with xGen® Lockdown® Probes (IDT). We then reviewed cerebral or hypothalamic-pituitary abnormalities in 32 patients using magnetic resonance imaging (MRI).
Results
Among the 56 patients, we found, up to now, some 26 genetic variants including FGFR1, GnRHR, CDH7, TAC3, WDR11, HS6ST1, PROKR2 and KISSR genes. In this series, five new variants (class3 to 5) were present in the following genes: TAC3 gene (c.238+1 G>A, class 5), FGFR1 gene (c.169C>A, p.Leu57Met, class 3), CDH7 gene (c.7212_7214del,p.Arg2405del, class 3), KISS1R (c.502G>A, p.Val168Ile, class 3) and a deletion of KISSR. A total of 21 patients presented a normal brain MRI, whereas 11 other patients presented structural abnormalities: a Chiari type 1 malformation (CM1) ($n=3$), an anterior pituitary hypoplasia ($n=3$), a Rathke's pouch cyst ($n=1$), a septo-optic dysplasia ($n=2$), an hydrocephalus ($n=1$) and an aracnoidal cyst ($n=1$). Among the group of abnormal MRI, only one patient with CM1 presented a new pathogenic variant in *FGFR1* gene (c.1025T>A; pLeu342*). Among the 21 patients with normal MRI, seven patients were heterozygous for one pathogenic variant.
Discussion
In our cohort, CM1 was found in three of the 32 patients (9.3%) who performed a brain MRI. In the general population, incidence of CM1 is estimated at 0,7%. CM1 and CHH have not been previously reported, although CM1 and cerebellar herniation were seen in GHD or in multiple hormone deficiency patients. We found a new *FGFR1* mutation for one of our patients with CM1. Common variants in genes involved in somitogenesis and fetal vascular development may confer a susceptibility for CM1: the contribution of FGFR1 to these defects deserve more investigations.
Conclusion
In this large Belgian series of CHH patients, we describe, for the first time, five new pathogenic variants. Moreover, we suggest a new syndromic association between CHH and CM1. Multicenter studies and systematic brain MRI may be required to extend the phenotype and the genotype of CHH patients.

Bioassay-based characterization of novel androgens

Alison Heather[1], Elliot Cooper[1] & Adam Cawley[2]
[1]University of Otago, Dunedin, New Zealand; [2]Australian Racing Forensic Laboratory, Sydney, Australia.

Chemical-analytical methods are currently in use as the gold standard approach for the detection of androgens, designer androgens and selective androgen receptor modulators (SARMs) in serum and urine samples from athletes as well as in sports supplements. These methods are exquisitely sensitive and selective. However, they have the disadvantage in that the androgens that being surveyed for must have delineated structures. Designer androgens or SARMs that have divergent structures from the characterized reference list can be missed with analyte methods because their specific analytical fingerprints are not defined. In vitro cell based androgen receptor (AR) bioassays are based on probing the biological pathway of androgen action and therefore are capable of identifying the presence of any AR-activating compound in a sample. Moreover, by basing the AR bioassays in different host cells (eg. yeast- no metabolism or cofactors; HEK293- limited metabolism but has cofactors; HuH7- active metabolism and cofactors) the relative AR potency of activating compounds can be measured. Using this tandem AR bioassay approach, 15 SARMs, recently detected as sports doping agents, were analyzed for relative AR potency. For S-1, S-6, S-23, S-24, ostarine, andarine, LG-121071, Rad-140, LGD-2226, 93746 and BMS-564929 all showed only moderate intrinsic AR bioactivity in the yeast bioassay, however potency increased dramatically with active metabolism. Some of these SARMs showed AR potencies far beyond that measured for the endogenous androgens, testosterone or dihydrotestosterone. AC262536 and MK0773 were weak SARMs even after active metabolism. By contrast, ACP-105 and YK-11 were both potent SARMs, with and without metabolism. Together, these results have implications for the anabolic potential of these SARMs, thus they pose a real threat to sports doping.

Mitochondrial phenotype of FOXL2 variants associated with Blepharophimosis, Ptosis and Epicantus Inversus Syndrome (BPES)

Ilaria Ferrari[1], Raffaella Rossetti[1], Stefania Bigoni[2], Lisa Petrone[3] & Luca Persani[4,5]
[1]Laboratory of Endocrine and Metabolic Research, IRCCS Istituto Auxologico Italiano, Cusano Milanino, Italy; [2]UOL Medical Genetics, University of Ferrara, Ferrara, Italy; [3]Department of Clinical, Experimental and Biomedical Sciences, University of Florence, Florence, Italy; [4]Division of Endocrine and Metabolc Diseases and Laboratory of Endocrine and Metabolic Research, IRCCS Istituto Auxologico Italiano, Milan, Italy; [5]Department of Clinical Sciences and Community Health, University of Milan, Milan, Italy.

Primary ovarian insufficiency (POI) is a highly heterogeneous condition defined by the occurrence of amenorrhoea, hypoestrogenism and hypergonadotropinism in women under 40. POI onset can be triggered by multiple factors, such as iatrogenic events, environmental conditions, autoimmunity or genetic alterations. When the ovarian insufficiency occurs as a consequence of either chromosomal or genetic alterations, it can be associated with other congenital abnormalities and classified as part of a syndrome. Genetic alterations of the transcription factor FOXL2 are associated with the onset of the blepharophimosis, ptosis and epicantus inversus syndrome (BPES), an autosomal dominantly inherited condition in which eyelid dysplasia occur either in association (BPES type 1) or not (BPES type 2) with POI. By genetic screening of several BPES-affected women we identified two novel nonsense FOXL2 variants: p.E92* variant in a fertile woman with regular menses at the time of sampling and her prepuberal daughter, and p.Y186* variant in a woman with primary amenorrhea. To unravel the impact of the novel variants on protein function, the subcellular localization of WT and mutant FOXL2 was investigated in transiently transfected HeLa cells by confocal microscopy. Surprisingly, while both FOXL2-WT and FOXL2-p.Y186* signals were confined to the nucleus, mislocalization of the FOXL2-p.E92* variant to mitochondria was revealed by colocalization with the mitochondrial marker TOM20 and confirmed by cellular fractionation. Moreover, evaluation of mitochondrial morphology in FOXL2-p.E92* cells revealed a significant shift from an interconnected network of mitochondria to a more fragmented state compared to FOXL2-WT- and FOXL2-p.Y186* cells. On this regard, it is widely known that mitochondrial fusion-to-fission rate is finely tuned in response to metabolic or environmental stress, and that an increase in mitochondrial fission enables the removal of damaged mitochondria and facilitates apoptosis. The increase in mitochondrial fragmentation in FOXL2-p.E92* cells therefore suggests that this variant might have a toxic effect on cell metabolism. This hypothesis is further supported by its increased degradation by the ubiquitin-proteasome system, as confirmed by treatment with the proteasome inhibitor MG132.In all the experiments conducted thus far, the FOXL2-p.Y186* variant behaviour did not differ from that of the WT, and further studies are underway to characterize its functionality inside the nucleus. On the other hand, given the importance of mitochondrial dynamics in both oocyte metabolism and tissue aging, our experimental data suggest that the FOXL2-p.E92* might eventually determine the onset of POI in the BPES-affected patients.

Depletion of the primate-specific luteinizing-hormone receptor splice variant 'exon-6A' impairs LH-, but not hCG-mediated signaling in human primary granulosa cells

Livio Casarini[1,2], Laura Riccetti[1], Samantha Sperduti[1], Clara Lazzaretti[1], Alessia Masini[1] & Manuela Simoni[1,2,3]
[1]Unit of Endocrinology, Department of Biomedical, Metabolic and Neural Sciences, University of Modena and Reggio Emilia, Modena, Italy; [2]Center for Genomic Research, University of Modena and Reggio Emilia, Modena, Italy; [3]Department of Medicine, Endocrinology, Metabolism and Geriatrics, Azienda Ospedaliero-Universitaria di Modena, Modena, Italy.

Introduction
A primate-specific luteinizing hormone (LH) receptor (LHCGR)-variant was suspected to discriminate between maternal choriogonadotropin (hCG)- and fetal LH-functioning. It is the so-called "LHCGRex6A", truncated, intracellular receptor isoform produced by alternative cryptic exon stop-codons located between the 6th-7th out of 11 exons. Its function is unknown, although pseudohermaphroditism and 46-XY female-like phenotype were associated with *LHCGRex6A* mutations, in spite of intact *LHCGR* wild-type. LHCGR-6A was proposed as a key-mediator of hCG-signals in primates.
Aim
In order to address evolutionary issues related to LHCGRex6A, we evaluated the functions of this isoform in modulating LHCGR-driven LH- and hCG-signals *in vitro*.
Methods
Cell model is human primary granulosa lutein cells (hGLC), naturally expressing both the wild-type and LHCGRex6A, treated by siRNA for their selective depletion. siRNA efficacy was evaluated by qPCR, Western blotting and immunofluorescence, cell viability by MTT assay. Impact of LHCGRex6A on steroidogenic-signals was evaluated as LH- and hCG-dependent 2-h cAMP production by ELISA, 15-min CREB and ERK1/2 phosphorylation by Western blotting, 12-h *STARD1*- and *CYP19A1*-target gene expression by qPCR, 8-/24-h synthesis of progesterone by immunometric-assay. Forskolin-stimulated hGLC served as controls and data were normalized over cell number ($5x10^4$ cells-per-well).
Results
LHCGRex6A mRNA and protein analysis, and immunofluorescence under permeabilizing/*non*-permeabilizing conditions certified siRNA efficacy. Viability of siRNA- and mock-transfected hGLC confirmed experimental reliability. Equipotent, 500 pM LH and 100 pM hCG concentrations resulted in similar cAMP levels by mock-treated hGLC, while hCG induced 3-fold higher cAMP increase than LH in siRNA-treated hGLC (cAMP-LH = 14.0 ± 8.7 pmol/ml; cAMP-hCG = 33.1 ± 16.2; basal = 0.5 ± 0.3; means ± S.E.M.; Mann-Whitney's; $P < 0.05$; $n = 6$). Consistent with cAMP, hCG induced higher downstream pCREB activation than LH, while no different pERK1/2 activation was found, as well as *STARD1* and *CYP19A1* expression (ANOVA; $P \geq 0.05$; $n = 3$), reflecting the qualitatively different LH/hCG-specific signal. While no different 8-h LH-/hCG-induced progesterone response was found, 24-h hormone production were about 2-fold higher upon hCG than LH exposure of siRNA-treated hGLC (progesterone-LH = 35.7 ± 5.5 ng/ml; progesterone-hCG = 64.0 ± 11.3; basal = 24.2 ± 3.2; means ± S.E.M.; Mann-Whitney's; $P < 0.05$; $n = 5$). Controls provided similar results.
Discussion
LHCGRex6A depletion impaired LH-, but not hCG-specific steroidogenic-signal in spite of functional LHCGR-expression, suggesting evolutionary relevance of the receptor-variant functioning during fetal stages in primates. LHCGRex6A roles would be investigated in the not-readily available primate male testis cells, providing wider picture of LH/hCG co-evolution.

The value of androstenedione and DHEA-S levels in diagnosis of polycystic ovary syndrome in young women

Aleksandra Kruszyńska, Agata Tuszyńska & Jadwiga Słowińska-Srzednicka
Medical Centre of Postgraduate Education, Warszawa, Poland.

Context
Polycystic ovary syndrome (PCOS) is a very common endocrinopathy affecting approximately 6–18% of women of reproductive age. It is also the most common cause of infertility due to anovulation. PCOS is characterized by menstrual disorders, polycystic or enlarged ovaries on ultrasound, but hyperandrogenism is the central feature of PCOS. Assessing of serum testosterone level (T) or free T is recommended by the guidelines in the diagnosis of PCOS. Diagnostic value of androstenedione is undetermined. Dehydroepiandrosterone sulfate (DHEA-S), an androgen nearly exclusively produced by the adrenals, is increased in many women suffering from PCOS, however its measurement is often omitted.
Aim
The aims of the study were:
1. to assess the frequency of increased level of testosterone (T), androstenedione (A) and DHEA-S in PCOS patients;
2. to examine the level of androgen suppression in low-dose (1 mg) night dexamethasone suppression test (LDDST) in PCOS patients.

Subjects and Methods
We analysed data of 195 young (median age 24.76 years) women, who were the patients of our Endocrinology Department, in whom PCOS was recognized with AES Criteria (2006) and T, A and DHEA-S level were measured. In $n = 104$ patients LDDST was performed.
Results
1. Increased T was found in $n = 61$ (31%) subjects and in $n = 15$ (8%) it was the only one elevated androgen (A and DHEA-S were within normal range).

2. Increased A was found in $n=97$ (50%) subjects and in $n=35$ (18%) it was the only one elevated androgen (T and DHEA-S were within normal range).
3. Increased DHEA-S was found in $n=77$ (39%) subjects and in $n=19$ (10%) it was the only one elevated androgen (T and A were within normal range).
4. LDDST revealed 33% decrease in the concentration of T, 45% decrease in the concentration of A and 41% decrease in the concentration of DHEA-S.

Conclusions

1. The value of A and DHEA-S measurement in the diagnostic process of hyperandrogenism in PCOS is underestimated.
2. In case of women with PCOS, a significant part of A and DHEA-S is produced by ovaries.
3. The measurement of A and DHEA-S concentrations is essential and useful in the diagnosis of hyperandrogenism in PCOS.

Change in visceral fat and its relation with change in lipids in trans persons during hormonal therapy: results from a multicenter prospective study

Maartje Klaver[1], Chantal Wiepjes[1], Christel de Blok[1], Nienke Nota[1], Justine Defreyne[2], Thomas Schneider[3], Alessandra Fisher[4], Guy T'Sjoen[2], Martin den Heijer[1] & Renée de Mutsert[5]
[1]VU Medical Center, Amsterdam, Netherlands; [2]Ghent University Hospital, Ghent, Belgium; [3]Oslo University, Oslo, Norway; [4]University of Florence, Florence, Italy; [5]Leiden University and Medical Center, Leiden, Netherlands.

Introduction

Excess visceral adipose tissue (VAT) is strongly related to multiple cardiovascular risk factors such as dyslipidemia. Hormonal therapy (HT) in trans persons affects total body fat and body fat distribution, but the effect on VAT and its relation to changes in lipids is unknown. The aim of our study was to investigate the effect of one year HT on changes in VAT and its relation with changes in total cholesterol, HDL, LDL, and triglycerides after one year of HT.

Methods

In a multicenter prospective study at two university hospitals, 179 male-to-female trans persons (transwomen) and 162 female-to-male trans persons (transmen) underwent whole body dual-energy X-ray absorptiometry (Hologic Discovery A, Hologic Inc., USA) and laboratory measurements before and after one year of HT. Linear mixed models were performed to estimate changes over time and linear regression was used to examine the relation between changes in VAT with changes in lipids. Analyses were adjusted for age, body mass index (BMI), and smoking.

Results

In transwomen (median age: 29 years, IQR 23–43), VAT increased with 10 grams (range −289–251 grams, s.d.: 87) or 3% (95% CI 0;7), while abdominal fat increased with 13% (95% CI 9;18) and total body fat with 25% (95% CI 21;29). Changes in lipids per s.d. change in VAT were 0.2 mmol/l (95% CI 0.1;0.3) in total cholesterol, 0.1 mmol/l (95% CI 0.1;0.2) in LDL, 0.0 mmol/l (95% CI −0.1;0.0) in HDL, and 0.1 mmol/l (95% CI 0.0;0.2) in triglycerides. In transmen (median age: 24 years, IQR 21-33), VAT increased with 6 grams (range −331–179 grams, s.d.: 83) or 3% (95% CI −3;9), while total body fat decreased (−11%, 95% CI −13;−8) and abdominal fat did not change (−2%, 95% CI −6;2). Changes in lipids per s.d. change in VAT were 0.0 mmol/l (95% CI −0.1;0.1) in total cholesterol, 0.0 mmol/l (95% CI −0.1;0.1) in LDL, 0.0 mmol/l (95% CI −0.1;0.1) in HDL, and 0.1 mmol/l (95% CI 0.0;0.2) in triglycerides.

Conclusions

One year of HT resulted in large changes in total body fat, but in small mean changes in VAT, with a large inter-individual range in both transwomen and transmen. An increase in VAT was associated with small increases in total cholesterol and LDL in transwomen, but not in transmen.

GHR ablation in the brain or in leptin receptor expressing cells causes metabolic effects during pregnancy

Pryscila DS Teixeira, Isadora C Furigo & Jose Donato Jr
Department of Physiology and Biophysics, ICB/USP, Sao Paulo, Brazil.

Introduction

Pregnancy leads to extensive adaptations in the female's body, by changing the secretion and responses to several hormones. GH is required for fetal nutrition, growth during pregnancy and for mammary development and lactation, although its central effects are not completely clarified.

Aim

The aim of this study was to investigate whether central GH signaling regulates physiological and metabolic adaptations during pregnancy.

Methods

We produced mice carrying ablation of the GH receptor (GHR) either in neurons ($GHR^{flox/flox}/Nestin^{Cre}$) or in cells that express the leptin receptor ($GHR^{flox/flox}/LepR^{Cre}$). These females were mated and, when the first day of gestation was identified via the identification of the copulatory plug, they were individualized and further studied.

Results

Pregnant $GHR^{flox/flox}/Nestin^{Cre}$ females had higher food intake, weight gain, insulin sensitivity (ITT), and IGF-1 concentrations during pregnancy as well as lower adiposity, serum concentrations of insulin and leptin. During the lactation period, these females presented higher deposition of subcutaneous fat. The GHR deletion in leptin receptor cells also resulted in higher food intake and reduced adiposity in all evaluated periods. In addition, a better glucose tolerance, higher insulin sensitivity and lower serum concentrations of insulin and leptin were also observed in pregnant $GHR^{flox/flox}/LepR^{Cre}$ females.

Conclusion

These results indicate that GH plays a role in metabolic control during gestation. Other experiments are being conducted to better clarify the mechanisms involved.

Keywords: energy balance, gestation, growth hormone, cytokine signaling.

Association between preoperative thyrotrophin and clinicopathological and aggressive features of papillary thyroid cancer

Abbas Ali Tam[1], Didem Ozdemir[1], Cevdet Aydın[2], Nagihan Bestepe[1], Serap Ulusoy[2], Nuran Sungu[3], Reyhan Ersoy[1] & Bekir Cakir[1]
[1]Department of Endocrinology and Metabolism, Yildirim Beyazit University Faculty of Medicine, Ankara, Turkey; [2]Department of Surgery, Ataturk Training and Research Hospital, Ankara, Turkey; [3]Department of Pathology, Yildirim Beyazit University Faculty of Medicine, Ankara, Turkey.

Aim

We aimed to investigate the relation between preoperative serum thyrotrophin (TSH) and clinicopathological features in patients with papillary thyroid carcinoma (PTC) and microcarcinoma (PTMC).

Methods

Patients who underwent thyroidectomy and diagnosed to have benign nodular disease or PTC/PTMC in our clinic were evaluated retrospectively. Patients with a previous history of thyroid surgery, patients using antithyroid medications or thyroid hormone and patients with tumors known to be unresponsive to TSH were excluded. Histological variants of PTC were classified as nonaggressive (classical/conventional and follicular variants), aggressive (tall cell, diffuse sclerosing and columnar variants) and other variants.

Results

Data of 1632 patients were analyzed. Histopathological diagnosis was benign in 969 (59.4%) and malignant in 663 (40.6%) patients. Preoperative median serum TSH was significantly higher in malignant compared to benign group (1.41 IU/dl vs 0.98 IU/dl, $P<0.001$). Malignancy risk increased gradually as going from hyperthyroidism to euthyroidism and hypothyroidism (20, 40.6 and 59.1%, respectively, $P<0.05$). Serum TSH was lowest in benign nodular disease, higher in PTMC and highest in PTC ($P<0.001$). This was also true when patients with positive antithyroid peroxidase/antithyroglobulin and with lymphocytic thyroiditis were excluded from the analysis ($P<0.001$). Serum TSH was higher in patients with bilateral tumor, capsular invasion and lymph node metastasis (LNM) compared to patients with unilateral tumor, without capsule invasion and without LNM, respectively ($P=0.036$, $P=0.002$ and $P=0.001$, respectively). Patients with aggressive variant PTC had higher serum TSH than nonaggressive ones ($P<0.05$).

Conclusion

Preoperative serum TSH was associated with increased risk of thyroid cancer and LNM regardless of autoimmune thyroid disease. With the present study, for the

first time, we showed higher preoperative TSH in aggressive variants of PTC compared to nonaggressive ones.

Germline mutations in *KIF1B* gene in two families with familial non-medullary thyroid cancer (FNMTC)

Aida Orois Añón[1,2], Mireia Mora Porta[1,3], Irene Halperin Rabinovich[1,3], Sudheer Kumar Gara[2], Electron Kebebew[2] & Josep Oriola Ambròs[3,4]
[1]Department of Endocrinology and Nutrition, ICMDM, Hospital Clinic, Barcelona, Spain; [2]Endocrine Oncology Branch, National Institutes of Health, Bethesda, Maryland, USA; [3]University of Barcelona, Barcelona, Spain; [4]Department of Biochemistry and Molecular Genetics, CDB, Hospital Clínic, Barcelona, Spain.

Introduction
Familial non-medullary thyroid cancer(FNMTC) represents 3–9% of thyroid cancer cases. Although the susceptibility genes for syndromic FNTMC are known, most cases of FNMTC are nonsyndromic and the genetic causes are unknown.
Patients and methods
We conducted a multicenter study to identify a candidate susceptibility gene for nonsyndromic FNTMC. We collected blood specimens, clinical and pathological data from 38 kindreds with FNMTC (32 with two affected members, six with ≥ 3 affected members). Genomic DNA was extracted from peripheral blood samples and Whole-Exome sequencing (WES) was performed in 10 affected individuals from four kindreds with at least three cases of FNMTC in each kindred. We filtered and identified the germline SNPs and INDELs using Haplotype Caller using the GATK package. We identified and validated the likely pathogenic variants (LPV) by Sanger sequencing in 38 kindreds and in our own control group (50 healthy subjects).
Results
Sixty-eight percent were women, with a mean age at diagnosis of 42.6 ± 13.6 years. 90.4% had classic papillary thyroid cancer, 26% were bilateral and 46% were multifocal. Among genes with LPV and population frequency of $<5\%$, we identified two novel germline heterozygous mutations in kinesin family member1B gene (*KIF1B)* in two kindreds. In the first family, five of five affected members presented a mutation c.2680G$>$A (p.V894M) in exon 24 and three of four affected members in the other family had a c.2480C$>$T (p.T827I) mutation in exon 23. We believe that the remaining member could be a phenocopy considering the high prevalence of thyroid cancer. Both LPVs are described in ExAc database with population frequencies of $<0.2\%$. Importantly, we didn't find the V894M *KIF1B* variant in our control group. We didn't test T827I variant in control group as it was already described as a very rare variant (not present among 270 controls of diverse ethnic backgrounds). *KIF1B* is in the chromosomal region 1p36.22 and encodes a motor protein that transports mitochondria and synaptic vesicle precursors. Several studies suggested *KIF1B* as a potential tumor suppressor gene particularly in neuroblastomas.
Conclusions
We identified two families with FNMTC presenting two novel or rare germline variants in *KIF1B* gene. Further studies are needed to establish the potential pathogenic impact of these genetic changes, as well as its involvement as a possible risk factor to develop FNMTC.

GP226

Significant acceleration in dynamics of medullary thyroid cancer markers concentration – report of 26 cases

Tomasz Gawlik, Jolanta Krajewska, Aleksandra Kukulska, Zbigniew Wygoda, Sylwia Szpak-Ulczok, Aleksandra Krol, Zbigniew Puch & Barbara Jarzab
Department of Nuclear Medicine and Endocrine Oncology, Maria Sklodowska-Curie Memorial Cancer Center and Institute of Oncology, Gliwice Branch, Gliwice, Poland.

Calcitonin and carcinoembryonal antigen are biochemical markers of medullary thyroid carcinoma (MTC). Assessment of the dynamics of their serum concentration allow for calculation of their doubling times that are independent risk factors for overall survival and progression-free survival in MTC. It is generally accepted that the dynamics and the doubling times remain stable during follow-up.
Aim
The aim of the study was to retrospectively verify the stability of calcitonin and CEA doubling times during follow-up in a population of 1650 medullary thyroid carcinoma patients followed-up in a single center.
Results
We found and present 26 patients in whom during follow-up significant change in marker's doubling time was observed significantly influencing their prognosis and treatment.
Conclusion
We should not excessively delay follow-up visits in MTC patients with decreasing, stable or slowly increasing markers concentration as there is possibility of revealing rapidly-progressing clone. It would be beneficial to test the genetic background leading to reproductive or survival advantage of that clone in progressively observed patient.

GP227

The adverse effect of radioactive iodine therapy on bone marrow for differentiated thyroid cancer patients

Sheng-Fong Kuo[1], Bie-Yui Huang[1] & Jen-Der Lin[2]
[1]Department of Endocrinology and Metabolism, Chang Gung Memorial Hospital, Keelung, Taiwan; [2]Department of Endocrinology and Metabolism, Chang Gung Memorial Hospital, Linko, Taiwan.

Aims
Side effects of large dose of radioactive iodine (RAI) therapy for well-differentiated thyroid carcinoma are noted.There were insufficient data regarding bone marrow suppression and inflammatory response in patients with thyroid cancer who received RAI therapy in Asia;
Patients and methods
We performed the study at the Chang Gung Memorial Hospital in Keelung, Taiwan. Patients with papillary or follicular thyroid cancer who received more than 2.6 GBq (70 mCi) RAI were enrolled in this hospital based study. We evaluate the renal function, serum inflammatory marker and bone marrow suppression before and 1 week after RAI treatment. In addition, these analyses were also performed between thyroxine withdrawl and recombinant human thyrotropin (rh-TSH) injection groups.
Results
There have been 101 patients who completed the blood test. The WBC count decreased 1 week after radioiodine treatment compared with that before RAI treatment (6307 ± 1527/ul vs 5476 ± 1439/ul, $P < 0.001$). Among 72 patients with thyroxine withdrawl and 29 patients with rh-TSH injection, the WBC count was lower in patients with thyroxine withdrawl than those with rh-TSH injection although there is not statistically significant ($P = 0.080$). The serum creatinine level is significantly higher in patients with thyroxine withdrawl than those with rh-TSH injection ($P < 0.001$). There is no any difference regarding RBC count, platelet count and serum CRP level between thyroxine withdrawl and rh-TSH groups.
Conclusions
The data gives useful information in thyroid cancer patients taking high dose of RAI treatment, and helps to suggest dose adjustment concerning about radiation safety for the patients.

DOI: 10.1530/endoabs.56.GP227

GP228

Familial non-medullary thyroid carcinoma. Are we facing a different entity?

Pablo Remon-Ruiz, Ana Romero-Lluch, Suset Dueñas-Disotuar, Ignacio Cuenca, Juan Martos-Martinez & Elena Navarro
University Hospital Virgen del Rocio, Seville, Spain.

Background
Familial non medullary thyroid carcinoma (FNMTC) is a not very well known histopatologic entity. Nowadays there are controversial publications about his aggresiveness and prognosis
Objective
To know the clinical outcomes and histopathological characteristics of our patients with FNMTC and to compare them with a cohort of patients with sporadic non medullary thyroid carcinoma (CDT).
Methods
We conducted a retrospective descriptive study including 55 familial non medullary carcinoma patients belonging 27 families diagnosed beetwen 1983 and 2017. Every family had two or more first degree relatives with FNMTC. They were compared with an aleatory sample of our cohort of patients with sporadic differentiated thyroid carcinoma (DCT) (750 cases).
Results
25 (92.6%) families had 2 members affected. 7 (21.21%) families had one member diagnosed with papillary microcarcinoma. 70.9% were women. Median age at diagnosis was 45.9 (37.8–56.5) years. 15 (55.56%) families were siblings and 13 (48.15%) parent-child. The age of presentation between parents-child show a significative difference of 20 (15–27) years ($P<0.05$). Histologically, 85% were papillary, and 15% were follicular. Multifocality was observed in 38%,19.6% showed extrathyroid extension and 6% surgical margins affected. Staging at diagnosis revealed 67.3% of patients were at stage I, 7.7% stage II, 19.2% stage III, and 1.9% at stage VIb, the 3.8% of patients presented metastasis at diagnosis. Total thyroidectomy was carried in 93.3% patients, central neck cervical dissection was added in 51.1% and the 10.6% recieved also a lateral neck linphadenectomy. 55 (98.21%) recieved radioactive iodine remmant ablation. More than 1 RAI were applied in 9 (21.2%) patientes. Median radiactive activity recieved was 105 (100–118) mCi. After a median follow-up of 4 (1–8) years, excellent response was observed in 86.4%, indeterminated response (biochemical or estructural) in 4.5% and incomplete response in 4.5%. 2 cancer related deaths were observed in our cohort. We haven't found any mayor prognosis difference between our FNMTC and our sporadic DTC cohort. A higher presence of aggresive histology tumors was observed in the FNMTC cohort (10.7% Vs 4%, $P<0.05$).
Conclusions
We haven't found significative histopathological, survival or prognosis differences between our FNMTC and sporadic DCT cohorts. Although we have a wide series, families with three affected members are under represented. We have to consider the probability of sporadic disease in the pedigrees with only two members affected. Earlier age presentation in second generation patients was observed in our cohort.

DOI: 10.1530/endoabs.56.GP228

GP229

Is thyroid nodule size a factor to consider when deciding for fine-needle aspiration procedure?

Gintaras Kuprionis[1], Zygimantas Staras[2], Ugne Marcinkute[2], Jurgita Makstiene[3], Valdas Sarauskas[3] & Lina Barsiene[4]
[1]Department of Radiology, Lithuanian University of Health Sciences, Kaunas, Lithuania; [2]Lithuanian University of Health Sciences, Kaunas, Lithuania; [3]Department of Pathological Anatomy, Lithuanian University of Health Sciences, Kaunas, Lithuania; [4]Department of Endocrinology, Lithuanian University of Health Sciences, Kaunas, Lithuania.

Introduction
Fine-needle aspiration (FNA) is the most accurate diagnostic approach for determining thyroid nodule malignancy. Most nodules are benign, therefore, only suspicious ones require FNA. In 2017 American College of Radiology proposed a scoring system – Thyroid Imaging, Reporting and Data System (TI-RADS) for identifying clinically significant malignancies. Whether a nodule requires FNA depends on various criteria, one of which is the size. The aim of this study was to determine whether size is an important factor in deciding the necessity for FNA.
Methods
A total of 288 ultrasound images of patients with thyroid nodules were analysed. The nodules were scored, measured and assigned to one of five TI-RADS levels (TR): TR1 – benign, TR2 – not suspicious, TR3 – mildly suspicious, TR4 – moderately suspicious, TR5 – highly suspicious. The results were compared with histology findings.
Results
219/288 (76%) benign and 69/288 (24%) malignant thyroid nodules were verified histologically. Nodules were distributed as follows: TR1 – 17 (5.9%), TR2 – 27 (9.4%), TR3 – 72 (25.0%), TR4 – 126 (43.8%), TR5 – 46 (16.0%). The mean size of measured nodules was 2.05 ± 1.02 cm. In categories TR1 and TR2 100% of nodules were benign according to FNA. In TR3 68/72 (94.4%) of nodules were benign and 4/72 (5.6%) malignant, 38/72 (52.7%) <2.5 cm in size and 34/72 (47.22%) – ≥ 2.5 cm. None of the malignant nodules in TR3 were ≥ 2.5 cm. Negative correlation ($r_s = -0.298$, $P=0.011$) was found between size and malignancy. In TR4 93/126 (73.8%) of nodules were benign and 33/126 (26.2%) malignant, 59/126 (46.8%) <1.5 cm in size and 67/126 (53.2%) – ≥ 1.5 cm. Size of ≥ 1.5 cm had sensitivity of 39.39%, specificity of 41.94%, positive predictive value (PPV) of 19.40%, negative predictive value (NPV) of 66.10% and accuracy of 41.27%. No significant correlations between size and malignancy in TR4 were found. In TR5 14/46 (30.4%) of the nodules were benign and 32/46 (69.6%) malignant, 11/46 (23.9%) <1 cm in size and 35/46 (76.1%) – ≥ 1 cm. Size of ≥ 1 cm had sensitivity of 68.75%, specificity of 7.14%, PPV of 62.68%, NPV of 9.09% and accuracy of 50%. Negative correlation ($r_s = -0.304$, $P=0.04$) was found between size and malignancy.
Conclusion
Our study shows that thyroid nodule size threshold suggested in TI-RADS levels TR3 – TR5 is not reliable in predicting malignancy risk. Therefore, we think that nodule size is neither a good predictor of malignancy nor a good indicator for FNA.

Peptide receptor radionuclide therapy in patients with medullary thyroid carcinoma: predictors and pitfalls

Carolien Beukhof, Tessa Brabander, Francien van Nederveen, Loes van Velthuysen, Folkert van Kemenade, Yolanda de Rijke, Lideke Fröberg, Boen Kam, Wouter de Herder & Robin Peeters
Erasmus MC, Rotterdam, Netherlands.

Aim
To evaluate the effectiveness of Peptide Receptor Radionuclide Therapy with ^{177}Lu-octreotate (PRRT) for medullary thyroid carcinoma (MTC).
Background
There are few therapeutic options for progressive metastatic MTC. The Erasmus MC Center for Neuroendocrine Tumors has been at the forefront of developing PRRT for neuroendocrine tumors. PRRT has also been suggested to be a useful treatment for MTC, but evidence is very limited.
Methods
Retrospective evaluation of results of our ten years' experience with PRRT treatment in a highly selected group of MTC patients with progressive disease or refractory symptoms. In addition, a retrospective evaluation of uptake on historical ^{111}In-DTPA-octreotide scans was performed in patients with detectable tumor load >1 cm.
Results
Over the years, ten MTC patients were treated with PRRT. Forty percent of patients (4/10) showed stable disease at first follow up (8 months after start of therapy) whereas the other six were progressive. Patients with stable disease had the combination of both a high uptake on ^{111}In-DTPA-octreotide scan (grade $\geqq 3$; more than liver) and a clear somatostatin receptor type 2a (SSTR2a) expression on tumor by immunohistochemistry. Retrospective evaluation of historical ^{111}In-DTPA-octreotide scans of 35 non-treated MTC patients revealed uptake less than liver (Grade 1) in the vast majority of patients 31/35 (89%) with uptake similar as liver (Grade 2) in the remaining 4/35 (11%).
Conclusions
PRRT using ^{177}Lu-octreotate was only effective in the patients that had the combination of high uptake on ^{111}In-DTPA-octreotide scan ($>$liver) and in which the pathology report showed clear SSTR2a expression. This high uptake was only present in a very limited number of patients, suggesting that this treatment can only be considered for a highly selected group of MTC patients.

Related recurrence factors in a Spanish cohort of differentiated thyroid carcinoma. Cadit-CAM Study

Iván Quiroga[1], Julia Sastre[2], Manuel Delgado[3], Silvia Aznar[4], Visitación Álvarez[5], Belvis Torres[6], Javier González[7], Cristina Lamas[4], Mary Gaby Llaro[1], Florentino del Val[6], Dulce Calderón[7] & Jose Lop[2]

[1]Hospital Nuestra Señora del Prado, Talavera de la Reina, Spain; [2]Complejo Hospitalario de Toledo, Toledo, Spain; [3]Hospital General Universitario de Ciudad Real, Ciudad Real, Spain; [4]Complejo Hospitalario Universitario de Albacete, Albacete, Spain; [5]Hospital Universitario de Guadalajara, Guadalajara, Spain; [6]Hospital General la Mancha Centro, Alcazar de San Juan, Spain; [7]Hospital Virgen de la Luz, Cuenca, Spain.

Background and objective
Incidence of differentiated thyroid cancer (DTC) is increasing but not its mortality. Knowing recurrence factors is essential to plan its treatment. Recurrence related factors in our area were reviewed and compared with ATA risk stratification system.
Patients and Methods
The Cadit-CAM study was designed to evaluate characteristics of patients diagnosed of DTC in Castilla La Mancha, a region in the central part of Spain, during 15 years (from 2001 to 2015). The cohort in Cadit-CAM study included 1434 patients from seven regional hospitals. The variables analyzed were: sex, age, size, histopathologic subtype, multifocality, involved lymph nodes, lymphadenectomy, extrathyroidal extension, metastases at diagnosis (MTS), intentionally total thyroidectomy (ITT), anti-thyroglobulin antibodies with rising titers (TG-Ab). Treatments and evolution of patients who recurred were also evaluated.
Results
324 patients recurred (23%), being 82% ATA high risk (71 patients), 33% ATA intermediate risk (160) and 9% ATA low risk (93). Factors independently related to recurrence were MTS with OR 46.7 (95% CI 13–165); TG-Ab 4.86 (2.4–9.9); positive lymph nodes 4.38 (2.7–6.9), multifocality 2.2 (1.59–3.05), extrathyroidal extension 2.09 (1.4–3.1), size >3 cm 1.83 (1.23–2.72); male 1.64 (1.15–2.32). Those not statistically related to recurrence were ITT 1.33 (0.82–2.1); age 0.99 (0.98–1); lymphadenectomy 0.8 (0.5–1.28) and histology 0.7 (0.34–1.41). Recurrence treatments were: Iodine-131 (56%); surgery (31%), both (23%), kinase inhibitors (5%), observation (8%), and palliative surveillance, radiotherapy, cementation, and chemotherapy (<1%), For patients with recurrence the outcome at the end of the follow up was: 26% alive without evidence of disease, 24% alive with structural disease, 27% indeterminate or biochemically incomplete response and 10% died for DTC
Conclusion
23% of the patients with DTC recurred. Recurrence poor prognosis factors were MTS, TG-Ab, involved lymph nodes, multifocality, extrathyroidal extention, tumor size and male sex. ATA Risk stratification predicts recurrence, however two third of these patients were in ATA intermediate and low risk groups.

Imaging in clinical research devoted to medullary thyroid carcinoma: a systematic meta-analysis

Sergiy Kushchayev & Oleg Teytelboym
Mercy Catholic Medical Center, Darby, Pennsylvania, USA.

Background
We analyzed the role of imaging in the identification of medullary thyroid carcinoma (MTC) metastases and in the assessment of treatment response of the patients in clinical trials and research studies devoted to MTC.
Materials and methods
A search for published studies devoted to MTC from January 2010 to August 2017 was performed.
Results
Fifteen studies published in peer review journals that evaluated the effects of sorafenib, cabozanitinib, vandetanib and sunatenib were analyzed. In a pooled cohort of 922 patients with advanced MTC, metastases in lymph nodes were found in 70%, liver in 63%, lungs in 54% and bone in 44%. Eleven out of 15 publications described imaging modalities to assess metastases. Of those, all 11 reported the use of computed tomography (CT), five used magnetic resonance tomography (MRI), in two studies bone scintigraphy. Only one study reported the exploratory use of positron emission tomography/computed tomography (PET/CT) with 18-fluorodeoxyglucose and dynamic contrast-enhanced MRI. No study used PET/CT with fluorine-18-dihydroxyphenylalanine (18-F-DOPA). Imaging timing for initial and follow-up varied. All studies used Response Evaluation Criteria In Solid Tumors (RECIST) to assess the response to treatment. Cumulative analysis showed that overall complete response was diagnosed only in one case (0.3%); partial response in 30%, stable disease was noted in 60% and progressive disease in 10% without statistical significance between the studies and types of treatment used. A meta-analysis showed the limited use of modern imaging modalities for MTC and the lack of detailed description of radiological findings in all analyzed publications. There is no consensus and protocol on the radiological evaluation of MTC patients. New advanced imaging techniques (such as diffusion-weighted MRI, dynamic contrast MRI, PET/CT with 18-F-DOPA, 69-GA DOTATATE etc), which have high diagnostic value in oncology, were not used in presented studies.
Conclusion
1. Modern imaging modalities have limited use in clinical research and trials devoted to MTC.
2. Development and introduction of new imaging protocols will be very helpful for further research of new treatment modalities and comparison of the efficiency of different treatments.
3. New advanced imaging techniques may be helpful in advanced MTC and therefore should be evaluated.
4. RECIST does not adequately reflect changes related to treatment in MTC, therefore it should not use in the future.

Molecular profiling of a large papillary thyroid cancer series followed at a single center: data on mutation density, heterogeneity and phenotype-genotype correlations

Carla Colombo[1,2], Marina Muzza[1,2,3], Maria Carla Proverbio[2], Delfina Tosi[4,5], Chiara Pesenti[2,6], Stefania Rossi[4,5], Valentina Cirello[1], Simone De Leo[1], Gaetano Bulfamante[4,5], Stefano Ferrero[2,7], Silvia Tabano[2,6] & Laura Fugazzola[1]
[1]Division of Endocrine and Metabolic Diseases, IRCCS Istituto Auxologico Italiano, Milan, Milano, Italy; [2]Department of Pathophysiology and Transplantation, Università degli Studi di Milano, Milan, Milano, Italy; [3]Endocrine Unit, Fondazione IRCCS Ca' Granda-Ospedale Maggiore Policlinico, Milan, Milano, Italy; [4]Unit of Pathology, ASST Santi Paolo e Carlo, Milan, Milano, Italy; [5]Department of Health Sciences, Università degli Studi di Milano, Milan, Milano, Italy; [6]Division of Pathology, Fondazione IRCCS Ca' Granda Ospedale Maggiore Policlinico, Milan, Milano, Italy; [7]Department of Biomedical, Surgical and Dental Sciences, Università degli Studi di Milano, Milan, Milano, Italy.

Recent advances in the molecular classification of papillary thyroid cancer (PTC) have improved the diagnostic work-up and the care of patients with thyroid nodules and cancer, highlighting the need to routinely add information on the genetic pattern to the classification of cancer. The genomic background of a large series of 208 PTCs followed at a single Center was analysed by a custom MA genotyping platform (PTC-MA), which allows the simultaneous detection of 19 genetic alterations including point mutations and fusions in a sensitive, fast and economic way. The 74% of the cancers analysed has been genetically classified, being *BRAF*^{V600E} variant and *TERT* promoter mutations the most frequent alterations, followed by *RET/PTC* fusions. Fusions were significantly more frequent in younger ages, while *TERT* associated with older patients. Interestingly, in 20% of cases two or more mutations were found. In particular, a *TERT* promoter mutation was associated with *BRAF* and *RAS* mutations in 28.7 and 14.2%, respectively, and the co-occurrence of a fusion with ≥ 1 point mutation/s was also observed. In the majority of cases, allelic frequencies were consistent with the presence of the heterozygous mutation in virtually all the neoplastic cells. Nevertheless, in a minority of cases, mutations were detected by the PTC-MA assay even if present at low allelic frequencies indicating a tumor heterogeneity. A significant correlation of aggressive features was found with mutation density, but not with the allelic frequencies of driver oncogenes. The genotype-phenotype correlation revealed that aggressive clinical characteristics were more frequent in mutated cases, and the strong cooperative role of coexisting *BRAF*^{V600E} and *TERT* promoter mutations in the development of a group of PTCs displaying the worst clinicalpathological features was confirmed. In conclusion, a large monoinstitutional series of PTCs was fully genotyped by means of a cost and time-effective customized panel, revealing interesting data and implying the actual prospective to routinely include it in thyroid cancer classification, in view of a personalized therapeutic approach.

Title Evaluation of the CCK-2-receptor agonist 177Lu-PP-F11N for peptide receptor radionuclide therapy (PRRT) of medullary thyroid carcinoma - First results of a phase 0 'Lumed' Study

Christof Rottenburger[1], Guillaume Nicolas[1], Lisa McDougall[1], Felix Kaul[1], Michael Cachovan[2], Roger Schibli[3], Susanne Geistlich[3], Martin Béhé[3], Damian Wild[1] & Emanuel Christ[4]
[1]Division of Nuclear Medicine, University Hospital of Basel, Basel, Switzerland; [2]Siemens Healthcare GmbH, Forchheim, Germany; [3]Paul Scherrer Institute, Center of Radiopharmaceutical Sciences, Villigen, Switzerland; [4]Endocrinology, Diabetology and Metabolism, University Hospital of Basel, Basel, Switzerland.

Objectives
There is still an unmet need for an effective systemic therapy for advanced medullary thyroid carcinoma (MTC). Targeting the cholecystokinine-2 (CCK-2) receptor with radiolabelled gastrin analogues is a potential approach for radionuclide therapy, as MTC expresses CCK-2 receptors at a high incidence and density. Unfortunately, kidney and bone marrow toxicity precluded therapeutic applications of CCK-2 receptor specific compounds until now. The aim of this prospective study is the feasibility testing of targeting CCK-2 receptors with the novel 177Lu labelled gastrin analogue PP-F11N [DOTA-(DGlu)6-Ala-Tyr-Gly-Trp-Nleu-Asp-PheNH2]in six patients with metastasized MTC (ClinicalTrials.gov: NCT02088645).
Methods
Six patients received two injections of 1 GBq 177Lu-PP-F11N, one injection without and the other one with additional Physiogel infusion for nephroprotection. Planar scintigraphy and SPECT/CT scans were performed at several time points for up to 72 h post injection in order to calculate tumor- and organ doses using 3D voxel-based dosimetry. Blood samples were taken for the purpose of bone marrow dose calculation. ECG, blood count and blood chemistry were measured up to 12 weeks after the second administration of 177Lu-PP-F11N in order to evaluate adverse events.
Results
Apart from self-limiting flushing, nausea and vomiting (grade 1 according to CTCAE version 4.0), there were no adverse reactions observed. In all patients, radiotracer uptake in tumor tissue was visible in the scintigraphic images. Furthermore, uptake in the kidneys, stomach and colon was visible. The radiation doses to the tumors and organs were calculated for the three patients: dose range in tumors was between 1 and 1.5 Gy/GBq, dose range in kidneys 0.045–0.075 Gy/GBq (without Physiogel) and 0.07–0.15 Gy/GBq (with Physiogel), resulting in tumor-to-kidney dose ratios between 13.3 and 27.3. Calculated bone marrow doses were 0.01–0.02 Gy/GBq, resulting in tumor-to-bone marrow dose ratios between 50 and 150.
Conclusions
The administration of the new CCK-2 receptor ligand 177Lu-PP-F11N was safe. Visualization of metastasized/recurrent disease in all patients proves that the principle of CCK-2 receptor targeting of MTC with this new radiopharmaceutical is feasible. Preliminary results of the 3D voxel-based dosimetry in the first three analyzed patients indicated tumor doses that could enable radionuclide therapy. Dosimetry results for kidneys and bone marrow revealed low organ doses as well as excellent tumor-to-kidney and tumor-to-bone marrow ratios. Further studies will be necessary to evaluate the theranostic potential of 177Lu-PP-F11N in patients with MTC.

Does body mass index influence the clinical stage, treatment response and course of the disease in patients with differentiated thyroid cancer?

Danuta Gęsior-Perczak[1], Iwona Pałyga[1], Monika Szymonek[1], Artur Kowalik[2], Agnieszka Walczyk[1], Janusz Kopczyński[3], Katarzyna Lizis-Kolus[1], Tomasz Trybek1[1], Estera Mikina[1], Dorota Szyska-Skrobot[1], Klaudia Gadawska-Juszczyk[1], Stefan Hurej[1], Artur Szczodry[1], Janusz Słuszniak[4], Ryszard Mężyk[5], Stanisław Góźdź[6,7] & Aldona Kowalska[1,6]
[1]Holycross Cancer Centre, Endocrinology Clinic, Kielce, Poland; [2]Holycross Cancer Centre, Nuclear Medicine, Kielce, Poland; [3]Holycross Cancer Centre, Surgical Pathology, Kielce, Poland; [4]Holycross Cancer Centre, Surgical Oncology, Kielce, Poland; [5]Holycross Cancer Centre, Cancer Epidemiology, Kielce, Poland; [6]Jan Kochanowski University, Kielce, Poland; [7]Holycross Cancer Centre, Oncology Clinic, Kielce, Poland.

Introduction
Obesity is a serious health problem worldwide, especially in well developed countries. It is a cause of various diseases, including thyroid cancer. The relationship between obesity and prognostic factors of thyroid cancer is uncertain.
Aim of the study
Evaluation of relationship between the body mass index (BMI) and clinicopathological features increasing the risk of poor clinical course, treatment response and clinical outcome in patients with differentiated thyroid cancer (DTC).
Material
The study included 1,181 patients with DTC (88% women and 12% men) who were treated at a single center from 2000 to 2016, who underwent retrospective assessment of BMI and clinicopathological features before surgery. The relationship between clinical features of treatment response (excellent, indeterminate, biochemically incomplete, structurally incomplete) or final status of the disease (remission, persistent disease, death) and BMI was evaluated. Patients were stratified according to BMI (underweight, normal weight, overweight and obesity according to World Health Organization classification). Statistical analysis was performed using univariate and multivariate logistic regression analysis.
Results
Median follow-up was 7.7 years (1–16 years). BMI did not affect the response to treatment or outcome of the disease (remission, persistent disease, death). Obesity was more prevalent in men ($P=0.033$) and was more common in patients ≥ 45 years of age ($P=0.001$). We found statistically significant relationship of advanced TNM stage (III-IV) with increases in BMI ($P=0.029$), however this association disappeared after adjusting for age of ≥ 45 years ($P=0.832$).
Conclusions
Obesity in our study is not associated with more aggressive clinicopathological features of cancer, it is not a risk factor for higher clinical stage of cancer, it is not a prognostic factor for poorer treatment response and clinical outcome in DTC patients.

Neural stem cells expressing cytosine deaminase and interferon-β suppressed the growth and metastasis of anaplastic thyroid cancer cells

Hye-Ji Shin & Kyung-Chul Choi
Laboratory of Biochemistry and Immunology, College of Veterinary Medicine, Chungbuk National University, Cheongju, Chungbuk, Republic of Korea.

In this study, human neural stem cells (hNSCs) were used to cancer treatment strategy for anaplastic thyroid cancer (ATC) owing to their tumor tropic properties. Cytosine deaminase (CD) can convert a prodrug, 5-fluorocytosine (5-FC), to drug, 5-fluorouracil (5-FU), which inhibits tumor growth through DNA synthesis inhibition. Also, IFN-β expression suppresses tumor growth by apoptotic process. Then, we investigated tumor inhibition effect of hNSCs *in vitro* and *in vivo*. We currently studying on a xenograft *in vivo* model, SNU-80 cells (2.0×10^7cells/mouse) were injected subcutaneously (s.c.) after mixed with 1:1 volume ratio of Matrigel (BD Biosciences, Bedford, MA, USA) into the back of the mice. When the tumor volume reached at 150–200 mm^3, CM-DiI pre-labeled hNSCs were injected subcutaneously closed to the tumor mass. After SNU-80 cells and hNSCs injection, 5-FC (500 mg/kg per day) injected every day for 21 days to Intraperitoneal injection (i.p.). In trans-well migration assay, HB1.F3.CD and HB1.F3.CD.IFN-β cells selectively migrated to SNU-80 cells because of its tumor-tropic properties. Engineering NSCs were attributed to chemo attractant factors like uPAR, CXCR4, SCF and VEGFR2 secreted by SNU-80 cells. Also when co-cultured with HB1.F3.CD and HB1.F3.CD.IFN-β cells, SNU-80 cell viability was reduced in presence of 5-FC. In this study, we proved the hNSCs expressing CD (HB1.F3.CD) and IFN-β (HB1.F3.CD.IFN-β) genes therapeutic effect. As a result, hNSC therapy with prodrug 5-FC may helpful for the treatment of human anaplastic thyroid cancer. Furthermore, we are currently studying on a xenograft *in vivo* model to prove that selective anti-tumor effect of hNSCs.

Comparison in survival of the seventh and eighth editions of the American Joint Commision on Cancer in a Spanish cohort of differentiated thyroid carcinoma: Cadit-CAM Study

Julia Sastre[1], Belvis Torres[2], Silvia Aznar[3], Visitación Alvarez[4], Manuel Delgado[5], Javier Gonzalez[6], Ivan Quiroga[7], Sandra Herranz[4], Jose Joaquin Alfaro[3] & Miguel Aguirre[5]
[1]Complejo Hospitalario de Toledo, Toledo, Spain; [2]Hospital General La Mancha Centro, Alcazar de San Juan, Spain; [3]Complejo Hospitalario Universitario de Albacete, Albacete, Spain; [4]Hospital Universitario de Guadalajara, Guadalajara, Spain; [5]Hospital General Universitario de Ciudad Real, Ciudad Real, Spain; [6]Hospital Virgen de la Luz, Cuenca, Spain; [7]Hospital Nuestra Señora del Prado, Talavera de la reina, Spain.

Background and objective
The AJCC-TNM system is optimized to predict survival in patients with cancer. Since January 2018, the new eighth edition of this staging system will be used to classify patients diagnosed of differentiated thyroid carcinoma (DTC). This study aims to compare the seventh and eighth editions of the AJCC-TNM system in a Spanish Cohort of DTC.
Patients and Methods
The Cadit-CAM study was designed to evaluate characteristics of patients diagnosed of DTC in Castilla La Mancha (CAM), a region in the central part of Spain, during 15 years (from 2001 to 2015). The cohort in Cadit-CAM study included 1434 patients from seven hospitals. Staging criteria for the seventh and eighth editions were applied to the cohort. Disease Specific Survival (DSS) were calculated using the Kaplan-Meier method. Multivariate Cox proportional hazards model were used to estimate the association of each stage with survival in both editions.
Results
1426 patients were analyzed, 77% were women, with a mean age at diagnosis of 48.3 (15.6) years (y) and a mean follow up period of 5.8 (3.9) y, 92% papillary carcinomas. When TNM-8 was applied 26.1% of the patients were down-staged. In patients with $<$ 55 years at diagnosis (n: 947) 15.3% were reclassified and in patients $>=$55 years at diagnosis (N: 479) 50.1% were downgraded. The 10-years DSS rates in TNM-7 I, II, III and IV stages were 99.9, 95.7, 98.7 and 49.9% respectively. The 10-years DSS rates in TNM-8 stages were 99,8% (I), 89,1% (II), 42,6% (III) and 39,0% (IV) respectively.
Conclusion
A significant number of patients with DCT were down-staged from the seventh to the eighth edition in this cohort of Spanish patients. There was greater separation of survival curves based on disease stage using the eighth edition.

Carrying mutations truncating CHEK2 protein predisposes to thyroid neoplasms – preliminary report

Anhelli Syrenicz[1], Monika Koziołek[1], Marta Rudnicka[1], Anna Sieradzka[1], Cezary Cybulski[2] & Bartek Kiedrowicz[1]
[1]Department of Endocrinology, Metabolic Diseases and Internal Diseases, Pomeranian Medical University, Szczecin, Poland; [2]Department of Genetics and Pathology, International Hereditary Cancer Centre, Pomeranian Medical University, Szczecin, Poland.

Introduction
CHEK2 gene is one of the genes in the DNA repair complex. Dysfunction of genes in this complex leads to genomic instability and is regarded as a cause of tumorigenesis. CHEK2 mutations spectrum was assessed in many populations, including polish one. The most common are mutations truncating CHEK2 protein (1100delC, IVS2+1G>A, del5395) and a missense I157T CHEK2 mutation. Literature data indicate that mutations truncating CHEK2 protein lead to a five-fold increased risk of papillary thyroid cancer.
Aim
The aim of the study was to evaluate the relation between CHEK2 protein truncating mutations and prevalence of nodular goiter and thyroid cancer.
Material and methods
62 women, aged 25–60 years (average 42.5 years), with 1100delC, IVS2+1G>A and del5395 mutations of CHEK 2 gene were enrolled into the study. Thyroid ultrasound was performed with Aloka equipment with 7.5 MHz probe and blood sample was drawn to perform genetic tests. RFLP-PCR technique was used to detect IVS2+1G>A mutation, PCR to detect del5395 mutation and ASO-PCR using specific starter for an allele with single nucleotide deletion to detect 1100delC. Positive results of RFLP-PCR and ASO-PCR were subsequently verified by DNA sequencing.
Results
Among 62 women, 37 (59.7%) were diagnosed with nodular goiter and 25 (40.3%) had no thyroid lesions. In the group with nodular goiter 25 subjects (67.6%) underwent fine-needle aspiration biopsy (FNAB), 5 are planned for FNAB and 7 (18.9%) have not been qualified to FNAB because of too small dimensions of thyroid lesions and no sonographically suspicious features. Analyzing the group of 32 subjects (25 with FNAB and 7 without FNAB because of no indications), in 4 (12.5%) papillary thyroid cancer was initially diagnosed and afterwards confirmed with postoperative histopathological examination, 27 (84.4%) had benign lesions (20 had group II in The Bethesda System and in 7 basing on ultrasound features) and 1 (3.1%) the result was undetermined (group III).
Conclusions
1. Prevalence of nodular goiter in the study group was comparable to the general population.
2. Prevalence of papillary thyroid cancer in patients with nodular goiter carrying CHEK2 gene mutations was three-fold higher than prevalence of this cancer in general population.

Our preliminary conclusions may be redefined after performing thyroid diagnostics in more women carrying CHEK2 gene mutations.

GP239

The capability of the Bethesda System Reporting for Thyroid Cytopathology (TBSRTC) in identifying of thyroid carcinoma

Olga Nechaeva, Larisa Bavykina, Armine Kazaryan, Timur Britvin & Alexander Dreval
Moscow Regional Research Clinical Institute, Russian Federation, Moscow, Russia.

Aim
To assess the accuracy of the TBSRTC in verification of thyroid carcinoma in the region of Moscow county.
Material and methods
A retrospective study of data from electronic medical notes of 1,675 patients who underwent fine needle aspiration biopsy of nodular thyroid glands in 2016. The cytological conclusion was evaluated in accordance with the TBSRTC. In cases of surgical treatment (thyroidectomy or hemithyroidectomy) the cytological diagnosis was confirmed by morphology studies and then grouped into the following categories: malignant and benign. Specificity, sensitivity, PPV and NPV were calculated with Microsoft Excel 2016.
Results
The frequency distribution of Bethesda categories in the cohort studied was: 112 (6.7%) for category I, 1432 (85.5%) for II, 7 (0.42%) for III, 90 (5.4%) for IV, 11 (0.7%) for V, 23 (1.3%) for category VI. Surgical treatment was performed in 115 cases (6.9%) in patients: 1 from 112 pts in category I; in 36 from 1432 pts in category II; in 3 of 7 pts in category III; in 46 from 90 pts in category IV; in all 11 pts in category V; in 18 from 23 pts in category VI. Thyroid carcinoma was confirmed in 46 (40.0%) cases of surgical treatment group: 0 pts in category I, in 3 (8.3%) pts in category II, in 2 (66.7%) in category III, in 14 (30.4%) in category IV, in 9 (81.8%) pts in category V, in 18 (100%) pts in category VI. The sensitivity in detecting malignant neoplasms for categories IV+V+VI was 89.1% (95% CI 77–95.3%); specificity for category IV was 46.3% (35.1–58%); for category V 97.1% (90–99.2%); for category VI 100% (94.7–100%). PPV for category IV was 30.4 (19.1–44.8%); for category V 81.8 (52.3–94.9%); for category VI 100% (82.4–100%). NPV for category IV was 53.6 (42–65%); for category V 64.4 (54.9–73%); for category VI 71.1 (61.5–79.2%).
Conclusion
The highest PPV and NPV were noted in category VI, the lowest value was found in category IV. Sensitivity for categories IV+V+VI was high and majority of malignant cases were identified due to cytological investigation. More studies are needed to separate malignant nodules from benigh in category IV.

Orthotopic PDX Mouse Model of humanprimary Undifferentiated/ Anaplastic thyroid carcinoma

Miguel Chenlo[1,*], Joana Rodrigues[1,*], Manuel Narciso Blanco Freire[2], Maria del Carmen Suarez Farina[1], Magali Piso-Neira[3], Jose M Cameselle-Teijeiro[3] & Clara V Alvarez[1]
[1]Group of Neoplasia and Endocrine Differentiation Centre for Investigations in Molecular Medicine and Cronic Disease (CIMUS) and Institute of Investigaciones Sanitarias (IDIS), University of Santiago de Compostela (USC), Santiago de Compostela, Spain; [2]Department of Surgery, University Hospital of Santiago de Compostela (CHUS), University of Santiago de Compostela (USC), Santiago de Compostela, Spain; [3]Department of Pathology, University Hospital of Santiago de Compostela (CHUS), University of Santiago de Compostela (USC), Santiago de Compostela, Spain.
*These authors contributed equally to this work.

Undifferentiated/Anaplastic thyroid carcinoma (ATC) is one of the most aggressive and deadly cancers. It is characterized by loss of thyroid expression markers and no response to conventional treatments. ATC incidence is low representing $<2\%$ of all thyroid carcinomas. This, together with its high mortality, makes difficult the development of clinical trials. In our previous works, we have developed a system to culture patient-derived thyroid cancer cells (h7H) that is a good way to test new therapies. On the other hand, cell cultures don't maintain the complete tumor environment and 3D structure of a human cancer. Orthotopic patient-derived anaplastic tumors (PDX) in mouse could provide a relevant model to study the structural disease, test best culture-selected therapies and perform precision medicine.
Methods
We designed a retrovirus construct encoding a chimera Luciferase-IRES-mCherry. A patient-derived ATC primary culture grown in h7H was infected with this retrovirus. Cells were orthotopically implanted in NOD-SCID immune deficient mice through neck surgery using an in house developed minimally disruptive approach and a Hamilton device. During the following weeks, mice were followed *in vivo* using an IVIS imaging system and through neck palpation, measuring neck masses with a precise calliper. A small group of mice was sacrificed 5 weeks after injection. A second group of mice were sacrificed at week 10. The last group of mice was sacrificed at week 14. At autopsy, all organs were observed and neck tissue collected for pathology analysis, staining with relevant markers and final precise dimensions.
Results
All avatar mice presented a growing neck cancer with aggressive characteristics in the luminescent assay (growing intensity, neck invasion, displacement of neck structures). The pathology revealed a cancer with similar characteristics to human ATC (high mitotic index, thyroid, nerve and muscle invasion, vascular invasion, fibrin deposition, aberrant mitotic figures, giant cells, pleomorphic nuclei and multinucleated cells). Necrosis appeared after the 10th week of evolution. p53, Ki67, TTF1 and PAX8 markers were positive as expected using conditions similar to the ones in patients' samples.
Conclusions
Appropriate culture conditions are essential to obtain phenotype maintenance in patient-derived primary cultures. Our results showed local tumor growth and progression within the first week after cell implantation and its progression was followed along the weeks as big neck masses. We have obtained an avatar model that allows some pre-clinical studies during fourteen weeks. This model could offer a new tool for studying the biological mechanisms involved in ATC and test new therapies.

Detection of lncRNAs in thyroid nodule as new tool for tumor diagnosis: analysis by Droplet Digital PCR in Fine Needle Aspiration biopsy

Simona Nanni[1], Pietro Locantore[2], Lorenza Bacci[1], Aiello Aurora[3], Guido Fadda[1], Emanuela Traini[2], Rocco Bellantone[1], Claudio Grassi[1], Antonella Farsetti[3] & Alfredo Pontecorvi[1]
[1]Universitá Cattolica, Rome, Italy; [2]Fondazione Policlinico Gemelli, Rome, Italy; [3]CNR-IBCN, Rome, Italy.

Background
Differentiated Thyroid Carcinomas (DTC) represent more than 90% of thyroid tumors with good prognosis and long survival. Currently, patients with intermediate/high risk nodule as assessed by cytological staging may undergo surgery. According to ATA 2017 guidelines, all patients presenting thyroid nodules with suspicious ultrasound features (hypoechoic pattern, irregular margins, microcalcifications, etc.) and cytopathology TIR3B, TIR4 or TIR5 according to 2014-SIAPEC classification may undergo to surgery. However, not all nodules are malignant: about 25–30% of TIR3B, 50–80% of TIR4 and 95–99% of TIR5 are tumor, as assessed only upon thyroidectomy. Although it has been well established that lncRNAs (long non-coding RNA transcripts) play a fundamental role in cancer biology, knowledge about the specific role of these transcripts in the initiation and progression of DTC is still poorly understood.
Aim
The aim of this study is to identify a molecular profile based on lncRNAs expression that may discriminate between benign and malignant nodules.
Methods
A cohort of 50 patients, male to female ratio 1:5 was enrolled at the Endocrinology and Metabolism Diseases Unit, Fondazione Policlinico Gemelli, Rome Italy. Inclusion criteria: thyroid nodules more than 1 cm with suspicious ultrasound characteristics. Gene expression analysis was performed using Droplet Digital PCR (ddPCR) on the following biological samples: i) cells from Fine Needle Aspiration (FNA) biopsy, ii) residual cell samples from FNA prepared for cytology (FNA-ThP) and iii) fresh thyroid tissue explanted after surgery.
Results
A panel of transcripts were first analyzed by ddPCR on fresh DTC tissue: the three thyroid-specific genes (TG, TPO and NIS), six cancer-associated lncRNAs (MALAT1, NEAT1, HOTAIR, H19, PVT1, MEG3) and two housekeeping genes (GAPDH and P0). According to their higher expression in DTC, TG and MALAT1 were selected as markers for thyroid specificity and malignant phenotype, respectively. Next, gene expression by ddPCR was analyzed in both FNA and FNA-ThP samples after RNA extraction (Single Cells Shot, Biorad), reverse transcription (High Capacity kit, Applied Biosystems) and preAmp step (EvaGreen Master Mix, Biorad). As preliminary results, 6 out 14 patients (12 TIR2 and 2 TIR3) appear to express MALAT1 20-200 fold higher that TG or P0, with the following distribution: 2/2 TIR3 patients and 4/12 TIR2. Of note, 2/4 TIR2 were large thyroid nodules (3–4 cm).
Conclusion
In conclusion, characterization of selected lncRNAs in Fine Needle Aspiration biopsies may represent a novel diagnostic approach potentially contributing to take the final decision to proceed or not with surgery.

New markers of follicular thyroid cancer found with wide-panel next-generation sequencing

Martyna Borowczyk, Ewelina Szczepanek-Parulska, Szymon Dębicki, Bartłomiej Budny, Małgorzata Janicka-Jedyńska, Elżbieta Wrotkowska, Blanka Majchrzycka, Katarzyna Ziemnicka & Marek Ruchała
Poznan University of Medical Sciences, Poznan, Poland.

Introduction
Thyroid nodules may be detected in up to 67% of the adult population and constitute big diagnostic challenge. Presurgical differentiation of follicular lesions between follicular adenoma (FA) and follicular thyroid carcinoma (FTC) is particularly difficult. Commercially available gene panels cover only a few, selected mutations to help in discrimination between FA and FTC. The aim of this study was to comprehensively assess the genetic background of thyroid follicular lesions and to find genetic alterations that are present solely in FTC and therefore may serve as malignancy determinants.
Material and methods
The material from 50 consecutive formalin-fixed, paraffin-embedded (FFPE) FA and FTC specimens were re-reviewed to confirm the diagnosis and to indicate the most appropriate part of the specimen for DNA sample collection. DNA was acquired from FFPE. The NGS sequencing on *Ion PGM Sequencer* (*Thermo Fisher*, USA) employing *Ion AmpliSeq Cancer Hotspot Panel v2* was conducted. The obtained data from genomic experiments were subjected for analysis using dedicated software and compared with clinical data. In case when no alterations using *Cancer Hotspot Panel* was identified, an *Ion AmpliSeq Comprehensive Cancer Panel* was employed.
Results
The sequencing has revealed various mutations present only in case of FTC (but not in FA), which may serve as potential markers of malignancy of a follicular lesion, such as: *APC, CTNNB1, EGFR, FBXW7, HBF1A, HNF1A, KRAS, NRAS, PIK3CA, TP53.* The most common mutation was *TP53.* In the specimens of FA, *JAK3, NOTCH1* and *PDGFRA* mutations were found. *BRAF, KIT, PTEN* and *SMARCB1* were found in both FA and FTC, although were much more common

in the latter. After extension of the gene panel to *Comprehensive Cancer Panel* we found that *ARID1A, BLNK, MSH2* and *SYNE1* were present only in FA, with the most frequent occurrence of BLNK mutation.
Conclusions
The results of our study demonstrate that FA and FTC may differ with detectable genetic alterations, which may support advanced follicular lesions diagnostics. Using wide gene panel including various mutations previously reported in different malignancies might be a good strategy to differentiate follicular thyroid lesions both preoperatively (to decide on therapy) and postoperatively (to confirm diagnosis in doubtful cases). Finding of new genes possibly participating in FTC pathways may enable searching for novel targeted therapeutic methods.

Prognostic value of N0 classification in differentiated thyroid cancer

Bernardo Marques[1], Raquel Martins[2], Joana Couto[2], Jacinta Santos[2], Teresa Martins[2] & Fernando Rodrigues[2]
[1]Endocrinology Department, Portuguese Institute of Oncology of Coimbra FG, EPE, Lisboa, Portugal; [2]Endocrinology Department, Portuguese Institute of Oncology of Coimbra FG, EPE, Coimbra, Portugal.

Introduction
The TNM classification of the American Joint Committee on Cancer (AJCC) and the Union for International Cancer Control (UICC) is the most widely used thyroid cancer staging system. The 8th edition was published in 2016 and introduced modifications to the N0 classification. Histological analysis is no longer necessary for patients to be classified as N0, as long as there is no evidence of lymph node (LN) metastasis in the preoperative imaging tests or clinical evaluation. Therefore, patients may be classified as N0a (without cytological or histological evidence of LN metastasis) or N0b (without clinical or radiological evidence of LN metastasis). Our study aimed to evaluate and compare the prognosis of patients with differentiated thyroid carcinoma (DTC), classified as N0a or N0b.
Methods/design
This was a retrospective study of 594 patients identified from our institutional database, who underwent surgery for DTC between 2000 and 2014. All patients had: apparently complete tumour resection, absence of LN or distant metastasis at diagnosis and non-aggressive histological variant. The association between variables was evaluated using Shi-square and Student's *T*-tests.
Results
All patients were followed for a minimum of 3 years postoperatively (146.3 $\pm$ 92 months). The majority of patients were female (88%) and had papillary thyroid carcinoma (89%). Three hundred and forty six patients (58.2%) were classified as N0b and the remainder as N0a (41.8%). Mean age was similar in both groups (51.3 years in the N0a group and 50.4 years in the N1b group, $P=0.303$). There were no significant differences between N0 classification and tumor size (mean size 16.4 mm vs 18.4 mm, $P=0.135$), multifocality (24.4% vs 26.3%, $P=0.214$), extra-thyroid extension (16.7% in both cases, $P=0.738$), treatment with radioactive iodine (44% vs 51.4%, $P=0.1$), persistence of disease (1.3% vs 2.9%, $P=0.415$), recurrence of disease (0.8% vs 0.9%, $P=0.99$) and disease-specific mortality (0.4% vs 0.3%, $P=0.962$).
Conclusion
Our results suggest that there is no difference in outcome of patients classified as N0a or N0b, regarding disease specific mortality, recurrence and persistence of disease. Therefore, preoperative clinical and imaging evaluation of the cervical region should play a major role in the staging of DTC patients.

Implementation of the British Thyroid Association thyroid nodule classification: a general UK hospital perspective

Anastasia Dede[1], Niki Mavroeidi[2], Daniel Mazzoni[3], James Smellie[4], Indu Mitra[5] & Daniel Morganstein[1]
[1]Department of Endocrinology and Diabetes, Chelsea and Westminster Hospital, London, UK; [2]Acute Assessment Unit, Chelsea and Westminster Hospital, London, UK; [3]School of Medicine, Bond University, Gold Coast, Queensland, Australia; [4]Department of Endocrine Surgery, Chelsea and Westminster Hospital, London, UK; [5]Department of Radiology, Chelsea and Westminster Hospital, London, UK.

Introduction
In 2014, the British Thyroid Association (BTA) issued guidance on thyroid cancer and introduced a new scoring system for thyroid nodules based on their sonographic appearances (U1-U5). The guidelines specified that nodules with indeterminate or suspicious appearances (U3-U5) should undergo fine needle aspiration (FNA) assessment. This study audits the implementation of the guidelines in our hospital and evaluates any changes in the management of thyroid nodules.
Patients and methods
A list of all the patients undergoing thyroid ultrasound at Chelsea and Westminster Hospital over a 1-year period from January 2016 to December 2016 was obtained. A reference cohort of thyroid ultrasounds performed before the publication of the guidelines (July 2013 to June 2014) was also obtained from the electronic data base. Patients with no nodules and patients aged $<$ 18 years were excluded. The electronic records were used to collect data regarding U classification, FNA cytology, surgery and histopathology results for both groups.
Results
A total of 793 patients were identified: 352 in the pre-guidelines cohort and 441 in the post-guidelines cohort. Patients were matched for age (52 $\pm$ 15.8 and 52 $\pm$ 16.3 respectively) and gender (1 male: 9 female ratio, in both groups). There was 70% compliance in reporting U grading as per the classification system. Pre-guidelines, 35% (95% CI 0.29–0.42) of patients had an FNA compared to 22% (95% CI 0.18–0.27) post-guidelines ($P < 0.05$). Pre-guidelines, 9% (95% CI 0.06–0.12) of patients underwent surgery compared to 10% (95% CI 0.07–0.13) post guidelines ($P=0.64$). Thyroid cancer was confirmed in 2% (95% CI 0.09–0.48) of the cases pre-guidelines and in 1.9% (95% CI 0.08–0.38) of the cases post-guidelines ($P=0.86$).
Conclusions
Our results have demonstrated a reduction in the number of patients being subjected to FNA with no reduction in the number of surgeries or cancer detection. There were initial challenges in adherence to reporting a U classification and a number of interventions were implemented to increase this.

Dynamic risk stratification in the follow-up of children and adolescents with differentiated thyroid cancer

Rafael Selbach Scheffel[1], André Borsatto Zanella[1,2], Carla Fernanda Nava[1], Lenara Golbert[3], Erika Laurini de Souza Meyer[3], Márcia Punales[4], Iracema Gonçalves[4], José Miguel Dora[1] & Ana Luiza Maia[1]
[1]Thyroid Unit, Faculdade de Medicina, Hospital de Clínicas de Porto Alegre, Universidade Federal do Rio Grande do Sul, Porto Alegre, Brazil; [2]Endocrine Division, Pontifícia Universidade Católica do Rio Grande do Sul, Porto Alegre, Brazil; [3]Endocrine Division, Irmandade da Santa Casa de Misericórdia de Porto Alegre, Universidade Federal de Ciências da Saúde de Porto Alegre, Porto Alegre, Brazil; [4]Instituto da Criança com Diabetes e Hospital Criança Conceição - Grupo Hospitalar Conceição, Porto Alegre, Brazil.

Context
Risk stratification for persistent disease is an important step in pediatric differentiated thyroid cancer (DTC) management. The dynamic risk stratification (DRS) is a well validated system for adults, but not yet for children and adolescents.
Objective
To evaluate DRS performance and other prognostic factors in pediatric DTC.
Design
Cohort study.
Setting
Four DTC referral centers at tertiary teaching hospitals.
Patients
Patients aged $\leq$ 18 years at the time of DTC diagnosis.
Main outcome measures
All patients were classified according to risk stratification system of the 2015 ATA Children DTC guidelines. Patients were also classified according to DRS (excellent, indeterminate, biochemical, or structural incomplete responses). Disease status was evaluated after initial therapy and at last follow-up.
Results
Sixty-six patients were studied: 54 (81.8%) girls, age 14.5 $\pm$ 3.0 years, 62(93.9%) papillary thyroid carcinomas. Tumor size was 2.3 cm (P25-75,1.6-3.5), and 41 (63.1%) had cervical and 18 (27.7%) distant metastasis at diagnosis. All patients underwent total thyroidectomy and 63 (95.5%) received radioiodine. Patients were classified according to DRS after initial therapy ($n=63$) as follows: 21 (33%) excellent, 13 (21%) indeterminate, 6 (9%) biochemical, and 23 (37%) structural incomplete responses. Notably, after 6.0 years (P25-75,2.7-10.0), most

patients remained in the same category. Prognostic factors associated with persistent disease in the univariate analysis were TNM, ATA risk, DRS and stimulated postoperative thyroglobulin (sPOTg). Interestingly, the sPOTg cutoff of 37.8 ng/mL displayed 81% sensitivity and 100% specificity to predict excellent response.

Conclusion

DRS after initial therapy and sPOTg are strong predictors of disease status and might be helpful on defining follow-up strategies in pediatric DTC.

Genistein Increase Thyroid Hormone and 7 alpha-hydroxycholesterol concentrations in the liver of middle-aged male rats

Branka Šošić-Jurjević[1], Dieter Lütjohann[2], Dragana Miljić[3], Jasmina Ćirić[3], Svetlana Trifunović[1], Vladimir Ajdžanović[1], Branko Filipović[1], Josef Köhrle[4], Gordana Ušćebrka[5] & Verica Milošević[1]

[1]Institute for Biological Research 'Siniša Stanković', University of Belgrade, Belgrade, Serbia; [2]Laboratory for Special Lipid Diagnostics, Institute of Clinical Chemistry and Clinical Pharmacology, University of Bonn, Bonn, Germany; [3]Clinic for Endocrinology, Diabetes and Metabolic Diseases, Clinical Center of Serbia, University of Belgrade, Belgrade, Serbia; [4]Institute for Experimental Endocrinology, Charité University of Medicine, Berlin, Germany; [5]Department of Veterinary Medicine, Faculty of Agriculture, University of Novi Sad, Novi Sad, Serbia.

Obesity, a major public health problem, is associated with hypercholesterolemia and other metabolic disorders, which are potent risk factors for athero-thrombotic disease, a leading cause of mortality worldwide. Advances in both dietary and pharmacological interventions contribute significantly to prevention and treatment of modifiable risk factors. Consumption of purified soybean isoflavones was reported to reduce plasma and liver cholesterol levels. The precise mechanism has not been established, but it has been suggested that these effects occur through an increase in bile acid excretion. The initial and rate limiting step in the classical pathway of hepatic synthesis of bile acids from cholesterol is the enzymatic addition of a 7α hydroxyl group by cholesterol 7α-hydroxylase forming 7α-hydroxycholesterol. Thyroid hormones have been shown to up-regulate expression of this enzyme. We previously reported that subcutaneously administered genistein impaired thyroid functioning in middle-aged rats, but at the same time increased expression of T3-activated genes and increased deiodinase type 1 enzyme activity in the liver. In this study we aimed to further determine effects of genistein on concentrations of thyroid hormones, total cholesterol and 7α-Hydroxycholesterol in the liver. Thirteen-month-old male Wistar rats were injected subcutaneously with 35 mg/kg of genistein, while controls received vehicle alone daily during 4 weeks. For determination of iodothyronines liquid chromatography-mass spectrometry was applied, while total cholesterol and 7α-hydroxycholesterol were determined by gas chromatography/mass spectrometry. Our study results clearly demonstrate that genistein increased ($P<0.05$) concentration of T4 and T3 in the liver of middle-aged male rats. In line with this, concentration of 7α-hydroxycholesterol also increased ($P<0.05$), but the total cholesterol levels remained unchanged. In conclusion, genistein increased hepatic availability of thyroid hormones, in accordance with detected increase in 7α-hydroxycholesterol level in the liver. The obtained data brought new light on the mechanisms involved in biological processes in the liver induced by genistein.

Serum FT4 levels predict incidence of type 2 diabetes and cardiovascular disease in the general population

Bruce HR Wolffenbuttel, Jana V van Vliet-Ostaptchouk, Robert P van Waateringe, Hanneke JCM. Wouters, Sandra N Slagter, Reindert Graaff & Melanie M van der Klauw

University of Groningen, University Medical Center Groningen, Groningen, Netherlands.

Background

Skin autofluorescence (SAF), measured with the AGE-reader, predicts cardiovascular disease (CVD) and type 2 diabetes (T2D). Thyroid hormone levels (TH) may affect this association. In the present study, we examined whether TH predict 4-years risk of T2D, CVD and mortality in the general population independently of SAF.

Methods

We included 28245 participants (age 44 ± 12 years, BMI 25.9 ± 4.3 kg/m^2) of the Dutch Lifelines Cohort Study, who had SAF and TH (TSH, FT4, FT3, Roche Modular E170 Analyzer) measured, and were not known to have diabetes or CVD at baseline, or using medication influencing TH (including levothyroxine). Diagnosis of incident T2D was by self-report, or fasting blood glucose ≥ 7.0 mmol/l or HbA1c ≥ 6.5% at follow-up; diagnosis of incident CVD was by self-report. Metabolic syndrome (MetS) was defined by NCEP-ATPIII criteria. Mortality was ascertained with the Municipal Personal Records Database. The influence of TH on the composite outcome of incident T2D, CVD and mortality, and these outcomes separately, was evaluated with logistic regression.

Results

After a median follow-up of 4 (range 1–9) years, 325 participants had died, 415 developed CVD, and 377 developed T2D. For the composite outcome, TH were identical in cases vs. non-cases. Subjects with incident T2D were significantly older (54 vs 44 years), had lower FT4 compared to no-diabetes (15.2 ± 2.1 vs 15.6 ± 2.1 pmol/l, $P<0.0001$), but similar FT3 and TSH, while those with new-onset CVD were older (57 vs 44 years) and had borderline significantly higher FT4 levels (15.9 ± 2.1 vs 15.7 ± 2.2, $P=0.06$). Logistic regression showed that each 1.0 pmol/l lower level of FT4 was associated with an 11% higher T2D risk, adjusted for SAF, age and gender. After further adjustment for presence of MetS, glucose and/or HbA1c, FT4 retained its significance (OR 0.92, $P=0.006$). In contrast, each 1.0 pmol/l higher FT4 was associated with a 5% increased CVD risk ($P=0.02$), adjusted for SAF, age and gender but this association lost its significance when adjusting further for blood pressure and cholesterol. In the multivariate models, higher FT3 was associated with increased T2D and CVD risk; there was no association between TSH and outcome.

Conclusions/interpretations

Serum FT4 levels have opposite effects on risk of development of T2D and CVD in the general population, independent of SAF, and presence of metabolic syndrome. Next steps will be to elucidate underlying mechanism(s).

GP248

Thyroid function in early-treated adult PKU patients

Csaba Sumánszki[1], Erika Kiss[2], Erika Simon[2], Attilla Patócs[3,4,5] & Endre Nagy[6]

[1]2nd Department of Medicine, Semmelweis University, Budapest, Hungary; [2]1st Department of Pediatrics, Semmelweis University, Budapest, Hungary; [3]Department of Laboratory Medicine, Budapest, Hungary; [4]Molecular Medicine Research Group, Hungarian Academy of Sciences and Semmelweis University, Budapest, Hungary; [5]'Lendület-2013' Research Group, Hungarian Academy of Sciences and Semmelweis University, Budapest, Hungary; [6]Department of Internal Medicine, Faculty of Medicine, University of Debrecen, Debrecen, Hungary.

Introduction

Phenylketonuria (PKU) is a rare inherited metabolic disorder that leads to the toxic accumulation of phenylalanine (Phe) causing usually severe mental retardation and seizures. The basis of the lifelong therapy is low in natural-protein diet and Phe-free amino acid mixtures, that provide the daily necessary amino acids, vitamins and micronutrients, such as Iodine and Selenium. It is not well known, whether the adherence to the therapy can influence the thyroid function in early-treated adult PKU patients.

Method

A prospective, cross-sectional study was conducted to assess the thyroid function, ultrasound structure and Iodine status of early-treated adult PKU patients. Seventy-five PKU patients (age 18–41 years) were included in this study. Based on their blood Phe values they were divided into two groups, with the cut-off point being the upper limit of 600 μmol/l: on-diet ($n=27$) and loose-diet ($n=48$) group. Spot urine Iodine concentration (I) and Iodine/creatinine ratio (I/Cr), blood Phe, Tyr, free triiodothyronine (fT3), free thyroxine (fT4), fT3/fT4 ratio, thyroid-stimulating hormone (TSH), thyroglobulin, anti-thyroglobulin antibody, anti-thyroid peroxidase antibody were measured and thyroid ultrasound was performed. The results were compared between the two groups.

Results

None of the PKU patients have abnormal thyroid function. The prevalence of thyroid nodes seen on ultrasound was 21.3%. Blood Phe or Tyr even Phe/Tyr ratio were not associated with TSH, fT4, fT3 or fT3/fT4 ratio or with the antibodies. However, we observed a significant difference in the urine Iodine concentration

and I/Cr ratio between the two groups ($P<0.05$, $P<0.01$ respectively). The loose-diet group based on the I concentration (median of 99.14 μg/l, 28.8% <50 μg/l, 51.1% <100 μg/l) could be classified as Iodine deficient sub-population. Blood Phe correlated inverse with the I concentration and I/Cr ratio ($r=-0.28$, $P<0.05$; $r=-0.37$, $P<0.01$), while blood Tyr showed correlation with I/Cr ($r=0.30$, $P<0.05$). fT3, TSH, Thyroglobulin, thyroid antibodies and fT3/fT4 ratio showed no significant difference between the groups, however, fT4 was significantly higher in the on-diet group ($P<0.05$, on-diet: 14.15 pmol/l ± 1.9 S.D.; loose-diet: 13.23 pmol/l ± 1.3 S.D.).

Conclusion

The result of this study suggests that Iodine status is influenced by the adherence to therapy in early-treated adult PKU patients. However, thyroid function might not be affected in adult PKU.

Abnormal thyroid enzymes in critically ill patients with no known prior thyroid disorder are an independent predictor of mortality

Sherin Elsa Mathews[1], Naga Kanaparthy[2] & Kamala Kallur[1]
[1]Mount Sinai St Luke's and Mount Sinai West, New York, New York, USA; [2]Westchester Medical Center, Valhalla, New York, USA.

Background

Sick euthyroid syndrome is a well-known condition and no additional treatment is often required. However various authors have postulated that there is an effect of abnormal thyroid function on the outcomes of hospitalized patients. In our study, we chose to study the effect of thyroid function abnormalities and their independent effect on mortality of critically ill patients who had no known prior thyroid diseases.

Methods

Data was obtained from 'Medical Information Mart for Intensive Care III' database between 2001 and 2012. All patients whose Thyroid Stimulating hormone (TSH) and Thyroxine (T4) were tested were considered. Patients who had prior thyroid diseases were removed. The rest were split into multiple groups based on their TSH and T4 levels during their ICU stay. The groups are outlined in Table 1. Base outcome group was those with normal TSH and normal T4 (Group Zero - G0). Multinomial logistic regression with length of stay (LOS) and Simplified Acute Physiology Score (SAPS) II as co-variables were run to assess the Relative Risk Ratios (RRR) of 30-day mortality with altered TSH and T4 levels.

Table 1 RRR of 30-day mortality of patients admitted to critical care units compared to those with normal thyroid values (adjusted for SAPS II and LOS).

Group	T4	TSH	RRR	*P* value	95% Conf Interval
G0	Normal	Normal		Reference	
G1	Low	Low	3.8	0.021	(1.2–11.7)
G2	Low	Normal	2.1	0.031	(1.1–4.2)
G3	Low	High	2.1	0.002	(1.3–3.3)
G4	Normal	Low	1.2	0.314	(0.8–1.89)
G5	Normal	High	1.4	0.018	(1.1–1.9)
G6	High	Low	0.9	0.849	(0.4–1.9)
G7	High	Normal	1.7	0.040	(1.02–2.8)
G8	High	High	3.7	0.001	(1.7–7.7)

Results

Total of 2970 adult ICU admissions who had no underlying thyroid disease were considered for the study. Among them, two groups, G1 (High TSH and High T4) and G8 (Low TSH and Low T4) when compared to the base outcome had a significantly increased RRR of mortality. The RRR for 30-day mortality, among G1 compared to G0 was 3.79 ($P=0.021$) and 3.67 ($P=0.001$) in G8 compared to G0.

Conclusion

Among the critically ill patients and specifically for those without prior thyroid illness, we postulate that T4 and TSH can be used as independent predictors of mortality. When both the values are altered, it might signify a more profound metabolic derangement, needing specific attention, as compared to the traditional subclinical hypo and hyperthyroidism.

Assessment of carotid intima-media thickness and endothelial dysfunction in patients with hypothyroidism

Shrook Mousa[1], Alaa Abdelhamid[1,2], Maha Assem[1], Nashwa Tharwat[3] & Aasem Saif[1]
[1]Internal Medicine Department, Cairo University, Cairo, Egypt; [2]Vascular Laboratory, Cairo University, Cairo, Egypt; [3]National Nutrition Institute, Cairo, Egypt.

Introduction

Hypothyroidism is associated with increased risk of atherosclerosis. We assessed both carotid intima media thickness (CIMT), as a marker of atherosclerosis, and endothelial dysfunction in patients with hypothyroidism.

Methods

We included 70 female patients with hypothyroidism (age 18–55 years), 40 patients with overt and 30 patients with subclinical hypothyroidism (SCH). Forty age and sex matched subjects with normal thyroid functions were also included as a control group. CIMT was measured using high-resolution colour-coded Doppler ultrasonography. Endothelial function was assessed by measuring the percent of change in blood flow following heat mediated vasodilation using Laser Doppler flowmetry.

Results

CIMT was significantly higher in patients with overt and subclinical hypothyroidism as compared with the control group (0.7 + 0.2 and 0.6 + 0.2 mm respectively vs 0.45 + 0.07 mm, $P<0.001$ for both). The percent of change in blood flow following heat mediated vasodilation was significantly impaired in patients with overt and subclinical hypothyroidism as compared with the control group (327.5 + 17 and 545 + 406% respectively vs 897.7 + 195.4%, $P<0.001$ for both). The impairment was more significant in patients with overt hypothyroidism as compared with those with SCH ($P=0.014$). There was a significant negative correlation between CIMT and the percent of change in blood flow following heat mediated vasodilation in patients with overt and subclinical hypothyroidism ($P<0.001$ for both).

Conclusion

CIMT, as a marker of atherosclerosis, is significantly higher in patients with overt and subclinical hypothyroidism compared with normal control subjects. Impairment of endothelial function is a contributing factor to the increased risk of atherosclerosis in both groups of patients.

Thyroid-specific mitochondrial dysfunction results in abnormal thyrotropin responses

Kyong Hye Joung[1], Jung Uee Lee[2], Ji Min Kim[1], Sang-Hee Lee[3], Seong-Min Kim[4], Hyun Jin Kim[1] & Minho Shong[1]
[1]Chungnam National University School of Medicine, Daejeon, Republic of Korea; [2]Mary's Hospital, Catholic University of Korea, Daejeon, Republic of Korea; [3]Institute of Molecular Biology & Genetics, Seoul National University, Seoul, Republic of Korea; [4]Chungnam National University and Hospital, Daejeon, Republic of Korea.

Background

Optimal production of cellular energy and metabolites in mitochondria is one of the most important factors in endocrine organs that accomplish the momentary adaptation to ligand stimulation, such as insulin secretion and aldosterone biosynthesis. Although it has been suggested that thyroid gland function is also largely dependent on mitochondrial function, functional behavior of thyroid gland on compromised mitochondrial function remained to be identified. In this study, we have developed the new animal model of thyroid-specific mitochondrial dysfunction using standard gene targeting technology to understand the role of mitochondria OxPhos dysfunction in thyroid gland.

Methods

We have analyzed the histological and functional phenotypes of the mice which has thyroid specific mitochondrial dysfunction by targeting *Crif1* gene which is involved in intramitochondrial production of OxPhos complex subunits.

Results

We analyzed the phenotypes of the mice with mitochondrial OxPhos deficiency. Homozygote thyroid-specific mitochondrial dysfunction (ThyCKO) mice retarded growth and died prematurely in PN21 to 35 days with severe thyroid dysfunction. Histology of homozygote ThyCKO mice showed distortion of thyroid follicles and oncocytic change of cells. Serum TSH and thyroid hormone levels showed no difference between 10 week old wild type and heterozygote

ThyCKO mice. Unexpectedly, TSH injections (6 μg/day) to 10 week old heterozygote ThyCKO mice exacerbated ER swelling combined with destruction of mitochondrial cristae structure, resulting in lower secretion of thyroid hormone.
Conclusion
This study suggested that mitochondrial OxPhos defect may cause structural and functional changes of thyrocyte which may lead the progressive chronic nonautoimmune failure of thyroid gland.

GP252

T3 enhances GLUT2, PEPT1 and CD36/SR-B2 content in the intestinal epithelium of mice

Andressa Harumi Torelli Hijo & Francemilson Goulart-Silva
University of São Paulo, São Paulo, Brazil.

Introduction and aim
Thyroid hormones (THs) regulates metabolism in adults, such as controlling energy balance by regulating energy expenditure and its storage. Hyperthyroidism increases thermogenesis, which results in the increase of the metabolic rate. THs, when combined with their receptor, can induce the expression of some genes, which can reflect on the content and activity of specific proteins. There are studies showing that THs affect the uptake of nutrients, such as glucose and peptides, but it is not well known how it works. Therefore, the current study has the aim to evaluate the impact of hypo and hyperthyroidism in the nutrients transporters content, such as carbohydrate, peptides and lipids transporters in the intestinal epithelium.
Materials and methods
In this study, mice C57BL/6, male and adults were distributed in three groups: control (vehicle/saline), hypothyroid (Propylthiouracil - PTU) and hyperthyroid (Triiodo-L-thyronine - T3). The animals were injected with saline, PTU (12.5 mg/Kg) or (T3 0.25 μg/g) for 30 days. At the end of the treatment, the mice were killed and the intestinal epithelium was removed to evaluate the transporters of carbohydrates (SGLT1, GLUT2 e GLUT5), protein hydrolysate (PEPT1) and lipids (NPC1L1, CD36/SR-B2 e FATP4) by Western blotting technique. Since NHE3 plays an important role in the sodium and peptides absorption, it was evaluated as well.
Results
Hyperthyroidism increased the GLUT2, CD36/SR-B2 and PEPT1content when compared to the control mice. SGLT1, GLUT5, FATP4 and NPC1L1 remained unchanged after T3 treatment. T3 induced a little increase of NHE3, but not statistically yet. The hypothyroidism did not affect the nutrients transporters nor NHE3 compared to the control group.
Conclusion
Since THs increase the glucose uptake by intestine through sodium independent mechanism, which is well-established, the increased GLUT2 in the intestine after T3 treatment could explain how THs stimulate glucose absorption. Furthermore, T3 also increased PEPT1 and CD36/SR-B2 content, which could be a physiological mechanism to provide nutrients (glucose, amino acids and fatty acids) and sustain the high metabolic demand and thermogenesis, which are common findings in the hyperthyroidism condition.

Identification of new thyroid hormone dependent biomarkers for a successful replacement therapy

Sebastian Nock[1], Kornelia Johann[1], Lisbeth Harder[1], Carolin S Höfig[2], Vanessa Kracke[3], Beatrice Engelmann[3], Georg Homuth[3], Uwe Völker[3], Jens Mittag[1] & Georg Brabant[1]
[1]Department of Internal Medicine I - Molecular Endocrinology, University of Lübeck, Lübeck, Germany; [2]Institute of Experimental Endocrinology, Charité – Universitätsmedizin Berlin, Campus Virchow-Klinikum, Berlin, Germany; [3]Department of Functional Genomics, Universitätsmedizin Greifswald, Greifswald, Germany.

Thyroid hormones (TH) play a pivotal role in embryonal and postnatal development in vertebrates, hence, their secretion is highly regulated. In clinical practice TSH and free T4 (fT4) are commonly used as the most reliable parameters to evaluate the TH status. But they only represent the TH receptor β driven status of the hypothalamic-pituitary-thyroid axis while organ or tissue specific TH availability may be different. This discrepancy originates in the tissue specific unequal distribution of proteins modulating local T3 signalling like TH transporters, deiodinases and TH receptors (TRα and TRβ). To identify patients with tissue specific hypo – or hyperthyroidism, new biomarkers are urgently needed. By comparing studies of experimental thyrotoxicosis in human and mouse using OMICs techniques, we discovered 16 serum proteins concordantly regulated in both species, which are predominantly expressed in liver, lymphoid system or extracellular matrix. To validate these putative targets, we conducted a follow-up mouse study with a Methimazol and sodium perchlorate induced hypothyroid group and a T3 or T4 induced hyperthyroid group. Subsequent qPCR analysis revealed gene expression changes of our candidates under hypo – and/or hyperthyroid conditions in liver, bone and spleen. To characterise these putative biomarkers in greater detail, we aimed to determine the secreting cell types and validate their T3-dependence in different model systems. We therefore investigated target gene expression of the human hepatocyte cell line HepG2, primary murine osteoclast, -blasts and isolated murine B-cells, T-cells and monocytes under either eu-, hypo- or hyperthyroid conditions or with a mutation in either TRα or TRβ or both. Among these candidates the expression of the macrophage derived protein, CD5L, was highly T3-dependent in liver, spleen and bone. CD5L is thus regarded as the most promising putative TH – biomarker to be further investigated under pathophysiological clinical conditions.

Proteome analysis of 3,5-T2-treated primary mouse hepatocytes

Janine Golchert[1], Julika Lietzow[2], Uwe Völker[1], Georg Homuth[1] & Josef Köhrle[2]
[1]Department of Functional Genomics, Interfaculty Institute for Genetics and Functional Genomics, University Medicine Greifswald, Greifswald, Germany; [2]Institute of Experimental Endocrinology, Charité – Universitätsmedizin Berlin, Berlin, Germany.

Introduction
Besides the classical thyroid hormones T4 and T3 the endogenous thyroid hormone metabolite 3,5-diiodothyronine (3,5-T2) attracted attention during the last years due to its metabolic activity. 3,5-T2 exerts thyromimetic action on the hypothalamus-pituitary-thyroid axis and the heart as well as on energy and lipid metabolism. In previous liver transcriptome analyses of 3,5-T2-treated lean and diet-induced obese male mice, effects on hepatic lipid, steroid, xenobiotic, and thyroid hormone metabolism were observed.
Objectives
Applying an untargeted mass spectrometry based proteome analysis approach for 3,5-T2-treated primary mouse hepatocytes, we intended to confirm previous *in vivo* transcriptome data and to identify novel protein targets and pathways of hepatic 3,5-T2 action.
Materials & methods
Primary hepatocytes isolated from male mouse liver were cultivated under FCS-free conditions and treated with 100 nM 3,5-T2 for either 6, 24, 48 or 72 h ($n = 3$ per group). Proteins were prepared and digested using Trizol and FASP (filter-aided sample preparation), respectively. Proteomes were analyzed using LC-MS/MS measurement and data analysis was performed *via* MaxQuant and GeneData Analyst software. Pathway analysis of proteins exhibiting significantly altered amounts was carried out using the Ingenuity Pathway Analysis (IPA) software.
Results
The proteomics approach revealed 852 proteins exhibiting significantly altered amounts in 3,5-T2-treated primary hepatocytes compared to their time matched controls ($P \leq 0.05$, fold change $\geq |1.5|$). Notably, the highest number of proteins with significantly changed amounts was observed after 48 h of treatment, while after 6 and 24 h 4.5-times less proteins were altered. The greatest overlap of 92 proteins was observed between the time points 24 and 48 h of 3,5-T2 treatment. As identified by IPA, proteins showing significant alterations mainly belong to the pathways 'EIF2 signaling', 'regulation of eIF4 and p70S6K signaling', 'mTOR signaling', various degradation pathways for intermediary metabolites, as well as proteins involved in steroid hormone metabolism.
Conclusion
The untargeted mass spectrometry approach identified a variety of proteins and pathways altered by 3,5-T2 treatment in primary mouse hepatocytes as well as the confirmation of previously indicated 3,5-T2 effects on mouse liver transcriptomes and functional readouts. To further extend our knowledge of 3,5-T2 action, a transcriptome analysis of the current study is planned to create a complementary dataset.

MicroRNA-4443 causes CD4+T cells dysfunction by targeting TRAF4 in Graves' disease

Yicheng Qi[1,2], Guang Ning[2] & Shu Wang[2]
[1]Renji Hosptial, Shanghai, China; [2]Ruijin Hosptial, Shanghai, China.

Context
Aberrant CD4+T cell function plays a critical role in the process of Graves' disease (GD). MicroRNAs (miRNAs) are important regulators of T cell activation, proliferation and cytokine production. However, the contribution of miRNAs to CD4+T cell dysfunction in GD remains unclear.
Objective
To investigate how certain miRNA causes aberrant CD4+T cell function in GD patients.
Methods
We compared the expression pattern of miRNAs in CD4+T cells from untreated GD patients with those from healthy controls. The most significantly dysregulated miRNAs were selected and their correlations with clinical parameters were analyzed. The effect of miR-4443 on CD4+T cells cytokines production and proliferation was assessed. The potential gene target was identified and validated.
Results
GD patients had unique pattern of miRNA expression profile in CD4+T cells comparing to healthy subjects. MiR-10a, miR-125b and miR-4443 were the three most significantly dysregulated miRNAs. The elevated miR-4443 levels were strongly correlated with clinical parameters in an independent dataset of untreated GD patients (N=40) while miR-4443 was normally expressed in GD patients with euthyroidism and negative TRAb level. We found that miR-4443 directly inhibited TNFR-associated factor (TRAF) 4 expression to increase CD4+T cells cytokines secretion as well as proliferation through the NF-κB pathway. Furthermore, the TRAF4 levels in GD patients were inversely correlated with miR-4443, and knocking down TRAF4 had a similar effect with miR-4443 overexpression.
Conclusion
The increased expression of miR-4443 induced CD4+T cells dysfunction by targeting TRAF4, which may cause Graves' diseases.

Are Thyrotropin Receptor Antibodies (TRAb) being used to diagnose the aetiology of hyperthyroidism?

Chloe Desmond[1] & Aftab Ahmad[2]
[1]University of Liverpool Medical School, Liverpool, UK; [2] The Royal Liverpool and Broadgreen University Hospitals, Merseyside, UK.

Introduction
Hyperthyroidism is a prevalent condition which affects approximately 2% of the female population and 0.2% of the male population in the UK. 75% of cases are caused by the auto-immune condition, Graves' disease. Thyrotropin receptor antibodies (TRAb) are raised in 90% of patients with Graves' disease and are commonly used to investigate the aetiology of thyrotoxicosis.
Background
TRAb can be used to confirm Graves' disease due to its high sensitivity and specificity, at 98 and 99% respectively. The National Institute for Health and Care Excellence (NICE) clinical advice is to test for TRAb in patients with confirmed hyperthyroidism. Patients who have negative antibodies should then undergo radionuclide thyroid uptake scans.
Aim
To see if patients who attended the endocrinology outpatient clinic at the Royal Liverpool University Hospital had TRAb tested, and to compare this to other methods of investigating the aetiology of hyperthyroidism.
Method
The records of 150 patients who attended the endocrinology outpatient clinic from 2003 to 2017 were analysed. Data was collected to assess if they had TRAb tested. This data was compared to the number of patients who had thyroid peroxidase (TPO) antibody tested, and whether radionuclide thyroid uptake scans were performed.
Results
In the sample of patients, aetiologies of thyrotoxicosis included Graves' disease (107), toxic multi-nodular goitre (33), solitary toxic nodule (1), thyroiditis (6) and non-specified hyperthyroidism (3). 95.33% of these patients had TRAb tested, 81.33% had TPO tested and 63.33% had a thyroid uptake scan. Of the patients who had Graves' disease, 57% of patients had a thyroid uptake scan despite having a positive TRAb assay.
Conclusion
From this audit it can be confirmed that most of the patients with hyperthyroidism, who attended the endocrinology outpatient clinic, had their TRAb tested. However, it has been shown that there is an overuse of thyroid uptake scans in patients with Graves' disease who had a positive TRAb assay. This demonstrates that in clinical practice there is a lack of continuity between interpreting TRAb results and ordering uptake scans. By only performing the scans in TRAb negative patients, clinicians can provide a more clinically efficient and cost-effective service.

Impact of TSH during the first trimester of pregnancy in obstetric and fetal complications: Usefulness of 2.5 mIU/l cut-off value

Berta Soldevila[1,2,3], Marta Hernández[4,5], Carolina López[4,5], Laura Cacenarro[1,6], María Martínez-Barahona[7,2], Elisabet Palomera[2,8], Ferran Rius[4,5], Albert Lecube[4,5,3], María José Pelegay[9], Jordi García[10], Dídac Mauricio[1,2,3] & Manel Puig-Domingo[1,2,3]
[1]Endocrinology and Nutrition Department, Germans Trias i Pujol University Hospital, Badalona, Spain; [2]Institute for Health Science Research Germans Trias i Pujol, Badalona, Spain; [3]CiBER de diabetes y enfermedades metabólicas (CIBERDEM), Instituto de Salud Carlos III, Madrid, Spain; [4]Endocrinology and Nutrition Department, Arnau de Vilanova University Hospital, Lleida, Spain; [5]Biomedical Research Institute of Lleida, Lleida, Spain; [6]Endocrinology and Nutrition Department, Hospital Privado Universitario de Córdoba, Córdoba, Argentina; [7]Paediatrics Department, Universitary Germans Trias i Pujol Hospital, Badalona, Spain; [8]Research Unit, Mataró Hospital, Mataró, Spain; [9]Gynecology and Obstetrics Department, Arnau de Vilanova University Hospital, Lleida, Spain; [10]Paediatrics Department, Arnau de Vilanova University Hospital, Lleida, Spain.

Background
An association of pregnancy outcomes with subclinical hypothyroidism have been reported, however, there still exists a strong controversy regarding whether subclinical hypothyroidism ought to be dealt with or not. The latest American Thyroid Association's guideline gives support to a higher TSH upper reference range of 4 mIU/l than the one proposed a few years ago of 2.5 mIU/l for the first trimester of pregnancy, in the absence of local normal ranges of TSH. In spite of this, the controversy regarding the upper limit of TSH during pregnancy for the treatment of subclinical gestational hypothyroidism seems to be far from being clarified.
Objective
To evaluate the association of fetal-maternal complications with first trimester maternal TSH values.
Patients and methods
A retrospective study in a single tertiary care hospital was performed. Thyrotropin (TSH) universal screening was performed between weeks 9–12 of gestation in 1981 pregnant women during 2012. Outcomes included fetal-maternal complications and newborn health parameters.
Results
Median TSH was 1.72 (0.99–2.61) mIU/l. The incidence of perinatal loss, miscarriage and stillbirth was 7.2, 5.9 and 1.1% respectively. Median TSH of women with and without miscarriage was 1.97 (1.29–3.28) vs 1.71 (0.96–2.58) mIU/l ($P=0.009$). Incidence of preeclampsia was 3.2%; TSH in these women was 2.10 (1.40–2.74) vs 1.71 (0.98–2.59) mIU/l in those without ($P=0.027$). TSH in women with dystocia in labor was 1.76 (1.00–2.53) vs 1.68 (0.94–2.59) mIU/l and in those who gave birth with normal progression ($P=0.044$). Women with TSH 2.5–5.1 mIU/l had a higher risk of perinatal loss (OR 1.589 (1.085–2.329), $P=0.017$), miscarriage (OR 1.702 (1.126–2.572), $P=0.012$) and premature birth (OR 1.379 (1.013–1.876), $P=0.041$). There was no association with the other outcomes analyzed. A composite variable was constructed including fetal-maternal complications and newborn health parameters in order to assess which TSH value would predict an adverse outcome by using ROC curves. The area under the curve obtained was 0.528, not allowing the definition of a useful cut-off point predicting adverse outcomes.
Conclusions
Our data support that higher levels of TSH within the reference normal concentrations during the first trimester are associated with higher risk of adverse

obstetric outcomes (perinatal loss, miscarriage and premature birth). In our study, there is not a useful crude TSH cut-off point predicting adverse outcomes.

Influence of levothyroxine treatment in pregnant women with thyroid antiperoxidase antibodies

Paula Fernandez Martinez, Rocio Aguado Garcia, David Emilio Barajas Galindo, Tania Ramos Martinez, Elena Gonzalez Arnaiz, Sara Garcia Arias, Mirian Alejo Ramos, Ana Hernandez Moreno, Maria Ballesteros Pomar & Isidoro Cano Rodriguez
Complejo Asistencial Universitario de Leon, Leon, Spain.

Introduction
Thyroid antiperoxidase antibodies above the cut-off value (ATPO +) may increase the risk of maternal-foetal complications and could modify the treatment criteria. The aim of the study is to consider the impact of levothyroxine administration on maternal-foetal complications in ATPO+ pregnant women with delivery in 2016.
Methods
In Leon's health area (Spain), universal screening for gestational thyroid dysfunction is performed. ATPO + was ≥35 U/ml (Immulite 2,000). The cut-off for subclinical gestational hypothyroidism (HSG) was TSH >3.72 mU/l (Roche kit) The maternal-foetal variables studied were gestational age, birth weight and type of delivery:
-Preterm birth is considered when pregnancy's completed before week 37.
- Low birth weight is considered <2500 gr.
The qualitative variables were expressed by absolute numbers and percentages, and the quantitative variables in mean and standard deviation. The X2 test was used to evaluate differences between proportions and T student test to compare means. The association among risk factors and treatment was studied by relative risk and confidence interval.
Results
We analysed 1980 deliveries, 22 miscarriages and 18 deliveries outside our hospital. 87 were eliminated by previous treatment with thyroxine. Of 1672 screenings: 142 (8.50%) had ATPO +, 286 (17.11%) HSG and in 55 (3.29%) HSG and ATPO+ coexist. We studied 131 ATPO+ pregnant women: 45% ($n=59$) of patients received treatment during pregnancy. Of those who received treatment during pregnancy, presented preterm delivery 3.39% vs 11.11% that didn't receive thyroxine (RR: 0.31, 95% CI: 0.07–1.40). The mean gestational age of the newborns was 39.05 (1.53) weeks, for patients treated with levothyroxine, it increases up to 39.15 (1.4) weeks, slightly higher than those who didn't receive treatment ((38.97 (1.64) ($P=0.50$)). We found 6.78% children with weight <2500 gr in patients with treatment and 5.56% in those who weren't treated ($P=1.00$). 15 untreated women (20.83%) underwent a caesarean section and 10 treated pregnant women (16.95%) ended their pregnancy as a caesarean section ($P=0.84$). The average dose of thyroxine was 71.53 µg/day (0.95 µg/kg per day). With this dose, the average TSH at the end was 1.76 mU / l.
Conclusion
According to these results, there is neither positive or negative impact of the administration of levothyroxine to pregnant women ATPO +. There may be a protective tendency on preterm delivery, although larger studies are needed.

Thyroid disorders in patients with advanced neoplastic disease treated with immune checkpoints inhibitors

Enzamaria Fidilio, Mayra A Velásquez, Eva Sanz, Ángel M Ortiz, Andreea Ciudin, Jorge Mesa & Carlos Zafón
Department of Endocrinology and Nutrition, Vall d'Hebron Universitary Hospital, Barcelona, Spain.

The use of immune checkpoint inhibitors (ICPI) for treatment of different advanced cancers has opened a new therapeutic window. Thyroid dysfunction is an often side effect described for these drugs.
Objectives
To describe the thyroid alterations found in oncologic patients undergoing treatment with ICPI.
Materials and methods
A descriptive, retrospective study of oncologic patients receiving treatment with ICPI referred to the Endocrinology Clinic of our Center for thyroid disorders from October 2013 to January 2018.
Results
Thirty-four patients were detected, mean age 59.9 years old (from 34 to 79), 64.7% were women. Neoplasm treated were mainly breast (17.6%), lung (17.6%) and melanoma (14.7%), among others. The immunotherapy received was in monotherapy regimen in the majority of cases (73.5%), using a combination of ICPI in the remaining cases (Pembrolizumab 35.3%, Atezolizumab 20.6%, Nivolumab + Ipilimumab 14.7%, Nivolumab 11.8%, Nivolumab + Anti-LAG3 8.8%, Tremelimumab + Durvalumab 2.9%, Tremelimumab 2.9%, PDR001 2.9%). Before starting immunotherapy, 74% of patients were euthyroid, 18% had clinical or subclinical hypothyroidism, in two cases the previous thyroid status was unknown, and only one patient initiated immunotherapy with subclinical hyperthyroidism. Patients had a mean follow-up of 42.1 ± 36.4 weeks, 61.8% of patients presented asymptomatic transient hyperthyroidism as first alteration 8.7 ± 8.8 weeks after initiating the ICPI, the remaining developed asymptomatic hypothyroidism as first thyroid function alteration, on average 15.7 ± 13.2 weeks after initiating immunotherapy. During follow-up, all patients with hyperthyroidism developed hypothyroidism 6.7 ± 4.2 weeks later. When analyzed separated, those who received ICPI in monotherapy or combination, the combined therapy group presented hyperthyroidism earlier than the monotherapy group (3.4 ± 1.0 weeks vs 12.6 ± 9.1 weeks). No specific treatment was reported for patients with hypertiroidism, however substitutive Levothyroxine was iniciated when hypothyroidism was found. At the end of the follow-up 64.7% continued on Levothyroxine, althought only 48.6% of patients continued on treatment with ICPI. In 31.4% of patients immunotherapy was stopped due to progression of the neoplastic disease and in 5.7% due to immunotherapy related toxicity, but none because of the thyroid function alterations.
Conclusions
In our series, more than half of the patients initially presented with transient hyperthyroidism with subsequent hypothyroidism and the rest with hypothyroidism as first dysfunction, requiring replacement therapy with levothyroxine in most cases. These alterations did not merit the suspension of ICPI. Patients treated with combination of ICPI develop hyperthyroidism earlier compared with patients receiving ICPI as monotherapy.

Early low dose rituximab for active thyroid eye disease: an effective and well tolerated treatment

Elizabeth Insull[1], Helen Turner[2], Joel David[3] & Jonathan Norris[1]
[1]Oxford Eye Hospital, Oxford, UK; [2]Department of Endocrinology, Oxford Centre for Diabetes, Endocrinology and Metabolism, Oxford, UK; [3]Rheumatology Department, John Radcliffe Hospital, Oxford, UK.

Background
Thyroid eye disease (TED) is an autoimmune inflammatory disease that can be both disfiguring and potentially sight threatening. Suppression of inflammation in active disease can reduce the risk of visual loss and limit long-term sequelae of the disease. Current disease management involves suppression of inflammation using glucocorticoids. The aim of our study was to evaluate the efficacy of early disease intervention with targeted immunomodulatory therapy to alter the disease course. This paper reports the efficacy of low dose rituximab in reducing clinical activity in TED in a small population.
Methods
A retrospective audit of consecutive patients with active TED at the Oxford Joint Thyroid Clinic (Ox-TED) managed primarily with rituximab. Patients with a VISA clinical activity score of three or more were considered to have active disease and were included in the study. Exclusion criteria included age less than 18 years, pregnancy or breastfeeding, a previous adverse reaction to rituximab, active infection, immunocompromised state or positive HIV or hepatitis serology. All patients were treated with a 100 mg rituximab infusion and 500 mg IV methylprednisolone. Further glucocorticoid or steroid sparing agents were given if clinically indicated. VISA clinical activity score, VISA overall severity score and Oxford Quality of Life score were recorded at baseline and subsequent follow-up visits. TSH receptor antibody (TRAb) levels and B cell subsets were recorded at baseline and following treatment. Any adverse reactions were documented.
Results
Twelve patients were followed up for an average of 6.3 months (1–12 months). VISA clinical activity scores significantly decreased from baseline to most recent

follow up (4.69–1.58, $P<0.001$). VISA overall severity scores significantly reduced by 50% from 12 to 6, $P<0.001$. The average cumulative dose of IV methylprednisolone was 2.25 g, half the cumulative dose recommended by EUGOGO for patients with moderate to severe active TED. Rituximab induced a significant depletion in B-cells ($CD19^+$), $n=11$, $P<0.001$. In those patients with markedly elevated serum TRAb levels >2.5 IU/L ($n=7$) two reduced to moderate levels (0.5–2.5 IU/l) and five remained markedly elevated. A transient infusion related rash was the only adverse effect noted in four patients. QOL scores did not differ markedly before and after treatment.

Conclusion

Low dose rituximab is an efficacious, well-tolerated and safe treatment for active TED; reducing disease activity and allowing reduced administration of systemic steroid.

DOI: 10.1530/endoabs.56.GP260

Analysis of serum immunoglobulin G4 (IgG4) levels in euthyroid subjects with autoimmune thyroid disease and goiter in a Single Medical Center in Taiwan

Wan-Chen Wu & Fen-Yu Tseng
National Taiwan University Hospital, Taipei, Taiwan.

Immunoglobulin G4-related disease (IgG4-RD) is a newly identified syndrome characterized by high serum IgG4 levels and increased IgG4-positive plasma cells infiltration. IgG4-related thyroiditis (IgG4-RT) was first prescribed based on the immunohistochemistry in 2009. Some of Hashimoto's thyroiditis (HT), Graves' disease (GD) and Riedel thyroiditis were reported to be classified as IgG4-RT based on high serum IgG4 level or histopathological findings. However, the prevalence of IgG4-RT in HT and GD varies in previous reports. There were inconsistent results in the clinical features in IgG4-RT and its relationship to thyroid auto-antibodies. This study is to evaluate serum IgG4 levels in subjects with autoimmune thyroid disease (ATD), and the relationship of serum IgG4 level and thyroid auto-antibodies. A total 185 subjects, including 23 men and 162 women with thyroid diseases were enrolled. 58 subjects had GD in remission, 61 subjects had HT, and 66 subjects had goiter or multinodular as control group. All participants did not receive any anti-thyroid drugs, levothyroxine, or immunosuppressive treatment. The median (interquartile range) serum IgG4 levels were 51.4 (34.4–105.0), 53.4 (32.5–86.8), and 67.5 (38.3–111.0) mg/dl in subjects with GD, HT, and goiter, respectively. There was no significant differences of serum IgG4, IgG levels, and IgG4/IgG ratio between these three groups. There were 9 (15.8%), 5 (8.2%), and 14 (21.2%) subjects had elevated IgG4 levels (>135 mg/dl) defined by serological diagnostic criteria of IgG4-RD in each group, which also showed no statistical differences. Of these 28 subjects with elevated IgG4 levels, 6 (21.4%) were male, which showed a higher male proportion. The mean age was 45.3 ± 12.4 years, which was younger than those with normal IgG4 levels (50.8 ± 11.4 years). However, there were no significant differences in thyroid auto-antibodies, including TSH receptor ($4.3\pm8.7\%$ vs $6.4\pm10.1\%$, $P=0.313$), anti-TPO (122.6 ± 198.7 IU/ml vs 229.6 ± 457.0 IU/ml, $P=0.225$), and anti-thyroglobulin (119.9 ± 264.7 IU/ml vs 217.6 ± 870.5 IU/ml, $P=0.558$) antibodies between subjects with elevated IgG4 and without elevated IgG4. Only one subjects was diagnosed of monoclonal gammopathy of undetermined significance. There was no significant extra-thyroid organ involvement as seen in IgG4-RD in the other 27 subjects. There were no significant differences in serum IgG4 levels, and the prevalence of elevated serum IgG4 level in subjects with GD, HT, and goiter in this study.

Thyroid disorders in patients treated with inmune checkpoint inhibition therapy

Nerea Eguílaz, Ander Ernaga, Emma Anda, Javier Pineda, Ana Irigaray & Juan Manuel Zubiría
Complejo Hospitalario de Navarra, Pamplona, Spain.

Objective

Immune checkpoint inhibitors (ICPI) have become an effective therapeutic option for certain advanced malignant tumours. Immune-related adverse events affecting thyroid function are among the most frequent toxicities. The aim of our study is to determine the prevalence of thyroid disorders in patients undergoing treatment with ICPI.

Methods

Retrospective study including all patients treated with ICPI in our centre, from 07/2015 to 12/2017. Patients were divided into three groups, according to the drug received: Nivolumab, Pembrolizumab or Atezolizumab. Those patients treated with levothyroxine before ICPI therapy were excluded. We used the SPSS program, version 20.

Results

A total of 79 patients were treated with ICPI in our centre; seven of them being treated previously with levothyroxine were excluded. We studied 72 patients, 70.8% men (51/72) with a mean age of 64 ± 8.6 years. 44 patients (61.1%) were treated with nivolumab, 14 patients (19.4%) with atezolizumab and 14 (19.4%) with pembrolizumab. The 54.2% ($n=39$) had lung cancer, followed by melanoma 19.4% ($n=14$), bladder 11.1% ($n=8$), kidney 8.3% ($n=6$), colon 4.2% ($n=3$) and ovarian cancer 2.8% ($n=2$). In 16 patients (22.2%), thyroid side-effects were detected. Two of 16 patients (12.5%) had autoimmune thyroid disease prior to treatment. Mean thyrotropin (TSH) before ICPI therapy was 1.47 (0.39–4.18) mU/l. The most frequent thyroid disorder was subclinical hyperthyroidism in 12/16 patients (75%); the median onset was 5 weeks (range, 1–52). Out of these, 8/12 patients presented transient thyrotoxicosis, 3/12 continued with subclinical hyperthyroidism and 1/12 evolved to hypothyroidism. None of them received antithyroid drugs. 4/16 patients (25%) developed hypothyroidism, without a previous hyperthyroid phase; the median onset was 9 weeks (range, 8-22). 60% hypothyroid patients needed treatment with levothyroxine. No patient needed interruption of ICPI treatment because of thyroid dysfunction. 35.7% of patients treated with atezolizumab developed thyroid disorders, 28.6% of pembrolizumab and 15.9% of nivolumab ($P=0.16$). Indeed, in terms of age, sex and type of tumour, no significant differences were found between those who developed thyroid disorder or not.

Conclusions

In our study, 22.2% of patients with IPCI treatment developed thyroid side-effects. Of these patients, 50% presented transient thyrotoxicosis, 31.3% developed hypothyroidism and 18.7% developed persistent subclinical hyperthyroidism. The median onset was 5 weeks for hyperthyroidism and 9 weeks for hypothyroidism.

Thyroid peroxidase antibody-positivity, but not isolated thyroglobulin antibody-positivity, is associated with non-thyroidal autoimmune diseases - a population study of more than 8000 Danes

Sofie Bliddal[1], Inge Bülow Pedersen[2,3], Nils Knudsen[4], Allan Carlé[2,3], Lena Bjergved[5], Claus Henrik Nielsen[6] & Ulla Feldt-Rasmussen[1]
[1]Department of Medical Endocrinology, Copenhagen University Hospital (Rigshospitalet), Copenhagen, Denmark; [2]Department of Endocrinology, Aalborg University Hospital, Aalborg, Denmark; [3]Department of Clinical Institute, Aalborg University, Aalborg, Denmark; [4]Department of Endocrinology, Copenhagen University Hospital (Bispebjerg), Copenhagen, Denmark; [5]Department of Endocrinology, Copenhagen University Hospital (Herlev), Copenhagen, Denmark; [6]Institute for Inflammation Research, Copenhagen University Hospital (Rigshospitalet), Copenhagen, Denmark.

Introduction

Autoimmune thyroid disease is associated with other autoimmune diseases. However, most studies are register-based cohort studies or investigate selected patient populations. In a large national cross-sectional population-based study, we investigated positivity of thyroid peroxidase- or thyroglobulin-antibodies (TPOAbs or TgAbs) in association with non-thyroidal autoimmune disease.

Methods

As part of The Danish Investigation of Iodine Intake and Thyroid Diseases (DanThyr), two cross-sectional population studies with identical protocol were performed (1997–1998, $n=4649$, and 2004–2005, $n=3570$). Participation involved blood tests and questioning by a medical doctor on history of various diseases. TPOAbs and TgAbs were analysed by radioimmunoassay (DYNOtest, BRAHMS, Germany, cut-off: 60 U/ml). Non-thyroidal autoimmune diseases included rheumatoid arthritis, pernicious anaemia, vitiligo, and diabetes. Logistic regression analyses were adjusted for age, smoking, sex, cohort origin, and familial disposition. Ethical approval and informed consent were obtained.

Results

Of 8105 included participants, 1304 (16.1%) were TPOAb- or TgAb-positive. Hypo- or hyperthyroidism was reported by 2.8 and 2.9%, respectively; 0.6%

reported both. Of the 937 (11.6%) participants reporting non-thyroidal autoimmune disease, 20.3% were thyroid antibody-positive ($P<0.001$ compared to participants without non-thyroidal autoimmune disease), 6.7% reported hypothyroidism, and 4.5% reported hyperthyroidism. In adjusted logistic regression analysis, thyroid antibody-positivity was associated with a significantly higher odds ratio of non-thyroidal autoimmune disease (14.6% vs 11.0%, $P<0.001$, adjusted odds ratio (aOR) 1.3 95%CI:1.1–1.5, $P=0.008$). In participants reporting hypothyroidism, 27.6% reported non-thyroidal autoimmune disease (vs 11.0%, $P<0.001$, aOR 2.5 95%CI:1.8–3.4, $P<0.001$). Hyperthyroidism was associated with nonthyroidal autoimmune disease (17.6% vs 11.3%, $P=0.005$); however, not in adjusted analyses (aOR 1.4 95%CI:0.96–1.9). Excluding participants reporting hypo- or hyperthyroidism, non-thyroidal autoimmune disease was still more prevalent in thyroid autoantibody-positive than -negative participants (13.1% vs 10.6%, $P=0.01$). Among the 190 participants with non-thyroidal autoimmune disease and thyroid autoantibody-positivity, 158 (83.1%) were TPOAb-positive. Participants with TPOAb-positivity combined with TgAb-positivity had similar frequencies of non-thyroidal autoimmune disease as those with isolated TPOAb-positivity (15.3% vs 15.1%). The prevalence among 32 participants with isolated TgAb-positivity was similar to that of thyroid antibody-negative participants (11.9% vs 11.0%, $P=0.62$).

Conclusion

More than 16% of the general population were thyroid autoantibody-positive, which (also without history of thyroid dysfunction) was associated with non-thyroidal autoimmune disease. Especially participants with reported hypothyroidism or TPOAb-positivity, but not those with isolated TgAb-positivity, had increased prevalence of non-thyroidal autoimmune disease. Attention should be paid to polyautoimmunity in patients with hypothyroidism and TPOAbs.

Thyroid function in pregnant women; relation to Gestational Diabetes Mellitus (GDM) and Body Mass Index (BMI)

George Simeakis, Evangelia Vogiatzi, Panagiota Konstantakou, Evangelia Zapanti, Katerina Saltiki, Maria Alevizaki & Eleni Anastasiou
Endocrine Unit, Department Clinical Therapeutics, Medical School National Kapodistrian University, Athens, Greece.

Objectives

The interplay between thyroid function and metabolic state has been studied in many population subgroups. For pregnant women thyroid and metabolic parameters, including glucose homeostasis, are of great importance for a successful outcome. We examined aspects of thyroid function in relation to GDM and BMI in pregnant women referred to our Department.

Methods

We studied 520 women during 24^{th} – 32^{nd} gestation week. Demographic characteristics were recorded and a 75 gr OGTT was performed. Plasma glucose and insulin levels were measured at time 0'-60'-120'. HbA1c and thyroid parameters (TSH, FT4, FT3, FT3/FT4 ratio) were evaluated at time 0'. Thyroid parameters were subjected to multivariate analysis of variance (MANOVA) with the presence of GDM (GDM vs Normal [N]) and BMI (obese ($BMI \geq 30$ kg/m^2) vs non-obese ($BMI < 30$ kg/m^2)).

Results

Of 520 pregnant women, 226 (43.5%) were diagnosed with GDM according to IADSPG/WHO criteria. GDM women were significantly older (33.6 ± 6.2 vs 29.1 ± 6.8 years) and had greater BMI (30.1 ± 5.4 vs 27.7 ± 5.7 kg/m^2). TSH levels were lower among non-obese women with GDM versus N (1.8 ± 1.0 vs 2.1 ± 1.2 μUI/ml, $P=0.037$). FT4 in obese GDM women was lower than in non-obese GDM and obese Normal (11.7 ± 2.3 vs 12.2 ± 1.8 and 12.4 ± 1.5 pmol/l respectively, $P=0.03$). FT3 levels differed significantly only in the GDM women, between obese and non-obese (4.5 ± 0.6 vs 4.2 ± 0.6 pmol/l, $P \leq 0.001$). In accordance, FT3/FT4 ratio was significantly higher in obese GDM women compared to obese Normal and non-obese GDM (0.39 ± 0.07 vs 0.36 ± 0.08 and 0.35 ± 0.06 respectively, $P=0.03$).

Conclusions

This study shows that (i) GDM is associated with lower TSH levels. (ii) Lower FT4 is associated with both obesity and GDM. (iii) Higher FT3 is associated with obesity in GDM women. (iv) Higher FT3/FT4 ratio is related with the simultaneous presence of GDM and obesity. The pathophysiological mechanisms involved in thyroid hormone metabolism in relation to the presence of GDM and/or obesity need to be further elucidated.

Thyroid Non Cancer - Benign Thyroid Disease/Treatment

GP265

Nodule size as predictive factor of efficacy of radiofrequency ablation in treating autonomously functioning thyroid nodules

Andrea Palermo[1], Anda Mihaela Naciu[1], Mario Iozzino[2], Valerio Pasqualini[2], Carla Simeoni[3], Silvia Manfrini[1], Gaia Tabacco[1], Alessandro Casini[4], Giuseppe Campagna[4] & Roberto Cesareo[4]
[1]Unit of Endocrinology and Diabetes, Campus Bio-Medico University, Rome, Italy; [2]Department of Radiology, 'S. M.Goretti' Hospital, Latina, Italy; [3]Workers Compensation Authority (INAIL) – Research Area, Rome, Italy; [4]Thyroid Disease Center, 'S. M. Goretti' Hospital, Latina, Italy.

Background

Radiofrequency ablation(RFA) has been advocated as an alternative to radioiodine and/or surgery for the treatment of autonomously functioning benign thyroid nodule (AFTN). However, only a few studies have investigated the efficacy of RFA on AFTN. Furthermore, these studies are characterized by several biases about patient selection, number of RFA treatments, short clinical and radiographic follow-up. A recent prospective 12-month study has demonstrated that one single RFA treatment was able to withdraw anti-thyroid medication in 50% of the hyperthyroid patients who remained euthyroid afterwards. However, no defined pre-treatment factors able to predict the response to the RFA in Treating AFTN have been clearly identified.

Aim

To evaluate the success rate of RFA to restore euthyroidism in a cohort of adult patients with small solitary AFTN compared to medium-larger ones. Secondary end-points included volume reduction and conversion rate from hot to cold nodules at thyroid scintiscan.

Methods

This was a 24-month prospective monocentric open parallel-group trial. Twenty-nine patients with AFTN were divided into two groups based on thyroid volume: 15 patients with small nodules (<12 ml) in group A and 14 patients with medium nodules (>12 ml) in group B. All patients underwent a single session of RFA and were clinically, biochemically and morphologically evaluated at baseline and at 1, 6, 12 and 24 months after treatment. At the end of the study period, a thyroid scintiscan was performed.

Results

After RFA, there was a larger volume reduction in group A compared to group B ($P<0.001$ for each follow-up point). After RFA, there was greater nodule volume reduction in group A compared with group B ($P<0.001$ for each follow-up point). In group A, there was a greater increase in TSH levels than in group B at 6 ($P=0.01$), 12 ($P=0.005$) and 24 months ($P<0.001$). At 24 months, the rate of responders (subjects with euthyroidsm without metimazole) was greater in group A than in group B (86 vs 45%; $P<0.001$). At 24 months in group A, 86% of nodules converted from hot to cold compared with 18% in group B ($P<0.001$).

Conclusions

This study shows that a single RFA was effective in restoring euthyroidsm in patients with AFTN, mainly in small nodules. Nodule volume seems to be a significant Predictive Factor of Efficacy of RFA in Treating AFTN. Larger prospective studies are needed to confirm our findings.

Radiofrequency ablation for benign symptomatic thyroid nodules: evaluation of clinical efficacy

Mikhail Vozdvizhenskii, Andrey Orlov, Aleksandr Makhonin, Vladimir Stadler & Yana Matyash
Samara Regional Clinical Oncology Center, Russian Federation, Samara, Russia.

Purpose

Thyroid nodules are an extremely common occurrence. The aim of the study is to evaluate the results of radiofrequency ablation (RFA) for benign symptomatic thyroid nodules.

Materials and methods

Three hundred and sixty two patients with benign symptomatic thyroid nodules (TIRADS/ Bethesda: TIRADS 2, TIRADS 3/THY 2) were included in this research: 355 women and 7 men. The median age of the group was 48 (24–76). The mean nodule size was 3.5 (1.5–9.5) cm. In 280 cases nodules had solid content, in 82 cases – mixed solid and cystic content. In case of cystic component, aspiration was needed before performing RFA. The mean duration of RFA was 3 (1.5–7) min. All the procedures were performed under local anesthesia with real

time ultrasound control. Technique of dynamic RFA was applied. Internally cooled 1.0–1.2 mm-gauge, 70–100 mm length, 0.5, 0.7, 1.0, 1.5, 2.0 cm active tip electrodes were used. During the procedure permanent control of hoarse voice was carried out to avoid complications. The follow-up period of patients was 1–30 months.

Results

At 1-month follow-up the mean volume reduction was 30 (15–50)%. In further follow-up the reduction of nodule volume was 50% at 6-month follow-up and 75% at 9-month follow-up. RFA was needed to repeat for 19 patients that had an initial nodule size more than 4.5 cm. None of patients experienced any major complications. A surgery was required for four patients whose nodules did not decrease in volume (15%) during the first month follow-up.

Conclusion

RFA is a minimally invasive technique for treatment of benign thyroid nodules with high clinical efficacy.

Response to Liothyronine therapy: Efficiacy of therapy and assessment of biochemical and physiological predictors

Christopher Philbey[1] & Mohammed Malik[2]
[1]Hull Royal Infirmary, Hull, UK; [2]North Lincolnshire and Goole NHS Foundation Trust, Scunthorpe, UK.

Introduction

Levothyroxine is the globally preferred therapeutic compound for primary hypothyroidism. Due to expense and poor efficacy, Liothyronine is not used as first line treatment. This study was formed to answer the ESE's recent call for data on symptomatic response to Liothyronine and predictors of that response.

Method

Patients with failure of symptomatic relief on levothyroxine were invited to try Liothyronine. 23 patients were enrolled. They underwent validated physiological and psychological evaluations which were reviewed at 3, 6 and 12 months for variation and sustainability. Weight, skin quality, mood and fatigue were taken as clinical markers of improvement. Serum thyroid factors were analyzed. Datapoints were then compared with regression analysis to identify any pre-intervention factors that could indicate treatment response.

Results

68% reported an improvement in any clinical factor at month 3 but at month 12, only four patients had sustained improvement from baseline. This was in weight loss >2 kg (2), skin quality (1) and mood (1). Those with weight reduction also improved in at least one other category. No pre-intervention variables examined were linked to therapeutic response, neither age at onset ($r=0.0004$), duration of illness ($r=0.04$), level of Thyroid Perioxidase antibody ($r=0.006$), initial TSH ($r=0.05$), initial t4 ($r=0.14$) or initial t3 level ($r=0.03$). The sustained positive responders showed a tendency to regress towards the mean TSH value, whereas those with transient benefit suppressed.

Discussion

From meta-analyses, we expected a positive response rate varying from 15 to 30% at 1 year. Our data conforms with 17% response across all variables. The most common referral reason for 'therapeutic failure' was low energy and mood, yet only 8% of enrolled patients benefited. Perceived weight has been strongly correlated with symptomology and from our results, a weight loss of >2 kg at 3 months was the only objectively measurable clinical factor to indicate a successful 1 year trial. Supraphysiological dosing with liothyronine is likely the cause of the numerous but transient reported benefits at month 3 given the gradual suppression of TSH in the long term. There remains no pre-intervention indicator identified that would effectively predict response to liothyronine and thus the authors recommend that a decision to offer a therapeutic trial is left to clinician's judgement; that they inform the patient that there is no measurable effect on mood and fatigue; that if there is not >2 kg weight loss at month 3, the medication trial should be withdrawn as there is no evidence to continue.

Tailored thyroxine treatment and gastric acid output in humans

Camilla Virili, Giovanni Bruno[2], Maria Giulia Santaguida[1], Barbara Porowska[3], Silvia Capriello[1], Corrado De Vito[4], Carola Severi[2] & Marco Centanni[1]
[1]Department of Medico-surgical Sciences and Biotechnologies, Sapienza University of Rome, Latina, Italy; [2]Department of Internal Medicine and Medical Specialties, Sapienza University of Rome, Roma, Italy; [3]Department of Cardio-thoracic-vascular Surgery and Organ Transplantation, Sapienza University of Rome, Rome, Italy; [4]Department of Public Health and Infectious Diseases, Sapienza University of Rome, Rome, Italy.

Hypothyroid patients with gastric disorders require a higher dose of oral thyroxine (T4) to reach target serum TSH. *In vitro* evidence supports the notion that the variations of gastric pH may also interfere with T4 dissolution profile. The present study is aimed at confirming in vivo the supposed correlation between the gastric pH, directly measured during endoscopy, and the therapeutic dose of thyroxine using a controlled treatment schedule. A total of 61 tablet T4-treated hypothyroid patients (52 W/9M; median age $=51$ years; BMI $=25.2$) have pledged to take thyroxine in fasting conditions, abstaining from eating or drinking for one hour. Gastric juice for pH evaluation as well as multiple biopsy specimens were collected in all patients during endoscopy. The dose of T4 was calculated in each patient and compared to the one observed in age- and BMI-matched group of patients but positively devoid of gastrointestinal and/or pharmacological interference to measure the excess of T4 required. The results were plotted against the actual pH and the H^+ concentration titrated with $NaOH^-$ in each patient. All patients reached target serum TSH (median $=1.29$ mU/l) but the dose of oral thyroxine required increased along with the rising gastric pH ($r^2=0.1209$; $P<0.0223$) and the diminished H^+ concentration ($r^2=0.1275$; $P<0.0219$). A multivariate analysis revealed that pH act as an independent variable in determining the dose of T4 ($P<0.029$). Noticeably, even the excess of T4 dose (ED) required, plotted against gastric acidity in each patient, was highly correlated with the increased pH ($P<0.001$) and the decreased H^+ concentrations ($P<0.0001$). Patients were then subdivided in two groups, using as cutoff the median value of their pH in the whole sample (2.4; IQ $=1.5$–6.1). Required T4 dose was slightly increased only in eight out of 34 patients (23%) in group A (median pH $=1.52$; median increase $=15\%$). In group B (median pH $=6.36$), on the contrary, 25 patients out of 27 (93%; $P<0.0001$) needed a higher T4 dose and the median increase was huge ($+47\%$). Increased T4 requirement was also unevenly distributed in patients with atrophic gastritis (90%), with pangastritis (73%) and with antritis (40%). The results of this *in vivo* study enlighted a highly significant correlation between gastric pH and the need for thyroxine in humans.

Body composition changes during treatment of severe thyroid disorders. Is it always fat?

Ariadna Zybek-Kocik[1], Nadia Sawicka-Gutaj[1], Ewelina Szczepanek-Parulska[1], Tomasz Krauze[2], Przemysław Guzik[2] & Marek Ruchała[1]
[1]Department of Endocrinology, Metabolism and Internal Medicine, Poznan University of Medical Scineces, Poznań, Poland; [2]Department of Cardiology-Intensive Therapy, Poznań University of Medical Sciences, Poznań, Poland.

Severe thyroid disorder are associated with important metabolic changes. After restoration of euthyroidism, as a result of proper treatment, usually body metabolism also normalizes. Up to date, there are conflicting reports about the changes in body composition of patients during treatment of severe hyperthyroidism and hypothyroidism. The aim of this study was to evaluate the body composition and glucose level changes in subjects affected by Graves disease and autoimmune thyroid disease before the treatment and after achieving

euthyroidism. The study group consisted of 33 patients affected by hyperthyroidism diagnosed with Graves' disease, and 20 patients suffering from hypothyroidism due to autoimmune thyroid disease. In all patients body composition with the use of bioimpendace method, glucose and thyroid-related hormones levels were evaluated at the moment of diagnosis and after restoration of euthyroidism. The mean observation time was 10.5 months for hypothyroid group and 7 months for hyperthyroid group. After restoration of euthyroidism hypothyroid group presented decreased body weight, body mass index, fat-free mass, muscle mass. There was no changes in fat mass and glucose concentration. On the other hand, in the hyperthyroid group achieving euthyroidism was associated with increase in body weight, BMI, fat mass, fat percentage, as well as decrease in glucose concentration. There was no significant difference in muscle mass. The changes in body weight, BMI and fat mass correlated positively with TSH changes and negatively with fT3 and fT4 changes. Muscle mass changes correlated positively with TSH changes and negatively with fT3 changes. To conclude, while increased body mass after the treatment of hyperthyroidism was a result of predominantly fat accumulation, hypothyroid patients lost their body weight mainly due to decreased muscle mass. However, both hyperthyroidism and hypothyroidism causes fat as well as muscle tissue changes.

Personalised euthyroid targets based on a deterministic mathematical model

Enlin Li[1] & Melvin Khee-Shing Leow[1,2,3,4]
[1]Duke-NUS Medical School, Singapore, Singapore; [2]Tan Tock Seng Hospital, Singapore, Singapore; [3]Singapore Institute for Clinical Sciences, Singapore, Singapore; [4]Lee Kong Chian School of Medicine, Nanyang Technological University, Singapore, Singapore.

Research in recent years has shown that biochemically euthyroid levels of thyrotropin (TSH) and serum free thyroxine (FT4) as determined by laboratories may not necessarily equate to clinical well-being of patients. The defined normal range of TSH and FT4 are wide and may differ from patients' optimal range of TSH and FT4. We have previously described a deterministic mathematical model that can predict each patient's unique homeostatic set point, which gives the optimal TSH and FT4 values of each patient. This model is built on a parameterised inverse exponential relationship between TSH and FT4. In this retrospective study of 142 patients who had undergone thyroidectomy, we used the model to compute the predicted TSH and FT4 values based on thyroid function tests obtained post-thyroidectomy. The predicted values were then compared with the average TSH and FT4 obtained pre-thyroidectomy, when the patients were clinically euthyroid. Bland-Altman analysis of the differences between the predicted values and the average pre-thyroidectomy values shows that there is a mean difference of 0.15 mU/l, 95% CI (−0.03, 0.34), between the predicted TSH and average pre-thyroidectomy TSH and a mean difference of 2.87 pmol/l, 95% CI (2.55, 3.24), between the predicted FT4 and average pre-thyroidectomy FT4. Despite minor differences between the predicted values by the model and the average pre-thyroidectomy values of the patients, our mathematical model is able to narrow the range at which a patient can be considered as being euthyroid. Therefore, the personalised euthyroid targets derived from the model is able to provide clinicians with more guidance in managing patients who remain symptomatic despite having normal TSH or FT4 values.

GP272

US-guided percutaneous microwave ablation for benign thyroid nodules: a prospective multicenter study

Ping Liang
Chinese PLA General Hospital, Beijing, China.

Purpose
To evaluate the clinical outcomes of percutaneous MWA in treating BTNs under US guidance with a prospective multicenter study.

Materials and methods
From January of 2013 to December of 2015, the total number of 603 patients with 664 benign thyroid nodules (BTNs) at four participating institutions in China was enrolled in the multicenter study. Before ablation, the mean maximal diameter and the mean volume of the target nodules were 2.92±0.93 cm (ranged from 2.0 to 6.3 cm) and 7.72±9.16 ml (ranged from 0.38 to 70.16 ml), respectively. The clinical outcomes of safety and efficacy were evaluated and analyzed by SPSS 22.0 during follow-up period.
Results
For evaluation of efficacy, compared to those in baseline, the mean maximal diameter and the mean volume of the ablated BTNs significantly decreased with the volume reduction ratio (VRR) of 64.4±43.5%, 78.4±48.2%, 82.5±49.7%, and 81.1±70.4% at 3, 6, 12 months and last follow-up, respectively. The vascular, symptomatic and cosmetic scores related the target nodules statistically improved after ablation. For evaluation of safety, the major complications included cervical nerve injuries in 16 patients (injuries of recurrent laryngeal nerve in 15 and sympathetic nerve in one) and nodular ruptures in four patients. The incidences of minor complications and side effects were 5.8% (35/603) and 4.6% (28/603), respectively.
Conclusion
To draw the conclusion of the prospective multicenter study, US-guided percutaneous MWA is a safe and effective method for the treatment of BTNs in selected patients.

Reduced quality of life and persistent complaints in treated hypothyroid patients

Ellen Molewijk[1], Maayan Martens[1], Eric Fliers[2], Pierre Zelissen[3], Koen Dreijerink[4], Ad van Dooren[1] & Rob Heerdink[1]
[1]University of Applied Sciences Utrecht, Utrecht, Netherlands; [2]Academic Medical Center Amsterdam, Amsterdam, Netherlands; [3]University Medical Center Utrecht, Utrecht, Netherlands; [4]VU University Medical Center Amsterdam, Amsterdam, Netherlands.

Background
Hypothyroidism is a common endocrine disorder and the standard treatment is replacement therapy with levothyroxine (LT4). Although many hypothyroid patients improve upon treatment with LT4, a proportion seems to experience residual hypothyroid complaints despite treatment, even when plasma TSH and FT4 are within reference ranges.
Methods
Using an on-line survey we investigated i) the health-related quality of life (QoL) (ThyPRO), ii) the activities of daily living (SF-36), iii) hypothyroid-related symptoms (ThySHI) in diagnosed, treated hypothyroid patients (>18 years, treated >6 months) and control persons (without thyroid disease, >18 years). In patients, the time course of symptoms from diagnosis until 3 years was asked (retrospectively, ThySHI). Patients and control persons were recruited by e-mails from patient organizations, posters in pharmacies and health centers and Twitter/Facebook. For data analysis (ThyPRO, 0–100 scale, *t*-test; daily functioning, 1–5 scale and ThySHI 0–3 scale, Mann-Whitney; time course symptoms, Friedmann-Dunnett; confounding factors, ANCOVA) IBM SPSS 24 was used.
Results
In this cohort consisted of 1667 patients (mean duration of illness 12.2± s.d. 9.9 years) and 275 controls. Treated hypothyroid patients had i). a significant decrease in health-related QoL and all domains (fatigue, vitality, cognition,

anxiety, depressivity, emotional susceptibility, social life, daily life), as compared to controls (mean total QoL 39.9 vs 19.1 resp. and all domains $P<0.001$), ii). Significantly more impairment with activities of daily living ($P<0.001$), and iii). significantly higher scores for symptoms related to hypothyroidism, as compared to control persons (all $P<0.01$). Symptoms generally decreased after 3 years of treatment, with fatigue, reduce daily functioning, coldness, muscle pain/cramps and being overweight as the most intense residual complaints. Many patients (78.5%) reported having complaints despite taking thyroid medication and reported not feeling well (77.8%) while their blood values were within range. TSH level, age, gender and duration of illness did not significantly affect total QoL, whereas the M3 comorbidity index did. Desiccated thyroid hormone users (9.4%) had a significantly better mean total QoL than LT4 users (90.5%) (36.0 vs 40.6, $P=0.003$).

Conclusions

Persistent complaints, such as reduced health-related quality of life, reduced daily functioning, and residual hypothyroid related symptoms, are common in this group of hypothyroid patients despite replacement therapy. Caregivers should be aware that persistent complaints can be present in treated hypothyroid patients, despite following current guidelines, and that these remaining symptoms may affect their quality of life and daily functioning.

Congenital adrenal hyperplasia in lady with severhirsutism and virilization due to 3B-hydroxysteroid dehydrogenase deficiency

Faiza Qari
King Abdulaiz University, Jeddah, Saudi Arabia.

A 30-year-old woman pakistani patient was admitted to king Abdulaziz University hospital in Jeddah, Saudi Arabia with history of severe abdominal pain, vomiting and hypotension. She was born with Ambiguous genitalia and operated at age 8 years. She has severe hirsutism, with score of 18 and virilization. There are no family history of congenital adrenal hyperplasia. Physical examination showed her height was 151 cm and weight 42 kg. For evolution of hirsutism and virilization. Endocrinological data showed heigh DHEA-S and urinary 17 KS levels were moderately increased, while plasma testosterone, androstenedione and urinary 17 OHCS levels were normal. CT the abdomen and pelvis were normal. The patient had increased plasma 17-hydroxypregnenolone and DHEA concentrations in response to ACTH. 17-hydroxypregnenolone is 6.2 ng/ml and increase up to 10.5 30 minute after ACTH stimulation. DHEA-S is 5.3 ng/ml and increase to 13.8 nm/ml after ACTH stimulation. She had increased ratios of 17-hydroxypregnenolone of DHEA to androstenedione. After administration of 2 mg dexamethasone twice daily, all glucocorticoid and androgen levels including their metabolites decreased, indicating that the excessive androgen was derived from the adrenal glands. BMD showed severe osteoporosis with T score – 3.5. Patient was treated with dexamethasone,1 mg twice daily, Densoumb 60 mg Im once every 6 month as well social and psychological support. The patient felt that hirsutism was improved; the shaving frequency decreased from twice a day to once a day and the texture of the hair became softer and less coarse.

Endogenous stimulation in adrenal venous sampling (AVS) in differential diagnosis of primary hyperaldosteronism (PA)

Anastasia Rybakova, Ivan Sitkin, Galina Kolesnikova, Nadezda Platonova, Ekaterina Troshina, Natalia Romanova & Dmitry Beltsevich
National Medical Research Centre of Endocrinology, Moscow, Russian Federation.

Relevance
Due to numerous causes of PA, AVS allows differentiating variant nosological forms of PA. The importance of differential diagnosis is due to the fact that surgery is reasonable only with unilateral variant of PA, while in idiopathic hyperaldosteronism surgery isn't a method of choice.
Purpose
To assess the diagnostic possibilities of using AVS against the background of endogenous stimulation of adrenocorticotropic hormone (ACTH) in the early morning hours for choosing the method of treatment of PA.
Materials and methods
Fourty-eight patients were prospectively enrolled for AVS, average age 40y.o. (2011–2017), with arterial hypertension, adrenal glands lesion according to CT and laboratory confirmed PA (elevated aldosterone-renin ratio and postinfusion level of aldosterone). Average size of lesion was 2 cm (1.5–3), density from −1 to +10HU, and with bilateral damage, the second gland was hyperplastic (about 10mm). We measured reliable level of selectivity gradient as 3:1, then we calculated the result of lateralization gradient, and more than 2 shows unilateral aldosterone production, less than 2 shows bilateral aldosterone production.
Results
According to CT, unilateral macrogyperplasia was detected in 13 patients (27% of total), all of them were confirmed to have unilateral hyperproduction of aldosterone according to AVS. Unilateral microhyperplasia was detected in 12 patients (25%); among them 4 (8.3% of total) was confirmed unilateral hyperproduction according to AVS. It was detected that bilateral macrogyperplasia was in 23 patients (48%), of which 6 patients (12.5% of total) showed bilateral hypersecretion of aldosterone.
Conclusion
CT didn't correspond with the results of AVS in 4.1% cases. In absence of AVS, surgery in these patients wouldn't have been implemented. In 20% cases was identify bilateral hyperproduction and relying only on CT, adrenalectomy could be done unreasonable. Given our data, it can be concluded that AVS is an important step in the differential diagnosis of PA.

Congenital adrenal hyperplasia in 46xx male

Mona Salem, Hemmat El Haddad, Elham Yousief, Maha Assem & Randa Salam
Faculty of Medicine Cairo University, Cairo, Egypt.

Disorders of sex development create medical and social dilemma. Maleness with XX genotype is a rare genetic condition affecting one in 24,000 new-born males. Characterized by a spectrum of clinical presentation, ranging from normal male genitalia to ambiguous sex.
Case report
A 31 years old patient with ambiguous genitalia raised as a male. He came to our endocrinology clinic to stabilize his male identity by surgical correction, no parental consanguinity. The patient has five brothers. Two of them were born with sexual ambiguity and both died at the age of 6 months due to asthenia, weakness and, failure to thrive. His medical suffering started since birth when his mother discovered that he was born with an empty scrotum. He underwent a surgery for undescended testes at the age of 2. The surgeon didn't find the testes, but when the ultrasonography was done, it revealed the presence of a uterus. He had his adrenarche at the age of 12 (well developed axillary, pubic and chest hair). His male type of boldness at the age of 17. Physical examination showed Height: 162 cm, Weight: 63 kg, BMI: 24.0 kg/m^2. He possessed coarse hair all over his body including auxiliary, pubic and chest area. Genital examination revealed Microphalus (enlarged clitoris: size is 7 cm) with penoscrotal hypospadias empty Scrotum. The results of laboratory analyses were as follows: follicle-stimulating hormone: 4.6 mIU/ml (N:0.7–11.1), luteinizing hormone: 3 mIU/mL (N: 0.8–7.6), and testosterone: 2.2 ng/mL (N: 2.5–8.4 mg/mL). Estradiol (E2): 24.2 pg/ml (N:15–56), Serum DHEA: 7.1 ng/ml (M&F 0.2–9.8). Androstenedione: >10 ng/ml (N:0.75–2.05), 17 hydroxyprogesterone: >4000 ng/dl (N: <77 ng/dl) Serum sodium: 144.0 mmol/L (N:132.0–145.0),Serum potassium: 3.6 mmo/L (N:3.5–5.1). karyotype analysis showed 46,XX. Abdominal pelvic U/S non visualized testis, Both ovaries are seen functioning with follicles noted, The uterus seen with endometrial line. Bulky right supra renal gland, MRI abdomen revealed Both suprarenal glands are diffusely enlarged: eliciting intermediate T1 and T2 signal intensity with no focal lesions. Classic congenital adrenal hyperplasia (21-hydroxylase deficiency) was diagnosed, the patient received a one month course of 15 mg hostacortin however he refused to continue treatment.
Conclusion
21-hydroxylase deficiency should be considered in the differential diagnosis of cases presented with ambiguous genitalia in early childhood, treatment decision must be made for each individual. Considering social, psychosexual development, psychological and cultural factors.

Diagnostic difficulties of Pseudo-Cushing states in women: about 24 cases

Najoua Lassoued, Yosra Hasni, Maha Kacem, Molka Chaieb, Amel Maaroufi & Koussay El Ach
Endocrinology Department, Farhat Hached University Hospital, Sousse, Tunisia.

Introduction
Differentiation between mild Cushing's syndrome (CS) and Pseudo-Cushing syndrome (PCS) can be extremely difficult. A Pseudo-Cushing state can be defined as a part or all of the clinical features that resemble a true CS with some evidence of hypercotisolism but the resolution of the underlying primitive state results in the disappearance of this Cushing state-like. The aim of this work was to describe the diagnostic difficulties of 24 cases of PCS.
Patients and methods
A descriptive study of 24 women referred to the endocrinology department for suspicion of CS.
Results
The mean age of the patients was 33.3 years old. Nine patients were followed for hypertension, 7 for type 2 diabetes and 2 for depression. On examination, the average body mass index was 41.43 kg/m^2. The average waist circumference was 118.5 cm. With respect to CS elements, 83.33% of patients had truncal obesity, 29.16% had facial erythrosis, 16.66% had buffalo hump, 16.66% had hirsutism, 8.33% had acne, 16.66% had purple stretch marks and 16.66% has intertrigo. No patient had muscular atrophy or bruising. In the biology, the fasting glucose level was 1.41 g/L on average, the mean triglyceride level was 1.25 g/L and the mean HDL-cholesterol level was 0.44 g/L. About one third of these patients had a metabolic syndrome. The overnight dexamethasone suppression test was negative in 50% of our patients whereas the standard 2-day dexamethasone suppression

test was positive in all our patients which allowed us to retain rather the diagnosis of a PCS. Abdominopelvic ultrasound showed hepatic steatosis in seven patients and ovarian dystrophy in one patient. Bone densitometry was requested in two patients with a normal bone profile for age.
Discussion and conclusion
Pseudo-Cushing states share many of the characteristics of CS, including overproduction of cortisol. The hypercotisolism of PCS is caused by the increased activity of the CRH neuron which stimulates the production and release of ACTH. Despite the fact that some symptoms are more specific to CS than PCS, the diagnosis depends always on laboratory results.

Is adrenocortical carcinoma in children a different spectrum?

Sabaretnam Mayilvaganan, Anjali Mishra, Gaurav Agarwal, Amit Agarwal & SK Mishra
Sanjay Gandhi Postgraduate Institute of Medical Sciences, Lucknow, India.

Background
Adreno cortical carcinoma (ACC) is a rare malignancy associated with aggressive biological behavior and poor outcome. The reported incidence in literature is about approximately two cases per million population's.These tumors might be functional or non-functional depending on their ability to secrete various adrenocortical hormones. ACC occurring in children and adults show distinct characteristics and there is not much literature regarding the differences. Since it is a rare disease large sample size is a difficulty.
Aim
The aim of this study was to study Clinico-pathologic profile and outcome of ACC occurring in children and adults.
Methods
This study (January 1990–June 2017) was carried out in a tertiary referral centre, included 60 patients with Adreno cortical carcinoma. Patients aged 18 years or more were classified as adults and rest as children. Demographics, clinical profile, hormonal profile, details of surgical procedures, histology and/ or cytology reports and follow up findings were noted. Survival analysis was performed using Kaplan Meir method and significance of various factors was calculated by Cox regression analysis. Various factors and outcome were compared. A P value of less than 0.05 was considered significant.
Results
There were 20 children and 40 adults. Mean Age was 8 ± 5.7 (M: F = 1: 2.1) and 44.4 ± 15 years (M: F = 1:1.1). Prevalence of functioning tumors was significantly high in children (85 vs 40% $P = 0.001$), and Incidentaloma in adults (6.3 vs 51.7% $P = 0.05$). Tumor stage distribution at presentation was comparable in both groups. 85% children and 62.5% of adults were operated. The mean tumor size and weight were 10.9 vs 13.7 cm ($P = 0.08$), and 392.9 vs 892.9 gm ($P = 0.24$) respectively. Adults had better five year overall survival (OS) than children. On univariate analysis stage of disease ($P = 0.008$), surgical intervention ($P = 0.004$), Weiss score ($P = 0.006$) and hormonal secretion ($P = 0.04$) were significantly associated with OS in adults but not in children. No factor was found significant on multivariate analysis.
Conclusions
Except for high prevalence of functioning tumors in children, there was not much difference in clinicpathologic attributes. Larger studies and multicentre studies are needed so that guidelines can be framed and diverse management can be avoided.

Travelling distance and support group participation in patients with chronic adrenal insufficiency

Michael Dölle[1], Sabine Schneidewind[1], Rodica Mia Memmesheimer[2], Michael Peter Manns[1], Christoph Terkamp[1], Holger Leitolf[1] & Steffen Zender[1]
[1]Medical School Hannover, Department of Gastroenterology, Hepatology and Endocrinology, Hannover, Germany; [2]Helios Klinikum Gifhorn, Klinik für Kinder- und Jugendheilkunde, Gifhorn, Germany.

Adrenal crisis is a life-threatening complication in patients with adrenal insufficiency. In order to prevent critical situations, patients have to increase their glucocorticoid dose in distressing situations. Continuous education of patients concerning dosage adaption in challenging situations seems to be important for long term management. As previously shown, both acute illness and emotional stress may lead to critical situations. In every outpatient visit patients should be able to address dosage problems concerning their daily living. In addition to that support group meetings and educational courses for emergency management for patients with chronic adrenal insufficiency seem to be a good possibility for discussing challenging situations. We wanted to know whether patients are interested in support group meetings and whether they already attended. Additionally, we wanted to know what distances patients are willing to travel to attend educational meetings. We decided to ask patients before attending our educational program teaching management of critical situations for patients with any kind of chronic adrenal insufficiency including self-application of parenteral hydrocortisone. We included 43 patients attending our educational program in 2017. Most of the patients (88%) had never attended a support group meeting. Many of those stated that they did not know about any known offer of a support group meeting (74%), while 8% mentioned long travelling distances. Only two patients were not interested in support group meetings. Two more were recently diagnosed and were not yet able to attend any meeting. Nearly all patients (95%) had never attended a special education program teaching emergency situation management before, although 45% had suffered from an adrenal crisis before. For attending our education program mean travel distance was 40 km, while maximum travel distance was 155 km. In summary, only a few patients are not interested in attending support group meetings. Most of them are willing to participate but lack information about any offers. For attendance patients tolerate longer travelling distances (mean travel distance 40 km). We recommend informing all patients about self-support groups and educational meetings on a regular basis.

Evaluation of tumor size and hormonal status of elderly with adrenal incidentaloma

Fulden Sarac[1], Sumru Savaş[1] & Pelin Tutuncuoglu[2]
[1]Ege University Medical Faculty, Department of Geriatric Medicine, İzmir, Turkey; [2]Atatürk Training and Research Hospital, Department of Endocrinology and Metabolism, İzmir, Turkey.

Incidentalomas (AI) are clinically inapparent adrenal masses. Patients present hormone excess or mass effect, but part of them is clinically silent. They are discovered inadvertently in the course of diagnostic testing or treatment for other clinical conditions. The aim of the study was to investigate the clinical value of tumor size and hormonal status of elderly patients with adrenal incidentaloma (AI).
Subjects and Methods
Forty-four elderly with AI was diagnosed AI discovered by magnetic resonance (MR). The demographics of patients, imaging features, functional status and histological results were evaluated, retrospectively.

Results
Thirty-two (72.7%) of the patients were females and 12 (27.7%) of them were males. Mean age of the patients was 69.1 ± 13.0 years. 5 (11.3%) of the patients' age were ≥ 75 years. Mean volumes of AI found to be 3.12 ± 0.7 cm. In 6 (50.0%) of the elderly male with AI, sizes of tumor found to be ≥ 3.5 cm and were operated. Histological findings in operated male were myelolipoma (two male patients) and metastatic epidermoid cancer originating from lung (two male patients). Mean levels of Dehydroepiandrosterone (DHEAS), cortisol, vanil mandelic acid (VMA), aldosteron, 17-hydroxyprogesterone (17-OHP) were found to be 289.3 ± 89.2 (ng/ml); 15.3 ± 3.56 (μg/dl); 4.0 ± 1.1 (mg/24 h); 121.1 ± 21.3 (pg/mL); 1.0 ± 0.3 (ng/ml) respectively.
Conclusion
The frequency of AI in the female elderly was higher than thats of male elderly. However, mean levels of tumor size in male elderly than thats of female elderly. This is a preliminary report, future studies are needed.

Evaluation of adrenal function in Cushing's syndrome model rats

Toshiro Seki[1], Atsushi Yasuda[1], Natsumi Kitajima[1], Masami Seki[2], Masayuki Oki[1] & Masafumi Fukagawa[1]
[1]Tokai University School of Medicine, Kanagawa, Japan; [2]Seirei Numazu Hospital, Shizuoka, Japan.

Cushing's syndrome is caused by cortisol-secreting adrenocortical adenoma. Surgical resection of cortisol-secreting adenoma results in secondary adrenal insufficiency in most cases. The main mechanism of adrenal insufficiency is that the residual adrenocortical tissue becomes atrophied as a result of chronic suppression of the hypothalamic-pituitary-adrenal (HPA) axis by excessive cortisol levels. Therefore, we have analyzed Cushing syndrome model rats following the previous year's report in order to develop a new treatment that promotes early functional improvement in postoperative remaining adrenal glands. Increase in blood pressure (117 ± 16 mmHg), decrease in body weight (380 ± 25 g), suppression of ACTH (43 ± 18 pg/ml) and reduction of adrenal weight (14.4 ± 1.7 mg) were significantly confirmed in dexamethasone-treated rats ($n = 8$) compared to the control group ($n = 8$), and a decrease in ratio of adrenal cortex to medulla was also confirmed. These results were similar findings in the previous year. In this experiment, adrenal function was evaluated by reverse transcription PCR (RT-PCR) of adrenal gland tissue and measurement of mRNA. The expression level of *CYP11B1* mRNA was calculated as cortisol productivity, and the expression level was significantly decreased in the dexamethasone administration group (0.09) compared to the control (1.00). It was confirmed that the hormone secretion ability of the adrenal cortex was significantly decreased endocrinologically in the model rat as compared with control rats. Our group is now conducting experiments to evaluate the improvement of remaining adrenal function by administering synthetic ACTH formulation.

Does Hemodialysis (HD) affect the overall testosterone (T) and luteinizing hormone (LH) levels in T-treated hypogonadal Congenital Adrenal Hyperplasia (CAH) male with associated chronic kidney disease (CKD)? A pilot single center matched case report

Zoran Gluvic, Milena Lackovic[1], Vladimir Samardzic[1], Jelena Tica Jevtic[1], Marina Vujovic[1], Bojan Mitrovic[1], Vesna Popovic-Radinovic[1], Violeta Mladenovic[2], Jovana Kusic[1], Rodoljub Markovic[1], Tamara Jemcov[1] & Esma R. Isenovic[3]
[1]Zemun Clinical Hospital, Zemun, Serbia. [2]Clinic for Endocrinology, Kragujevac, Serbia. [3]Lab. for radiobiology and molecular endocrinology, Institute for nuclear sciences "Vinca", Belgrade, Serbia.

Introduction
CAH is among the most common inherited metabolic disturbances, caused by Ar mutations of genes that encode enzymes involved in the adrenal steroids synthesis. Male hypogonadism and CKD can complicate the course of CAH. Additionally, HD can influence the CAH management by unpredictable effects of ultrafiltration on the levels of administered drugs. The aim of our study is to demonstrate the influence of HD on LH/T levels of eugonadal male as well hypogonadal male with CAH under T-substitution, both with CKD.
Material and Methods
CAH 38-years-old male and age/gender-matched control has had a regular thrice-weekly maintenance HD on the same device (*Gambro AK200 Ultra S*) in Zemun Clinical Hospital. CAH hypogonadal male is under parenteral T 250 mg (D1) on regular 3-weeks intervals. According to approved study protocol, blood samples were collected in determined points (D0, 1, 7, 14, 21 for T-treated and D0 and 21 for control patient) for the purpose of T and LH measurements before and after HD session. Analyses were performed by *DXI-600 Beckman Coulter* device.
Results
Obtained data are showed in Table.

Hormones	Before T (D_0)		D_1		D_7		D_{14}		D_{21}	
	<HD	>HD	<HD	>HD	<HD	>HD	<HD	>HD	<HD	>HD
LH_C (1.2–8.6) [U/l]	6.52	6.90							6.20	5.66
T_C (6.07–27.1) [nmol/l]	7.66	7.44							8.63	7.59
LH_{T_t}	18.61		22.74	26.51	1.72	2.17	0.86	0.41	2.91	2.79
T_{T_t}	5.85		15.97	12.66	12.04	17.33	11.11	11.11	7.89	9.23

HD = Hemodialysis; < - before HD; > - after HD; D = day; C = control patient; T_t = testosterone-treated patient.

Discussion
Our results demonstrated the regular male age-related LH/T levels in control examinee, with no significant change after HD sessions. T level at D0 lower than normal revealed that patient was not T-overdosed (i.e. regarding previous T-dose and interval of administration). The expected trends of T-levels increase and LH-levels decrease were registered in initial control points of T-treated patient. However, the other way round trend of the observed hormone levels were registered in later control points in the same patient. Additionally, there were no extreme changes in the LH/T levels before and after HD sessions at control points in both examinees. The ultimate control point hormone levels of both examinees were in the reference range.
Conclusion
HD does not significantly influence LH/T levels in eugonadal and T-treated hypogonadal CAH patient, both associated with CKD. The LH/T levels are reliable markers of the quality of T-substitution in HD-treated patients.

A rare case of Cushing's syndrome due to adrenal adenoma complicated by familial adenomatous polyposis

Chihiro Ebashi[1], Noritaka Ono[2], Yasuhiro Hata[3], Hiroshi Harada[4], Takayoshi Yamada[5] & Hisashi Sugano[6]
[1]Department of General Medicine, Kochi Health Sciences Center, Kochi, Japan; [2]Department of Urology, Kochi Health Sciences Center, Kochi, Japan; [3]Department of Radiology, Kochi Health Sciences Center, Kochi, Japan; [4]Department of Plastic Surgery, Kochi Health Sciences Center, Kochi, Japan; [5]Department of Gastroenterology, Kochi Health Sciences Center, Kochi, Japan; [6]Departmet of Diabetes and Endocrinology, Kochi Health Sciences Center, Kochi, Japan.

Introduction
Adrenal adenoma is one of the extraintestinal lesions associated with familial adenomatous polyposis (FAP). Only four cases of Cushing's syndrome due to adrenal adenoma complicated by FAP, including ours, have been reported to date.
Case report
A 37-year-old woman presented with pretibial edema and hirsutism. She was diagnosed with FAP at 8 years old. She had undergone resection of craniopharyngioma at 10 years old and repeated removal of desmoid tumors. Polyposis was observed in the stomach, duodenum, upper jejunum, and large intestine. Polypectomy was performed for a large intestine lesion. Her mother and younger sister also had FAP, but her mother had died of colorectal cancer. The patient had developed hypertension and menstrual abnormalities at the age of 35 years. She also had diabetes (HbA1c 7.7%) and was obese (BMI 31.1 kg/m^2). Upon physical examination at our hospital, facial fullness, morbid obesity, a buffalo hump, striae, pretibial edema, subcutaneous bleeding spots, and hypertrichosis were detected. Laboratory assays revealed hypercortisolism (17.2 μg/dl), indicating the circadian rhythm loss of cortisol secretion, no suppression in the low- and high-dose dexamethasone suppression tests, and high levels of urine free cortisol (240 μg/day). ACTH levels were always

suppressed (< 2 pg/ml). There was no excess catecholamine, and the renin-angiotensin system was normal. CT revealed a left adrenal mass measuring 5.3× 5.2×4.7 cm. She underwent left laparoscopic adrenalectomy. She was diagnosed with Cushing's syndrome owing to the left adrenal gland tumor, which was pathologically diagnosed as adenoma. Genetic analysis of APC via the direct sequence method showed a mutation in codon 1517 (CAG (Gln) → TAG (STOP)), which has been reported in patients with an extraintestinal manifestation of FAP.
Discussion
Brain tumors, papillary adenocarcinoma of the thyroid, hepatoblastoma, retinal pigment epithelium hyperplasia (CHRPE), osteoma, desmoid tumors, and adrenal adenomas are known extraintestinal manifestations of FAP. FAP is an autosomal dominant hereditary disease that occurs due to an *APC* mutation on the chromosome locus 5q21-22. *APC* consists of 15 exons and 2844 codons. The highest cumulative mutation frequencies in extra-colonic manifestations are found between codons 976–1067 and 1310–2011, for example, desmoid tumors, which frequently show mutations in codons 1309–1580. However, no genotype-phenotype correlations have been established for adrenal adenoma or functional adrenal adenoma. This association will likely be elucidated with more reports like this case study.

Hypoglycemic coma as first manifestation of primary adrenal insufficiency in a septic patient with severe hypokalemia and hypomagnesemia

Maria Chrysoulaki[1], Vasiliki Daraki[1], Grigoria Betsi[1], Maria Sfakiotaki[1], Maria Dolapsaki[1], Theodoros Liarigkovinos[1], Kostas Stylianou[2] & George Samonis[1]
[1]Department of Endocrinology, Diabetes and Metabolic Diseases, University Hospital of Crete, Heraklion, Greece; [2]Department of Nephrology, University Hospital of Crete, Heraklion, Greece.

Introduction
Adrenal crisis due to primary adrenal insufficiency may result in severe morbidity and mortality if undiagnosed or ineffectively treated. Main manifestations are hypotension (>90%), hyponatremia (70–80%), and hyperkalemia (30–40%), while hypoglycemia is rare. An unusual case of a septic patient with hypokalemia and hypomagnesemia with hypoglycemic coma as first manifestation of acute adrenal insufficiency is presented.
Case presentation
A 51-yr-old woman, with tetraparesis after a cervical spine fracture 20 years ago, was admitted to Intensive Care Unit for septic shock due to osteomyelitis of the right hip. She received empirically several antimicrobials such as vancomycin, amikacin, daptomycin, tigecyclin and high doses of fluconazole. After clinical improvement, she was transferred to the *Department of Orthopedics,* where she started to complain of anorexia, fatigue, nausea and polyuria. Laboratory tests revealed normal serum sodium, hypokalemia and hypomagnesemia due to increased urine losses of respective cations, nephrogenic diabetes insipidus and renal tubular acidosis. A month later, she had two episodes of seizures with subsequent loss of consciousness. Her blood pressure was low (85/56 mmHg). Laboratory evaluation showed very low blood glucose levels, confirming the diagnosis of hypoglycemic coma. Hormonal evaluation revealed low levels of cortisol and aldosterone with high levels of ACTH and renin, indicating acute adrenal failure. Abdominal CT scan showed normal size adrenal glands, with no sign of adrenal hemorrhage. Investigation for infections such as tuberculosis, fungi, CMV and HIV, commonly associated with primary adrenal insufficiency, was negative. Previous fluconazole therapy was considered as the most possible etiology of adrenal dysfunction. Hydrocortisone replacement treatment led to restoration of blood glucose and blood pressure levels. It is remarkable that, despite adrenal insufficiency, severe hypokalemia and the associated nephrogenic diabetes insipidus, resisted and were both restored only after correction of serum magnesium.
Conclusion
Fluconazole in high doses may inhibit adrenal steroidogenesis and may cause adrenal failure. In addition, antibiotics commonly used in acutely ill patients, such as amikacin, may cause renal damage, with electrolyte disturbances, such as hypomagnesemia and hypokalemia. The diagnosis of acute adrenal failure caused by fluconazole may be obscured in septic patients with antibacterial-induced renal damage. Sudden appearance of severe hypoglycemia in such patients must be taken into account as a sign of adrenal insufficiency and must be investigated and treated appropriately.

P14

Preoperative treatment with metyrapone in patient with Cushing's syndrome due to adrenal adenoma: a pilot prospective study

Soraya Puglisi[1], Paola Perotti[1], Mattia Barbot[2], Paolo Cosio[1], Carla Scaroni[2], Antonio Stigliano[3], Pina Lardo[3], Valentina Morelli[4], Elisa Polledri[5], Iacopo Chiodini[4], Giuseppe Reimondo[1], Anna Pia[1] & Massimo Terzolo[1]
[1]Internal Medicine, Department of Clinical and Biological Sciences, University of Turin, Orbassano, Italy; [2]Endocrinology Unit, Department of Medicine DIMED, University of Padua, Padova, Italy; [3]Endocrinology Unit, Department of Clinical and Molecular Medicine, Sant'Andrea Hospital, University of Rome, Roma, Italy; [4]Endocrinology Unit, Department of Clinical Sciences and Community Health, University of Milan, Milano, Italy; [5]Laboratory of Toxicology, Department of Clinical Sciences and Community Health, University of Milan, Milano, Italy.

Background and objectives
Metyrapone has been approved for the treatment of patients with Cushing's syndrome from all causes, but only few retrospective clinical studies are available. The aim of our study was the prospective assessment of metyrapone as pre-operative treatment.
Methods
Before adrenalectomy, 7 patients with ACTH-independent Cushing's syndrome due to adrenal adenoma were prospectively treated with metyrapone for 3 months, with endocrine work-up and clinical evaluation at screening and at predefined evaluation time points (Day 14, 31, 48, 65, 82).
Results
In all patients, UFC levels decreased up to normal range from baseline to Day 82 [609 (188–1476) vs. 69 (28–152) nmol/24 h, $P<0.02$], with a reduction of serum and salivary cortisol levels, and no significant increase of plasma ACTH and serum DHEAS levels. Clinical improvement was reported on quality of life [+16.7 (+4.2;+52.00) points, $P<0.04$) and pressure control [systolic pressure, −25 (−52;−10) mmHg, $P<0.01$; diastolic pressure, −16 (−50;+2 mmHg), $P<0.03$)]. No significant change in weight, electrolytes, glycemic and lipid profile was reported. Although in women a significant increase of testosterone and androstenedione was reported, no worsening of clinical hyperandrogenism was observed. All drug-related adverse events (nausea, fatigue, low grade fever, edema of lower limbs and facial rash) were grade 1 or 2 and generally transient.
Conclusions
This prospective pilot study demonstrated that metyrapone is effective in normalizing biochemical and clinical parameters in patients with Cushing's syndrome due to adrenal adenoma before surgical intervention, with minimal side effects.

Clinical features of adrenal incidentalomas

Danijela Radojkovic[1], Milica Pesic[1], Milan Radojkovic[2], Sonja Kostic[1], Sanja Curkovic[1], Sasa Radenkovic[1], Vojislav Ciric[1] & Slobodan Antic[1]
[1]Clinic of Endocrinology, Diabetes and Metabolic Disorders, Clinical Centre, Nis, Serbia; [2]Surgery Clinic, Clinical Centre, Nis, Serbia.

Introduction
Adrenal incidentalomas (AI) are tumours revealed during radiological procedures in patients without previous suspicion for adrenal disease. This study was conducted to determine the frequency of functional AI.
Patients and methods
Thirty-eight patients with AI were included in the study. The following parameters were considered: patient age, gender, size and location of the tumour, and radiological characteristics of adrenal masses. In order to determine hormonal activity of incidentalomas the following tests were done: basal cortisol values and day-night rhythm, adrenocorticotropic hormone (ACTH) overnight dexamethasone suppression test, vanillymandelic acid (VMA) in 24 h urine, electrolytes, haematocrit (HCT), acid-base status, oral glucose tolerance test (OGTT) and chromogranin A (CgA).
Results
Patients consisted of 22 females (57.89%) and 16 males (42.1%) aged between 23 and 78. The highest incidence was in sixth decade (34.21%). Regarding the tumour localisation, 60.53% were found in the left ad-renal gland, 34.21% were visualised in the right, and 5.26% of the patients had bilaterally AI. The majority of analysed lesions were 1–4 cm in size (86.84%). Based on CT scans features, only two patients were highly suspicious of malignant AI. Hormonal evaluation showed that 32 patients (84.21%) had non-functional adrenal lesions. Among 6 patients with verified AI functional activity, 3 had pheochromocytomas, 2 were

diagnosed as Cushing's syndrome and one patient had aldosterone-producing adenoma. Adrenalectomy was performed in 9 patients. Histopathological examination confirmed suspected hormonal activity in 6 patients, adrenocortical carcinoma in one patient and secondary deposits due to bronchial carcinoma in one patient.

Conclusion

Along with technology advances detection of AI is significantly increased. Two crucial tasks for physician are: 1. to distinguish functional from nonfunctional adrenal tumour and 2. to conclude whether it is benign or malignant one. Even though the frequency of functional AI is low and malignant AI even lower, thorough diagnostic procedures should be conducted in order to triage patients for surgical treatment.

DOI: 10.1530/endoabs.56.P15

P16

Rare incidence of primary adrenocortical carcinosarcoma: a case report

Cristina María Díaz Perdigones, Isabel María Cornejo Pareja, Miguel Damas Fuentes, Maria Molina Vega, Carmen Hernández García, Araceli Muñoz Garach & Francisco José Tinahones Madueño
Hospital Virgen Victoria, Malaga, Spain.

Introduction

Adrenal tumors are common tumors with a prevalence of around 3% in a population over the age of 50 years. In contrast, adrenocortical carcinoma (ACC) is a rare malignancy (incidence 1–2 per 1 million population) with a heterogeneous presentation and a variable but generally bad prognosis. Patients present with evidence of adrenal steroid hormone excess in approximately 60% of cases.

Case report

A 49-year-old woman with symptoms of facial swelling, weight gain; predominantly abdominal, appearance of hair on face and neck, high blood pressure, bruising and insomnia during the last four months. In addition, polymenorrhoea in the last two menstrual cycles. No medical history of interest except the start of antihypertensive treatment in the last year. The patient exhibited clinical features associated with excessive steroid hormone or catecholamine levels. Thus, blood tests with an adrenal hormone profile were requested:

low dose dexamethasone suppression	26 μg/dl
24-hour urinary cortisol	686 μg/24 h
ACTH	<5 pg/ml
Metanephrines	93μg/24 h
Normetanephrines	24 μg/24 h
Adrenalin	not detectable
Dopamine	109 μg/ 24 h
Aldosterone/ plasma renin activity	<30

These clinical symptoms and analytical alterations led to the discovery of a 8x8x11 cm heterogeneous hypoechoic left adrenal mass on an abdominal magnetic resonance. After surgery adrenal cortical carcinoma with areas of necorsis and hemorrhage is confirmed. It exceeded adrenal gland and reached peripancreatic tissues. It presented perineural invasion but no vascular invasion. Negative immunostaining for steroidogenic factor 1, melanA markers and chromogranin A was confirmed. The surgery was completed with right suprarenalectomy, tail and body pancreatic resection and nodulectomy of segment three of the liver (it confirmed intraoperative metastasis). The treatment regime usually depends on cancer stage. Two major staging systems are used: the American Joint Committee on Cancer (AJCC) TNM staging system and the ENSAT staging system(European Network for the Study of Adrenal Tumors). The ENSAT staging system is essentially the same as the AJCC system, but reserves stage IV only for tumors with distant metastasis. In our patient, we are in stage IV, pTN3NxM1 and following the criteria of ENSAT he had started mitotane-EDP (doxirubicin-cisplatin-etoposide). Moreover, she is taking hidroaltesona 20-10-10 mg daily because there is an increase in cortisol metabolism secondary to mitotane.

Conclusion

In advanced ACC, mitotane is still the standard of care. However, most patients will experience progress and will require rescue therapies due to the delayed diagnosis and aggressiveness of the ACC. Thus, new treatment concepts are urgently needed.

Clinical and biochemical outcomes in surgically treated patients with primary aldosteronism. A multicentric retrospective study

Almudena Vicente[1], Alejandro Sirvent[2], Sandra Herranz[3], Cristina Lamas[2], Ana Martínez[1] & Julia Sastre[1]
[1]Hospital Virgen de la Salud, Toledo, Spain; [2]Hospital General Universitario, Albacete, Spain; [3]Hospital Universitario, Guadalajara, Spain.

Background

Although unilateral primary aldosteronism (PA) is the most common surgically correctable cause of hypertension, no standard criteria exist to classify surgical outcomes. The Primary Aldosteronism Surgical Outcome (PASO) study was an international project to develop consensus criteria for outcomes and follow-up of adrenalectomy for unilateral PA.

Objetives

To determine the proportions of patients achieving complete, partial, or absent clinical and biochemical success in accordance with the consensus criteria and to identify preoperative factors associated with outcomes in surgically treated patients with PA in three centers from Castilla La Mancha (Spain).

Design

Multicentric retrospective observational study.

Methods

We analysed clinical data from 53 patients with a diagnosis of unilateral PA who underwent surgery between 1999 and 2016, of whom 41 had postsurgical biochemical data. Treatment was guided by computed tomography (CT) scans**.** Preoperative adrenal vein sampling (AVS) was performed in 15 patients. We used the PASO standardised outcomes criteria (complete, partial, and absent success of clinical and biochemical outcomes) based on blood pressure, use of antihypertensive drugs (ADs), plasma potassium and aldosterone concentrations.

Results

Fifty three patients (30 male / 23 female); aged 52.4 ± 11.2 years were studied. Mean postsurgical follow-up was 44.6 months (range 0-240). Complete clinical success and partial clinical success were achieved in 27 (50.9%) and 19 (35.8%) patients, respectively. In patients with postsurgical biochemical data, complete biochemical success and partial biochemical success were seen in 29 (70%) and 5 (12%), respectively. In univariate analysis, patients with complete clinical success were significantly younger than patients with partial or absent success (49.3 ± 10 vs 56.8 ± 10 vs 57.2 ± 8.7 years) ($P < 0.01$). Complete clinical success were more frequent in women (59.3% vs 26.3% vs 16.7%) ($P < 0.05$). Number of preoperative ADs, level of preoperative arterial blood pressure or serum potassium levels did not differ significantly between patients with different outcomes. Using binary logistic regression analysis only female sex was independently associated with complete success (OR 6.5 CI 95% 1.2-36.9, $P < 0.05$).

Conclusion

In our study, unilateral adrenalectomy for PA achieved complete or partial clinical and biochemical success in the majority of patients (86.7% and 82% respectively). Younger patients and female patients were more likely to have a favourable surgical outcome.

Intraoperative hypertensive crisis as a key symptom in a normotensive patient with primary aldosteronism – clinical case

Agnieszka Kuzior[1], Ana Delia Santana-Suarez[1], Manuel Esteban Nivelo-Rivadeneira[1], Paula Fernandez-Trujillo-Comenge[1], Claudia Arnas-Leon[2], Carmen Acosta-Calero[2], Sara Quintana-Arroyo[2] & Francisco Javier Martinez-Martin[2]
[1]Endocrinology & Nutrition Department, Hospital Universitario de Gran Canaria Doctor Negrín, Las Palmas de Gran Canaria, Spain; [2]Endocrinology & Nutrition Department, Hospitales San Roque, Las Palmas de Gran Canaria, Spain.

Primary aldosteronism is now recognized as the most frequent cause of secondary hypertension, accounting for 5–10% of the total cases of hypertension. Reportedly it is associated with a risk of cardiovascular events above and beyond hypertension development. Notwithstanding its high prevalence and serious complications, it is widely infradiagnosed. Hereby we present the case of a normotensive 50-year old female patient who was diagnosed of probable left

hypernephroma, but after anesthetic induction surgery was aborted due to a hypertensive crisis. The patient was referred to our Endocrinology Clinic in order to rule out pheochromocytoma. Anamnesis revealed recurrent hypokalemia (up to 2.6 mEq/L). Glucose, glomerular filtration rate, lipids and TSH were normal, K + 4.24 mEq/L, Aldosterone 59 ng/dL, PRA 0.7 ng/mL/h, ratio 84.3, Metanephrine 30 pg/mL, Normetanephrine 69 pg/mL, Cromogranine A 5.8 ng/mL. 24h ABPM showed normal mean values of BP and HR (118/76 mmHg, 77 bpm), with an isolated peak of 234/146 mmHg 81 bpm at 12:20. The abdominal CT report did not mention adrenal anomalies but on review the left adrenal image suggests nodular hyperplasia. A confirmatory captopril test did not elicit aldosterone suppresion (0' – > 120': 29.9 – > 21.7 ng/dL). The patient was treated with spironolactone 12.5 mg/day, she remains asymptomatic, with normokalemia, normotension and unsuppressed PRA. Pheochromocytoma was ruled out and a 4-cm left renal mass was successfully removed, the pathology diagnosis was oncocytoma, with negative extension. Surgical removal of the left adrenal was not considered. We conclude that normotensive primary aldosteronism is not harmless: it may cause hypertensive crisis and severe hypokaliemia. Evolution to resistant hypertension has also been reported. It must be considered as a diagnostic possibility in normotensive patients with unexplained hypokalemia.

Adrenal insufficiency during prednisolone treatment in patients with polymyalgia rheumatica or giant cell arteritis – prevalence and clinical approach

Stina Willemoes Borresen[1], Toke Laursen[2], Bente Jensen[2], Linda Hilsted[3], Else Marie Bartels[4], Ulla Feldt-Rasmussen[1] & Henning Locht[2]
[1]Department of Medical Endocrinology, Copenhagen University Hospital, Rigshospitalet, Copenhagen, Denmark; [2]Center for Rheumatology and Spine Diseases, Copenhagen University Hospital, Frederiksberg Hospital, Frederiksberg, Denmark; [3]Department of Clinical Biochemistry, Copenhagen University Hospital, Rigshospitalet, Copenhagen, Denmark; [4]The Parker Institute, Copenhagen University Hospital, Frederiksberg Hospital, Frederiksberg, Denmark.

Introduction
Prednisolone is standard treatment of polymyalgia rheumatica (PMR) and giant cell arteritis (GCA), but many patients are reluctant to discontinue prednisolone treatment even after remission of the inflammatory conditions. Prednisolone-induced adrenal insufficiency can give manifest or latent symptoms, causing failure to taper and withdraw prednisolone. We therefore aimed to find the prevalence of adrenal insufficiency in prednisolone-treated patients with PMR/GCA.
Methods
A cross-sectional study of PMR/GCA patients treated with prednisolone for >6 months, currently 2.5–10 mg/day. Forty-seven patients (34 women) were included consecutively from the Rheumatology Outpatient Clinic. Adrenal function was evaluated by a fasting 250 μg Synacthen test in the morning following being prednisolone-free for 48-hours and oestrogen treatment free for P-weeks. P-cortisol concentrations were measured by Roche Elecsys® Cortisol II assay. Adrenal insufficiency was defined as P-cortisol <420 nmol/l 30 minutes after Synacthen injection (local assay specific cut-off). All patients with adrenal insufficiency were subsequently followed in a close rheumatologic-endocrine collaboration. Prednisolone tapering was based on PMR/GCA remission, Synacthen tests were performed regularly and the need for hydrocortisone stress doses/daily supplementations was adjusted accordingly.
Results
The 47 patients (mean age 73 years (SD 7.3)) were treated with prednisolone for median 23 months (range 5.4–139 months), with a mean current prednisolone dose of 5.3 mg/day (SD 2.0). Seven patients (15%, $CI_{95\%}$: 7.4–28%) had adrenal insufficiency. Current prednisolone dose correlated negatively with 30 min P-cortisol (−32 nmol/l/mg prednisolone, $CI_{95\%}$: −9.5–−55 nmol/l/mg, $P=0.0066$, $r=-0.39$), but adrenal insufficiency occurred across the entire prednisolone dose range (2.5–10 mg/day). There was no correlation between duration of treatment and 30 min P-cortisol ($P=0.24$, $r=-0.17$). ACTH levels were low within reference range (mean 4.6 pmol/l (SD 2.9)). Insufficient patients were informed of the condition and administration of necessary hydrocortisone stress doses. Subsequently, 5 patients were able to discontinue prednisolone treatment, 2 of whom recovered adrenal function, whereas 3 still need daily hydrocortisone replacement. Two patients were unable to stop prednisolone treatment due to PMR/GCA disease activity, and have occasionally needed excess steroid doses to overcome stress/adrenal crises.
Conclusion
Iatrogenic adrenal insufficiency occurred in 15% of low-dose prednisolone treated patients with PMR/GCA. In most patients prednisolone could be discontinued due to recovery of adrenal function or by switching to oral hydrocortisone. This illustrates the importance of a close collaboration between rheumatology and endocrinology.

Prevalance of primary aldosteronism in hypertensive patients: epidemiological data from a tertiary centre

Nikolaos Voulgaris[1], Labrini Papanastasiou[1], Sofia Vlachou[1], Evangelia Kyriazi[1], Ernestini Tyfoxylou[1], Nikoletta Monastirioti[1], Chara Kapsali[1], Liana Charalampidou[1], Zachaki Aglaia[1], Athanasia Kalantzi[1], Christos Gravvanis[1], Athina Markou[1], Eirini Giagourta[1], Theodora Kounadi[1], Eva Kassi[2], Gregory Kaltsas[3] & George Piaditis[1]
[1]Department of Endocrinology and Diabetes Center, 'G Gennimatas' General Hospital, Athens, Greece; [2]Department of Biological Chemistry, Medical Scholl, National and Kapodistrian University of Athens, Athens, Greece; [3]Department of Pathophysiology, Laikon Hospital, National and Kapodistrian University of Athens Medical School, Athens, Greece.

Introduction
Primary aldosteronism (PA) is the most common cause of endocrine hypertension. Its prevalence varies from 5-15%, which depends mainly on the cut-offs of the diagnostic tests.
Aim
To estimate the prevalence of PA in patients with different stages of hypertension based on a dynamic overnight diagnostic test.
Methods
One hundred ninety nine hypertensive patients were divided in 3 groups according to the stage of hypertension, as defined by the European Society of Hypertension. The three groups consisted of 77 patients at stage 1 [systolic blood pressure (SBP) 140 to 159mmHg and/or diastolic blood pressure (DBP) 90 to 100 mmHg], 65 patients at stage 2 (SBP 160 to 179 mmHg and/or DBP 100 to 109 mmHg and 57 patients at stage 3 (SBP ≥180 mmHg and/or DBP≥110 mmHg) respectively. Evaluation of PA was based on the combination of valsartan, captopril and dexamethasone suppression test (DCVT). Post DCVT aldosterone (ALD)>3 ng/dl and post-DCVT aldosterone to renin (ALD/REN) ratio>0.32 ng/dL/μU/mL were applied simultaneously to establish the diagnosis of PA.
Results
The diagnosis of PA using the DCVT test was confirmed in 60 of 199 patients giving a prevalence of 30,1%. The prevalence of PA according to the stage of hypertension was 27,2%(21/77) in patients of stage 1, 27,6%(18/65) in patients of stage 2, and 36,8%(21/57) in stage 3.
Conclusion
Using the DCVT a remarkably increased prevalence of PA (30,1%) was observed. The higher prevalence was observed in patients with severe hypertension (stage 3). Our data suggest that all hypertensive patients, especially those with severe hypertension should be tested for PA.

Renin: a possible novel marker for the efficacy of pharmacological treatment of primary aldosteronism

Nikolaos Voulgaris[1], Sofia Vlachou[1], Evangelia Kyriazi[1], Eleni Papaoikonomou[1], Ernestini Tyfoxylou[1], Nikoletta Monastirioti[1], Chara Kapsali[1], Aglaia Zachaki[1], Liana Charalampidou[1], Theodora Kounadi[1], Athina Markou[1], Labrini Papanastasiou[1], Eirini Giagourta[1], Eva Kassi[2], Gregory Kaltsas[3] & George Piaditis[1]
[1]Department of Endocrinology and Diabetes Center, 'G Gennimatas' General Hospital, Athens, Greece; [2]Department of Biological Chemistry, Medical Scholl, National and Kapodistrian University of Athens, Athens, Greece; [3]Department of Pathophysiology, Laikon Hospital, National and Kapodistrian University of Athens Medical School, Athens, Greece.

Introduction
Primary aldosteronism (PA) treatment is either pharmacological with aldosterone receptor antagonists (MRAs) or surgical with the resection of the responsible adenoma. The efficacy of MRAs treatment is based on the normalization of blood pressure (BP) in relation to potassium levels. However, it remains unclear whether the stimulation of renin levels during treatment could serve as an additional marker of adequate MR blockade.
Aim
To investigate prospectively the effectiveness of MRAs on BP control in PA patients in correlation with renin levels.
Methods
Thirty eight patients diagnosed with PA, were treated with MRAs and were prospectively followed –up at regular intervals ranging from 3 to 12 months. All patients were instructed to have 2 consecutive BP measurements twice daily. Systolic (SBP) and diastolic (DBP) BP target were <135 and <85 mmHg respectively. Renin levels >7.8 μU/ml were considered as unsuppressed. In patients with raised BP (SBP or DBP) or renin levels <7.8 μU/ml MRAs dose was gradually increased.
Results
At the first follow up visit, 10 of 38 (26.3%) PA patients had normal SBP, DBP and unsuppressed renin levels. The initial MRAs dose ranged from 25 to 100 mg (mean 57.2 mg). Patients with unsuppressed renin levels had lower DBP compared to patients with suppressed renin levels (77.6 ± 7.3 mmHg vs 83.15 ± 8.7 mmHg, $P=0.04$). Patients with either elevated BP or suppressed renin levels received higher MRAs dose, which ranged from 50 to 200 mg (mean 104.5 mg). At the last follow-up 24 of 33 (72.7%) patients had normal BP and unsuppressed renin levels. Compared to the 1st follow-up, at the last follow up visit the PA patients improved SBP (136.9 ± 9.9 mmHg *vs* 127.8 ± 9.14 mmHg, $P<0.001$), DBP (80.2 ± 8.9 mmHg vs 75.6 ± 5.6 mmHg, $P=0.04$), raised renin (9.9 ± 8.1 μU/ml vs 16.3 ± 9.8 μU/ml, $P<0.001$) and potassium levels (4.2 ± 0.5 vs 4.4 ± 0.3 mEq/L, $P=0.024$). In addition, there was a negative correlation between mean MRAs doses and renin levels (r-0.42, P 0.014) at the last follow-up indicating that the higher MRA doses were needed in patients with supressed renin levels at the beginning of the study.
Conclusion
The targeted MRAs pharmacological treatment leads to an increase of renin levels and more effective BP control. According to our data, unsuppressed renin levels in combination with BP could be used as a novel marker of adequate MR blockade and can predict BP control.

Conn Syndrome Presented with Muscle Weakness

Elif Sevil Alaguney[1], Goknur Yorulmaz[2], Funda Canaz[3], Bartu Badak[4] & Nur Kebapci[1]
[1]Eskisehir Osmangazi University Division of Endocrinology, Eskisehir, Turkey; [2]Eskisehir Osmangazi University Division of Endocrinology Eskisehir Osmangazi University Division of Endocrinology, Eskisehir, Turkey; [3]Eskisehir Osmangazi University Department of Pathology, Eskisehir, Turkey; [4]Eskisehir Osmangazi University Department of General Surgery, Eskisehir, Turkey.

Introduction
Aldosterone producing adenoma, called Conn syndrome, accounts for 10 percent of all hypertension cases. It should be remembered in patients with hypokalemia and hypertension however, this is not a rule. Conn syndrome can be presented with hypertension but normal potassium levels. Also, rarely it can be presented with hypokalemia but normal blood pressure as in our case.
Case report
34-year-old female patient complained about difficulty in walking and trips and falls without a cause. Assessment in neurology clinic revealed low potassium levels (2.6 meq/l) and normal sodium levels in the upper limit (141 meq/l). The patient is referred to our clinic. Abdominal ultrasound showed a 12×6 mm hypoechoic nodule in the right adrenal zone consistent with adrenal adenoma. She denied history of hypertension. Family history did not suggest Conn syndrome. Aldosterone levels were 257 pg/ml, plasma renin activity was 0.45 ng/ml/h, aldosterone/renin ratio was 57.1 after correction of serum potassium levels. Two controls gave similar results. Cortisol level was 15.61 μg/dl, ACTH level was 25.9 pg/ml. Cortisol levels were suppressed to <1.8 μg/dL after 1 mg dexamethasone suppression test. 24-hour urinary cortisol level was 37 μg/day (3.5–45). DHEAS level was 159 μg/dl (35–430). 24-h ambulatory blood pressure revealed a median blood pressure of 125/85 mm/Hg. Computed tomography for adrenal gland showed 16x10 mm lesion in right adrenal gland medial crus with a HU density of -2 which is consistent with adrenal adenoma. Left adrenal gland was normal. The patient was referred to surgery for aldosterone producing unilateral adrenal adenoma and undergone right adrenalectomy. The post-operative pathology was consistent with adenoma. The patient did not need potassium replacement after two days, as potassium levels were normal.
Discussion
Diuretic treatment, Bartter syndrome and persistent vomiting can cause hypokalemia without hypertension. However, primary hyperaldosteronism can also be presented with hypokalemia without hypertension. The differential diagnosis is easy as renin levels are low in Conn syndrome in contrast with others. Our patient had low renin and high aldosterone levels suggesting primary hyperaldosteronism. The pathology revealed adrenal adenoma. The maintenance of normal levels of potassium after surgery supported the diagnosis of Conn syndrome.

Large Oncocytic Adrenocortical Tumor with Uncertain Malignant Potential

Betul Aydin Buyruk[1], Goknur Yorulmaz[1], Belgin Efe[1], Bartu Badak[2], Deniz Arik[3] & Nur Kebapci[1]
[1]Eskisehir Osmangazi University Division of Endocrinology, Eskisehir, Turkey; [2]Eskisehir Osmangazi University Department of General Surgery, Eskisehir, Turkey; [3]Eskisehir Osmangazi University Department of Pathology, Eskisehir, Turkey.

Introduction
Oncocytic tumor of adrenal gland was defined as a neoplasm composed exclusively or predominantly of oncocytes which are large and polygonal cells with eosinophilic cytoplasm because of abnormal accumulation of mithochondria. Oncocytic neoplasms of the adrenal cortex are extremely rare and are usually non-functioning, benign and incidentally detected.
Case
A 40-year old male patient, for whom a large mass in the adrenal gland was diagnosed incidentally on abdominal ultrasonography and MRI. The physical examination and laboratory tests were within normal limits. On the dynamic abdominal MRI imaging $9.5 \times 9.5 \times 10.5$ cm mass lesion was observed in the right surrenal region. 24-hour urine dopamine and VMA levels were slightly higher [VMA: 8.4 mg/24 h (0–6.6 mg/24 h) and Dopamine: 435.1 μg/24 h (<400 μg/24 h)]. Right -side adrenalectomy was applied to the patient. The histopathological diagnosis was reported by the Pathology Department as oncocytic adrenocortical tumor with uncertain malignant potential according to the Lin-Weiss-Bisceglia system (Large size and capsule invasion were detected). Immunohistochemistry (IHC) of the tumor cells were found positive for synaptophysin and negative for inhibin and chromogranin.
Conclusion
Adrenocortical oncocytoma is a very rare abnormality observed within the adrenal cortex. It is usually benign, non-functioning, large and diagnosed incidentally. Adrenal gland masses are best visualized on CT or MRI but still no definitive features can differentiate benign from malignant adrenal oncocytic neoplasm on imaging. Diagnosis is made histopathologically, so adrenalectomy is the mainstay of therapy and laparoscopy is now the most diffuse approach. According to Weiss criteria: the presence of one major criteria (high mitotic activity, atypical mitoses or venous invasion) indicating malignancy, one to four minor criteria (Large size, necrosis, capsular or sinusoidal invasion) indicating uncertain malignant potential (borderline) and the absence of criteria indicates a benign tumor. Our case was interesting because malignancy was clinically suspected before the operation, but the mass was found to be an oncocytic adrenocortical tumor with uncertain malignant potential through postoperative histologic assessment. Therefore, an oncocytic adrenocortical tumor with

uncertain malignant potential as in this case is considered to require long-term follow-up through clinical, hormonal, and imaging evaluation owing to its malignant potential.

Conjugated steroids could be a reserve stock for rapid conversion into free ones during stress

Michaela Dušková[1], Lucie Kolátorová[1], Katerina Šimůnková[1], Mikuláš Kosák[2], Martin Hill[1], Hana Pospíšilová[1], Hana Jandíková[2], Monika Šrámková[1] & Luboslav Stárka[1]
[1]Institute of Endocrinology, Prague, Czech Republic; [2]Third Department of Medicine, General University Hospital and First Faculty of Medicine, Charles University, Prague, Czech Republic.

Hypoglycaemia stimulation serves as a model of physiological function of adrenal action during the stress reaction. The study aimed to describe the differences of steroid response between hypoglycemia and various doses of Synacthen (as ACTH stimulation alone). The goal of the study was to investigate the physiology of adrenal response. Twenty four steroids were measured in plasma using gas chromatography - mass spectrometry after stimulation of 1 μg, 10 μg and 250 μg of Synacthen and after insulin administration in thirteen healthy subjects. Steroid conjugates significantly decreased in the first 20 minutes of stimulation by hypoglycemia, but did not change after 1 μg, 10 μg or 250 μg Synacthen administration. No differences between the secretion of adrenal androgens after stimulation by Synacthen or by hypoglycaemia were observed. The results suggest that the conjugated steroids in the circulation can serve as a reserve for rapid conversion into free steroids in the first minutes of the stress situation. The difference between hypoglycaemia and ACTH stimulation may be in concordance with the hypothesis that additional mechanism could be important in steroids reaction to the stress situation. This study was supported by the project MHCZ–DRO (Institute of Endocrinology – EU, 00023761) and grant 17-28692A.

Presence of comorbidities related to hypercortisolism in a case series on adrenal incidentaloma (AI)

María José Picón César, María Molina Vega, Carmen Hernández García, Cristina Díaz Perdigones, Miguel Damas Fuentes & Francisco Tinahones Madueño
Virgen de la Victoria Hospital, Málaga, Spain.

Introduction
The European Society of Endocrinology Clinical Practice Guideline defines follow-up recommendations for AI based on the 1 mg overnight dexamethasone suppression test and the presence of associated comorbidities. Follow-up is not recommended for AI presenting serum cortisol levels post dexamethasone $\leq$1.8 μg/dl neither those presenting serum cortisol levels post dexamethasone between 1.9–5 μg/dl (defined as 'possible autonomous cortisol secretion' –PACS-) in absence of comorbidities (such as arterial hypertension, diabetes, dyslipidemia, osteoporosis or obesity). On those patients presenting PACS and comorbidities the functional status should be reassessed after 6–12 months.
Objective
To evaluate hypercortisolism related comorbidities in a case series on AI patients attended in a specialized unit on diseases of the adrenal glands.
Patients and methods
We analyzed data from 237 AI diagnosed from February 2014 to June 2017. After excluding patients with hormonally active AI, malignancy or lesions not requiring follow-up (such as myelolipoma, adrenal hyperplasia or lesions $<$1 cm), 174 patients were catalogued as non-functioning AI. We compared the presence of comorbidities between patients presenting serum cortisol levels post dexamethasone $\leq$1.8 μg/dl (non-pathological –NP-) and those with PACS.
Results
From 237 patients, 78.1% were referred from: Urology Department 42, Gastroenterology Department 55, Internal Medicine Department 28 and Pneumology Department 11. 58.6% (102) were women and 41.1% (72) men. Mean age: 62.6$\pm$11.4 years (26–86). 80.5% (140) unilateral masses, most frequently on left adrenal gland (92/42). Masses on left side were bigger (2.43$\pm$1.15 cm, 1–8.2 cm) than those on right side (2.11$\pm$0.96 cm, 0.6–5.5 cm). From 174 non-functioning AI, 58.6% (113) presented NP and 34.5% (61) PPAC. Comorbidities: 58% (101) hypertension, 32.2% (56) diabetes, 33.9% (59) dyslipidemia and 31% (54) obesity. Mean BMI: 30.1$\pm$7.4 kg/m^2. Not statistically significant differences were found in prevalence of comorbidities between NP and PACS: arterial hypertension (52% vs 66%, $P=0.053$), diabetes (27.5% vs 38.9%, $P=0.133$), dyslipidemia (33.3% vs 34.7%, $P=0,849$), obesity (33.3% vs 27.8%, $P=0.288$).
Conclusions
A closer follow-up is recommended, in patients with AI, depending on presence of comorbidities, assuming those patients with comorbidities to have a higher risk of develop a marked hypercortisolism in the future. However, we have observed that comorbidities are present independently of serum cortisol levels post dexamethasone. Therefore, presence of comorbidities not seems not be attributable to the presence of subclinical hypercortisolism.

Increased levels of Interleukin-6 in patients with primary and secondary hypocortisolism: A case-control study

Amir-Hossein Rahvar[1], Martin Riesel[2], Tobias Graf[3] & Birgit Harbeck[3]
[1]University Hospital of Hamburg, Department of Endocrinology, Hamburg, Germany; [2]University Hospital of Luebeck, Department of Endocrinology, Luebeck, Germany; [3]University Hospital of Luebeck, Department of Cardiology, Luebeck, Germany.

Context
Hypocortisolism has been associated with increased cardiovascular risk (CVR) and mortality. Higher levels of certain inflammatory markers such as Interleukin-6 (IL6) in patients with adrenal insufficiency (AI) may partly explain the increase in CVR. Recent studies demonstrate an increased prevalence of cardiovascular disease (CVD) in patients with elevated IL-6 levels. Hypocortisolism is generally treated with glucocorticoid replacement therapy (GRT). Current GRT regiments fail to adequately mimic the physiological rhythm of endogenous cortisol leading to temporary supra- and infraphysiological levels of cortisol.
Objective
This study aims to evaluate serum levels of Interleukin-6 in patients with primary or secondary AI receiving hydrocortisone replacement therapy (HRT) in a clinical setting.
Material and methods
Ten patients (8 female, 2 male, mean age in years: 53,4, range 28–67) with either primary or secondary AI on HRT were analyzed for cortisol and interleukin-6 levels over the course of two days. Blood samples were drawn in 3-hour intervals. A cardiopulmonary exercise test was performed during the second day to induce stress. The results were compared to 5 healthy individuals. One female control patient was excluded because of tendinitis (Data not shown). Hydrocortisone was taken orally twice a day, once in the morning and once midday (mean dose: 28.75 mg, range 15–42.5). Exclusion criteria were coronary heart disease, inflammatory diseases, valvular heart disease and heart arrhythmia.
Results
A total of 10 AI patients and 4 healthy controls were included in this study. Both groups were comparable with respect to sex and age. Compared to healthy controls, patients with primary or secondary AI showed higher levels of IL-6 over the course of two days (mean IL-6 AI group: 8.1 μg/dl (range: 4.25–14.15) vs healthy controls 5.1 μg/dl (range: 2.54–8.8); $P=0.0970$). At midnight of the first day AI patients showed significantly higher levels of IL-6 compared to healthy controls (mean IL-6 at 2400 h: 7.56 μg/dl vs 3.15 μg, $P=0.0375$) while midnight serum cortisol levels were higher in healthy controls (mean cortisol at 2400 h: 2.65 μg/dl vs 1.37 μg; $P=0.25$).
Conclusion
Our study indicates that hypocortisolism in AI may lead to a compensatory secretion of IL-6, therefore increasing the risk of cardiovascular disease and ultimately mortality. Retarded hydrocortisone preparations with a dual-release may deliver a new therapy option in avoiding increased levels of IL-6 in AI patients.

A new *ARMC5* mutation responsible for primary bilateral macronodular adrenal hyperplasia

Isabel Mazarico[1], David Subías[1], Miriam Guitart[2], Rosa Maria Bella[3], Lara Albert[1], Florencia Luchtenberg[1], Irene Berges[1], Ismael Capel[1], Albert Cano[1], Laia Casamitjana[1], Olga Giménez-Palop[1], Assumpta Caixàs[1] & Mercedes Rigla[1]
[1]Endocrinology and Nutrition Department, Parc Taulí Hospital Universitari. Institut d'Investigació i Innovació Parc Taulí I3PT, Universitat Autònoma de Barcelona, Sabadell, Spain; [2]Genetics Laboratory, UDIAT-Centre Diagnòstic, Parc Taulí Hospital Universitari, Institut d'Investigació i Innovació Parc Taulí I3PT, Universitat Autònoma de Barcelona, Sabadell, Spain; [3]Pathology Service, Parc Taulí Hospital Universitari. Institut d'Investigació i Innovació Parc Taulí I3PT, Universitat Autònoma de Barcelona, Sabadell, Spain.

Introduction
Primary bilateral macronodular adrenal hyperplasia (PBMAH) is a rare cause (<2 percent) of endogenous Cushing's syndrome, usually characterized by enlarged adrenal glands containing multiple functioning nonpigmented macronodules. PBMAH was thought to be sporadic, but recently a genetic component has been described. Specifically, inactivating mutations in *ARMC5* (Armadillo-repeat containing 5), a suppressor gene, have been found in many familial cases of PBMAH, and are thought to be the most common genetic cause of this disorder. We report a case of PBMAH with a not previously reported *ARMC5* mutation.
Case report
A 65-year-old man was referred for the study of hypogonadotropic hypogonadism. Blood test revealed an elevated 0800 h cortisol of 27.5 μg/dl. 24-hour urinary free cortisol (UFC) level was high (201.7 μg/24 h) and after 1mg dexamethasone overnight his baseline cortisol failed to suppress (21.5 μg/dl). Baseline ACTH was undetectable (<1 pg/ml). The computed tomography (CT) scan revealed multiple large nodules throughout both adrenal glands consistent with benign cortical adenomas (right gland 63×31 mm and left gland 41×39 mm). Functional study was completed without showing other disorders. Screening for aberrant adrenal receptors showed a total response to terlipressin (+163.98%) and a partial response to upright posture (+39.57%). A molecular analysis by sequencing *ARMC5* gene identified a heterozygous splicing mutation, c.476-2A>T (NM_0011005247.1), not previously reported. The mutation will most likely lead to an in-frame loss of exon 2 from the transcript. Therefore, we confirmed the diagnosis of PBMAH type 2 caused by a mutation in the *ARMC5* gene. Genetic testing of the patient's son did not show the mutation. Adrenalectomy of the largest gland was performed, achieving normal UFC levels and restitution of the gonadal function.
Conclusion
PBMAH is an underrecognized genetic condition that can lead to Cushing's syndrome with the consequent increase of the morbimortality. Identifying a pathogenic mutation of *ARMC5* and performing a genetic screening for predisposition to PBMAH could lead to earlier diagnosis and prevention of long-term complications of Cushing's syndrome.

Secondary adrenal insufficiency – is not this diagnosis often made too hasty?

Lucyna Papierska, Karolina Nowak, Agnieszka Lebek-Szatanska, Marta Juszczyszyn, Piotr Glinicki & Wojciech Zgliczynski
Department of Endocrinology, Centre of Postgraduate Medical Education, Warsaw, Poland.

Introduction
Isolated corticotropic insufficiency of hypophysis with consecutive secondary adrenal insufficiency is a very rare disease. Literature notes difficulties in proper recognition and necessity of differential diagnosis, including among others chronic fatigue syndrome. In recent years, in Poland we observe more and more frequently setting this diagnosis – only on the basis of low ACTH an cortisol concentrations, despite of proper stimulation with 250 μg$^{1\text{-}24}$ACTH. As a result patients are treated with glucocorticoids, which, even in substitution doses increase risk of metabolic syndrome development.
Aim of the study
Our aim was to validate a diagnosis of secondary adrenal insufficiency in patient on prolonged treatment with Hydrocortisone.
Method
In 77 consecutive patients with Hydrocortisone treatment (6–24 months) referred to Clinic with diagnosis of secondary adrenal insufficiency (despite of proper stimulation with 250 μg 1-24 ACTH.), the 1mcg $^{1\text{-}24}$ACTH stimulation (proper cortisol concentration >18 μg/dl) then the Metyrapone tests (proper deoxycortisol concentration >7.5 μg/dl) were performed. Tests were done after 2-days cessation in Hydrocortisone medication.
Results
Only in 13 patients (17%) low-dose ACTH test confirmed diagnosis of adrenal insufficiency, and in 10 of them also after-metyrapone deoxycortisol concentrations were too low. In 22 (28%) persons with proper stimulation after 1 and 250 μg $^{1\text{-}24}$ACTH insufficient deoxycortisol increase after Metyrapone was stated. In the others 42 (55%) patients results of the both test were correct. In this group we were able to successfully stop Hydrocortisone treatment.
Conclusions
1. In significant percentage of the cases recognized as secondary adrenal insufficiency only on the basis of random cortisol and ACTH measurements the diagnosis can be false-positive.
2. In patients with isolated corticotropin deficiency classic stimulation test with $^{1\text{-}24}$ ACTH can give false-negative results and should be followed by low dose $^{1\text{-}24}$ACTH test and Metyrapone test.

Assessing the new Primary Aldosteronism guidelines recommendation to omit confirmatory testing in selected patients – severity of hypokalaemia may be included

Sarah Tan[1], Meifen Zhang[2], Joan Khoo[2] & Troy Puar[2]
[1]Ministry of Health Holdings, Singapore, Singapore; [2]Department of Endocrinology, Changi General Hospital, Singapore, Singapore.

Background
Patients with an elevated aldosterone renin ratio (ARR) should proceed for a confirmatory test to diagnose primary aldosteronism (PA) before undergoing further investigations such as CT imaging and adrenal venous sampling. The recent 2016 clinical guidelines have included a new recommendation: that in the setting of spontaneous hypokalaemia, undetectable plasma renin, and plasma aldosterone concentration (PAC) >20 ng/dl, patients may not require further confirmatory testing. We retrospectively evaluated the utility of this, in all patients diagnosed in our tertiary unit over the last 17 years.
Methods
All patients who had undergone both a screening test (ARR) and salt loading tests (SLT) in Changi General Hospital, Singapore, from 2001 to 2017 were included. Hypokalaemia was taken as $K < 3.5$ mmol/l (laboratory reference 3.5–5.0 mmol/l). Positive salt loading test was taken as post-salt loading PAC > 10 ng/dl. We assessed the sensitivity and specificity of the above criteria in predicting a positive salt loading test.
Results
90 patients, mean age 53.3±12.7 years, 51 (56.6%) males, underwent both screening ARR and confirmatory SLT from 2001–2017. 65.5% (59 of 90) patients had a positive SLT. 12.2% (11 of 90) patients fulfilled the above criteria of spontaneous hypokalaemia, undetectable plasma renin, and PAC > 20 ng/dl. Of these 11 patients, 10 (90.9%) had a positive SLT. The above criteria had a specificity of 96.8% and sensitivity of 16.9% in predicting salt loading positivity. The positive predictive value was 90.9%. In the 1 patient who fulfilled the new criteria but had a negative SLT, the lowest potassium level was 3.4 on several occasions (without other contributory factors), with baseline aldosterone 21.8 ng/dl, renin undetectable, and post-SLT aldosterone 3.46 ng/dl. The remaining 10 patients all had a potassium level of ≤3.0 mmol/l.
Conclusion
The new additional criteria (spontaneous hypokalaemia, undetectable plasma renin, and PAC >20 ng/dl) was demonstrated to be highly specific for positive salt loading test results, which would have benefitted 11% of our patients who would not have needed to undergo a confirmatory test. However, one patient with mild spontaneous hypokalaemia had a negative confirmatory test. Hence, the severity of spontaneous hypokalaemia should also be taken into account, and our

data suggest that a potassium level of ≤3.0 may be included in the criteria, to help accurately identify patients who do not need further confirmatory tests.

Addison's disease due to adrenal tuberculosis; A case report

Semih Ozyurt[1], Ozlem Celik[2], Gülsah Unlüoglu[3] & Huseyin Celik[4]
[1]Department of Internal Medicine, Acibadem University School of Medicine, Istanbul, Turkey; [2]Division of Endocrinology and Metabolism, Department of Internal Medicine, Acibadem University School of Medicine, Istanbul, Turkey; [3]Yedikule Teaching Hospital for Chest Diseases and Thoracic Surgery, Istanbul, Turkey; [4]Endocrinology and Metabolism Clinic, Istinye University, Liv Hospital, Istanbul, Turkey.

During the past decades, incidence of adrenal tuberculosis has been greatly decreased due to the introduction of antituberculosis drugs. It is reported that primary adrenal insufficiency (PAI) results from adrenal tuberculosis accounting for only 15%–20% patients in developed countries. Adrenal tuberculosis is the major cause of chronic PAI especially in developing countries. A 53 year old man presented with a 3 month history of generalized weakness, anorexia, weight loss and dizziness. His past medical history was unremarkable. Physical examination showed hypotension (85/60 mmHg) and nevuses in many parts of body. Laboratory evaluation was significant for hyponatremia, hyperkalemia and mildly increased creatinin and C-reactive protein values. Cortisol level was 3.8 mcg/dl with an ACTH level of 662 pcg/ml which was consistent with the diagnosis of primary adrenal insufficiency. A contrast enhanced abdomen magnetic resonance imaging (MRI) showed a mass,measuring 20×15 mm in the medial limb of right adrenal gland and a mass measuring 22×25 mm in the lateral limb of right adrenal gland and masses measuring 20×15 mm and 20×14 mm at the level of the left adrenal gland corpus. The masses showed heterogenity and necrotic components after contrast. Thorax CT showed sequelae findigs on apex of the right lung probably due to tuberculosis. Due to the possibility of adrenal malignancy or metastasis 18F-fluorodeoxyglucose positron emission tomography (FDG PET) CT scan was additionally performed. FDG PET-CT scan showed uptake only in the adrenal glands on both sides. Tru-cut biopsy was performed on the right adrenal gland. Cytology revealed necrotising granulomatous reaction supporting tuberculosis. A diagnosis of adrenal insufficiency secondary to tuberculosis was made, and treatment with hydrocortisone, fludrocortisone for adrenal insufficiency and antitubercular therapy was started. After 2 months the masses were not seen on the left adrenal gland, size of the masses on the right adrenal gland was decreased. He is still using hydrocortisone, fludrocortisone and antitubercular therapy.

How can cortisol-normalized adrenal venous sampling miss some Conn's adenoma

Elea Duparc[1], Georgiana Constantinescu[1,2], Olivier Ormezzano[3], Frederic Thony[4], Mathieu Rodiere[4], Jean-Philippe Baguet[3], Celsio Gomez-Sanchez[5], Fabio Fernandes-Rosa[6], Nathalie Sturm[7], Philippe Chaffanjon[8] & Olivier Chabre[1]
[1]Endocrinologie CHU, Grenoble, France; [2]Endocrinology University Hospital, Iasi, Romania; [3]Cardiologie CHU, Grenoble, France; [4]Radiologie CHU, Grenoble, France; [5]University of Mississippi Medical Center, Jackson, MS, USA; [6]INSERM, U970 Paris Cardiovascular Research Center, Paris, France; [7]Anatomopathologie CHU, Grenoble, France; [8]Chirurgie Endocrine CHU, Grenoble, France.

Introduction
In patients with primary aldosteronism (PA) international consensus claim that adrenal venous sampling (AVS) performs better than CT scan in determining lateralization of aldosterone secretion. The SPARTACUS study has however reported similar performances for lateralization by CT scan and AVS in patients with PA and a unilateral adrenal mass. The standard procedure for AVS uses cortisol values to validate the selectivity of catheterization and to normalize the aldosterone values before calculating lateralization index (LI). In this study we show that normalisation by cortisol in AVS can induce a wrong lateralization of aldosterone secretion in some patients with PA.
Objective
To analyze discordances between lateralization predicted by CT scan or by AVS in patients with PA and a unilateral adrenal mass.
Methods
Monocentric retrospective analysis of data of 33 selective AVS in patients with PA and a unilateral adrenal mass. AVS was performed simultaneously on both adrenal veins (AV) without stimulation and normalized with cortisol but also epinephrine. LI>4 was considered significant. Immunohistochemical analysis of CYP11B1, CYP11B2 and CYP17 was performed in the adrenal adenoma of one patient.
Results
One patient with severe hypertension and hypokalemia showed PA, no hypercortisolism and a 2 cm right adrenal mass. AVS was selective in both AV and cortisol-normalized AVS showed right/left LI = 0.8, ruling out lateralization, despite higher absolute values of aldosterone, but also cortisol, in the right AV. By contrast epinephrine-normalized AVS showed right/left LI = 6.25. The patient showed poor tolerance of anti-aldosterone treatment and eventually underwent right adrenalectomy, resulting in normalization of BP and remission of PA. Immunochemical analysis of the right adrenal adenoma showed expression of CYP11B2 but also CYP11B1 and CYP17, which allows to secrete both aldosterone and cortisol. Analysis of the 32 other patients identified five discordances between cortisol-normalized AVS lateralization and epinephrine-normalized AVS, with 2/5 patients showing concordance in epinephrine-normalized AVS and CT scan.
Conclusion
Cortisol-normalized AVS can fail to detect lateralization of aldosterone secretion by some Conn's adenoma which secrete not only aldosterone but also cortisol. These adenoma are not necessarily detectable pre operatively as they may show a normal 1mg Dexamethasone test. They have recently been reported to be frequent and may represent one explanation for the good performances of CT scan in the SPARTACUS study. We propose that AVS aldosterone values be normalized on epinephrine or on any product secreted by the adrenal gland, but not by the adenoma.

ACTH stimulation test for study of primary aldosteronism

Nelson Cunha[1], Leonor Gomes[1,2], Isabel Paiva[1], Diana Oliveira[1,2], Adriana Lages[1], Mara Ventura[1], Lúcia Fadiga[1], Diana Catarino[1] & Francisco Carrilho[1]
[1]Serviço de Endocrinologia Diabetes e Metabolismo, Centro Hospitalar e Universitário de Coimbra, Coimbra, Portugal; [2]Faculdade de Medicina da Universidade de Coimbra, Coimbra, Portugal.

Introduction
Primary aldosteronism (PA) is the principal cause of arterial hypertension potentially treatable. The diagnosis is dependent of tests to identify patients who will benefit most with surgical treatment. ACTH stimulation test (AST) has been described as a useful confirmatory test, potentially identifying bilateral disease in patients without adrenal tumors.
Aim
Evaluate the AST in patients with hypertension and positive screening test for PA, which performed saline infusion test (SIT).
Methods
Retrospective observational study which included 12 patients that performed SIT and AST as confirmatory tests for PA, from May to October of 2017. IST consisted in infusion of 2,000 ml of 0.9% saline over 4 h. Was considered positive if plasmatic aldosterone concentration (PAC) ≥ 100 pg/ml, negative < 50 pg/ml and indeterminate between ≥50 pg/ml and <100 pg/ml. AST consisted in intravenous injection of 250 μg of tetracosactide acetate with measurements of PAC and plasmatic cortisol at every 30′ for 2 h and was considered positive if PACmax/cortisol ≥8.5. Bilateral disease was considered if PACmax/cortisol <18.2 and no adrenal tumor on CT scan.
Results
Median age was 54 years and 75% were female. Six patients had adrenal tumor on CT scan, four without tumor and two were unknown. Of patients with adrenal tumor, 1/3 were at right, 1/3 at left and 1/3 bilateral. All patients were treated with antihypertensive agents except 1. The median PACmax/cortisol was 10.5 (IQR 8.56–15.52). 8 reached PACmax at 60′, 3 at 30′ and 1 at 90′. Three patients had positive SIT and also positive AST (PACmax/cortisol = 12.18–106.32). 2 patients had negative SIT and also negative result at AST (PACmax/cortisol = 5.04–8.49). Of seven patients with indeterminate result at SIT, the AST was negative in only 1 (PACmax/Cortisol = 7.4). Patients with positive AST presented higher PAC at SIT (P = 0.013) and lower K+ levels (P = 0.02). Of patients without adrenal tumor, one had diagnosis excluded in both tests and the others presented PACmax/cortisol <18.2, consistent with bilateral PA.

Conclusion
This data show that results between SIT and AST in positive and negative cases were consistent. In cases where SIT was indeterminate, AST may be useful as a confirmatory test of PA. Patients without adrenal tumor presented an AST result consistent with bilateral PA, reducing the need for adrenal catheterization in this context. However, a larger sample is required for the validation of AST as a diagnostic test, as well as for assessing the benefits of PA treatment in patients with positive AST.

Value of 131I-Norcholesterol scintigraphy in the evaluation of primary hyperaldosteronism

Anna Casteràs, Diego Villasboas-Rosciolesi, Amparo García-Burillo, Eugenia Espinel, Carles Zafón, Jordi Mesa & Joan Castell-Conesa
Vall d'Hebron Universitary Hospital, Barcelona, Spain.

Background
131I-norcholesterol scintigraphy (INCS) is currently not considered a main confirmatory and localizing study in primary aldosteronism (PA), however few recent data is available. On the other hand, adrenal venous sampling (AVS) is technically difficult, and may also lead to erroneuos diagnosis.
Aim
To describe the performance of INCS, done under dexamethasone (DXM) supression, in daily practice.
Patients and methods
Retrospective study of the 36 INCS-DXM performed from 1/2011 to 12/2017 at our centre, that were requested in cases of PA to decide surgery. DXM 4 mg/day was administered from day -7 to the fourth day of detection. Images were adquired at 24, 48 h, and late images, off of DXM, on 5th/7th day.
Results
20 (55.56%) were male, mean age was 58.6 ± 13.7 years. INCS was negative in 22 patients (61,1%), 11 cases (30.5%) showed unilateral autonomous nodular uptake (UANU). In three cases the report was glandular assymetry (2) or bilateral hyperplastic behaviour (1), and were treated conservatively. After committee decision nine patients (25%) were operated on (laparoscopic adrenalectomy). Eight of them had congruent UANU with ipsilateral adenoma by CT, and blood preassure ressolved completely (7) or improved (1). Only one patient with negative INCS was adrenalectomized and cured of Conn's adenoma, standing for the only false negative result (11%). 3 cases with UANU were not operated on (one had serious comorbidities, one showed contralateral adenoma on CT but refused AVS, one mild case preferred medical treatment). The sensitivity of INCS among surgical confirmed cases was 88.8%. In this series, INCS-UANU was associated to adrenalectomy (P 0.01). Hypokaliemia was associated to INCS positivity ($P<0.016$) and to surgery ($P<0.001$). Supressed renin (<0.5 ng/ml/h) did correlate to INCS positivity (P 0.001) and adrenalectomy (P 0.045), however neither plasmatic aldosterone nor aldosterone/renin ratio >30 did. Adenoma's mean size was not related to INCS result (P 0.7) or to surgical management (1.74 ± 1.2 vs 1.72 ± 0.45 mm) (P 0.9). Neither the INCS result nor the treatment were associated to gender, however, the mean age of the operated was significantly younger (47.4 ± 15.1 vs 62.2 ± 11.6) (P 0.022).
Conclusions
The usefulness of INCS in the work up of primary hyperaldosteronism due to Conn's adenoma is confirmed, with a sensitivity of 88%. INCS is a minimally-invasive functional imaging that should be taken into account before performing AVS.

A four months infant survival case of waterhouse–friderichsen syndrome

Laura Teodoriu[1], Danut Teodor[2], Maria-Christina Ungureanu[1,2], Letitia Leustean[1,2], Bianca Ioan[1] & Cristina Preda[1,2]
[1]Emergency Hospital 'St. Spiridon', Iasi, Romania; [2]University of Medicine and Pharmacy 'Grigore T. Popa', Iasi, Romania.

Introduction
The Waterhouse–Friderichsen syndrome is a fulminating infection, often leading to mortality in a matter of hours by producing acute adrenal insufficiency (adrenal hemorrhage) at a time when their response is crucial to address acute stress.
Case report
We present the case of a 4 months boy with high fever 40 °C, vomiting, diarrhea, lethargy, maculopapular rash followed by petechiae and purpura. Biological tests revealed important leukocytosis and thrombocytopenia. Gram staining of cerebrospinal fluid pointed out gram-negative diplococci and latex agglutination testing was positive for type B meningococcal infection. With Glasgow Coma Scale of four the patient was admitted in the Intensive Care Unit and the evolution was positive with biological and clinical resolution after 14 days. ACTH 209 pg/ml (0–46 pg/ml) and cortisol 4.3 μg/dl (5–25 μg/dl) outlined the adrenal insufficiency.
Conclusion
Despite the high mortality rate (55–60%) our patient survived due to fast and accurate diagnosis. The incidence of Waterhouse–Friderichsen syndrome in Romania is 5.88/year/100,000 population aged 0–2 years, more frequent in countryside area males with poor socio-economically status as our patient's case.
Key words: Waterhouse–Friderichsen syndrome, meningococcaemia, infant.

Hypoaldosteronism induced by trimethroprim: hyponatremia is frequent

Lorea Herraiz, Ane Azcutia, Alejandro Santiago, Paz de Miguel, Irene Crespo, Martin Cuesta, Ines Jimenez, Alfonso Calle & Isabelle Runkle
Hospital Clínico San Carlos, Madrid, Spain.

Introduction
Hypoaldosteronism is characterized by the development of hyperkalemia, but can also induce hypovolemic hyponatremia. Trimethroprim can cause hypoaldosteronism through mineralocorticoid resistance. That hypoaldosteronism can induce hyponatremia in absence of Addison's disease has been questioned. We studied the electrolyte disturbances found following initiation of trimetroprim therapy.
Material and methods
Retrospective, analytical. Laboratory tests of 100 consecutive patients receiving trimethroprim in 2017 in a tertiary hospital, after excluding patients with baseline (B) hyperkalemia or hyponatremia. Electrolytes mmol/l. Hyponatremia: serum sodium (SNa) <135; hyperkalemia: serum potassium (SK) >5. Baseline electrolytes were compared to maximum SK and nadir SNa after starting trimethroprim. Results in mean (S.D.), or median (interquartile range).
Results
Age: 71.55 (13.55), 51% males. Bcreatinine: 0.77 mg/dl (0.56–1.13). BSK: 4.14 (0.58). SK rose 0.65 (0.74) ($P<0.0001$). SK increment was >0.2 in 76%: 0.92 (0.6) ($P<0.0001$). 35% patients developed hyperkalemia. 10%: SK >5.5. BSK was higher in patients developing hyperkalemia: 4.32 (0.58), than in those maintaining normokalemia: 4.04 (0.6) ($P=0.018$). BSNa:138 (2.9) descended to 135.6 (4.5) ($P<0.0001$). 46% developed hyponatremia: SNa 132.3 (3.8), 6/46 without a SK rise. BSNa in patients presenting hyponatremia was lower: 137.8 (2.8) than in those not: 139.6 (2.76) ($P=0.002$). 25/35 patients presenting hyperkalemia developed hyponatremia. In these, creatinine rose from 0.82 mg/dl (0.6–1.28) to 0.99 (0.59–1.67) ($P=0.038$). There was a weak correlation between SK elevation and SNa descent: $r=-0,26$ ($P=0.034$). Days of treatment (DOT): 7.5 (5–11.5), with weak positive correlation between DOT and SK increment ($r=0.31$) ($P=0.01$), negative correlation for SNa ($r=-0.31$) ($P=0.01$). Weak positive correlation between trimethroprim-cumulative dose and SK changes ($r=0.23$) ($P=0.04$), negative for SNa ($r=-0.27$) ($P=0.01$). Blood gas bicarbonate descended <23 mEq/l in 5/28. No patient had cortisolemia determined. There was no significant difference in SK or SNa changes in 64/100 patients receiving pharmacological doses of prednisone/methyl-prednisolone versus those not. K rise and-or Na descent were not significantly influenced by heparin, ACE inhibitors, ARBs, NSAIDS, beta-blockers, or furosemide therapy, gender, age, the presence of Diabetes Mellitus, urinary tract infection or obstructive uropathy.
Conclusions
Trimethroprim-induced hypoaldosteronism is frequent, potentially causing hyperkalmia and, more often in our series, hyponatremia. In patients presenting both, creatinine levels rose, suggesting hypovolemia onset. Trimethroprim, inducing mineralocorticoid resistance, could also be unmasking subclinical Addison's Disease. However, the fact that steroid medication in 64% of patients affected neither K rise nor Na descent suggests that these electrolye disturbances should not be attributed to Addison's Disease.

Utility of adrenal venous sampling for the differential diagnosis of primary hyperaldosternoism subtypes

Laura Delegido-Gómez[1], Raquel Miralles-Moragrega[1], Clara Navarro-Hoyas[1], Victoria González[2], Fernando Sánchez-Blanco[3], Javier Irurzun[3] & Joaquín Serrano[4]

[1]Servicio de Endocrinología y Nutrición, Hospital General Universitario de Alicante, Isabial-Fisabio, Alicante, Spain; [2]Laboratorio de hormonas, Servicio de análisis clínicos, Hospital General Universitario de Alicante, Alicante, Spain; [3]Sección de Radiología intervencionista, Servicio de Radiología, Hospital General Universitario de Alicante, Alicante, Spain; [4]Servicio de Endocrinología y Nutrición, Hospital General Universitario de Alicante; Isabial-Fisabio, Alicante, Spain.

Introduction

In patients with primary hyperaldosteronism, distinguishing between unilateral and bilateral adrenal hypersecretion is critical in assessing treatment options. Adrenal venous sampling (AVS) has been advocated by some to be the gold standard for localization of the responsible lesion however is invasive, technically challenging, and difficult to interpret. Adrenal computed tomographic scanning (TC) is mandatory before AVS but more studies are warranted to identify its sensitivity and specificity for subtype differentiation.

Objectives

To study the utility of the MVS in the diagnosis of subtype of PAH and its concordance with the CT.

Methods

A retrospective study of 51 patients with a biochemical diagnosis of primary hyperaldosteronism who all underwent CT scan and AVS before and after ACTH stimulation. The aldosterone-to-cortisol ratio (AC) was computed for each sample to correct for varying capture and dilution of adrenal venous effluent. Patients that demonstrated unilateral hypersecretion of aldosterone were referred for an adrenalectomy. Diagnosis of a unilateral hyperfunctioning adrenal gland was made if the AC ratio on one side was at least four times greater than on the contralateral side and the peripheral samples. An AC ratio that was lower than periphery on the unaffected side (<0.5) especially after stimulation suggested a suppressed gland and therefore a unilateral hyperfunctioning gland on the contralateral side. Diagnosis of bilateral hyperplasia was made if the AC ratio on both sides was elevated and the response to stimulation was similar with no gradient observed between the two sites.

Results

Of 26 patients that had a unilateral abnormality on CT scan, four patients lateralized to the contralateral side by AVS, and seven patients had AVS consistent with bilateral hyperplasia. Therefore, 11 patients (21%) would have had either an unnecessary adrenalectomy or adrenalectomy of the nonfunctioning adrenal gland if AVS was not performed. In 12 patients that showed bilateral disease on CT scan, AVS lateralized to one side in eight patients and was concordant with the CT scan in 4 patients. In 13 patients that had no abnormality on CT scan, seven lateralized with AVS. 15 patiens (29.5%) would have been deprived of a curative suprarenalectomy. Of the group of 51 patients, 25 patients (50%) would have been inappropriately managed based on CT scan findings alone.

Conclusions

Because 50% of patients would have been inappropriately managed based on CT scan findings, patients with biochemical evidence of primary hyperaldosteronism and considering adrenalectomy should have AVS.

Non-classic congenital adrenal hyperplasia clinics characteristics and treatment response cohort study

Alin Abreu Lomba[1], Melanie Santrich[2], Claudia Gonzalez Bermudez[3], Lina del Carmen Salazar[3], Ana Bolena Muriel[3], Milton Gomez[3] & Mauricio Hernandez[3]

[1]Centro Medico Imbanaco, Cali, Colombia; [2]Universidad Javeriana, Cali, Colombia; [3]Universidad Libre, Cali, Colombia.

Introduction

Non-classic congenital adrenal hyperplasia (NCCAH) is an autosomal recessive disorder, that affects adrenal steroidogenesis, and it is characterized by an enzymatic defect in corticosteroids biosynthesis. NCCAH diagnosis is based on the determination of 17a-hydroxiprogesterone (17a-OHP) basal levels, and levels after stimulation with adrenocorticotropic hormone (ACTH), and it is confirmed with molecular testing. Treatment is still controversial, and it must be individualized because there are not steroid regimens to treat patients with NCCAH.

Objective

This study aims to describe the clinical characteristics, and compares the treatment response in patients with NCCAH that went to endocrinology consultation in a high complexity health institution in Cali, Colombia.

Methods

The study was conducted in a cohort of patients that registered at hospital since January 2006 to December 2016, with one year follow up, collecting 38 patients with NCCAH, diagnosed by clinical suspicion and confirmed with ACTH test. We describe the population and measure the response of 17-OH progesterone, testosterone and dehydroepiandrosterone sulfate (DHEA-S), at 6 and 12 months after treatment with dexamethasone and ethinyl estradiol plus cyproterone acetate. A $P<0,05$ was considered to establish statistically significant differences.

Results

Of the 38 patients included as total sample, the average age of participants was 25 years (s.d. 8, 9 years), average BMI was 28.3 kg/cm (s.d. 4.3). In the variance analysis we found for 17-OH progesterone levels a median of 15.9 ng/ml (IQR 12–19) at baseline, 1.65 ng/ml (IQR 1.4–3.3) at 6 months and 1.1 ng/ml (IQR 0.73–1.7) at 12 months. Total testosterone levels had a median of 103 ng/dl (IQR 79–138) at baseline, 62 ng/dl (IQR 50–77) at 6 months and 48 ng/dl (IQR 32–59) at 12 months. DHEA-S levels had a median of 452 µg/dl (IQR 370–536) at baseline, 209 µg/dl (IQR 154–306) at 6 months and 144 µg/dl (IQR 105–208) at 12 months, showing a decrease in hormone levels after the beginning of treatment, all statistically significant ($P<0.05$). Testosterone levels were influenced by BMI ($P=0.04$).

Conclusion

Pharmacologic intervention with dexamethasone at different doses, added to ethinyl estradiol plus cyproterone acetate, showed favorable results, by decreasing the serum levels of the measured hormones, during all the follow up period with statistically significant difference. Additionally, it was found that the testosterone values are influenced by BMI, without finding any difference in the other variables.

A rare incidentaloma: adrenal schwannoma

Hatice Sebile Dokmetas[1], Hande Ogul Hıncal[2], Yasar Ozdenkaya[3], Fatih Kilicli[1] & Burcu Saka[4]

[1]Istanbul Medipol University, Medical School, Department of Endocrinology, Istanbul, Turkey; [2]Istanbul Medipol University, Medical School, Department of Internal Medicine, Istanbul, Turkey; [3]Istanbul Medipol University, Medical School, Department of General Surgery, Istanbul, Turkey; [4]Istanbul Medipol University, Medical School, Department of Pathology, Istanbul, Turkey.

Introduction

Adrenal schwannoma is an extremely uncommon cause of incidentaloma. It originates from neural sheath Schwann cells of the adrenal gland. Herein, we report a case of left adrenal schwannoma that could not be diagnosed preoperatively.

Case report

A 53 years old female morbid obese (BMI: 66.68 kg/m^2) patient was referred to endocrinology policlinic because of 5 cm left adrenal mass detected on abdominal screening while preparing patient to bariatric surgery. In patients medical history she has been diagnosed with obesity, hypertension and type 2 diabetes mellitus for 8 years. She was using oral antidiabetics, zofenopril and alpha receptor antogonist for hypertension. We ceased zofenopril treatment before testing function of adrenal mass. Plasma renin activity, serum potassium, aldosterone, cortisol (11.2 µg/dl, normal range: 6.2–19.4), dopamin, and 24 h urine fractionated metanephrines levels were in normal ranges, but in 1 mg dexametasone suppression test patients' serum cortisol level was 2.23 µg/dl. We decided to left laparoscopic adrenalectomy because of mass size and subclinical Cushing syndrome. In histopathological examination of *material* obtained by surgical *excision* reported 4.5 cm adrenocortical adenoma contained myelolipomatous metaplasia and 3 mm adrenal schwannoma. After surgery, we found a suppressed cortisol level (0.58 µg/dl) with 1 mg dexametasone suppression test.

Discussion

A schwannoma in the adrenal gland is very rare and typically originates from the adrenal medulla. The low incidence and asymptomatic nature of the disease with no hormonal production make a definitive diagnosis of schwannoma in the adrenal region difficult leading to misinterpretation of the mass as an adrenal adenoma or cancer.

Cardiovascular risk in patient with incidentally detected adrenal masses – associated with metabolic syndrome and hypercortcism

Stanislava Zivkovic[1], Svetlana Jelic[2] & Aleksandra Jevic Ivanovic[1]
[1]General Hospital Euromedik, Belgrade, Serbia; [2]University Medical Center Bezanijska kosa, Belgrade, Serbia.

Background
Adrenal incidentalomas (AI) represent incidentaly discovered adrenal mases, without simptoms or signs suggestive of adrenal pathology, at the time of visualization. It is well-known that overt or subclinical hypercorticism, as well as metabolic syndrome (MetS) harbour increased CV risk.There is still persisting debate on eventual cause-effect relationship of AI with metabolic syndrome MetS or probability of simply more frequent occurance of AI among these patients.
Objective
The aim of this investigation was to assess the 10-year CV risk in patients with AI, as well as the impact of the presence of MetS or hypercorticism on CV risk in thise patients.
Methods
Study included 64 patients with AI, 49 patients with MetS and without adrenal pathology and 23 patients with proven Cushing's syndrome. For the identification of MetS, the International Diabetes Federation (IDF) definition was used. The patients were diagnosed with subclinical hypercorticism (SC) based on the presence of laboratory abnormalities of the hypothalamic-pituitary-adrenal axis, without clinical signs of Cushing's syndrome and hypercortisolism. Ten-year CV risk was assessed for every subject using the Framinghamskog score system.
Results
Prevalence of MetS among patients with AI was high (76.6%) and did not differ significantly from its prevalence among patients with proven Cushing's syndrome (69.6%). Presence of MetS significantly affected estimated 10-year CV risk in patients with AI (MetS+: 24.39% vs MetS-: 14.58%, $P<0.05$), while such impact of SC was not observed (SC+: 23.63% vs 21.23%, ns) in these patients. Among parameters that were tested, the most important predictors of 10-year CV risk, among patients with AI, as well as in those with MetS and those with proven Cushing's syndrome, proved to be age, high density cholesterol and fasting plasma glucose.
Conclusions
High prevalence of MetS in patients with AI and its influence on amplification of CV risk, indicate the necessity of inclusion of screening on its components, beside usual screening of adrenal function, in regular follow-up of these patients. This approach could allow appropriate and more agresive treatment aiming at the prevention of adverse cardiovascular events.
Key words: adrenal incidentaloma, metabolic syndrome, subclinical hypercorticism, cardiovascular risk

Outcomes of patients undergoing surgery for primary aldosteronism based on adrenal venous sampling and/or radiological lateralisation indicate a role for both modalities in case selection

Lauramay Davis[1], Dylan Lewis[2], Jennifer Clough[1], Benjamin C Whitelaw[1], Jackie Gilbert[1], Salvador Diaz-Cano[3], David R Taylor[4], Royce P Vincent[4], Jonathan Hubbard[5], Gabriele Galata[5], Klaus-Martin Schulte[5] & Simon J B Aylwin[6]
[1]Department of Endocrinology, King's College Hospital, London, UK; [2]Department of Radiology, King's College Hospital, London, UK; [3]Department of Histopathology, King's College Hospital, London, UK; [4]Department of Clinical Biochemistry (Viapath), King's College Hospital, London, UK; [5]Department of Endocrine Surgery, King's College Hospital, London, UK; [6]Department of Endocrinology, King's College Hospital, London, UK.

Background
Adrenal venous sampling (AVS) is considered the gold standard for lateralisation of aldosterone production in patients with primary aldosteronism (PA). However, in some patients AVS is not technically successful and management may depend on radiological findings.
Aim
To determine 1) the success rate of AVS and 2) the outcomes after surgery related to the lateralisation modality.
Method
156 patients were included who presented 2007–2017 with a confirmed diagnosis of PA. Success of AVS was defined by the Endocrine Society 2016. Outcome criteria were 1) systolic blood pressure <140/90 mmHg 2) serum potassium <3.8 mmol/l 3) serum aldosterone <140 pmol/l 4) 0–1 anti-hypertensives post-op or two medications fewer than pre-op. The cohort was divided into approximate tertiles based on the year of referral: 2007–2013, 2014–15 and 2016–17
Results
Success rate of AVS increased from 30% (2007–13) to 77% (2016–17) ($P<0.001$). 26 (16%) were of young age, had a solitary lesion and were referred for surgery (group I). 94 underwent AVS, of whom 39 (41%) had a unilateral source (group IIA); 12 (13%) had bilateral secretion (group IIB) and 43 (45%) had non-diagnostic AVS (group IIC). 41 of the total were treated medically (group III). 148/156 underwent imaging: unilateral adenoma (95, 64%) dominant nodule (28, 18%) or no lesion (25, 16%). 69 patients proceeded to surgery: 23/26 (88%) from group I, 28/39 (71%) of patients from group IIA and 18/43 (43%) from group IIC. Post-operatively: 57% of patients had BP<140 (30% preop) $P=<0.01$; 71% serum potassium <3.8 (14% preop) $P=<0.01$; serum aldosterone fell from 1050 to 254 pmol/l ($P<0.01$), the number of anti-hypertensives decreased to from 2.6 to 0.9 post-operatively. Interestingly, there were no statistically significant differences between groups I, IIA and IIC in meeting successful outcome as defined by the ES Guidelines: these were met in 50% of those in group I, 41% of group IIA and 53% of those in IIC.
Conclusions
Increased experience and technical refinement led to an significant increase in success rates of AVS. Patients treated with surgery had good clinical outcomes. However, we found equivalent success rates between those patients with lateralisation from AVS or radiology. This suggests that in patients where AVS is inconclusive or non-diagnostic, a proportion of patients will still improve with surgery.

The response of C_{19}- Δ^5-steroids to ACTH stimulation

Hana Pospíšilová[1], Michaela Dušková[1], Lucie Kolátorová[1], Mikuláš Kosák[2], Martin Hill[1], Hana Jandíková[1], Kateřina Šimůnková[1], Monika Šrámková[1] & Luboslav Stárka[1]
[1]Institute of Endocrinology, Prague, Czech Republic. [2]Third Department of Medicine, General University Hospital and First Faculty of Medicine, Charles University, Prague, Czech Republic.

The adrenal androgens dehydroepiandrosterone, dehydroepiandrosterone sulfate, androstenedione, 5-androstenediol and 11β-hydroxy-androstenedione have a wide spectrum of important physiological effects. Aim of our study was to find differences in reaction of the C19 Δ5-steroids between healthy women and patients with adrenal insufficiency in various doses of Synacthen (1 ug, 10 ug and 250 ug). Our study involved seven healthy women and six premenopausal females (BMI and age matched) with primary adrenal insufficiency. C19 Δ5-steroids and their polar conjugates were measured in plasma using gas chromatography-mass spectrometry. Both free and conjugated steroids in patients did not show significant increase, in contrast to the levels in healthy controls (in all doses of Synacthen). Except for free DHEA and 7β-hydroxylated dehydroepinadrosterone derivatives, even the basal levels significantly differed between the patients with adrenal insufficiency and healthy controls. Changes of steroids conjugates during the ACTH test were insignificant in healthy controls. DHEA and its hydroxylated metabolites could be valuable markers of the integrity of the HPA axis. The art of stimulation of 7- and 16-hydroxylated metabolites of DHEA can help our understanding of the formation sequence of these compounds.

Non-classical form of congenital adrenal hyperplasia in patients with bilateral incidentalomas – hormonal and genetic analysis

Elwira Przybylik-Mazurek, Anna Kurzyńska, Anna Skalniak & Alicja Hubalewska-Dydejczyk
Jagiellonian University in Krakow, Medical College, Krakow, Poland.

Incidentalomas of adrenal glands are found in approximately 0.4–4.4% of abdominal CT-scan examinations and some of them can be caused by congenital adrenal hyperplasia (CAH). Bilateral masses can be detected in 10–15% of cases. CAH is one of the most common autosomal recessively inherited disorders. Non-classical form of congenital adrenal hyperplasia (NCCAH), is the milder form of the 21-hydroxylase deficiency, with the estimated incidence of 1:1000 worldwide.

Aim
The aim of the study was to estimate the prevalence of NCCAH in patients with incidentally discovered bilateral adrenal tumors. In patients with biochemical confirmation of NCCAH genetic analysis of *CYP21A2* gene was performed.
Material and methods
One hundred patients, 22 males aged 62.8 (±9.9 years) and 78 females aged 61.9 (±8.4 years) with bilateral adrenal incidentalomas, treated in Department of Endocrinology, University Hospital in Cracow, were involved in the study. The median diameter of an adrenal tumor was 27.8 mm (±10.35 mm). All the tumors were accessed in CT scans as benign ones. In all patients basal and ACTH-stimulated 17-hydroxyprogesterone (17-OHP) serum concentrations were measured. The biochemical diagnosis of NCCAH was established in patients with the basal and/or stimulated 17-OHP level ≥10 ng/ml.
Results
Twenty-seven patients (27%) – five males and 22 females were diagnosed with NCCAH. Genetic screening was performed in 66.7% of all, in three cases changes in *CYP21A2* gene were revealed.
Conclusions
1. NCCAH should be taken into consideration in patients with bilateral adrenal incidentalomas.
2. Hormonal test results still play a crucial role in the diagnosis of NCCAH.
3. Genetic analysis of *CYP21A2* mutations maybe also useful in NCCAH diagnosis.

Adrenal insufficiency in treated PMR: The tip of the iceberg

Rebecca Sagar & Afroze Abbas
Leeds Centre for Diabetes and Endocrinology, St James' University Hospital, Leeds Teaching Hospitals, Leeds, UK.

Background
Prolonged, high dose glucocorticoid therapy is used in to treat a number of rheumatological diseases, including polymyalgia rheumatica (PMR), giant-cell arteritis (GCA) and large vessel vasculitis (LVV). However there can be significant consequences of long-term glucocorticoid use, including iatrogenic adrenal insufficiency, due to suppression of the hypothalamic-pituitary-adrenal axis. This study aims to evaluate the prevalence, investigation and recovery of iatrogenic adrenal insufficiency in patients with PMR, GCA and LVV at a large UK teaching hospital.
Methods
We retrospectively identified patients seen in rheumatology outpatient clinics with a diagnosis of PMR, GCA or LVV, who had cortisol levels or short synacthen tests (SST) performed, between January 2014 and November 2017. Data were collected using a standardised proforma which included demographics, co-morbidities, maximal glucocorticoid dose and duration, clinical symptoms and details of investigations for adrenal insufficiency (i.e. SST results or cortisol values).
Results
We evaluated a total of 95 patients. The mean duration of prednisolone use was 4 years, 3 months (range 11–204 months). Over 30% of patients used a peak dose of prednisolone greater than or equal to 40 mg. 72% of all patients had symptoms possibly consistent with adrenal insufficiency. In total, eighty patients had a SST, mostly via the rheumatology department. On retrospective review of the SST results by a consultant endocrinologist, 33% of all tests were found to have sub-optimal cortisol levels. However 17.5% of baseline SSTs were not conducted appropriately. Of the patients who were found to have abnormal results, only 35% went on to have a repeat SST. 54% of the repeat SSTs showed normal adrenal function. Of the asymptomatic patients, 51.9% ($n=14$) had baseline tests consistent with adrenal insufficiency. The mean time to adrenal recovery overall, from baseline test was 18 months. 18% of patients with evidence of adrenal insufficiency had their prednisolone switched to a shorter acting glucocorticoid. Despite having an abnormal SST result, 43% patients were not referred to an endocrinologist.
Conclusion
Our study suggests there is a high prevalence of adrenal insufficiency in both symptomatic and asymptomatic groups in this patient population. The vast majority of patients with abnormal SST results did not have suitable follow-up tests and a large proportion were not referred to endocrinology. These results suggest the need for a joint pathway of care for evaluation of adrenal insufficiency in this patient group. Further studies, evaluating the optimal intervention strategies to aid adrenal recovery are also needed.

Decreased quality of life in male patients with primary adrenal insufficiency of Indian origin

Eesh Bhatia & Mahaveer Singh
Sanjay Gandhi Postgraduate Institute of Medical Sciences, Lucknow, India.

Background
In contrast to patients of European origin, primary adrenal insufficiency (PAI) in Indians is more common in males and often results from infectious etiologies (tuberculosis, Histoplasmosis). Most patients are treated with prednisolone, rather than hydrocortisone (HCT). A poor quality of life (QOL) has been reported in European patients with AD, but not in other populations. A few studies have also reported a high frequency of hypogonadism in PAI.
Objectives
To study the QOL and frequency of hypogonadism in Indian male patients with PAI.
Methods
In a cross sectional study, we recruited 37 male patients with PAI (age median (range) 53 (26–64) years; duration of illness 5.8 (1.4–28) years; 95% on prednisolone; 57% with infectious etiology). All patients were administered the short form SF36v2 questionnaire, previously validated in Hindi, to assess their QOL. A questionnaire regarding more specific symptoms of hypogonadism was also administered. An early morning serum total testosterone (T) was collected; in patients with low T (<10.4 nmol/l), the test was was repeated. Age, sex and, body mass index matched healthy controls ($n=76$) were studied.
Results
When compared with controls, patients had a highly significant reduction in QOL in each individual domain of SF36v2 ($P<0.001$), and in the summary physical ($P<0.001$) and mental component ($P<0.04$) domains. Twenty five (65%) patients had at least 1 symptom, while 17 (46%) had ≥3 symptoms suggestive of hypogonadism. However, only 5 (13.5%) patients had T<10.4 nmol/l. On multivariate analysis, the average daily glucocorticoid dose (hydrocortisone equivalent/m^2) was strongly associated with decreased QOL across most domains, while T2DM and increasing age were associated with poor QOL in a few domains. However, serum testosterone did not predict QOL.
Conclusion
A poor QOL was noted in all domains in male patients with primary adrenal insufficiency. A higher daily glucocorticoid dose was independently associated with poor QOL in most domains. While symptoms of hypogonadism were frequent, the frequency of decreased serum testosterone was low.

The measurement of the renin–angiotensin–aldosterone system in patients with adrenal tumors with arterial hypertension

Natalia Romanova, Nadezhda Platonova, Natalia Molashenko, Larisa Nikankina & Ekaterina Troshina
Edocrinology Research Centre, Moscow, Russian Federation.

Introduction
This problem has a major social and medical significance. The prevalence of secondary endocrine hypertension is around 40%, of which primary aldosteronism is up to 15% and is usually developed at working age. Despite of improvement of diagnostical two-step method of finding primary aldosteronism, none of these test results can be considered reliable because of false positive and false negative results. That's why the problem of endocrine hypertension diagnosis especially primary aldosteronism is still very important. We made a research of the renin–angiotensin–aldosterone system (RAAS) and urinary aldosterone excretion in patients with arterial hypertension and adrenal tumors to improve diagnosis of primary aldosteronism.
Objective
To explore the renin–angiotensin–aldosterone system (RAAS) and 24-h urinary aldosterone excretion in patients with adrenal tumors and arterial hypertension.
Methods
We enrolled 59 patients with adrenal tumors in combination with arterial hypertension [blood pressure ≥ 140/90 mm Hg by antihypertensive drug classes, 85% females, age 52±12.5 years (mean±standard deviation)], who had hormone-producing adenomas (aldosterone-producing adenoma $n=27$, cortisol-producing adrenal adenoma $n=8$ and pheochromocytoma $n=5$) and non-functioning adrenal adenomas in combination with arterial hypertension ($n=19$). The RAAS (angiotensin II, angiotensinogen, prorenin) of plasma and serum is measured in peripheral blood by Enzyme Immunoassay**,** and aldosterone is determined in 24-hour urine by Enzyme Immunoassay.

Results
Patients with aldosterone-producing adenoma ($n=27$) in compared with non-functioning adrenal adenomas in combination with arterial hypertension ($n=19$) didn't have different results of RAAS: angiotensin II ($P=1.0$, median 29.6 pg/ml, interquartile range 23.4–35.6), angiotensinogen ($P=1.0$, median 15.4 µg/ml, interquartile range 13.5–18.8) and prorenin ($P=0.351$, median 688.5 pg/ml, interquartile range 418–1133.5). Though 24-h urinary aldosterone level in patients with aldosterone-producing adenoma ($n=27$) were statistically significantly higher than in patients with non-functioning adrenal adenomas with arterial hypertension ($n=19$) ($P=0.042$, median 17.1 µg/day, interquartile range 9.6–31.1).
Conclusion
24-h urinary aldosterone level may be diagnostically helpful in discriminating to clarify the diagnosis of primary aldosteronism, which, along with the definition of aldosterone-renin ratio (ARR) and confirmatory tests, can be a diagnostic criterion for diagnosing.

The renin-angiotensin-aldosteron system in primary adrenal insufficiency

Peter Wolf[1], Johanna Mayr[1], Marko Poglitsch[2], Alois Gessl[1], Anton Luger[1], Yvonne Winhofer[1] & Michael Krebs[1]
[1]Medical University of Vienna, Vienna, Austria; [2]Attoquant Diagnostics, Vienna, Austria.

Background
Despite adequate hormone replacement therapy, evidence suggests that mortality is increased in patients suffering from primary adrenal insufficiency (AI), mainly because of cardiovascular diseases. Since activation of the renin-angiotensin-aldosteron system (RAAS) plays an important role in the development of hypertension and cardiovascular disease we aimed to investigate, if there are differences in AI compared to healthy controls.
Methods
Eight patients with AI (female $n=5$; male $n=3$; age 56 ± 21; BMI $22{,}8\pm2{,}8$ kg/m^2; mean blood pressure 140/83 mmHg)) and eight matched healthy volunteers (female $n=5$; male $n=3$; age 52 ± 21; BMI $25{,}2\pm4{,}3$ kg/m^2; mean blood pressure 135/84 mmHg) were included. Blood was drawn in the morning in the fasting state to measure serum electrolytes, renin-, aldosterone, cortisol and ACTH concentrations. Assessment of physiologically active angiotensin concentrations and equilibrium analysis was performed by RAS fingerprint measurements.
Results
In patients suffering from AI RAAS activity was increased with significantly elevated concentrations of renin ($P=0.027$), angiotensin-1 ($P=0.022$), angiotensin-2 ($P=0.032$), angiotensin-1-7 ($P=0.03$) and angiotensin-1-5 ($P=0.03$), as well as in a reduction in aldosteron-angiotensin-2 ratio (AA2-Ratio, $P=0.003$) compared to controls, resulting in a characteristic RAAS fingerprint. Plasma renin activity was strongly correlated with the sum of angiotensin-1+ angiotensin-2 ($r=0.983$; $P<0.01$).
Conclusions
AI is associated with a unique RAAS fingerprint. Physiologically active angiotensin concentrations are highly elevated, despite adequate hormone replacement therapy. This might contribute to the reported increased cardiovascular risk and should be investigated in future trials.

Percutaneous microwave ablation of adrenal remnant tissue. A novel treatment modality for persistent Cushing's disease

Rozana Ramli, Raya Almazrouei, Saira Hameed, Florian Wernig, Amir Sam, Edward Leen, Fausto Palazzo, Nigel Mendoza, Emma Hatfield, Niamh Martin & Karim Meeran
Imperial College Healthcare NHS Trust, London, UK.

A 29-year-old lady presented with features of Cushing's syndrome in October 2014. Investigations confirmed ACTH–dependent Cushing's syndrome. An MRI scan showed a 4.5 mm right-sided pituitary lesion and subsequent inferior petrosal sinus sampling confirmed a central source of ACTH hypersecretion. She underwent trans-sphenoidal pituitary surgery in January 2015. Histology confirmed a corticotroph adenoma with a Ki-67 proliferation index of 1%. However, a mean cortisol of 298 nmol/l on a cortisol day curve was highly suggestive of persistent hypercortisolaemia. MRI scanning confirmed small-volume residual tumour in the right anterior sella. She remained symptomatic and underwent a second trans-sphenoidal pituitary surgery in April 2015. Histology from this surgery showed normal adenohypophysis only. The second surgery was complicated with a post-operative CSF leak and meningitis. A cortisol day curve 6 weeks later showed a mean cortisol level of 474 nmol/l and further biochemistry investigations confirmed persistent hypercortisolaemia. Following MDT discussions, the patient underwent bilateral adrenalectomy in March 2016, with some difficulty encountered during removal of the left adrenal gland. As expected, histology of both adrenals showed evidence of adrenal hyperplasia. She was commenced on Prednisolone and Fludrocortisone postoperatively. She continued to have difficulty losing weight 5 months post-adrenalectomy (went up to 119 kg). An overnight dexamethasone suppression test confirmed persistent Cushing's disease (9 am cortisol 383 nmol/l). Prednisolone was discontinued and she was commenced on Metyrapone. MRI Pituitary showed a right-sided pituitary adenoma extending between the intra- and supracavernous internal carotid artery segments. A Ga68 DOTATATE whole body PET CT showed appearance consistent with residual hyperplastic adrenal tissue in the left suprarenal region. She was discussed in the Pituitary and Adrenal MDT meetings where percutaneous ablative approach of the residual adrenal tissue was considered due to the risks associated with further pituitary surgery or pituitary radiotherapy, or repeat abdominal surgery. She underwent CT-guided microwave ablation of the left adrenal remnant (120W) in July 2017, following which she was re-started on Prednisolone. Following the procedure, she improved significantly both clinically and biochemically. Her weight went down to 109 Kg after 6 months. Morning cortisol went down from 476 to 168 nmole/l. This was accompanied by ACTH rise from baseline 492 to 1558 ng/l. This case illustrates that percutaneous ablative approach of adrenal remnant tissue and possibly entire adrenal glands should be considered in the treatment of challenging Cushing's disease.

Risk estimator for autonomous cortisol secretion in adrenal incidentalomas. Retrospective study of 100 cases

Marta Araujo Castro[1,2], Miguel Sampedro Núñez[1], Elena Fernández González[1], Nerea Aguire Moreno[1] & Mónica Marazuela Azpiroz[1]
[1]Servicio de Endocrinología y Nutrición. Hospital Universitario de la Princesa., Madrid, Spain; [2]Servicio de Endocrinología y Nutrición. Hospital Rey Juan Carlos, Madr, Spain.

Purpose
A combined model of clinical, biochemical and radiological variables could help to predict autonomous cortisol secretion (ACS) in adrenal incidentalomas (AI).
Methods
We analyzed retrospectively 100 patients diagnosed of AI between 2011 and 2015. AI was defined as an adrenal mass >1 cm, accidentally discovered by radiologic examination. ACS was ruled out (ACS-) by serum cortisol post-dexamethasone suppression test (Nugent) <3 µg/dl, and was confirmed by levels ≥ 3 µg/dl, normal cortisoluria and no typical data of Cushing's syndrome. The statistical analysis was performed with STATA 13.0. For multivariate analysis variables were selected by a pvalue <0.1 on univariate analysis and previous literature findings.
Results
Ninety-three patients were included in the statistical analysis. Mean age was 62.9 years and 54% were women. Fourteen patients (15%) had ACS. In the univariate analysis, the variables associated with higher risk of ACS (expressed in odds ratio (OR) and/or the proportion/mean of the variable in ACS and ACS-) were: Nugent test (3.6 vs 1.5 µg/dl, $P<0.00$) and maximum adenoma diameter (MAD) (26.8 vs 17.2 mm, $P=0.02$). Higher risk of ACS was not related with age (64 vs 63 years, $P=0.57$), sex (ratio of masculinity 1.4 vs 0.8, $P=0.4$), HTA (OR 1.7, 71.4 vs 44.9%, $P=0.08$), diabetes (OR = 1.4, 36 vs 25.6%, $P=0.4$), obesity (OR = 0.6, 25 vs 37.6%, $P=0.4$), osteoporosis (OR = 1.3, 9.1 vs 7.2%, $P=0.8$), glucose (108.3 vs 105.5 mg/dl, $P=0.7$), cortisoluria (70 vs 59.7 µg/24 h, $P=0.5$), DHEAS (70.2 vs 46.2 µg/dl, $P=0.1$); ACTH (20.1 vs 18.2 pg/ml, $P=0.7$) or bilaterality (OR = 1.4, 20 vs 15%, $P=0.7$). No differences were found between ACS and radiological characteristics in the CT scan (calcification, necrosis, lipid content). In the logistic regression analysis, the variables male sex, age, HTA, diabetes, Nugent, DHEAS, MAD and bilaterality were included to elaborate the ACS predictor score. It was found that the model with the best predictive power for the ACS diagnosis included age, Nugent test and DHEAS levels, with sensitivity of 89% and specificity of 100%.

Conclusions
15% of AI in our series had ACS. We identified Nugent test and MAD as predictors of ACS. The combined model with the best ACS diagnostic accuracy combined age, Nugent test and DHEAS levels, with a specificity of 100%. This combined score could be a very useful tool to identify ACS with a higher diagnostic value than the Nugent test alone regardless of the cutoff point used. Its high specificity makes it especially indicated in the screening of AI.

DOI: 10.1530/endoabs.56.P49

Is the adrenal vein sampling the gold standard diagnostic test for the subtyping of primary aldosteronism?

Ana Jiménez Portilla[1], Elena Mena Ribas[1], Antonia Barceló Bennasar[2], Juan Manuel Martínez Ruitort[3], Cristina Álvarez Segurola[4], Mercedes Noval Font[1], Carlos Antich Barceló[1], Guillermo Serra Soler[1], Iñaki Argüelles Jiménez[1], Santiago Tofé Povedano[1] & Vicente Pereg Macazaga[1]
[1]Endocrinology Department. Universitary Hospital Son Espases, Palma de Mallorca, Spain; [2]Clinical Analysis Department, Palma de Mallorca, Spain; [3]Radiology Department, Palma de Mallorca, Spain; [4]General Surgery Department, Palma de Mallorca, Spain.

Introduction
Primary aldosteronism (PA) is the most common cause of secondary hypertension (5–10%) and it is underdiagnosed. Less than 50% of patients with PA have hypokalemia. The tests for determinate subtype of PA are cross-sectional imaging (adrenal CT or MRI) and adrenal vein sampling (AVS). The AVS seems to be important to direct appropriate therapy and surgery is the preferred treatment for patients with unilateral disease.
Material and methods
We reviewed 29 patients with PA confirmed by saline infusión test (SIT) who underwent AVS. We described the baseline characteristics and the results of the AVS. We analyzed the concordance between imaging and AVS.
Results
Our study included 24 men (82.8%) and five women (17.2%) with a median age of 59.5 years (39–76). The median age of diagnosis of hypertension was 43 years (25–57) and the time passed until the diagnosis of PA was 13 years (1–26). The median body max index was 30.81 (21.44–47.80). Twenty-three patients had family history of hypertension (79.3%). The median value of blood pressure was: systolic 150 mmHg (130–192) and diastolic 90 mmHg (74–111). Twenty-three patients were treated with 3 or more antihypertensive drugs (79.3%). Twenty-six patients had hypokalemia (89.7%), with a median potassium of 2.9 mEq/L (2.4–3.9) and a median MDRD of 88.3 (47.1–106.2). 40% of patients had hypertensive retinopathy (8 of 20 patients examined) and 70.4% had left ventricular hypertrophy (19 of 27 patients examined). Cross-sectional imaging was normal in 10 patients (34.5%) and abnormal in 19 (65.5%): unilateral mass in 16 and bilateral masses in 3. AVS was lateralizing in 19 patients (65.5%), non-lateralizing in 5 (17.2%), indeterminate in 2 (6.9%) and technical AVS failure in 3 (10.3%). Imaging and AVS were concordant in 61.5% of patients. All patients who underwent surgery (adrenalectomy) normalized potassium (n = 15). After follow up, 20% of patients were completely cured (normotensive without antihypertensive drugs) and 80% demonstrated improvement (better blood pressure control or decrease in number of antihypertensive drugs).
Conclusions
The high percentage of hypokalemia suggests that PA is underdiagnosed in our area. The clinical suspicion is important because these patients have a much higher cardiovascular risk profile than patients with essential hypertension, and it is demonstrated by the high prevalence of left ventricular hypertrophy. Due to the poor performance of cross-sectional imaging, it is indicated to perform AVS as a better test for determination of PA subtype and decide the appropriate treatment.

A descriptive study of patients with adrenocortical carcinoma treated in hospital clinico san carlos (HCSC) over the last 20 years

Elvira Barrio, Elvira Ramos, Paz de Miguel, J. Angel Diaz, Concepcion Sanabria, Martin Cuesta, Ines Jimenez, Patricia Espinosa, Antonio Garcia & Angel Molino
Hospital Clínico San Carlos, Madrid, Spain.

Introduction
Adrenocortical carcinoma (ACC) is a rare and aggressive tumor that accounts for 0.2% of cancer-related deaths. Case series and prospective studies are very limited due to its low prevalence. Current knowledge is based primarily on the opinions of experts in specialized units. The aim of this study is to perform a descriptive analysis of the management and prognosis of patients with ACC in HCSC in the last 20 years.
Material and methods
Eighteen cases of ACC between 1997 and 2017 in HCSC were retrospectively reviewed. All data were analyzed including demographic, epidemiological and clinical information using SPSS 15.0. The study obtained the approval of the local Ethics Committee.
Results
11/18 (61%) were male and the mean age was 54.8 (s.d. 15.3). Diagnosis was incidental in 5/18 (27.8%). The most common presentation (6/18, 34.6%) was constitutional symptoms. 39% of the tumors (7/18) were functioning; 2 patients presented Cushing's syndrome, 2 hyperandrogenism, 2 presented with both and 1 with hyperaldosteronism. In 2/18 (11%) serum hormone levels were not performed. 4/18 (22%) were never evaluated by an endocrinologist. All patients had CT performed, 5/18 (28%) had MRI, 4/18 (22%) had PET and MIBG-scintigraphy, and 7/18 (39%) had FNA. The mean size was 118.4 (s.d. 69.9) mm. 13/18 (72%) were located on the left side. Upon diagnosis, 9/18 (50%) and 5/7 (71.4%) of the functioning were in stage IV. 16/18 (89%) had surgery (open in 14/18, 87%). 12/18 (67%) received mitotane (between 1 and 57 months), whose plasma levels were monitored only in half of them. It was discontinued in 3/12 (25%) due to adverse effects. 7/18 (39%) received different lines of chemotherapy, 7/18 (39%) targeted therapies, 3/18 (16.6%) radiotherapy and 1/18 (5.5%) chemoembolization. 5/18 (28%) received only palliative care. 14/18 (78%) are deceased. Median survival time was 41 months (min 2 – max 92) with no significant differences according to stage (except stage I), functionality or use of mitotane therapy.
Conclusions
In our centre, ACC was an uncommon tumor with poor prognosis regardless of sex, stage (except in stage I), treatment applied or tumor functionality. It was usually diagnosed in middle-aged patients and in advanced stages. The most common treatments used were surgery and mitotane. We also noticed that there is a considerable lack of standardization in the treatment strategy of this tumor for advanced cases in our centre. Patients with ACC should be treated in highly specialized units by a multidisciplinary team.

Bilateral adrenalectomy for occult ectopic Cushing's syndrome in two patients with catastrophic hypercortisolism

Oya Topaloglu[1], Nagihan Bestepe[1], Bulent Yalcin[2], Mehmet Kilic[3], Melike Rusen Metin[4], Gulin Ucmak[5], Reyhan Ersoy[1] & Bekir Cakir[1]
[1]Department of Endocrinology and Metabolism, Yildirim Beyazit University School of Medicine, Ankara, Turkey; [2]Department of Medical Oncology, Yildirim Beyazit University School of Medicine, Ankara, Turkey; [3]Department of General Surgery, Yildirim Beyazit University School of Medicine, Ankara, Turkey; [4]Department of Radiology, Ataturk Education and Research Hospital, Ankara, Turkey; [5]Department of Nuclear Medicine, Oncology Research and Training Hospital, Ankara, Turkey.

Introduction
Ectopic adrenocorticotropic hormone (ACTH) secretion is a less common cause of Cushing syndrome(CS) and is seen in 5 to 10% of patients with endogenous hypercortisolism. The most common types are bronchial carcinoids and small cell lung carcinoma. However, in approximately 10–20% of the cases, overt tumor cannot be found. Here, we described two patients with catastrophic hypercorticolism associated with ectopic CS and who were treated with bilateral adrenalectomy.
Case 1
A 47-year-old female patient had a history of a total abdominal hysterectomy and bilateral salpingo-oopherectomy operation due to clear cell ovary carcinoma 7 months ago. She was treated with chemotherapy. After 3rd dose chemotherapy, she had been hospitalized and treated due to sepsis associated with urinary tract infection. During the follow-up period in oncology, hypokalemia was detected and she was referred to our department due to severe muscle weakness in lower extremities and hypokalemia (serum K: 2.2 mEq/l). 24-h urinary free cortisol, ACTH measurement, dexamethasone suppression test (DST) demonstrated an ACTH dependent hypercortisolism. The inferior petrosal sinus sampling was indicative for an ectopic ACTH secretion. CT-scans of the thorax and abdomen, FDG-PET/CT scan and Ga68 DOTATATE PET/CT scans, were unable to demonstrate malignancy. Previous ovarian pathology was screened for ACTH secretion and evaluated as negative. Antifungal and metyrapone were started and then bilateral adrenalectomy was performed.

Case 2
A 71-year-old male patient who had a medical history of metastatic prostate carcinoma was referred to our department due to severe hypopotasemia, muscle weakness, refractory hypertension, peripheral edema. He had a history of second operation 3 months ago due to tumoral enlargement at the base of the urinary bladder and it was evaluated as infiltration of the prostate carcinoma. 24-h urinary free cortisol, ACTH measurement, DST demonstrated an ACTH dependent hypercortisolism. CT-scans of the thorax and abdomen, FDG-PET/CT scan and Ga68 DOTATATE PET/CT scans, were negative for malignancy. Medical therapy was started. But refractory hypertension, parenteral potasium infusion need were not suspended. Bilateral adrenalectomy was perfomed. He died due to pulmonary embolism 2 months after adrenalectomy.
Conclusion
Common treatmant options of Cushing syndrome consist of tumor management, somatostatin analogs, steroidogenesis inhibitors. Bilateral adrenalectomy is a highly effective treatment for patients with severe hypercortisolism if rapid control of hypercortisolism is desired. Mortality is high especially in patients with severe co-morbidities and mostly it depends on the prognosis of the underlying malignant tumor.

In vitro effects of KCNJ5 mutations on cellular death mechanisms

Elke Tatjana Aristizabal Prada[1], Celso E Gomez-Sanchez[2], Martin Reincke[1] & Tracy A Williams[1,3]
[1]Medizinische Klinik und Poliklinik IV, Klinikum der Universität, Ludwig-Maximilians-Universität München, Munich, Germany; [2]University of Mississippi Medical Center, Jackson, MI, USA; [3]Division of Internal Medicine and Hypertension, Department of Medical Sciences, University of Torino, Torino, Italy.

Introduction
Primary aldosteronism (PA) is the most frequent form of endocrine hypertension and is commonly caused by an aldosterone producing adenoma (APA). Germline and somatic mutations in the *KCNJ5* gene have been found in up to 40% of APAs and demonstrated to play a crucial role in the pathophysiology of PA.
Aim
Here we characterize and investigate the effects of the most common *KCNJ5* mutations on cellular death mechanisms based on an *in vitro* model.
Methods
Cell lines in COS7 or HAC15 cells stably expressing KCNJ5 mutants (G151R, L168R, G151E, T158A) and a control cell line transfected with empty vector were established using a cumate-inducible PiggyBac vector system. Cell viability and cell death (necrosis and apoptosis) were determined by WST-1 assays or flow cytometry following induction with cumate.
Results
In COS7 cells, the KCNJ5 -G151E and -L161R mutants caused the highest proportion of cell death followed by -G151R and -T158A following cumate induction (0 μg/ml to100 μg/ml). Expression of KCNJ5-T158A in COS7 or HAC15 cells resulted in a similar loss of cell viability. All KCNJ5 mutants tested showed an increase in cell death by apoptosis or necrosis with necrosis causing a greater proportion of cell death than apoptosis, when induced with cumate (5 μg/ml and 25 μg/ml). The KCNJ5 mutations that induced the highest level of necrosis were G151E and L168R followed by G151R and T158A.
Conclusion
KCNJ5 mutations cause cell death mostly through necrosis, albeit to a different extent.

The role of DHEAS in the diagnosis of possible autonomous cortisol secretion by incidentally discovered adrenal adenomas

Marianna Minnetti, Emilia Sbardella, Maria Rosaria DI Giorgio, Laura Rizza, Elisa Giannetta, Riccardo Pofi, Chiara Graziadio, Carla Di Dato, Andrea Lenzi & Andrea M Isidori
Department of Experimental Medicine, Sapienza University of Rome, Rome, Italy.

Introduction
Although possible autonomous cortisol secretion (pACS) is the commonest endocrine dysfunction detected in patients with adrenal incidentalomas, the diagnosis of this condition is still challenging. Dehydroepiandrosterone sulfate (DHEAS) is an adrenal androgen secreted by adrenal glands under the regulation of ACTH. DHEAS does not follow a circadian rhythm and has a long half-life in serum. Because of these features, low blood concentration of DHEAS has been recently investigated as a screening marker of pACS. Nevertheless, data regarding the diagnostic accuracy of DHEAS to predict pACS are sparse and contradictory.
Methods
74 patients with adrenal incidentalomas were evaluated in the context of ERGO trial (NCT02611258). Clinical, hormonal and radiological assessment were performed to exclude Cushing's syndrome, pheochromocytoma, Conn syndrome, adrenocortical carcinoma, late-onset congenital adrenal hyperplasia, myelolipoma and metastasis. Cortisol levels after a 1-mg overnight dexamethasone suppression test between 51 and 138 nmol/l, confirmed by 48-h Liddle tests, were used to classify patients as pACS. DHEAS ratios were calculated by dividing the DHEAS by the lower limit of the respective reference range according to age and gender.
Results
36 patients were diagnosed with adrenal adenoma associated with pACS (pACS group) and 38 with non-functioning adrenal adenoma (NF control group). There were no difference in age (pACS: 65.8 ± 11.3 years; NF: 64.03 ± 11.0 years; $P = 0.560$), body mass index (pACS: 27.71 ± 5.5 kg/m^2; NF: 27.8 ± 4.2 kg/m^2; $P = 0.942$), and sex (pACS: female 23/31; NF: female 17/33; $P = 0.110$) between the two groups. Mean DHEAS ratio was significantly lower in the pACS compared to the NF group (pACS: 1.24 ± 1.55; NF: 2.68 ± 0.86; $P < 0.001$). Furthermore, there was a negative correlation between the post-dexamethasone cortisol levels and DHEAS ratio ($r = -0.382$; $P = 0.002$). ROC analyses [AUC 0.837 (0.737–0.936); $P < 0.0001$], showed that a DHEAS ratio of 1.56 suggested a sensitivity of 81% and specificity of 71% for the diagnosis of pACS with a positive predictive value of 73.5%, a negative predictive value of 78.6% and reaching an accuracy of 75.8% in predicting pACS.
Conclusion
Our study shows that DHEAS ratio may contribute to the diagnostic work-up in patients with adrenal incidentalomas. A single basal measurement of age and gender-adjusted DHEAS ratio could be included as an advantageous screening test for the detection of possible autonomous cortisol secretion. Further studies are needed to confirm the role of DHEAS screening in the diagnostic evaluation of pACS.

Abnormal salivary cortisol result in patient with low probability of Cushing disease

Ali Ahmed, Najeeb Shah & Kamrudeen Mohammed
Hull Royal Infirmary, Hull, UK.

We presenting a case of 26 old lady who is known to have Denys-Drash syndrome, epilepsy and bronchial asthma who presented with history of recent significant weight gain, extensive abdominal bruising and significant muscle weakness which she described literally as not able to use her upper limbs to move to help shuffle her bottom in the floor, a manoeuvre that she was able to do before. Patient is on Carbamazepine, sodium valporate, levetiracetam , salbutamol and Pulmicort inhalers (budesonide), Laxido,And Midazolam. On examination patient was normotensive, a degree of the abdominal striate, proximal muscle weakness could not be elicited clinically. The general practitioner enquired whither the patient presentation could be a manifestation of Cushing syndrome,in this pateint the modality of investigation need to be selected carefully, patient is already on Carbamazepine which could affect both UFC and plasma cortisol as it is interferes of the chromatographic methods and can also induce hepatic clearenece of Dexamethasone, so salivary cortisol was chosen for this test, but the result showed significant high cortisol level in many different occasions (see table below), after further questioning it appears that the patient was using the Pulmicort inhaler before having the test,this lead to the significant high cortisol found.
Discussion
Salivary cortisol measurement is well established method to measure plasma free cortisol concentration, aiding the diagnosis of cortisol excess and deficiency state,it had the advantage of being free from the interference of physiological or pathological effect of CBG /albumin, ease of sampling, and lack of the stress of venepuncture. The required standered is to obtain the salivary sample using collection of passive drooling saliva or asking patient to chew a cotton pledget – (Salivette®). Salivary samples should not be collected within 30 min of brushing teeth, drinking. No ingestion of any foods of animal origin within 3 h prior collection. Any sample with blood contamination should be discarded, smoking affect salivary 11beta-hydroxysteroid dehydrogenase type 2, this increases

salivary cortisol so it should be avoided on the day of the test. The potential steroid contamination of the sample including topical or inhaled steroid is something we need to be careful with when interpreting the salivary cortisol result this was clearly missed in this case.

Improved salivary cortisol rhythm with dual-release hydrocortisone

Filippo Ceccato[1], Elisa Selmin[1], Chiara Sabbadin[1], Miriam Dalla Costa[1], Giorgia Antonelli[2], Mario Plebani[2], Mattia Barbot[1], Corrado Betterle[1], Marco Boscaro[1] & Carla Scaroni[1]
[1]Endocrinology Unit, Department of Medicine – DIMED, University Hospital of Padova, Padova, Italy; [2]Laboratory Medicine, Department of Medicine – DIMED, University Hospital of Padova, Padova, Italy.

Introduction and aim
The purpose of replacement therapy in Adrenal Insufficiency (AI) is mimicking endogenous cortisol levels as closely as possible: dual release hydrocortisone (DR-HC) has been introduced to replicate the circadian cortisol rhythm. Multiple daily saliva collections could be used to assess the cortisol concentration during real-life: our aim was to study the salivary cortisol rhythm in AI.
Materials and methods
We prospectively evaluated, in an observational study, 18 outpatients with AI (11 primary and 7 secondary AI), switched from conventional treatment (conv-HC, 25 mg/day) to the same dose of DR-HC. We collected 6 samples of saliva in a day, measuring cortisol (F) and cortisone (E) with LC-MS/MS. 43 matched healthy subjects served as controls. To assess endogenous daily F exposure we computed the Area Under the Curve (AUC) for salivary F levels at the different time-points respect to the ground (SalAUC) according to the trapezoidal formula. We divided the day in two different parts, the first covering the morning ($SalAUC^{morning}$), and the second covering the afternoon and the evening ($SalAUC^{afternoon}$).
Results
F levels of patients during conv-HC and after switch to DR-HC were similar in the morning, and lower in the afternoon/evening with DR-HC. Considering daily cortisol exposure, SalAUC was lower with DR-HC despite assuming the same GC dose. Specifically, morning $SalAUC^{morning}$ levels were similar among conv-HC and DR-HC, contrariwise $SalAUC^{afternoon}$ was lower with DR-HC. Morning F was lower in patients than controls: a value <3 nmol/l presented 90% SE and 98% SP in detecting patients (AUC 0.979). Also morning E levels were able to differentiate AI from controls: E <9.45 nmol/l presented 95% SE and 94% SP to detect patients with AI (AUC 0.982). Cortisol rhythm in patients with DR-HC was closer to controls, especially in the afternoon/evening: normalization of evening cortisol exposure ($SalAUC^{afternoon}$) was observed only in patients with DR-HC. F to E ratio levels were similar between patients with conv-HC and DR-HC, and allowed us to exclude glucocorticoid contamination. A reduction of total cholesterol levels was observed with DR-HC; HbA1c levels dropped with DR-HC in diabetic patients (57 to 52 mmol/mol, $P=0.045$).
Conclusions
Salivary cortisol is a reliable tool to assess the improvement of cortisol profile in patients treated with DR-HC, and might provide new insights in the study of patients with AI.

A case of adrenal Cushing's syndrome initially presenting with diabetic ketoacidosis

Edson Nogueira, Koteshwara Muralidhara, Mushtaqur Rahman, Daniel Darko & Shivshankar Seechurn
Department of Endocrinology & Diabetes, Northwick Park Hospital, London, UK.

A 49-year-old female was admitted to medical HDU with diabetes ketoacidosis (DKA) and newly diagnosed diabetes. Six months previously she was diagnosed with malignant hypertension. She had poorly controlled blood pressure despite treatment with four anti-hypertensives, which were her only regular medication. She had never used any medications or creams containing glucocorticoids. She had no history of hypokalaemia and reported no use of liquorice. She recently attended an outpatient appointment with a cardiologist and investigations including MRA of renal arteries and echocardiogram were all reported as normal. She complained of a 6-month history of lethargy, severe weight gain, and a two-month history of easy bruising, lower-limb weakness, and increasing polyuria and polydipsia. There was no history of headache, palpitations, flushing, or diaphoresis. On examination, she had a BMI of 41 kg/m^2, she had multiple bruises, off-color abdominal striaes, and proximal myopathy evident on lower limbs. She had no signs of androgen excess. Upon transfer to a general medical ward she was under the care of the endocrinology team. IFCC-HbA1C checked on admission was 102 mmol/mol, showing a large increment when compared to 30 mmol/mol measured 6 months previously. Anti-glutamic acid decarboxylase and anti-islet cell antibodies were both negative. Cortisol level post overnight-dexamethasone suppression was high at 163 nmol/l (RR <50 nmol/l). Total urine cortisol was 472 nmol in 24hours, confirming hypercortisolaemia. Tests were done when renal function was normal. Adrenal CT revealed a 2.6 cm right-adrenal adenoma (absolute washout=69%). 24-h urine metanephrines (×2) and aldosterone-renin-ratio were all within normal range. ACTH level was 15.9 ng/l (RR: 0–46). Adrenal androgen measurements are still being processed. In view of her inconclusive ACTH results, an MRI of the pituitary has also been requested and it is still pending. She was discharged on basal-bolus insulin and regular anti-hypertensives with a plan for urgent follow up in endocrinology clinic and discussion of results on adrenal MDT. This is a case of rapidly developing Cushing's syndrome leading to life-threatening presentation with malignant hypertension and DKA. Glucose intolerance associated with Cushing's syndrome is usually only mild to moderate in severity. Marked hyperglycaemia, glycosuria, and polyuria are uncommon, and ketosis is rare. Appropriate management could potentially lead to total remission of diabetes and hypertension.

P58

The diagnostic accuracy of increased late night salivary cortisol for Cushing's Syndrome: a real-life prospective study

Filippo Ceccato[1], Giorgia Marcelli[2], Marianna Martino[2], Carolina Concettoni[2], Marina Brugia[2], Laura Trementino[2], Grazia Michetti[2] & Giorgio Arnaldi[2]
[1]Endocrinology Unit, Department of Medicine – DIMED, University Hospital of Padova, Padova, Italy; [2]Division of Endocrinology, Department of Clinical and Molecular Sciences (DISCLIMO), Umberto I Hospital, Polytechnic University of Marche, Ancona, Italy.

Introduction and aim
A prompt diagnosis of Cushing's Syndrome (CS) in high-risk populations is mandatory: 1-mg dexamethasone suppression test (1-mg DST); late night salivary cortisol (LNSC) and urinary free cortisol (UFC) are recommend, despite thresholds calculated in retrospective studies. Our aim was to study the diagnostic accuracy of LNSC measured with chemiluminescence assay in a prospective study, confirming discrepancies with mass spectrometry (MS).
Materials and methods
We enrolled 117 controls and 164 suspected-CS (final CS=47, non-CS=117). In case of increased LNSC, high clinical suspicion of CS or adrenal incidentaloma, patients were hospitalized in order to exclude/confirm CS.
Results
We found a large number of false positive results: 35 out of 81 subjects with increased LNSC were non-CS (15 diabetic and 20 obese patients). 2 out of 29 patients with adrenal incidentaloma presented an impaired serum cortisol rhythm. Considering 16 nmol/L as threshold for CS diagnosis, overall LNSC revealed sensitivity (SE) of 97% (95% CI 0.817–0.993) and specificity (SP) of 84% (95% CI 0.772–0.871) in the whole group of subjects considered. If we considered the group of non-CS (those patients with increased likelihood to have a CS), the number of false positive results increased, and therefore the SP decreased to 70% (95% CI 59.8–76.3). SP dropped to 60% (95% CI 49–68.3) if we discharged patients with adrenal incidentaloma. Therefore, we re-computed the threshold of LNSC only in the group of CS compared to non-CS: increasing the cut-off (21.9 nmol/l) we gained in SP (77%) and lost in SE (92%). We measured cortisol with MS in those patients with increased LNSC results in chemiluminescence or high clinical suspicion of CS. MS confirmed the false negative LNSC result of the one patient with confirmed CS and normal cortisol rhythm with chemiluminescence (respectively 1 and 0.6 nmol/l). Considering the 35 non-CS subjects with false positive increased LNSC in chemiluminescence, in half cases MS analyses revealed a normal LNSC.
Conclusions
LNSC measured in automated chemiluminescence is reliable in clinical practice: it present a high diagnostic accuracy to exclude hypercortisolism in patients with normal cortisol levels. MS could be used to reduce the number of false positive

results, nevertheless some non-CS subjects with functional hypercortisolism could have a mild impairment of cortisol rhythm.

Cardiovascular features of possible autonomous cortisol secretion in patients with adrenal incidentalomas

Emilia Sbardella[1], Marianna Minnetti[1], Denise D'Aluisio[2], Laura Rizza[1], Maria Rosaria Di Giorgio[1], Riccardo Pofi[1,3], Elisa Giannetta[1], Annarita Vestri[4], Mary Anna Venneri[1], Sergio Morelli[2], Andrea Lenzi[1] & Andrea M Isidori[1]
[1]Department of Experimental Medicine, 'Sapienza' University of Rome, Roma, Italy; [2]Department of Internal Medicine, 'Sapienza' University of Rome, Roma, Italy; [3]OCDEM, University of Oxford, Oxford, UK; [4]Department of public health, 'Sapienza' University of Rome, Roma, Italy.

Introduction
Low-grade incomplete post-dexamethasone cortisol suppression in patients with adrenal incidentalomas, recently redefined as possible autonomous cortisol secretion (pACS), has been associated with increased cardiovascular events and mortality. However, prospective studies documenting cardiac abnormalities in these patients are lacking.
Methods
In the context of ERGO trial NIH (NCT02611258), between July 2016 and September 2017, 71 consecutive patients with adrenal lesions were prospectively screened for hypercortisolism by dexamethasone suppression test. Complete anthropometric, metabolic and hormonal parameters were recorded along with full cardiac ultrasound assessment and noninvasive measurement of arterial stiffness. All patients underwent chemical-shift magnetic resonance imaging to characterize the adrenal lesions. Cardiovascular outcomes were recorded in blind.
Results
According to post- dexamethasone suppression cortisol values (post-DST), 34 patients had pACS and 37 non-functioning adenomas (NFA). The two groups were similar in sex, BMI, age distribution, cardiovascular risk factors and comorbidities. Left ventricular mass index (LVMI) was increased in pACS compared to NFA ($P=0.006$), and correlated to the post-DST cortisol level ($r=0.347$; $P=0.004$). The post-DST cortisol levels explained up to 7.3% of LVMI variance ($P=0.018$). Compared to NFA, patients with pACS had a higher prevalence of diastolic dysfunction (35.1% vs 82.6%; $P=0.001$), and worse arterial stiffness assessed through pulse wave velocity ($P=0.033$).
Conclusions
In apparently asymptomatic patients, mild autonomous cortisol secretion can sustain early cardiac and vascular remodeling, independently of other risk factors. The morphological and functional cardiovascular changes observed in pACS underline the need for further studies to correctly define the long-term management of this relatively common condition.

Expert patients are better prepared to survive adrenal crisis than most – but still lack training in injection method

Katherine White[1] & Phillip Yeoh[2]
[1]Addisons Disease Self Help, London, UK; [2]The London Clinic, London, UK.

We examined online questionnaire responses received Dec 2017 – Jan 2018 from a sample of well-informed adrenal patients belonging to the Addison's Disease Self-Help Group (N=374). ADSHG members reported levels of preparedness to self-manage during adrenal emergencies that were strikingly higher than any UK clinic survey.

- 88% reported wearing medical jewellery
- 80% had an in-date injection kit with them at the time of their most recent adrenal emergency
- 74% carried an ADSHG emergency steroid alert card

Familiarity with injection method was disappointingly low even in this "expert patient" cohort.

- 40% had viewed the ADSHG's online injection demonstration videos
- 36% had received 1- 1 injection training from an endocrine nurse
- 22% had received 1-1 injection training from a GP or practice nurse
- 15% had practiced injection method at an ADSHG group meeting

Educational materials launched by ADSHG since its previous member survey in 2013 appear to have made only a modest, positive contribution to patient competence in injection method (Table 1).

Table 1

Who gave injected hydrocortisone for most recent adrenal emergency	2013 N=300	2017 N=160	*P* value
Myself or family member	36%	46%	$P=0.022$
Pre-hospital or hospital clinician	59%	50%	$P=0.027$

These findings emphasize that endocrine units could do more to address patient safety. Ensuring all steroid-dependent patients are well-equipped and trained in how to survive adrenal crisis requires more systematic attention and resourcing across all clinics.

Histopathological characteristics of lipid-poor adrenal adenomas

Valentina Vicennati[1], Elena Casadio[1], Antonio De Leo[2], Cristina Mosconi[3], Cristina Nanni[4], Saverio Selva[5], Guido Zavatta[1], Eleonora Rinaldi[1], Uberto Pagotto[1], Donatella Santini[2] & Guido Di Dalmazi[1]
[1]Division of Endocrinology and Centre for Applied Biomedical Research, Department of Medical and Surgical Sciences, Alma Mater Studiorum, University of Bologna, Bologna, Italy; [2]Operative Unit of Pathology, St Orsola Malpighi Hospital, Bologna, Italy; [3]Diagnostic and Interventional Radiology Unit, Department of Diagnostic and Preventive Medicine, St Orsola-Malpighi Hospital, Bologna, Italy; [4]Divison of Nuclear Medicine, St Orsola-Malpighi Hospital, Bologna, Italy; [5]Division of General Surgery, Department of Medical and Surgical Sciences, Alma Mater Studiorum, University of Bologna, Bologna, Italy.

Background
Up to 30% of incidentally-discovered adrenal masses are lipid-poor adenomas (LPA). The clinical significance of LPA is poorly understood. The aim of the study was to investigate histopathological features of LPA and their association with radiological parameters.
Methods
A total of 39 patients with radiological evidence of LPA were included. LPA was defined as an adrenal mass with pre-contrast Hounsfield units (HU) ≧10, associated with absolute washout >60% or relative washout >40% after contrast infusion. Patients underwent hormonal work-up for primary aldosteronism (aldosterone/plasma renin activity ratio >30 in orthostatic position and after Captopril test) and pheochromocytoma (elevated urinary metanephrines). Hypercortisolism was defined as cortisol levels after 1 mg-dexamethasone suppression test >50 nmol/l. F18-Fluoro-Deoxy-Glucose (FDG)-PET scan was performed in 31/39 patients. In resected tumors, Weiss, Lin-Weiss-Bisceglia, and PASS score were calculated, where appropriate.
Results
Radiological characteristics of the population were as follows (mean±SD): tumor diameter 23.0±10.9 mm, pre-contrast density 27.5±10.2HU, absolute and relative washout 68.1±7.6% and 50.7±7.5%, respectively, and FDG-PET scan 6.1±4.6 SUV. Hormonal evaluation showed Cushing's syndrome in 7/39 patients (18%), subclinical hypercortisolism in 11/39 subjects (28%), primary aldosteronism in 2/39 patients (5%) and elevated metanephrines in 2/39 subjects (5%). The remaining cases (17/39, 44%) were non-secreting. Eighteen patients underwent adrenalectomy because of tumor diameter ($n=2$), hormonal hypersecretion ($n=9$) and high FDG-PET SUV (n=7). Histopathological examination showed adrenocortical adenoma in 12/18 cases (66%) and adrenocortical carcinoma in 3/18 tumors (17%), as defined by Weiss score. Hemangioma was diagnosed in 1/18 cases. The two remaining tumors were pheochromocytoma (PASS score 3 and 7). Among all adrenocortical tumors, abundant granular eosinophilic cytoplasm was found in 11/15 cases (73%). By applying the Lin-Weiss-Bisceglia score, one tumor was confirmed malignant, whereas 3/11 tumors were borderline. Weiss score was positively associated with pre-contrast density (Odds Ratio [OR] 1.088, 95% Confidence Interval (CI) 1.018–1.163, $P=0.013$) and absolute washout (OR 1.105, 95%CI 1.005–1.216, $P=0.039$). Lin-Weiss-Bisceglia score was positively associated with tumor diameter (OR 1.045, 95%CI 1.015–1.076, $P=0.003$) and pre-contrast density (OR 1.046, 95%CI 1.002–1.091, $P=0.039$).
Conclusion
LPA represents a heterogeneous class of tumors, which may include pheochromocytoma and adrenocortical carcinoma. In our pilot study, 5/18 (28%) LPAs were classified as malignant or borderline at histopathological analysis. Eosinophilic cytoplasm is a common finding in those tumors and Lin-Weiss-Bisceglia score may be used to avoid overdiagnosis of malignancy.

DOI: 10.1530/endoabs.56.P61

Different biological and functional features in patients with Cushing's disease harboring micro- or macro-adenomas

Filippo Ceccato[1], Marianna Martino[2], Silvia Pinelli[1], Laura Trementino[2], Mattia Barbot[1], Marco Boscaro[1], Giorgio Arnaldi[2] & Carla Scaroni[1]
[1]Endocrinology Unit, Department of Medicine – DIMED, University Hospital of Padova, Padova, Italy; [2]Division of Endocrinology, Department of Clinical and Molecular Sciences (DISCLIMO), Umberto I Hospital, Polytechnic University of Marche, Ancona, Italy.

Background
ACTH-secreting pituitary adenomas represent two-thirds of Cushing's syndrome (CS), the so-called Cushing's disease (CD). These tumors are sometimes > 10 mm in maximal diameter (macro-CD), but the majority of them are < 10 mm (micro-CD). The aim of this study was to compare baseline characteristics of patients with micro-CD and macro-CD.
Materials and methods
Clinical, hormonal and radiological data of 226 patients with CD were retrospectively collected (195 females, mean age 43 ± 13 years; micro-CD $n = 195$, macro-CD $n = 31$) in two Italian referral centers for CS. Surgical remission was defined in case of hypocortisolism (morning serum cortisol < 50 nmol/l) early after surgery and need for substitutive glucocorticoid treatment for at least 4 months. Data are presented as mean and standard error (m/SE), $P < 0.05$ was considered significant.
Results
Basal ACTH levels were higher in patients with macro-CD (160/44 vs 60/4 ng/l, $P < 0.001$), however basal cortisol levels were similar (645/20 vs 710/81 nmol/l), therefore ACTH-cortisol ratio was higher in macro-CD (0.21/0.03 vs 0.09/0.01, $P < 0.001$), suggesting that macro-corticotropinomas might secrete non-functional corticotrophin, considering the increased ACTH secretion in macro-CD. Regarding dynamic tests, ACTH peak after CRH was double in micro-CD (+195/18 vs +99/17%, $P < 0.05$), despite similar cortisol peak: we could speculate that only the normal corticotroph cells are able to generate a significant response to CRH. Response to desmopressin test and adrenal feedback to low (1 mg) or high doses (8 mg) of dexamethasone test were preserved (mean cortisol suppression 72% in both groups after 8 mg). Late night salivary cortisol, midnight serum cortisol and urinary free cortisol (normalized for upper limit of normality) were similar among two groups, as well as clinical collected data (blood pressure, glucose metabolism, lipid profile, sodium/potassium levels, gender and age). In a subset of patients ($n = 125$) at least 2 years of follow-up were available: the surgical remission rate was similar between subjects with micro- and macro-CD.
Discussion
Patients with micro- and macro CD presents, despite their clinical similarities, have different biological and functional features, thus not affecting the outcome of neurosurgery.

Salivary cortisol as a diagnostic tool for hypercortisolism in Cushing's syndrome and adrenal incidentaloma

Lia Ferreira, Cláudia Amaral, Isabel Palma & Helena Cardoso
Endocrinology Department, Centro Hospitalar do Porto, Porto, Portugal.

Background
The lack of circadian rhythm is a marker of Cushing's syndrome (CS). Therefore, salivary cortisol rhythm has been suggested for studies on the hypothalamic–pituitary–adrenal (HPA) axis. Late-night salivary cortisol has been used recently by many centers as a first line diagnostic test for CS, yet its accuracy is still on debate.
Aim
To evaluated the performance of morning and late night salivary cortisol in patients with CS and adrenal incidentaloma (AI).
Patients and methods
We performed a case-control study including asymptomatic patients with AI in whom CS was rule out (with other screening and diagnosis tests) and patients with confirmed CS and analyzed morning (MSC) and late-night salivary cortisol (LNSC) levels and MSC-to-LNSC difference. We assessed the accuracy of LNSC in the CS screening, considering as a cut-off a 0.350 μg/dl, previously validated by our laboratory. Statistical analysis was performed using SPSS v22.0, considering statistical significance at the 0.05 level.
Results
We included 81 patients with AI and 11 patients with CS (ten patients with active Cushing's disease and one patient with ectopic CS). The majority of patients were female in both groups (61.7% and 81.8%, $P = 0.167$ in AI and CS, respectively), but patients with AI were older than CS patients (66 years, min-máx 38–92 vs 55 years, min-máx 28–75; $P < 0.05$). The LNSC median level was significantly higher in the group of patients with CS (0.634 μg/dl (min-máx 0.192–1.280) vs 0.230 μg/dl (min-máx 0.054–1.140); $P < 0.001$) but no significant differences were found in median MSC levels among the two groups (0.735 μg/dl (min-máx 0.266–2.210) vs 0.506 μg/dl (min-máx 0.054–2.590); $P = 0.084$). The median MSC-to-LNSC difference was 0.740 μg/dl (min-máx −0.46–0.93) in CS patients and 0.322 μg/dl (min-máx −0.78–2.46) in AI patients ($P = 0.051$). LNSC above 0.350 μg/dl achieved a sensibility of 90.9% and a specificity of 77.8% in the diagnosis of CS, with positive and negative predictive values of 35.7% and 98.4%.
Conclusions
In this population, patients with CS presented LNSC levels significantly higher than patients with AI, but MSC levels and the MSC-to-LNSC difference weren't significantly different between the two groups. The cut-off of 0.350 μg/dl to the LNSC presented a good accuracy with a very high NPV and it's a useful tool for the diagnosis of CS.

Bilateral macronodular adrenal hyperplasia with autonomous cortisol secretion

Claudia Nogueira[1], Filipe Cunha[1], Pedro Souteiro[2], Sofia Castro Oliveira[2] & Joana Mesquita[3]
[1]Centro Hospitalar de Trás-os-Montes e Alto Douro, Vila Real, Portugal; [2]Centro Hospitalar de São João, Porto, Portugal; [3]Centro Hospitalar de Entre o Douro e Vouga, Santa Maria da Feira, Portugal.

Introduction
Bilateral macronodular adrenal hyperplasia is a rare cause of Cushing's syndrome (CS) characterized by multiple adrenal nodules >1 cm. It can be diagnosed in patients with overt CS but is more often diagnosed incidentally, especially in the 5th or 6th decades of life.
Clinical case
61-year-old woman with type 2 diabetes, arterial hypertension and dyslipidemia treated with metformin + sitagliptin 1000/50 mg bid, valsartan + hydrochlorothiazide 160/25 mg qd, bisoprolol 2.5 mg qd, atorvastatin 20 mg qd. Irrelevant family history. After right hemicolectomy for a colon polyp with high-grade dysplasia she performed a CT scan which showed nodular thickening of the adrenal glands with bilateral hypodense nodules, the largest in the right adrenal gland with 32 mm and in the left with 31 mm. She was referred to the Endocrinology appointment. She complained of anxiety and fatigue. At physical examination: weight 66.8 kg, height 150 cm, BMI 29.7 kg/m^2, arterial pressure 159/93 mmHg, heart rate 77 bpm, central obesity, thin limbs; no reddish purple striae, facial plethora, easy bruising, dorsocervical fat pad or proximal myopathy. Biochemical study showed high serum cortisol levels after 1-mg overnight dexamethasone suppression test (DST) in two separate measurements (24.7 and 20.4 μg/dl), absence of cortisol suppression after the longer dose DST (serum cortisol 14.4 μg/dl), late-night serum cortisol of 11.4 μg/dl, normal urinary free cortisol in two separate measurements ((59.4; 34.5; 62.1 μg/day (N:4.3–176.0)) and morning serum ACTH of 1.0 ng/l in two measurements. Bone mineral density was normal. A follow-up CT scan showed enlargement of the adrenal glands, which contained multiple spontaneously hypodense and bilateral nodules, measuring the largest one 3 cm in the right side and 3.1 cm in the left. The nodules were well delimited, without interstitial calcifications, suggestive of multiple adrenal adenomas. The investigation for ectopic adrenal receptors was negative.
Discussion
This is a case of bilateral macronodular adrenal hyperplasia with autonomous cortisol secretion. The patient symptoms and comorbidities may be related to excessive cortisol secretion. In the absence of a clear picture of CS adrenalectomy is not recommended. However, unilateral adrenalectomy of the largest lesion is a possibility. In this case, since there was no overt CS, the comorbidities were controlled under medical treatment and there was similar involvement of both glands, we decided for active surveillance to avoid the consequences of bilateral adrenalectomy.

A systematic survey of low S-cortisol levels at the department of clinical chemistry: indications for testing and frequency of undiagnosed adrenal insufficiency

Anna-Karin Åkerman[1,2], Inga Bartuseviciene[3], Charlotte Höybye[2,4] & Sophie Bensing[2,4]

[1]Department of Medicine, Örebro University Hospital, Örebro, Sweden; [2]Department of Molecular Medicine and Surgery, Karolinska Institute, Stockholm, Sweden; [3]Department of Clinical Chemístry, Karolinska University Hospital, Stockholm, Sweden; [4]Department of Endocrinology, Metabolism and Diabetes, Karolinska University Hospital, Stockholm, Sweden.

A systematic survey of low S-cortisol levels at the department of clinical chemistry: indications for testing and frequency of undiagnosed adrenal insufficiency.

Background

S-cortisol is frequently analyzed at clinical chemistry departments. Low levels of S-cortisol needs to be promptly acted on if the cause is undiagnosed adrenal insufficiency (AI). The causes of S-cortisol testing are however multiple and low levels are necessarily not alarming if found in patients already under clinical evaluation or surveillance. Consequently, far from all clinical chemistry departments have as routine to alert clinicians on low S-Cortisol, potentially delaying AI diagnosis.

Aim

To identify individuals with S-cortisol $<$ 150 nmol/l and determine the indication for testing and the number of cases of undiagnosed AI.

Material and methods

We retrospectively went through the results from all S-Cortisol analyses performed at the Clinical chemistry department at the Karolinska university hospital during six months, January 1 until June 30 2013. Individuals with S-cortisol $<$150 nmol/l were identified and their medical records were reviewed to determine the indication for S-cortisol testing.

Results

993 S-cortisol analyses $<$150 nmol/l were identified. Medical records were available from 866 individuals (female 539, children 94). The most common indication for the S-cortisol testing was dexamethasone inhibition test n 334, followed by monitoring of pituitary insufficiency n 62. In 146 patients the indication for testing was unclear and not stated in the records. In 2% (*n* 19) of the patients previously undiagnosed AI was identified. Many patients were severely ill at the time of testing, 78 (9%) later deceased from other causes than AI, but in one case, undiagnosed Addison's disease.

Conclusion

S-cortisol is frequently analyzed and the most common cause of testing is evaluation or surveillance of patients already carefully cared for. A handful of patients however suffer from undiagnosed AI. If establishing a routine to alert clinicians on low S-cortisol levels, indication for the analysis should be marked in ordered to avoid unnecessary concern.

Evaluation of cardiometabolic profile of patients submitted to unilateral adrenalectomy

Raquel Vaz de Castro[1], Cristiana Costa[1], Tânia Matos[1], Catarina Quadros[2], Dolores Lopez[2], Sónia do Vale[1] & Maria João Bugalho[1]
[1]Endocrinology Department, Hospital de Santa Maria, Centro Hospitalar Lisboa Norte, Lisboa, Portugal; [2]Pathology Department, Hospital de Santa Maria, Centro Hospitalar Lisboa Norte, Lisboa, Portugal.

Background and aims

It is known that unilateral adrenalectomy as treatment for autonomous secreting adrenal cortex adenomas effectively reduces cardiometabolic risk. Non-autonomous secreting adenomas are not expected to increase cardiometabolic risk, but this has not been thoroughly explored.We evaluated the blood pressure and glycemic profile before and after unilateral adrenalectomy for both autonomous and non-autonomous secreting adrenal cortex adenomas.

Patients and methods

This is a retrospective study of 30 consecutive patients submitted to unilateral adrenalectomy, assisted in a tertiary hospital.We evaluated systolic (SBP) and diastolic (DBP) arterial blood pressure, fasting glycemia,sodium (Na), potassium (K) and number of anti-hypertensive and anti-diabetic agents, 6 months before and after undergoing unilateral adrenalectomy for both secretory and non-secretory adrenal cortex adenomas.

Results

Patients' mean age was 55 $\pm$ 13 (21–77) years old and 70% were female. 9 (30%) had a cortisol or aldosterone secreting adenoma documented before surgery. Overall, mean tumor's maximum diameter was 29 $\pm$ 12 mm. 15 (50%) patients had hypertension and 3 (10%) were diagnosed with diabetes mellitus before surgery,requiring a mean of 1.2 $\pm$ 0.3 anti-hypertensive drugs and 0.3 $\pm$ 0.7 anti-diabetic agents per patient. After surgery, there was a significant reduction of the SBP (148 $\pm$ 21–123 $\pm$ 10 mmHg, $P=0.001$) and DBP(92 $\pm$ 16–78 $\pm$ 8 mmHg, $P=0.006$), an increase in serum potassium levels (4.1 $\pm$ 0.5–4.5 $\pm$ 0.6 mEq/l, $P=0.015$), a decrease in the number of anti-hypertensive agents (2.3 $\pm$ 1.4 to 1.3 $\pm$ 1.3 agents, $P=0.008$) and a decrease in fasting glycemia (121 $\pm$ 50–101 $\pm$ 31 mg/dL, $P=0.02$). Considering non-secretory adenomas separately, there was still a significant reduction of the SBP (147 $\pm$ 26 mmHg to 122 $\pm$ 11 mmHg, $P=0.022$), an increase in K levels (4.0 $\pm$ 0.4 mEq/l to 4.6 $\pm$ 0.6 mEq/l, $P=0.006$) and a trend towards less anti-hypertensive agents (2.1 $\pm$ 1.3 to 1.4 $\pm$ 1.4 agents, $P=0.054$). For patients with secreting adenomas there was a significant reduction in SBP ($P=0.018$) and DBP ($P=0.02$) and a trend to a lower fasting glycemia ($P=0.092$) after surgery.

Discussion

As expected, cardiometabolic profile improved in patients submitted to adrenalectomy for autonomous secreting adrenal adenomas.Notably, whatever the underlying mechanism,we also found an improvement in SBP and less need for anti-hypertensive agents after adrenalectomy for adenomas previously classified as non-autonomous secreting by clinical and biochemical evaluation.As a result, in both secreting and non-secreting tumors there was an improvement in cardiometabolic profile, which may improve long time cardiovascular outcomes.

Adrenal venous sampling in patients with ACTH-independent Cushing's syndrome

Eleni Papakokkinou[1,2], Hugo Jakobsson[1,2], Augustinas Sakinis[3], Andreas Muth[4], Bo Wängberg[4], Olof Ehn[1,2], Gudmundur Johannsson[1,2] & Oskar Ragnarsson[1,2]
[1]Department of Internal Medicine and Clinical Nutrition, Institute of Medicine at Sahlgrenska Academy, University of Gothenburg, Gothenburg, Sweden; [2]Department of Endocrinology, Sahlgrenska University Hospital, Gothenburg, Sweden; [3]Department of Radiology, Sahlgrenska University Hospital, Gothenburg, Sweden; [4]Department of Surgery, Institute of Clinical Sciences, Sahlgrenska Academy, University of Gothenburg, Sahlgrenska University Hospital, Gothenburg, Sweden.

Background

ACTH-independent Cushing syndrome (CS) accounts for 15–20% of endogenous CS. Approximately 10% of these patients have bilateral adrenal lesions where the differential diagnoses are primary bilateral adrenal macronodular hyperplasia (PBMAH), primary pigmented nodular adrenal disease (PPNAD), bilateral cortisol producing adenomas or a unilateral cortisol producing adenoma with a contralateral nonfunctioning adenoma. Also, the prevalence of subclinical CS is high in patients with bilateral incidentalomas. Management of these patients is challenging since the distinction between functioning and non-functioning adrenal masses cannot be determined by imaging. Adrenal venous sampling is the "gold standard" for distinguishing unilateral from bilateral aldosterone production. The role of the adrenal venous sampling (AVS) in patients with ACTH independent CS and bilateral adrenal lesions or normal adrenal glands is still not determined.

Methods

This was a retrospective analysis of 11 consecutive patients evaluated for ACTH-independent CS who were subjected to AVS at our institution between 2009 and 2017.

Results

Eight patients were referred for evaluation of bilateral adrenal incidentalomas, five of whom had subclinical CS and three overt CS. Three additional patients were referred due to overt CS. Thus, in total six patients had overt CS. Overt Cushing's syndrome: three patients had bilateral adrenal lesions. One of them had a unilateral dominant cortisol production and underwent left adrenalectomy. Two patients had bilateral cortisol production. One of them underwent bilateral adrenalectomy and histopathological diagnosis showed PBMAH. The other patient had a mild CS and was treated medically. Two patients had normal adrenal glands and bilateral cortisol production on AVS. Both underwent bilateral adrenalectomy and the histopathological examination showed PPNAD. The last patient, after extensive investigation, did not have ACTH-independent CS, but cyclic Cushing's disease. Subclinical CS: all patients had bilateral adrenal lesions. One patient had unilateral dominant cortisol production underwent unilateral adrenalectomy and developed adrenal insufficiency. The histopathological diagnosis was benign adrenal adenoma.

Conclusion

AVS distinctly contributed to appropriate choice of treatment in two of 11 patients. The role of AVS is limited in patients with CS, but may in some cases assist in the management decision of patients with ACTH independent CS and bilateral adrenal lesions or normal adrenal glands.

Association of the *Bcl*I glucocorticoid receptor polymorphism with metabolic parameters in female patients with adrenal incidentalomas

Sanja Ognjanovic, Jadranka Antic, Djuro Macut, Valentina Elezovic Kovacevic, Tatjana Isailovic, Bojana Popovic, Ivana Bozic Antic, Tamara Bogavac, Dusan Ilic, Milan Petakov & Svetozar Damjanovic
Clinic for Endocrinology, Diabetes and Metabolic Diseases, Clinical Centre of Serbia, Faculty of Medicine, University of Belgrade, Belgrade, Serbia.

Interindividual variations in tissue sensitivity to glucocorticoids have been partly attributed to polymorphisms in the glucocorticoid receptor (GR) gene. The aim of this study was to investigate the prevalence of subclinical hypercortisolism (SH) in women with adrenal incidentaloma (AI), and whether *Bcl*I variant of the GR gene may contribute to metabolic abnormalities frequently present in these patients. We evaluated 106 women with AI. Anthropometric characteristics included BMI, waist and hip circumference. SH was diagnosed in the presence of serum cortisol levels after 2-day low-dose dexamethasone suppression test (LDDST) >50 nmol/l with at least one of the following parameter (midnight serum cortisol >208 nmol/L, 24-h urinary free cortisol (UFC) >245 nmol/24 h, or adrenocorticotropin (ACTH) $<$ 10 ng/l). Non-diabetic patients underwent an oral glucose tolerance test with 75 g glucose. Insulin resistance was assessed by homeostasis model assessment (HOMA-IR) index. DNA was obtained from peripheral blood leucocytes. The polymorphism was detected using PCR, RFLP and DNA sequencing. The overall prevalence of SH was 20.2%. Carriers of the larger C allele of *Bcl*I polymorphism had significantly less suppression of cortisol levels after 0.5 mg dexametasone (126.4 ± 111.4 vs 80.9 ± 75.7 nmol/l, $P=0.026$), indicating relative GC resistance. No difference was noted in midnight and post LDDST serum cortisol concentrations, UFC, and ACTH levels. The mean age, BMI, waist circumference and waist-to-hip ratio did not differ between carriers and non-carriers. Most patients had central obesity. The prevalence of hypertension and dyslipidemia occurred with similar frequency in both groups. There was no significant difference in mean values of systolic and diastolic blood pressure and HOMA-IR index. The presence of the BclI polymorphism was associated with a reduced prevalence of type 2 diabetes in carriers compared with wild type (9.1% vs 26%, $P=0.034$). We demonstrated that female carriers of the larger C allele of *Bcl*I polymorphism display relative glucocorticoid resistance of the hypothalamic-pituitary adrenal axis and peripheral tissue. This polymorphism has a protective role and reduces the risk of diabetes in patients with AI especially in a state od subtle cortisol excess.

Adrenocortical carcinoma in the experience of one clinical center

Anna Kurzyńska, Elwira Przybylik-Mazurek, Marcin Motyka & Alicja Hubalewska-Dydejczyk
Jagiellonian University, Medical College in Krakow, Krakow, Poland.

Adrenocortical carcinoma (ACC) is a rare neoplasm with poor prognosis. Patients can present signs of hormone excess: virilisation, Cusging's syndrome or only enlarged abdominal mass. Incidentally ACC can be also detected in the ultrasonography. Some of 'non-hypersecretory' ACCs can produce non-bioactive hormones steroid precursors or not very big amount of them and sometimes patients present subclinical Cushing's symptoms. Surgery and adjuvant radio-therapy and chemotherapy with Mitotane is the treatment of choice. The aim of the study was to analyse clinical features, hormonal test results and prognosis in patients with secreting and non- secreting adrenal cancers.

Patients

The study group included 49 patients: 11 men and 38 women median age 68 year. Clinical examination, the imaging studies and hormonal assays were performed. Forty four patients underwent surgical treatment, five of them were qualified only to palliative treatment. Chemotherapy with Lysodren was administered in 39 patients.

Results

Secretory tumors were diagnosed in 23 cases and non-secretory in 26 cases. Twenty five patients are still alive and the median time of observation is 60 months (min 13 months, max 312 months). Nineteen patients of this group were classified as the 1-st or 2-nd stage and 14 were diagnosed as non-secretory tumors. Due to ACC progress 22 patients died during the time of observation, and two patient died due to surgical complications. The median time of observation in this group was 15,5 months (min. 1 month an max 192 months). In this group 12 patients were classified as 3-rd or 4-th stage and 12 patients were diagnosed as secretory tumors.

Conclusion

The poor prognostic factors in ACC are: size of tumor, presence of local and distant metastases and hormonal activity. Chemotherapy with Lysodren prolong life of patients, but is less effective in advanced disease.

Adrenocortical carcinoma: retrospective analysis of a series of clinical cases

Jersy Jair Cardenas Salas[1], Arturo Lisbona Catalan[2], Belén Goiburú-Chenu[2], Maria Isabel Esteban-Rodríguez[2], Rita María Regojo[2] & Cristina Alvarez-Escolá[2]
[1]Fundacion Jimenez Diaz University Hospital, Madrid, Spain; [2]La Paz University Hospital, Madrid, Spain.

Introduction

Adrenocortical carcinoma (ACC) is a rare and aggressive tumour. At diagnosis 21% has metastasis. Even after complete surgical removal, patients are at risk of recurrence as late as 10-12 years. The 5-year survival rate of Stage I to IV (ENSAT 2008) is 82%, 61%, 50% and 13% respectively.

Objetive

To describe the epidemiological and clinical characteristics, as well as the evolution, treatments and overall survival of patients diagnosed with ACC.

Methods

We identified 41 cases of ACC in the archive of the Pathological Anatomy department in La Paz University Hospital-Madrid (1969–2017). We reviewed the medical records of 24 cases that were followed in the our center (1984–2017).

Results

Of the 41 cases, 9 were children (21.5%), 23 women (56.10%). The median age of the children was 4 years, (P25–P50: 2–6), the mean age of the adults was 49.9 years (s.d.: 14.08). Total mortality in children was 50% and in adults 59%. The main characteristics of the 24 cases followed in our hospital is shown in the Table. An Stage IV case with complete remission and survival of more than 10 years was identified. ENSAT stage at diagnosis was a statistically significant variable for overall survival; it was not significant for sex, age, secretory status neither mitotane therapy in our cohort.

Table 1

	Children	Adults
N	4(16%)	20 (83%)
Female	4 (100%)	12 (60%)
Age (years)	5.5 (1.8–9.0)	53 (36–62)
Smoking/Previous Smoking	0/0	9 (47%)/4(21%)
Left Location	3 (75%)	8 (40%)
Secretory Tumor	4(100%)	10 (50%)
Cortisol	0	3
Androgens	4	3
Cortisol and Androgens	0	3
Aldosterone	0	1
ENSAT Stage at Diagnosis		
I	1 (25%)	6 (32%)
II	3 (75%)	10 (53%)
III	0	1 (5%)
IV	0	2 (10%)
ENSAT Stage at follow-up		
I	1 (25%)	5 (25%)
II	1 (25)	4 (20%)
III	0	2 (10%)
IV	2 (50%)	9 (45%)
Surgery Approach		
Laparoscopic	0	2 (10%)
Laparotomy	3 (75%)	16 (80%)
No surgery	1 (25%)	2 (10%)
Chemotherapy	1 (25%)	8(42%)
Radiotherapy	4%	0
Mitotane treatment	2 (50%)	10 (50%)
Recurrent Disease	1(25%)	7 (42%)
Survival		
1-year	2 (50%)	17 (85%)
5-year	2 (50%)	9 (45%)
10-year	2 (50%)	7 (35%)

Conclusions

Due to its infrequency, we believe that the epidemiological registry and the results of the different therapeutic approaches are convenient for a better treatment of this pathology.

Imaging characteristics of pheochromocytomas

Imen Sakka, Ibtissem Oueslati, Melika Chihaoui, Nadia Khessairi, Amal Rached, Meriem Yazidi, Amel Melki & Hedia Slimane
Department of Endocrinology, La Rabta Hospital, Tunis, Tunisia.

Introduction
Pheochromocytomas are uncommon neuroendocrine tumors arising from chromaffin cells of the adrenal medulla. The aim of our study was to assess imaging characteristics of pheochromocytomas.
Methods
The study was a retrospective analysis of 23 patients with pheochromocytomas. All participants had a computed tomography scan (CT). Several clinical and radiologic features were statistically analysed.
Results
The Mean age was 47.04 ± 12.31 years and the sex-ratio (M/F) was 0.39. All pheochromocytomas were unilateral. Malignancy was proven in five cases. The mean tumor size was 54.17 ± 29.47 mm (Extremes: 20–130 mm). Out of 23 participants, 19 patients had a tumour larger than 30 mm. There was no significant correlation between tumour size and urinary metanephrines ($P = 0.8$). However, a significant correlation between tumor size and the degree of malignancy ($r = 0.54$, $P = 0.03$) was identified. The majority of pheochromocytomas ($n = 22$) had attenuation values greater than 10 Hounsfield units with a heterogeneous enhancement in contrast-enhanced CT. Smaller lesions were typically homogeneous (3/4) whereas larger tumours were more heterogeneous (16/19). Calcifications, necrosis and cystic components were present in 3, 8 and 2 cases, respectively.
Conclusion
Computed tomography scan has been established as the main tool to identify pheochromocytoma, with an overall sensitivity of 89%. The typical appearance of a pheochromocytoma in computed tomography is a mass with a large size, high density greater than 10 Hounsfield units, avid contrast enhancement due to a rich capillary network, and delayed washout. Cystic changes, necrosis, and internal calcifications are commonly described in the literature.

Genetics in pheochromocytoma and paraganglioma: a case series

Paloma González Lázaro, Cristina Contreras Pacual, Julia Silva Fernández, Belvis Torres Arroyo, Francisco Javier Gomez Alfonso, Florentino Del Val Zaballos, Ines Gomez García & Álvaro García Manzanares
CH La Mancha Centro, Alcazar de San Juan, Spain.

Introduction
In most patients with familial history of pheochromocytoma/paraganglioma, leads in the majorty of cases to a postive genetic testing for mutations, and what's more in those patients with no familial antecedents, about 10–25% carry a mutation in one related gene. In these cases other aspects like, bilaterality, multiplicity or location must be taken into account.
Objective
The objective of the study was to discuss the importance of genetic testing in apparently sporadic cases.
Design
Nine probands, with no familial or personal antecedents of pheochromocytoma or paraganglioma, were analyzed for the major genes: VHL, RET, SDHB, SDHC and SDHD.
Results
Nine probands (six men and three women) with an average of 55.8 ± 10.3 years old were analyzed, 8 cases (88.8%) of pheochromocytoma and only one proband with non-fuctioning paragangliomas (mediastinal paraganglioma and glomus jugulare tumor). Genetic analysis was performed using a multi-gene panel testing for the major genes, for analyzing patients' blood and tumor samples. A rate of 33.3% for genetic mutations was found: RET (C634S) (1 of 9) and SDHD (c.242C > T (p.Pro81Leu)) (1 of 9), VHL (pVal84/Met) (1 of 9), in this last case no mutations were found on blood sample but the mutation for VHL was found in paraffin embedded sample. In our serie, genetic testing was performed on first grade relatives of patients affected, being diagnosed two first grade relatives of mutations during the study: one for VHL mutation and one for RET mutation, in this last case, with initial diagnosis of medullary thyroid cancer and development of pheochromocytoma in a five year follow-up interval.
Conclusions
We recommend genetic testing in all patients, not only in those with familial antecedents but also in sporadic tumors, regardless of age or location (In our serie 80% were unilateral adrenal masses, 10% bilateral masses and 10% extraadrenal location). We emphasise the importance of genetic testing in first grade relatives, as in our serie, in 22% of probands affected of pheochromocytoma/paraganglioma, at least one first grade relative was carrier of the mutation.

Analysis of a pheochromocytoma case series over 12 years: a specialty hospital experience

Manuel Cayón-Blanco, Virginia Naranjo-Velasco, Carolina García-Figueras-Mateos, Lourdes García-García-Doncel, Rosa Márquez-Pardo, M. Gloria Baena-Nieto & Francisco Mateo-Vallejo
Hospital SAS Jerez de la Frontera, Jerez de la Frontera, Spain.

Introduction
Pheochromocytomas are the most common tumours of adrenal medullary origin. The aim of this study is to describe the clinical manifestations, biochemical profile, preoperative pharmacological approach and hemodinamic outcomes in a series of patients with histologically proven pheochromocytoma treated in our center over 12 years.
Methods/design
Descriptive analysis including patients diagnosed with pheochromocytoma after histological examination. Patients with suspected tumour without histological evidence were excluded for assesment as well as those whose medical records were incomplete.
Results
Pheochromocytoma was histologically diagnosed in 11 out of 15 patients from 2002 to 2014. One patient was excluded because of incomplete medical records. There were 6 females and 5 males (F:M = 1.2:1), age ranged from 27 to 80 years. Presenting form was persistent and/or refractory hypertension in 2 patients, incidental adrenal mass in 2 cases and paroxysmal hypertension crisis in 5. Two cases presented as abrupt hypertensive emergency. The most common clinical manifestations were headache (7 cases), palpitations (6 cases) and perspiration (5 patients). Type of tumour secretion: norepinephrine (5), norepinephrine and epinephrine (4), norepinephrine, epinephrine and dopamine (2). All patients underwent successful surgical removement and unilateral adrenal mass was identified in all cases (left gland in 8 cases). Median mass size was 3 (range: 1.5–10) cm. Preoperative selective alfa-blockade was performed with phenoxybenzamine in 7 cases and 4 patients received non-selective alfa-blockade with doxazosin. Beta-blockade was needed in 9 cases. Preoperative systolic blood pressure: 130 (120–140 mm Hg), diastolic blood pressure 80 (71.2–87.5 mm Hg) and heart rate: 71 (65–85 bpm). Mean time until optimal pharmacological blockade: 21 days.
Conclusions
There were no classic presenting form for pheochromocytoma in our series, although clinical history and physical findings are helpful. There wasn't any standard approach in preoperative pharmacological blockade. Though therapeutic results were favourable, protocols for preoperative management may be considered in our center.

Laparoscopic surgery for pheochromocytoma: perioperative outcomes

Manuel Cayón-Blanco, Virginia Naranjo-Velasco,
Carolina García-Figueras-Mateos, Lourdes García-García-Doncel,
Rosa Márquez-Pardo, M. Gloria Baena-Nieto & Francisco Mateo-Vallejo
Hospital SAS Jerez de la Frontera, Jerez de la Frontera, Spain.

Introduction
Laparoscopic adrenalectomy is a promising alternative to open surgery although concerns exist in regard to laparoscopic treatment of pheocromocytoma. This report aims to describe the outcomes of laparoscopic resection for pheocromocytoma focusing particularly on intraoperative hemodynamic stability and postoperative outcomes.
Methods/design
Descriptive analysis including patients who underwent laparoscopic surgery for unilateral pheochromocytoma in our center. Patients who required emergency surgery were excluded from analysis, so every patient received previous alfa and beta blockade. Patients who didn't meet Roizen's criteria before surgery and patients with bilateral tumours or paraganglioma were also excluded. Intraoperative hemodynamic stability including need of vasoactive drugs was studied. Postoperative complications and length of stay from post-anesthesia or intensive care unit admission to discharge to conventional medical ward, were

recorded. Quantitative variables are described as median (range) or number of cases in which some particular clinical conditions were observed.
Results
Ten patients were included (six women, five men; median age: 53 (27–80) years. Median size of tumour: 2.8 (1.5–10) cm. Type of tumour secretion: norepinephrine (4), norepinephrine and epinephrine (4), norepinephrine, epinephrine and dopamine (2). Preoperative systolic blood pressure: 130 (120–140) mm Hg, diastolic blood pressure 80 (71.2–87.5) mm Hg and heart rate: 71 (65–85) bpm. All tumours were successfully removed. One laparoscopic procedure were converted to open procedure due to large mass size (above 10 cm). Intraoperative results: median operative time was 150 (90–180) min, median blood pressure was 92.5 (85–100) mm Hg, hypertensive crisis requiring use of vasoactive drugs and hypotensive crisis requiring volumen expanders were documented in 4 and 3 cases, respectively. No arrythmias were documented. Postoperative results: treatment for transient hypertension was needed in 2 cases, 2 patients suffered from hypoventilation and hypotension was found in 2. Median time from post-anesthesia/intensive care unit to discharge to conventional hospital ward: 48 (24–96) hours. Laparoscopic adrenalectomy was effective in normalization of endocrine profile in all cases.
Conclusions
Laparoscopic resection of pheochromocytomas can be accomplished safely by experienced surgeons. A short operative and post-anesthesia care wards stay with minimal intra and postoperative hemodynamic inestability coupled with eradication of endocrinopathy support the minimally invasive approach for adrenalectomy in the setting of pheochromocytoma.

Malignant pheochromocytoma discovered upon consultation for painful erections

Lourdes Garcia-Garcia-Doncel, Rosa Marquez-Pardo, Manuel Cayón-Blanco, Rosario López-Velasco & Gloria Baena-Nieto
Jerez Hospital, Jerez de la Frontera, Spain.

Introduction
Pheochromocytomas (PCCs) and paragangliomas (PGL) are rare but unique tumors. Only 10% of PCCs are malignant, defined by metastases. Metastases can be seen at diagnosis of the primary tumor or develop even 20 years later. Approximately half of patients with metastatic PCC/PGL have inherited SDHB mutations.
Case report
A 45-year-old man was referred to Urology for curvature of the penis and painful erections. Among his medical background highlighted high blood pressure and herniated disc intervened twice. Abdominal US revealed a large heterogeneous lesion in the right suprarenal region. A CT scan of the abdomen revealed a 9x5.8x6.1 cm heterogeneous right suprarenal mass. Laboratory analysis showed elevations in urine fractionates metanephrines (771 mg/24 h [25–312]) and normetanephrines (1425 mg/24 h [35–445]) levels. $^{1\text{-}123}$ MIBG scintigraphy revealed uptake in the right adrenal region. Two months after diagnosis blood pressure figures were raised, being difficult to control.Phenoxybenzamine was used for preoperative preparation prior to surgical resection. Nephrectomy and right adrenalectomy were performed. Histopathology confirmed pheochromocytoma with lymph nodes metastasis. At six months follow-up, 4 right retrocrural lymph nodes metastasis of 7–10 mm were detected in CT scan and confirmed by 18F-dopa PET. $^{1\text{-}123}$ MIBG scintigraphy did not reveal any uptake. Surgery was performed by high right para-aortic lymphadenectomy. Histopathological examination confirmed the diagnosis of pheochromocytoma metastasis in three nodes. Six months after surgery a follow-up 18F-dopa PET/TAC detected a 8-mm right retrocrural lymphatic metastasis with a maxSUV of 2.8. Catecholamines and metanephrines levels were within the normal range and blood pressure was controlled with enalapril. The genetic study performed in peripheral blood (SDHB) and tumor piece (SDHB, SDHC, SDHD, SDHA, SDHAF1, SDHAF2, RET, MEN-1, VHL, NF1, KIF1, BETA, MAX, TMEM127, MDH2, FH, EPAS1, HRAS) did not show genetic alterations. A 18F-dopa PET/TAC performed 4 years after the first surgery detected a retrocrural lymph node metastasis of 3 mm with a maxSUV of 2.2.
Conclusion
Complete resection is the only curative treatment in metastatic disease. Given the often indolent nature of the disease, other therapies (mainly 131I-MIBG, chemotherapy and/or radiation) are reserved for patients with severe symptoms or clear progression. A wait and see policy is recommended as first-line management in asymptomatic patients. The management of these patients requires a multidisciplinary follow up. Eventually a better knowledge about genetics might lead us to find better targets for therapy.

Can patients with a large sporadic pheochromocytoma and very high norepinephrine secretion be normotensive? Yes, they can!

Maria Dolores Perez-Ramada[1], Isabel Ramos-Gomez[1], Paula Fernandez-Trujillo-Comenge[2], Ana Delia Santana-Suarez[2], Manuel Esteban Nivelo-Rivadeneira[2], Agnieszka Kuzior[2], Carmen Acosta-Calero[2], Claudia Arnas-Leon[3], Sara Quintana-Arroyo[3] & Francisco Javier Martinez-Martin[4]
[1]Internal Medicine Department, University Hospital of Gran Canaria Dr. Negrin, Las Palmas de Gran Canaria, Spain; [2]Endocrinology & Nutrition Department, University Hospital of Gran Canaria Doctor Negrin, Las Palmas de Gran Canaria, Spain; [3]Endocrinology & Nutrition Department, Hospitales San Roque, Las Palmas de Gran Canaria, Spain; [4]Outpatient Hypertension Clinic, University Hospital of Gran Canaria Doctor Negrin, Las Palmas de Gran Canaria, Spain.

Introduction
Classically, hypertension (sustained or paroxysmal) is described in > 98% of diagnosed pheochromocytomas. Nowadays the systematic workup of adrenal incidentalomas has made uncovering normotensive pheochromocytomas no longer exceptional. However, normotensive pheochromocytomas have a catecholamine secretion characteristically lower than hypertensive pheochromocytomas. It must be emphasized that the perioperative hemodynamic instability is comparable in hypertensive and normotensive pheochromocytomas, and much higher than in non-pheochromocytoma adrenal masses.
Clinical case
After caustic ingestion, a 53-year-old male patient suffered extensive gastric ulcers and pyloric stenosis. He was referred to our Endocrinology Clinic because in a CT scan a dense heterogeneous mass measuring 4.4x4.6 cm with gross calcifications and lobulated outline was incidentally found in the right adrenal. The patient was asymptomatic, normotensive, had no medication except pantoprazol, and reported no history of hypokalemia, headaches or hypertensive crisis. The physical exam was unremarkable, with height 179 cm, weight 73 kg, BP 126/81 mmHg, HR 68 lpm. There were no signs of Cushing's syndrome. Glucose, creatinine and eGFR, ions, lipids, transaminases, GGT, blood count, TSH, cortisol, ACTH, LH, FSH and testosterone were normal. Fasting cortisol was 14.4 µg/dL, aldosterone 10.3 ng/dl, PRA 1.1 ng/ml/h, ratio A/PRA 9.4 (normal). Unexpectedly, plasma metanephrine was 35 pg/ml (normal), normetanephrine 2264 pg/ml (UNL 196), and cromogranin A 361.5 ng/ml (UNL 100) with 24 h urinary metanephrine 264 µg (normal) and normetanephrine 1656 µg (UNL 444). A MIBG/SPECT CT scan showed a right adrenal pheocromocytoma without additional lesions. 24 h ABPM was performed in order to confirm normotension. Awake BP was 128/75 mmHg with HR 81 lpm, sleep BP was 115/64 mmHg with HR 69 lpm, with normal dipper pattern, but there was an unexplained BP peak (159/84 mmHg) at 16:00. The patient is at present ready for right laparoscopic adrenectomy, having started treatment with doxazosin 4 mg bid followed by bisoprolol 10 mg bid, adequate hydration and ClNa supplements 6 g/24 h, with mild hypotensive symptoms.
Conclusions
We certainly would expect a patient with such a large epinephrine output to be hypertensive, but have no explanation why it was not the case. The workup of adrenal incidentalomas must include screening for pheochromocytoma even in normotensive patients. In order to prevent perioperative hemodynamic instability, patients with normotensive or hypertensive pheochromocytoma need the same preparation (including adrenergic blockade, hydration and salt supplementation) although it might elicit symptomatic hypotension.

Pheochromocytoma revelation modalities: about 23 cases

Fatima Zahra Zaher, Aymande Okoumou Moko, Sana Doubi, Sana Rafi, Ghizlane Elmghari & Nawal Elansari
Department of Endocrinology, Diabetes, Metabolic Diseases and Nutrition, Mohammed VI University Hospital, Marrakech, Morocco.

Introduction
Pheochromocytoma is an endocrine tumor developed in the chromaffin cells of the adrenal medulla and excessively secreting catecholamines in varying amounts and types. It represents a rare tumor, often benign, but serious considering its mainly cardiovascular complications. The purpose of our study is to specify the revelation methods of pheochromocytomas in our population.
Patients and methods
Our study has included 23 cases of pheochromocytomas followed in the endocrinology department of the Mohammed VI University Hospital of Marrakech between 2012 and 2017.

Results
The mean age of patients was 42.4 years, the sex ratio was 1.8 with female predominance. The circumstances of discovery were a triad of Menard in 69% of cases, an HTA in 43% including 2 cases of pre-eclampsia, an adrenal incidentaloma in 26%, an acute coronary syndrome in 2 cases, a transient ischemic attack in one case, a subocclusive syndrome in 1 case and during a histological examination of an operative specimen in 1 case. The most frequent location was on the right (50% of cases) with 4 cases of bilateral incidentaloma, the average size was 67 mm.
Discussion
Pheochromocytoma is a rare tumor whose variable clinical expression is dominated by the Menard triad and hypertension but which can be revealed by an acute array, surgical treatment is the only curative treatment but remains limited for malignant forms.

When the large tumor is not the first intention for removal-concomitant discovery of left adrenal pheochromocytoma and a possible retroperitoneal plexiform neurofibroma in a case of familial neurofibromatosis type 1- case report

Mariana Costache Outas[1], Alice Valcu[2], Andru Lamasz[3] & Cosmin Giulea[4,5]
[1]Coltea Clinical Hospital, Bucharest, Romania; [2]MM Clinic - Private Practice, Craiova, Romania; [3]Regina Maria Clinics, Bucharest, Romania; [4]Carol Davila University of Medicine and Pharmacy, Bucharest, Romania; [5]Elias University Emergency Hospital, Bucharest, Romania.

Neurofibromatosis type 1 (NF1) is a rare autosomal dominant disorder characterized by the development of multiple benign tumors of the nerves and the skin (neurofibromas) and areas of abnormal increased and decreased coloration of the skin. Pheochromocytoma develops in 0.1–5.7% of NF1 patients and plexiform neurofibroma in 30% of NF1 patients. We present a case of a 38-year-old female, without relevant personal, with a familial phenotype suggestive for NF1, evaluated for a two years history of tachycardia and hypertension. The clinical examination meet the criteria for NF-1 (skin tags with cutaneous and subcutaneous neurofibromas, café-au-lait spots and axillary freckling and Lisch nodules revealed in the ophthalmologic examination). She is the mother of two daughters, one of them with severe scoliosis. Laboratory testing showed pure autonomous adrenergic secretion with more than three times plasma metanephrine and normal normetanephrine. The abdominal MRI described a left adrenal mass of 22/21 mm and an inhomogeneous hypointense mass 62/42/49 mm that rises from the neural plexus situated between the right kidney psoas muscle and the posterior abdominal wall with central contrast enhancement suggestive of a plexiform neurofibroma. We performed removal of the left adrenal pheochromocytoma after alpha-adrenergic blockade. Following surgery, the patient had normalized the blood pressure and had normal range plasma metanephrine. Elective surgery for the abdominal plexiform neurofibroma is planned because of his malignant potential.

Why is it important to screen secondary endocrine hypertension in resistant cases? Lessons from a patient with progressive renal failure

Manuel Esteban Nivelo-Rivadeneira[1], Isabel Ramos-Gomez[2], Maria Dolores Perez-Ramada[2], Ana Delia Santana-Suarez[1], Agnieszka Kuzior[1], Paula Fernandez-Trujillo-Comenge[1], Carmen Acosta-Calero[1], Claudia Arnas-Leon[3], Sara Quintana-Arroyo[3] & Francisco Javier Martinez-Martin[4]
[1]Endocrinology & Nutrition Department, University Hospital of Gran Canaria Doctor Negrin, Las Palmas de Gran Canaria, Spain; [2]Internal Medicine Department, University Hospital of Gran Canaria Dr. Negrin, Las Palmas de Gran Canaria, Spain; [3]Endocrinology & Nutrition Department, Hospitales San Roque, Las Palmas de Gran Canaria, Spain; [4]Outpatient Hypertension Clinic, University Hospital of Gran Canaria Doctor Negrin, Las Palmas de Gran Canaria, Spain.

Introduction
Even though most hypertensive patients have essential hypertension, in the resistant cases the prevalence of secondary hypertension is much higher; therefore its screening should be mandatory. Resistant hypertension usually causes a progressive decline of renal function if blood pressure is not adequately controlled. Such decline is often irreversible; however a timely diagnosis leading to a resolutive treatment can alleviate or even revert the progression of the renal disease.
Clinical case
A 66 year old woman had been diagnosed of essential hypertension when she was 49 years old. She was treated with a combination of Fosinopril, Telmisartan, Amlodipine and Hydrochlorothiazide but her blood pressure was usually $>160/100$ mmHg; she had nephrotic syndrome with proteinuria >5 g/24 h and her eGFR was deteriorating (83 ml/min/1.73 m^2 in 2013, 40 ml/min/1.73 m^2 in April 2017). After complaining of abdominal pain, she was diagnosed of sigmoid adenocarcinoma, and underwent successful surgical rejection. In the presurgical workup, an incidental mass measuring 4.3x1.7 cm was found on top of the left adrenal in a CT scan, and she was referred to our Endocrinology Clinic. Lab tests showed metanephrin 117 pg/ml, normetanephrin 1464 pg/ml and cromogranin A 159.9 ng/ml. A MIBG/SPECT CT showed isolated hypercaptation next to the left adrenal. After adequate preparation, on 25/04/2017 a 4.3-cm mass was resected along with the adjacent left adrenal, which was normal. The final pathology diagnosis was paraganglioma (KI-67 negative, cromogranin A positive) without extracapsular extension. One month after surgery the patient was asymptomatic with normal blood pressure (113/67 mmHg) under treatment only with Manidipine 10 mg/day. The eGFR has improved (60 ml/min/1.73 m^2), albuminuria had decreased dramatically (232 mg/24 h) and cromogranin A and metanephrines were normal.
Conclusions
This case illustrates the importance of the etiologic diagnosis and treatment in secondary resistant hypertension. The patient was relentlessly progressing to end-stage renal failure but presently her blood pressure is well controlled while minimally treated, and her renal function has markedly improved.

Association of pheochromocytoma and neurofibrematosis type1: about 4 cases

Halima Fennoun, Siham El Aziz, Amal Mjabber & Asma Chadli
The Endocrinology Department of IBN Rochd University Hospital, Casablanca, Morocco.

Introduction
Pheochromocytoma is rarely associated with neurofibromatosis type 1 (NF1). We report 4 observations of hospitalized patients in theIbn Rochd University Hospital endocrinology department in Casablanca.
Observation 1
A 52-year-old male patient was admitted for NF1-associated malignant pheochromocytomawith paroxysmal hypertension, Menard triad, elevated methoxylated urinary derivatives (DMU), and 11 * 8 cm right adrenal mass with hepatic metastasis. A surgical excision of the mass was performed with death of the patient following a hemorrhagic shock.
Observation 2
A 62-year-old patient was admitted for bilateral pheochromocytoma associated with NF1. He had hypertension, Menard triad, and two right (10 * 9 * 8 cm) and left (2 cm) adrenal masses, with no extra-adrenal localization. Bilateral adrenalectomy was performed. Pathological study showed a right pheochromocytoma complete excision with left adrenal hyperplasia. We rated a persistence of a moderate hypertension.
Observation 3
A 26-year-old patient, was operated 4 times for a face shwanoma, was admitted for pheochromocytoma associated with NF1. He had hypertension without menard triad, raised DMU, and left adrenal mass of 3 cm. He died 1 month later by cerebral involvement.
Observation 4
A 22-year-old patient was admitted for pheochromocytoma associated with NF1 discovered by incomplete Menard triad, elevated DMU, right adrenal mass (68 × 80 mm) including IVC in its inferior vena cava retrohepatic portion. Patient did not receive a surgical excision.
Discussion
Our observations illustrate the need to look for pheochromocytoma in any patient with NF1 because of its serious consequences.

A retrospective audit on the peri-operative management of phaeochromocytomas: "Phenoxybenzamine or Doxazosin"?

Yun Ni Lee, Edel Casey, Asfand Baig Mirza, Sasala Wickramsinghe, Stuart Jones, Zoltan Nagy, Imran Syed, Anand Kelkar, Nemanja Stojanovic, Antony Pittathankal, Raj Tanday & Khash Nikookam
Barking, Havering and Redbridge University Hospitals NHS Trust, Greater London, UK.

Phaeochromocytomas are rare catecholamine secreting tumours with an incidence of 1:4500–1:1700 in the United States. Doxazosin and Phenoxybenzamine are alpha-1 selective and non-selective alpha blockers respectively which are commonly used to treat this condition peri-operatively. There are no randomized controlled studies comparing the effectiveness of these two medications. However, there are retrospective studies comparing these two medications; some favouring alpha-1 selective blockade and some showing no difference.

Aim:

To compare and contrast the effectiveness of Phenoxybenzamine and Doxazosin in treating phaeochromocytomas at our centre.

Methods:

Retrospective data collection of phaeochromocytomas, identified from elevated urinary metanephrines from the laboratory and coding for adrenalectomies over a five year period.

Results:

12 out of 171 patients with elevated urinary metanephrines had confirmed, 11 phaeochromocytomas and 1 paraganglioma. 11 out of 31 adrenalectomies performed were for phaeochromocytomas. Mean age of our cohort was 54 years, with 7 (58.3%) Males and 11 (91.6%) Caucasians. All patients were on beta blockers peri-operatively. In the Doxazosin group: $n=8$(66.7%), Mean pre-operative blood pressure (BP) = 128/80 mmHg, Mean intra-operative BP = 122/72 mmHg, Mean highest systolic and diastolic BP intra-operatively was 159 and 90 mmHg respectively, Mean length of surgery was 4 hours 15 minutes, Mean intra-operative fluids prescribed = 3.6 L, 4 patients(50%) were given other agents to control the BP intra-operatively ranging from 1 to 3 different agents. In the Phenoxybenzamine group: $n=4$(33.3%), Mean pre-operative BP = 121/73 mmHg, Mean intra-operative BP = 125/69 mmHg, Mean highest systolic and diastolic BP intra-operatively was 164 and 92 mmHg respectively, Mean length of surgery was 4 hours 40 minutes, Mean intra-operative fluids prescribed = 3.17 L, 1 patient(25%) was given 3 agents to control the BP intra-operatively.

Conclusion:

Doxazosin seems to be as effective as Phenoxybenzamine in the peri-operative management of this condition. Even though there were more patients in the Doxazosin group requiring other intra-operative agents to control the BP, it was not statistically significant ($\chi=0.6857$, $P=0.408$). Ideally, we need a bigger cohort to have the power to demonstrate the true significance of the differences between the two medications. There are a number of limitations in this audit, in particular, the sample size and the rarity of this condition. The experience of the anaesthetist could also be a contributing factor for the use of other agents intra-operatively.

25-OH vitamin D concentration and inflammation indicators in patients with non-functioning adrenal incidentalomas

Joanna Kowalska[1], Iwona Zieleń-Zynek[1], Justyna Nowak[1], Karolina Kulik-Kupka[1], Agata Kulpok[2] & Barbara Zubelewicz-Szkodzińska[1,2]
[1]Department of Nutrition-Related Disease Prevention; School of Public Health in Bytom, Medical University of Silesia, Katowice, Bytom, Poland; [2]Department of Endocrinology, Piekary Medical Center, St. Luke's Local Hospital in Piekary Ślęskie, Piekary Ślęskie, Poland.

It is a well-known fact that vitamin D has an impact on many tissues of human body. Recent studies showed that vitamin D deficiency has an influence on inflamation indicators in several endocrine diseases (for example PCOS, graves disease). The aim of the study was to demonstrate correlation between 25-OH vitamin D concentration and chosen inflammation indicators (C-reactive protein and insulin) in patients with non-functioning adrenal incidentalomas. Seventy-one patients hospitalized in Endocrinology City Hospital in Piekary in 2015–2017 with non-functioning adrenal incidentalomas were included to the study. Exclusion criteria were adenomas producting hormones, vitamin D supplementation, liver or kidneys failure. Biochemical parameters (C-reactive protein, 25-OH vitamin D concentration, fasting glucose, insulin, HBA1C% and HOMA-IR) were obtained during routinely performed tests in the hospital and taken from the patient's medical record. Anthropometric parameters were measured in the morning hours, in light clothes. The results were used to calculate the anthropometric indicators (BMI, BAI, VAI, WHR, WHtR). The collected data were statisstically analyzed using the Statistica 12 ($P\leq0.05$). In the analyzed group mean concentration of 25-OH vitamin D was 20 ± 8.4 ng/dl, fasting glucose 111.5 ± 29.8 mg/dl, insulin 13.2 ± 7.9 uU/mL, HBA1C% 6.1 ± 0.7, HOMA-IR 3.8 ± 2.9, CRP 2.8 ± 1.1. Insulin concentration correlated possitively ($P\leq0.05$) with BMI ($r=0.46$), BAI ($r=0.21$), WHR ($r=0.12$), WHtR ($r=0.42$). CRP was statistically higher ($P\leq0.05$) in patients with higher BMI ($r=0.13$), WHR ($r=0.07$), WHtR ($r=0.10$). There was no signifficant correlation ($P>0.05$) demonstrated neither between 25-OH vitamin D and CRP nor 25-OH vitamin D and insulin. The study indicates that the measurement of anthropometric parameters (BMI, BAI, WHR and WHtR) could reflect CRP and insulin concentration in the analyzed group with non-functioning adrenal incidentalomas. Vitamin D concentration in the studied group of patients does not demonstrate correlation with chosen inflammatory indicators. It is worth to enlarge studied group to confirm obtained results.

Arterial hypertension from the adrenal gland: Prognosis and predictive factors of recovery after chirurgical treatment

Ibtissem Oueslati[1], Amel Melki[1], Melika Chihaoui[1], Meriem Yazidi[1], Fatma Chaker[1], Ons Rejeb[1], Nejib Ben Abdallah[2] & Hedia Slimane[1]
[1]Department of Endocrinology, La Rabta Hospital, Tunis, Tunisia; [2]Department of Endocrinology, Charles Nicolle Hospital, Tunis, Tunisia.

Background

Arterial Hypertension from the adrenal gland accounts for approximately 3% of diagnosed hypertension. The long-term surgical cure rate of patients with adrenal hypertension varies widely and causes of persistent hypertension are not completely established. The Aim of our study was to assess the prognosis of arterial hypertension from the adrenal gland and to determine its recovery predictive factors.

Methods

It was a retrospective, descriptive and analytical study including 67 patients with arterial hypertension from the adrenal gland (29 patients with primary hyperaldosteronism (group 1), 27 patients with pheochromocytoma (group 2) and 11 patients with Cushing's syndrome (group 3)). Adrenalectomy was performed in all patients. Clinical and paraclinical data were determined before and after surgery. Hypertension recovery was defined by a blood pressure $<140/90$ mmHg without any antihypertensive drugs. Predictors of recovery were determined by calculating Odds Ratios.

Results

After adrenalectomy, a significant decrease in blood pressure was obtained in all three groups. The cure rate for hypertension was 52% in group 1, 37% in group 2, and 55% in group 3. Clinical and paraclinical profiles of patients recovered were comparable to those not cured in patients groups 1 and 3. In contrast, in group 2, cured patients had a lower prevalence of diabetes ($P=0.026$), a lower duration of hypertension ($P=0.003$), a lower LDL-cholesterol level ($P=0.022$), a higher creatinine level ($P=0.020$) and a lower prevalence of renal failure ($P=0.049$). For groups 1 and 3, we did not find any significant associations between recovery of hypertension and the most studied predictive factors in the literature, namely, young age, absence of family history of hypertension, duration of hypertension less than 5 years and the absence of overweight. However in group 2, the chances of curing hypertension were significantly multiplied by 10.1 in the absence of diabetes, by 8 in the absence of renal insufficiency and by 4.5 in the case of hypertension duration less than 5 years.

Conclusion

The persistence of hypertension after adrenalectomy could be the result of reduced ability to reverse pathological changes in the blood vessels or coexisting essential hypertension. Therefore, early screening and diagnosis, adequate hypertension control before surgery and management of associated comorbidities are mandatory in order to improve patients' outcome.

Metabolic and hormonal profile in primary aldosteronism as compared with essential hypertension

Raluca Trifanescu[1,2], Alexandra Smarandoiu[2], Andra Caragheorgheopol[2], Carmen Iordachescu[2] & Catalina Poiana[1,2]
[1]'Carol Davila' University of Medicine and Parmacy, Bucharest, Romania; [2]'C.I. Parhon' National Institute of Endocrinology, Bucharest, Romania.

Background
Primary aldosteronism is associated with increased vascular mortality and morbidity.
Aims
We aimed to assess metabolic and hormonal profile differences in patients with primary aldosteronism (PA) compared with patients with essential hypertension (EH).
Patients and methods
Thirty-one patients (11 M/20 F) with primary aldosteronism, aged 46.2 ± 12.9 years and 64 patients (24 M/40 F) with essential hypertension, aged 40.9 ± 13 years, were retrospectively reviewed. Plasma aldosterone and plasma direct renin were measured by chemiluminescence (CLIA).
Results
Systolic blood pressure was significantly higher in PA patients (214.1 ± 27.5 mmHg) than in patients with EH (197.8 ± 29 mmHg), $P = 0.02$, while diastolic blood pressure was similar. Body mass index tended to be higher in patients with EH (29.9 ± 6.4 kg/m^2) than in PA patients (27.8 ± 1.1 kg/m^2), $P = 0.07$. Serum fasting glucose, total cholesterol, HDL cholesterol, LDL cholesterol and triglycerides were similar between the two groups. PA patients had higher median midnight serum cortisol (4.3 μg/dl vs 1.83 μg/dl, $P = 0.057$), significantly higher median 0800 hrs. serum plasma cortisol after 1 mg dexamethasone suppression test (1.34 μg/dL vs 0.8 μg/dL, $P = 0.01$) and plasma metanephrines (50.4 pg/ml vs 29.4 pg/ml, $P = 0.048$) than patients with EH. Serum PTH levels were significantly higher in patients with PA (76.6 ± 23.7 pg/ml) than in patients with EH (46.7 ± 17.9 pg/ml), $P = 0.02$, while 25 OH vitamin D levels were similar.
Conclusion
PA patients showed a more severe systolic hypertension, with similar metabolic profile and an adverse hormonal profile with a slight cortisol and PTH excess.

Aortic root dilatation in primary aldosteronism: is treatment effective in reducing aortic damage?

Guido Zavatta[1], Guido Di Dalmazi[1], Carmine Pizzi[2], Eleonora Rinaldi[1], Elena Casadio[1], Silvia Ricci Bitti[1], Renato Pasquali[1], Uberto Pagotto[1] & Valentina Vicennati[1]
[1]Division of Endocrinology and Centre for Applied Biomedical Research, Department of Medical and Surgical Sciences, Alma Mater Studiorum, University of Bologna, Bologna, Italy; [2]Institute of Cardiology, University of Bologna, Bologna, Italy.

Introduction
Cardiovascular morbidity is more prevalent in primary aldosteronism (PA) than in essential hypertension. Preclinical studies have shown a possible association between ascending aorta dilatation and PA, probably mediated by the mineralocorticoid receptor.
Patients and methods
A total of 84 patients attending the Endocrinology Unit of the S. Orsola-Malpighi University Hospital of Bologna, (Italy) were evaluated. Thirty-nine patients had a diagnosis of PA. The control group (NS) consisted of 45 hypertensive patients with an adrenal adenoma or hyperplasia, in whom primary aldosteronism, hypercortisolism and pheocromocytoma were appropriately excluded. All patients underwent transthoracic echocardiographic assessment at baseline. Ten PA patients underwent adrenalectomy due to unilateral adrenal disease, whereas the remaining 29 PA subjects were treated with a mineralocorticoid receptor antagonist. The aortic root was measured on each echocardiographic assessment. PA patients underwent a further echocardiographic evaluation during follow-up.
Results
PA and NS groups were homogeneous as to age and body surface area. The aortic root was significantly higher at baseline in PA group as compared with NS group (34.9 ± 5.3 mm vs 32.2 ± 3.9 mm, $P < 0.01$). Age was significantly different between the surgically treated and medically treated PA patients (47.7 ± 9.1 years vs 57.1 ± 9.9 years respectively, $P = 0.01$). In PA group, the mean duration of follow-up was 4.2 ± 2.3 years. Within the surgically treated PA, the aortic root measured 34.9 ± 5.3 mm before adrenalectomy and 33.9 ± 4.9 mm at follow-up ($P = 0.47$). In the medically treated PA group, the aortic root measured 34.6 ± 4.7 mm at baseline and 35.1 ± 4.8 mm at follow-up ($P = 0.94$). Also, percentage variation did not show statistical significance in either group.
Conclusion
PA patients showed larger aortic roots as compared with a homogeneous hypertensive population. Our preliminary follow-up data suggest that treatment of primary aldosteronism might not reverse vascular damage, thus suggesting a pathogenesis of irreversible vascular fibrosis induced by aldosterone excess.

Long-term follow-up of congenital adrenal hyperplasia due to 11β-hydroxylase deficiency

Hamza Elfekih[1], Yosra Hasni[1], Wafa Badr[1], Asma Ben Abdelkrim[1], Bilel Ben Amor[1], Amal Maaroufi[1], Maha Kacem[1], Molka Chaieb[1], Moez Gribaa[2], Koussay Ach[1] & Ali Saad[2]
[1]Department of Endocrinology and Diabetology, Farhat-Hached University Hospital, Sousse, Tunisia. [2]Department of Cytogenetic and Reproductive Biology, Farhat-Hached University Hospital, Sousse, Tunisia.

Introduction
Congenital adrenal hyperplasia (CAH) due to an enzymatic defect in 11-beta-hydroxylase (11β-OHD) is the second most common cause of CAH representing 5-8% of cases. It is characterized by androgen excess, hypertension and hypokalemia. Here we describe the case of a patient having a CYP11B1 mutation and being followed-up during 33 years.
Observation
A 36-year-old Tunisian male was diagnosed with 11β-OHD at the age of three years revealed by precocious pseudopuberty. Laboratory findings was characterized by high serum concentrations of 11-deoxycortisol (656 nmol/l), high ACTH level (1500 pg/ml) and low plasma renin activity (0.7 ng/ml). A homozygous p.G379V mutation in exon 7 of the CYP11B1 gene was found. The patient was issued from consanguineous marriage. He had three other family members having the same disease and all treated by hydrocortisone. He had two healthy children aging respectively of three and one-year-old. Acute adrenal deficiency didn't occur during the follow-up. Hypertension associated with hypokalemia was discovered 23 years later and treated by calcium channel blocker. It has been complicated only by hypertensive retinopathy grade 1. The patient had a metabolic syndrome. He had an android fat distribution (BMI = 31.5 kg/m^2 and 102 cm abdomen circumference), a height of 169 cm, a normal external genitalia examination and bone density. The patient had normal glucose and triglyceride level with hypoHDLemia (0.23 g/l).
Discussion
CAH is an inherited autosomal recessive genetic endocrine disease. It is a group of diseases resulting from the deficiency of one of the steroidogenesis enzymes. 21-hydroxylase deficiency is the most common followed by 11β-OHD. In 11β-OHD, the p.G379V mutation found in our case in addition to the p.Q356X mutation have been described in Tunisian population. There is no systematic evaluation in adulthood of patients having 11β-OHD. Little is known regarding height, bone health, diabetes and mortality in those patients.

Rhabdomyolysis in a case with severe hypokalemia and Primary Hyperaldosteronism

Blertina dyrmishi[1], Taulant Olldashi[1], Majlinda Cani[1], Holta Sulaj[1], Entela Puca[2] & Ema Lumi[3]
[1]Hygeia Hospital Tirana Albania, Tirane, Albania; [2]UHC "Mother Teresa", Tirane, Albania; [3]Regional Hospital Korca, Korce, Albania.

Case Report
A 47 years old female was admitted to our hospital with muscle pain, weakness of the lower extremities, faligue, muscular cramps, nausea, anorexia and elevation of blood preasure. The muscular pain started 20 days ago and got worse over the last few days, she also had difficulty walking during these time. She denied fever, trauma history, vomiting, diarrhea and diuretic or statins use in the last days. The laboratory examinaition on admission showed severely low potassium values (1.4 mEq/L) and elevated values of creatine kinase, lactate dehydrogenase, troponin, myoglobin and aldosteron. Blood Gas Analysis revealed metabolic alkalosis.The patient had been under treatment for high blood pressure for more than six years, with ARBs and calcium channel blockers. Based on clinical, laboratory and imaging studies we suspected the diagnosis of of primary hyperaldosteronism associated with rhabdomyolysis due to severe hypokalemia as a cause was done. Treatment with I.V and oral hydration, Sol KCl and spironolactone was started. Our patient was wrongly diagnosed with essential high blood preassure. After admission to our hospital, we evaluated nad treated the patient, also prevented a potential acute renal failue from rhabdomyolysis and life-threatening arryhmias, and the diagnosis of Primary Hyperaldosteronism was made.

Keywords: Rhabdomyolysis, hypokalemia, CK, primary hyperaldosteronism.

Pheochromocytoma in young patient-challenges in clinical practice

Olivera Boskovic, Zlata Kovacevic & Milan Bogojevic
Clinical center of Montenegro, Podgorica, Montenegro.

A pheochromocytoma is a rare, catecholamine-secreting tumor that may precipitate life-threatening hypertension. The tumor is malignant in 10% of cases. Although pheochromocytoma has classically been associated with von Hippel-Lindau (VHL) syndrome, multiple endocrine neoplasia type 2 (MEN 2), and neurofibromatosis type 1 (NF1) there are now 10 genes that have been identified as sites of mutations leading to pheochromocytoma.
Method and materials A case report.
Results
We present a 27 years old patient with spontaneous hematoma of frontoparietal brain region. On digital subtraction angiography no vascular anomaly was detected. Intracerebral hematoma was in resorption in control with MRI. He had high blood pressure in several occasions, also he reported flushing in face during the physical activity and one to two mushy stools. During additional examination (ultrasonography and CT scan of abdomen) we found expansive mass in right suprarenal gland sized 70 mm, with postcontrast intensification. Chest X-ray was normal. Ultrasonography of thyroid showed nodule of 5 mm in right lobe. All day monitoring of blood pressure was in normal range. Examination of *fundus* of the *eye was normal. Echocardiographic ultrasound showed RVSP was* 28 mmHg, *tricuspid regurgitation 1+, and EDD of left ventricle 5.0 cm, ESD 3.3 cm and EF 63%. Immunological, hormonal status, plasma level of serotonin and tumor markers (NSE, CEA, CgA, calcitonin) were within normal range. Urinal catecholamine was repeated three times and was normal. Diurnal rhythm of cortisol was normal. Blood was taken for genetic analysis (VHL gene, TMEM, MLPA SDHx). Patient was prepared with* Phenoxybenzaminhydrochlorid and underwent surgery procedure. Histopathology tumor had 78 g sized 7×4.5 cm indicated it was Pheochromocytoma PASS 1/20 and immunohistochemically he was positive for CgA, Syn, S100, Ki67 < 0,1%. On the one year follow up abdominal MRI showed hyperplasia of left adrenal gland sized 20×13 mm. He still had episodes of high blood pressure and flushing. MIBG scintigraphy was normal. Hormonal and suppression test were normal. OGTT, tumor markers and catecholamine's were normal. Genetic study was negative for VHL MLPA and SDHx(B D C). TMEM and MAX (myc associated factor x) analysis are still in work. Scintigraphy of somatostatins receptors were normal. We preformed PET/CT with F18 DOPA, 231 MBq showed no signs of metabolic active disease.
Conclusion
In patients with spontaneous hematoma with no vascular anomaly, pheochromcytoma should be considered. Because of hyperplasia of left adrenal gland and undertaken analysis we decided for wait and watch

Opioid-induced secondary adrenal insufficiency

Oana Alexandra Petre[1] & Alice Albu[1,2]
[1]Elias Hospital, Endocrinology and Diabetes Department, Bucharest, Romania; [2]Carol Davila University of Medicine and Pharmacy, Bucharest, Romania.

Introduction
Opioids are commonly used for the treatment of pain, and their effects on the HPA (hypothalamic pituitary adrenal) axis may be under-recognised. In the present, a few non-systematic studies have investigated the effects of opioids on the HPA axis, but results have been conflicting. To our knowledge, there is only another case report of secondary adrenal insufficiency due to tramadol therapy, resulted in suppression on the HPA axis. We present the case of a 79 year old female who was referred to our clinic for endocrinological evaluation with a history of severe osteoporosis, treated with bisphosphonates and tramadol. At the referral, the patient was in mild distress due to the pain, with severe skeletal-muscle pain, fatigueness with the impossibility of maintain orthostatism, dispnea and dizziness. Clinical evaluation revealed normal blood pressure, IMC 34.7 kg/m^2 with pale skin. The paraclinic evaluation revealed undetectable values of ACTH <5 pg/ml with morning plasma cortisol concentrations of 3.14 microg/dl, respectively 7.93 microg/dl. Cortisol levels from the Synacthen test were 26.8 microg/dl, 34.6 microg/dl at 30 and 60 minutes respectively, but the normal values were correlated with the recent adrenal insufficiency. An incidental finding of a pituitary microadenoma was found on MRI. A diagnosis of tramadol-induced adrenal insufficiency was made. Other drugs containing glucocorticoids were excluded from her recent treatment. After three months under prednisone therapy 5 mg/day, the values of morning plasma cortisol 6.5 microg/dl and ACTH 11.16 pg/ml, with significant clinical improvement. Her prolactin levels raised to 52.6 ng/ml (RR 1.9–25 ng/ml), possible due to her secretant pituitary microadenoma.
Conclusion
This case raises awareness of the potential of opioids to influence adrenal status and is important that opiates should be added to the list of differential diagnosis in patients with newly diagnosed secondary adrenal insufficiency.

Keywords: opioids, Synacthen test, secondary adrenal insufficiency.

Intracerebral hemorrhage as a first sign of pheochromocytoma

Sandra Pekic Djurdjevic[1,2], Vladimir Jovanovic[2,3], Goran Tasic[2,3], Ivan Paunovic[2,4], Svetislav Tatic[2,5], Dusko Dundjerovic[2,5], Mirjana Doknic[1,2], Dragana Miljic[1,2], Marko Stojanovic[1,2], Zvezdana Jemuovic[1], Marina Nikolic Djurovic[1,2], Vera Popovic[2] & Milan Petakov[1,2]

[5]Clinic for Pathology, Medical Faculty, Belgrade, Serbia.

Pheochromocytomas and sympathetic paragangliomas are rare catecholamine-secreting tumors and represent very rare causes of intracerebral hemorrhage in young. Few cases of these neuroendocrine tumors which presented with intracerebral hemorrhage have been reported. A 32-year-old man presented to

our emergency department because of sudden onset of severe headache. He has a six months history of headache, palpitations and sweating. During examination he became somnolent and developed hemiplegia of the left side of the body. A computed tomographic scan of the brain showed a right temporoparietal hematoma. He was admitted to the Clinic for Neurosurgery and hematoma was evacuated. The patient was comatous, on assisted respiration and developed hypertensive crises. An examination for possible secondary causes of hypertension was undertaken. Plasma metanephrine value was elevated (414 pg/ml, reference values $<$90 pg/ml). Abdominal computed tomographic scans revealed a large mass (6 cm) in the right adrenal gland. After adequate control of the hypertension was achieved with an nonselective α and β adrenergic blockers, the tumor was excised. The histopathologic findings confirmed the diagnosis of pheochromocytoma. The genetic analysis demonstrated a duplication in exon 1 of VHL gene. We reported a rare, potentially fatal complication of pheochromocytoma, an intracerebral hemorrhage. This case and review of the similar rare cases in the literature illustrate the importance of early recognition of the characteristic symptoms of catecholamine excess in a young patient with hypertension.

Severe pheochromocytoma crisis, Type B, resulting in Takotsubo-like cardiomyopathy and fulminant refractory cardiogenic shock, successfully treated with extracorporeal membrane oxygenation (ECMO) but with fatal neurological sequelae for the patient.

Ernestini Tyfoxylou[1], Theodora Kounadi[1], Athina Markou[1], Labrini Papanastasiou[1], Liana Charalampidou[1], Evangelia Kyriazi[1], Nikolaos Voulgaris[1], Skampas Neoklis[2], Vlassios Pyrgakis[2] & George Piaditis[2]
[1]Department of Endocrinology and Diabetes, General Hospital 'G, Gennimatas', Athens, Greece; [2]Department of Cardiology, General Hospital 'G, Gennimatas', Athens, Greece.

Introduction
Catecholamine excess causes profound vasoconstriction, resulting in reduced intravascular volume. Pheochromocytoma crisis can be further complicated with acute stress (Takotsubo-like) cardiomyopathy, attributed to the toxic catecholamine effect on the myocardium, and cardiogenic shock leading to tissue ischemia.
Aim
To present a rare case of pheochromocytoma crisis, complicated with fulminant cardiogenic shock, which led to life-threatening end-organ damage.
Case report
A 34-year-old woman presented with a recent history of paroxysmal hypertension, palpitations and concomitant sweating. Echocardiogram and abdominal ultrasound had revealed a normal left ventricular ejection fraction (LVEF$>$55%) and a 7 cm mass in the right adrenal gland. Subsequently, she was admitted to the Endocrinology department, where hormonal workup showed elevated 24-h urine fractionated metanephrines and normetanephrines [18 266 μg/24 h (NR$<$800 μg/24 h) and 12 609 μg/24 h (NR$<$444 μg/24 h) respectively]. However, during the initial workup, the patient's condition deteriorated dramatically over a few hours, with no obvious physical, emotional or pharmacological triggering factor, following two episodes of hypertensive peaks (BP$\sim$200/120 mmHg) with symptoms of acute chest and abdominal pain, excessive weakness, sweating, pallor and wide fluctuations of blood pressure. Urgent electrocardiogram showed ST-segment depression in V4-lead and transthoracic echocardiography revealed a reduction of LVEF to $\sim$15% and a Takotsubo-pattern image of diffuse hypokinesia with apical ballooning. Phenoxybenzamine treatment was initiated immediately. Active haemorrhage or eruption of the adrenal tumour was excluded with emergency abdominal CT scan. The patient was transferred to the Cardiologic Intensive Care Unit, where her condition continued to deteriorate with abruptly elevated levels of cardiac enzymes and worsening tachycardia (160 bpm) non-responding to phenoxybenzamine and esmolol. Coronary artery angiography was normal. Despite attempts of cautious volume expansion the patient rapidly developed refractory cardiogenic shock, incipient multiple organ failure and hyperlactatemia (9 mmol/l) leading to intubation and initiation of central VA-ECMO support. Cardiac function was progressively restored and VA-ECMO was removed on day 12, with an LVEF$>$50%. Treatment with phenoxybenzamine was continued and right adrenalectomy was performed 18 days later. However, the patient's course had been complicated further with severe central nervous system damage, rhabdomyolysis and lower limb amputation due to thromboembolic events and hypoperfusion, with subsequent fatal hospital infections after a long-term ICU hospitalization.
Conclusion
Pheochromocytoma crisis can fulminantly develop into Takotsubo-like cardiomyopathy and refractory cardiogenic shock with fatal complications. In such perplexing cases, central VA-ECMO might be one of the few life-saving measures to be considered until myocardial function recovers allowing further management and surgical intervention.

Functionig adrenal incidentaloma false positive for 18F-FDG-PET/TAC

Serafino Lio[1], Roberta Scarpa[2] & Pietro De Bastiani[2]
[1]Department Internal Medicine-Endocrine Section-OC Oderzo-AULSS n.2, Oderzo-Treviso, Italy; [2]Department Internal Medicine-OC Oderzo-AULSS n.2, Oderzo-Treviso, Italy.

An adrenal incidentaloma $>$4 cm of size is considered suspected of malignancy and therefore often sent to the adrenalectomy for pathological verification. In these cases, in recent studies the role of 18F-FDG-PET / TAC has been evaluated. We report a case of 67 years old man hospitalized for abdominal pain, fever and oliguria in obese patient with a history of diabetes mellitus 2, chronic renal failure, arterial hypertension and subjected to PTCA about 10 years earlier for anterior descending coronary stenosis. The abdominal ultrasound shows hepatic steatosis, many microstones of the gallbladder and an adrenal lesion of about 4 cm. Blood and uroculture detect a gram positive sepsis and laboratory tests show a cholestatic jaundice with moderate hyperamylasemia as well as renal failure and worsening glycemic control. After a few days of adequate therapy with a marked improvement in clinical conditions and laboratory tests, the patient undergoes, a cholangioMRI that detects, in addition to cholelithiasis, a solid right adrenal lesion of 4.8 cm, without adipose content and with non-homogeneous enhancement. The 18F-FDG PET/CT in the suspicion of a malignant lesion has been performed which showed a hypermetabolism of the right adrenal adrenal lesion (SUV max 12.8). There was non uptake in other lesions. The dosage of adrenal hormones showed a pre-clinical hypercortisolism ACTH-indipendent with normality of mineralocorticoid serum levels and urinary metanephrines. The patient was sent to laparoscopic cholecystectomy and right adrenalectomy. The morphological and immunophenotypic pathological analysis show a picture of a mixed type adrenal oncocytoma.
In conclusion:
1. It is confirmed that adrenal incidentalomas $>$4 cm may not be malignant.
2. Also the 18F-FDG-PET/TAC positivity is not always specific to malignant lesion.
3. The adrenal oncocytoma, very rare adrenal tumor usually benign and non-functioning, can be considered in these cases.

Difficult Management of Autoimmune Polyglandular Syndrome Type 1

Denisa Petrescu[1,2], Cristina Alina Silaghi[1,2], Adriana Albu[3], Horatiu Silaghi[4], Ionela Lungu[1], Malina Suciu-Petrescu[5], Simona Bucerzan[6,7] & Carmen Emanuela Georgescu[1,2]
[1]County Emergency Hospital, Cluj Napoca, Romania; [2]Department of Endocrinology, 'Iuliu Hatieganu' University of Medicine and Pharmacy, Cluj Napoca, Romania; [3]Department of Medicine II, Cluj Napoca, Romania; [4]5th Department of Surgery 'Iuliu Hatieganu' University of Medicine and Pharmacy, Cluj Napoca, Romania; [5]Department of Pharmacology, Toxicology and Clinical Pharmacology, Cluj Napoca, Romania; [6]Pediatric Clinic I, Cluj Napoca, Romania; [7]Department of Pediatrics, 'Iuliu Hatieganu' University of Medicine and Pharmacy, Cluj Napoca, Romania.

Autoimmune Polyglandular Syndrome Type I (APS 1) is a rare monogenic disease, in which simultaneous or sequential dysfunctions of endocrine or nonendocrine glands appear. A 19-year-old woman was admitted for inappetence, nausea, vomiting, abdominal pain, chronic constipation, generalized paresthesia and vertigo. She was known with primary hypoparathyroidism (from the age of 5),

chronic autoimmune thyroiditis, mucocutaneous candidiasis, under treatment with calcitriol, calcium, magnesium and levothyroxine. The relevant clinical signs were periorbital, peribuccal and mucosae hyperpigmentation and in the areas exposed to pressure, but also hypotension and oligomenorrhoea. Laboratory assays revealed hepatocytolisis, hyponatremia (natrium: 118 nmol/l), hyperkalemia, hypoglycemia and hypocalcemia (ionic calcium: 4.05 mg/dl). Hormonal investigations indicated low cortisol value at 0800 h of 5.92 μg/dl, high ACTH level of 1092 pg/ml, decreased parathyroid hormone level of 2.5 pg/ml and normal thyroid stimulating hormone and free thyroxine values under levothyroxine. Follicle stimulating hormone (FSH) concentrations were high (23.4 μUI/ml), with low estradiol (<20 pg/ml), raising the suspicion of an ovarian insufficiency. The short Synacthen test revealed adrenal insufficiency. Taking into the consideration the association of the autoimmune diseases, the suspicion of APS1 was confirmed. An autoimmune hepatitis was excluded by specific negative antibodies. The endoscopy revealed chronic gastritis and the abdominal ecography indicated ovaries with follicular images. Large volumes of 0.9% saline were administrated and specific mineralocorticoid replacement was required. Hydrocortisone in bolus dose was adminstrated intravenous, and continued by oral therapy. After initiation of hydrocortisone treatment, a period of severe hypocalcemia followed, despite adequate intake of calcium and calcitriol. In contrast, under hydrocortisone substitution treatment, the menstrual cycle was adjusted, with normalization of estrogen and FSH levels at 2 months. In conclusion, we present a classic case of APS 1, but where hydrocortisone therapy for primary adrenal insufficiency has temporarily disturbed the calcium balance, but has normalized the ovarian function.

Pitfalls in differential diagnosis of adrenal masses

Ioana Alexandra Ambarus Popovici[1], Alina Chelaru[1], Laura Teodoriu[1], Raluca Balaceanu[1], Letitia Leustean[1,2], Cristian Ene Roata[3], Anda Tesloianu[4] & Cristina Preda[1,2]
[1]University Hospital 'St. Spiridon', Iasi, Romania; [2]University of Medicine and Pharmacy 'Gr. T. Popa', Iasi, Romania; [3]Regional Institute of Oncology, Iasi, Romania; [4]Pneumophtisiology Clinical Hospital, Iasi, Romania.

Introduction
Primary adrenal insufficiency (PAI) is a potentially life – threatening condition. About 75–80% of cases of PAI are caused by autoimmune destruction, while TB accounts for 7–20% of cases; however, adrenal tuberculosis is still the primary cause of PAI in developing countries. Adrenal tuberculosis is difficult to diagnose because symptoms are non-specific. Moreover, if the patient had no prior contact with TB patients, no past history of pulmonary TB and no active pulmonary lesions at presentation, the diagnosis is more difficult. The diagnosis is therefore often delayed and patients may first present with a life-threatening crisis.
Case report
An 63-year-old male patient was admitted in surgical department for important weight loss (30 kg in 12 months), weakness, nausea, fatigue and loss of appetite, mental confusion and dizziness. A chest and abdominal CT-scan with intravenous contrast revealed multiple mediastinal adenopathies and bilaterally enlarged adrenal glands with unomogenous nodular lesions (on the right – 16/13/22 mm, on the left – 50/38/47 mm) with diffuse calcifications and heterogeneous peripheral enhancement, highly suggestive for malignant tumors. He was directed to our clinic for specific investigations. At admission he was semiconscious and had low blood pressure – 90/60 mmHg and heart rate – 90/min. On physical examination slightly hyperpigmentation of the skin and buccal mucosa was observed. Blood results revealed hyponatremia, hyperpotassemia, *hypochloremia* and hypoglycemia. Serum cortisol level was <1 μg/dl and serum ACTH was >1250 pg/ml, confirming primary adrenal insufficiency and high dose intravenous hydrocortisone therapy was initiated rapidly. The patient general symptoms greatly improved under iv Hydrocortisone and he was redirected for surgical intervention, undergoing left suprarenalectomy. Histopathological examination revealed typical granulomatous inflammation with Langhans giant cells and caseous necrosis, the tissue PCR test confirming the presence of *Mycobacterium tuberculosis*. The patient was transferred to a tuberculosis hospital for specific treatment, a combination of four drugs was administered in addition to oral Hydrocortisone and Fludrocortisone. Over the next few weeks the patient's status markedly improved.
Conclusions
Computed tomography play vital role in the diagnosis of the PAI etiology, yet CT findings cannot always differentiate TB from other adrenal pathologies such as fungal infections, hemorrhage or malignancy. In our case, malignancy could not be excluded without first obtaining tissue for pathological examination. Adrenal TB is rare but an important disease entity that must be identified early, requiring prompt treatment with antituberculosis drugs and appropriate steroid therapy.

Introduction
Multiple endocrine neoplasia type 1 (MEN1) is an autosomal-dominant hereditary disorder characterized by the presence of two of the three main endocrine tumors that are parathyroid, pituitary adenomas and enteropancreatic tumors.
Case-report
We report a case of a 71-year-old obese patient with repeated unsuccessful attempts to weight loss who was admitted to the surgical department for the bariatric treatment of obesity (BMI = 48,22 kg/m^2); the preoperatory evaluation discovered hyperparathyroidism and an adrenal adenoma. Evaluated in the Iaşi Endocrinological Department, was diagnosticated also with non-functional pituitary macroadenoma and anterior pituitary insufficiency, two non-functional neuroendocrine pancreatic tumors and Recklinghausen neurofibromatosis. He underwent minim invasive partial parathyroidectomy due to high calcium level with local anesthesia, but with recurrence of hyperparathyroidism after 6 months. He initially refused pituitary or pancreatic surgery, now is reconsidering pituitary surgery due to high anesthesic risk for the next subtotal parathyroidectomy. The pancreatic tumors was nonsecreting and no evolutive signs during 2 years. Family investigation revealed son with primary hyperparathyroidism (operated) and prolactinoma (Cabergoline), one daughter with primary hyperparathyroidism (operated) and pituitary prolactinoma (Cabergoline) and one daughter with hyperprolactinemia. The grandchildren were clinical investigated (no endocrine tumors) and genetical tested.
Conclusions
We reported a rare case of familial syndrome of Multiple Endocrine Neoplasia type 1 and simultaneous occurrence of bilateral adrenal adenomas and Recklinghausen neurofibromatosis in a patient clinically diagnosed as having MEN type 1.
Keywords: Multiple endocrine neoplasia 1, primary hyperparathyroidism, prolactinoma, Recklinghausen neurofibromatosis.

Primary adrenal lymphoma in an HIV patient: a rare case of bilateral adrenal tumors

Maria Mavromati, Olivier Nawej, Olga Tsopra, Heba Al-Alwan, Francois Jornayvaz & Jacques Philippe
University Hospital of Geneva, Geneva, Switzerland.

A 44-year old male patient with HIV-1 stage C2 presented with intermittent fever and weight loss (10 kg in 3 months). He was being treated with tenofovir/emtricitabine and atazanavir, and had a CD4 levels of 705/mm^3 and HIV viral load of 1400 copies/ml. Upon admission, the complete blood panel showed anaemia and thrombocytopenia (haemoglobin: 75 g/l, platelets: 98 G/l), normal white blood cell count, normal hepatic tests and renal function, normal electrolytes and an elevated CRP (85 mg/l) and erythrocyte sedimentation rate (990 mm). Abdominal CT-scan showed bilateral adrenal tumours, 10×9×15 cm on the right and 11×8×6 cm on the left, without invasion of adjacent structures. PET-CT scan showed intense hypermetabolism of the adrenal masses. Bone morrow biopsy and flow cytometry were negative for lympho-proliferative disease. Plasma fractionated free metanephrines were normal, excluding pheochromocytoma. The patient had no physical signs of Cushing disease and morning plasma cortisol was 291 nmol/l. An adrenal biopsy was performed which showed primary effusion lymphoma, solid variant. The patient received chemotherapy treatment (associated with high dose glucocorticoids) which led to clinical improvement

and shrinkage of the adrenal masses (4×4 cm on the right and 3×2 cm on the left) at 4 months follow-up. Nevertheless, PET hypermetamolism of the adrenals persisted and right adrenalectomy was decided in order to rule out persistent disease. At that time, the patient had primary adrenal insufficiency, with low plasma cortisol levels (18 nmol/l in the morning and 211 nmol/l 1-h after injection of ACTH 250 mg) and high morning ACTH (75 ng/l). Histology confirmed disease remission. Differential diagnosis of bilateral adrenal masses includes bilateral pheochromocytoma, adrenal metastasis, bilateral adrenal carcinoma, haemorrhage, infection, congenital adrenal hyperplasia etc. Primary adrenal lymphoma is a rare cause, but is associated with adrenal insufficiency in more than 50% of cases. This is a rare case of extracavitary primary effusion lymphoma, solid variant, often associated with HHV8 infection, which was also found in our patient.

High Adrenocorticotropic Hormone before and after bilateral adrenal surgery

Ana Valea[1], Roxana Turturea[2], Oana Botezan[2], Mara Carsote[3], Bogdan Mircea Botezan[4] & Carmen Emanuela Georgescu[1]
[1]I. Hatieganu University of Medicine and Pharmacy & Clinical County Hospital, Cluj-Napoca, Romania; [2]Clinical County Hospital, Cluj-Napoca, Romania; [3]C.I. Parhon National Institute of Endocrinology, Bucharest, Romania; [4]Rehabilitation Hospital, Cluj-Napoca, Romania.

Introduction
Paraneoplastic Cushing syndrome is a rare form of endogenous ACTH (adrenocorticotropic hormone) dependent hypercortisolism. In some cases no overt ACTH secretion tumor can be found, which is why steroidogenesis inhibitors, and bilateral adrenalectomy remain the main therapeutic options.
Material and method
This is a case report investigated in several centers by performing biochemical, hormonal and imagery tests.
Case report
A 52-year female, without medical personal history was admitted for marked asthenia, muscle weakness, polyuria and polydipsia. Clinical examination revealed central obesity (BMI of 30 kg/m^2), enlarged supra-clavicle fat pads, blood pressure of 150/80 mmHg, hyperpigmented skin, legs edema. Hormonal profile showed high levels of morning plasma cortisol (634 mg/dl, normal 5–25 mg/dL), with loss of circadian rhythm, very high CLU (free urinary cortisol), of 4728 mg/24 h (normal 50–190 mg/24 h), high ACTH level (619.9 ng/l, normal 7.2–63.3 ng/l), non-suppression at low dose DXM (dexamatasone) and 2 day of 8 mg DXM, high testosterone level (2.16 ng/ml, normal 0.2–0.75 ng/ml). Biochemical parameters indicated hyperglycemia and high HgA1c (glycated hemoglobin of 10.2%, normal 4.8–5.6%), hypercholesterolemia, low potassium (1.84 mmol/l, normal 3.5–5.1 mmol/l), and hypocalcemia. No morphological changes were found on pituitary MRI (magnetic resonance imaging) and pulmonary CT (computed tomography) scan. Abdominal CT scan showed bilateral hyperplasia. PET-CT scan (positron emission tomography) revealed an uncertainty mesenteric mass measuring less than 1 cm. Diagnosis of paraneoplastic Cushing syndrome was established. All neuroendocrine tumor markers were in the normal reference range. Potassium supplements, insulin and methyrapone therapy were started, followed by bilateral adrenalectomy. A month later obvious clinical and biochemical improvement was achieved under therapy with glucocorticoid and mineralocorticoid therapy. Because ACTH level is still high (of 1329 pg/ml) a careful follow-up is required. The primary site of neoplasia is still under investigation.
Conclusion
Diagnostic and treatment of paraneoplastic Cushing syndrome are essential for limiting the metabolic consequences and improvement quality of life. Long life follow-up is needed especially for variants without obvious tumor.

Addison's disease due to bilateral adrenal hemorrhage as the first presentation of diffuse large B-cell lymphoma

Antonela Sabati Rajic, Tina Krokter Kogoj & Tomaz Kocjan
University Medical Centre Ljubljana, Ljubljana, Slovenia.

A 49-year-old previously healthy man suddenly felt severe and constant bilateral lumbar pain. Clinical examination was otherwise normal. Abdominal CT scan showed subacute hematomas in both adrenal glands (sized 10 cm right and 8 cm left). Basic laboratory tests were completely normal. Hormonal testing excluded pheochromocytoma and other hormonally active adrenal tumors. Adrenal insufficiency was confirmed by short Synacthen test and substitution therapy with hydrocortisone was introduced. Mineralocorticoid supplementation was not needed. Prolonged closure times and platelet dysfunction on aggregometry were also found. History for previous bleeding episodes in the patient and his family was negative. Tests for antiphospholipid syndrome were borderline positive. Repeated abdominal ultrasound (US) examinations showed a decrease in size of both adrenal hematomas, so the patient was discharged with hydrocortisone supplementation. Three weeks later, few days before the planned outpatient follow-up visit, patient sought medical help because of worsening bilateral lumbar pain and extreme weakness. Diagnosis of adrenal crisis was made, so he was admitted and treated with intravenous hydrocortisone and analgesics. Several follow-up US exams showed a gradual increase in size of both adrenal hematomas. Follow-up CT scan confirmed further hemorrhage in both adrenals, the diaphragm and the lower part of the left kidney. Angiographically, several microaneurysms were shown in the parenchyma of both kidneys, without active bleeding. Only on contrast-enhanced US solid formations in both adrenals and in left kidney were visible. Fine needle aspiration biopsy of the tumor in the right adrenal was not diagnostic, however, histological biopsy confirmed diffuse large B-cell lymphoma. 18F-FDG-PET-CT showed disseminated disease with the involvement of both adrenals, kidneys, small intestine and pelvis. The patient was transferred to oncology. Bilateral adrenal bleeding is most commonly caused by trauma, anticoagulation treatment, sepsis, surgery, antiphospholipid syndrome, bilateral pheochromocytoma or metastases. Of note, radiological picture of bilateral adrenal bleeding may be mimicked by lymphomas and bilateral metastases of malignant melanoma. When solid tissue is confirmed by imaging, definitive diagnosis could be made by biopsy, but only after exclusion of pheochromocytoma. Large, bilateral adrenal tumors may cause Addison's disease, which, if left unrecognized, may also endanger the patient.

17- α hydroxylase deficiency in an adult female patient with hypertention and hypokalemia

Eleni Georgiou, Dimitra Pappa, Pinelopi Thoda, Anastasia-Konstantina Sakali, Ioannis Gountios & Alexandra Bargiota
Department of Endocrinology and Metabolic Diseases, University Hospital of Larissa, Larissa, Greece.

Introduction
17- α hydroxylase deficiency, an autosomal recessive disorder, is a rare cause of Congenital Adrenal Hyperplasia (CAH). The disease is usally diagnosed during infancy and childhood. We present here a rare case of an adult woman with 17-α hydroxylase deficiency diagnosed for first time in adulthood.
Presentation
A 49 year old woman, with no previous medical history came to the emergency department of our hospital unconscious with GSC 3-4/15. A CT head revealed a cerebral hemorrhage for which the patient had surgery and was transferred to the intensive care unit (ICU). In ICU she had persistent hypertension and severe hypokalemia not responding to treatment. From her history and the clinical examination revealed lack of any secondary sexual characteristics and the patient had never had menstrual cycle. Biochemical examination showed severe hypokalemia (K 2.7 mmol/l) , metabolic alcalosis (PH 7.496) and basal serum cortisol was very low (0.925 μg/dl). ACTH (406 pg/ml) and progesterone (24.24 ng/ml) were elevated and she had high FSH (143 mIU/ml) and LH (46.66 mIU/ml), low estrogen (5 pg/ml), low plasma rennin (3.7 pg/ml), 17-OH-Pg (0.6 ng/ml), and testosterone (0.025 ng/ml). An abdominal CT performed which showed hyperplasia of both adrenal glands, (6.5 cm in diameter) and she had a normal female karyotype (46XX). Based in the above findings the diagnosis of 17-α hydroxylase deficiency was made and treatment with dexamethasone 0.5 mg and spironolactone 100 mg twice a day was initiated which resulted in blood pressure control and correction of the hypokalemia. The patient had a sister who had intra-abdominal testes removed in childhood, ambigous external genitalia, a male karyotype (46XY) and normotensive. Hormonal evaluation showed a very low serum cortisol, 17-OH-Pg, estrogen, testosterone and plasma rennin while ACTH, FSH, LH, progesterone were increased.
Conclusions
17- α hydroxylase deficiency is a rare form of CAH which can be underdiagnosed. Presenting features may vary within affected members of the same family. Blood pressure measurements should be carried out in all females presenting with hypogonadism and if hypertension is present 17- α hydroxylase deficiency might be suspected.

Li-Fraumeni syndrome and adrenal tumours: case report

Mariana Tomé[1], Jessica Guarino[1] & Marta Iturregui[2]
[1]Hospital Punta de Europa, Algeciras, Spain; [2]Hospital Quirón Campo de Gibraltar, Algeciras, Spain.

Introduction
Li-Fraumeni syndrome is a rare disorder that greatly increases the risk of developing several types of cancer, particularly in children and young adults. It is a hereditary disease with high penetrance autosomal dominant transmission that is due, in 70% of the cases, to germline mutations in the gene TP53. The most common cancers associated with this disorder are brain tumors, sarcomas, breast cancer and adrenocortical tumors.
Methods
We describe the case of a young female brought by her parents to our clinic after observing premature pubarche.
Results
We report the case of a 2-year-old female with pubarche since 18 months old. Her parents had not observed any other sign of androgenisation. At inspection we observed grade 3 pubarche with clitoral hypertrophy and no premature telarche. Blood test showed pre-puberal gonadotropins and 17-β-Estradiol; markedly elevated androgens: DHEA-S 3640 µg/dl (Normal Range 33–280), 17-OH-Progesterone >20 ng/ml, Testosterone 1.9 ng/ml ($N<0.8$ ng/ml for adult women) and cortisol 23 µg/dl (Normal range: 5–20). Suspecting an adrenal tumour we performed an MRI showing a mass of 4.5 cm in left adrenal. Adrenalectomy was performed less than one month later showing a lesion with capsule conservation, very low mitotic index and a minimum focus of vascular invasion. This lesion was considered as benign as it did not meet the criteria of a malignant lesion. A complete family history was made: on her maternal branch she had a cousin of 2 years old recently diagnosed of adrenal carcinoma. No other history of tumours on this side of the family. Two of her father aunts died of cancer under the age of 30 years old (breast cancer and brain tumour). Genetic study showed a mutation in c375G$>$A of TP53 gene in our patient confirming the diagnosis of Li Fraumeni Syndrome. Both parents are being studied and also his little cousin. After surgery all androgen levels normalized and no new lesions had been discovered in periodic abdomen ultrasounds.
Conclusions
Although Li Fraumeni syndrome is a rare disease we should consider it as a possible diagnosis in young patients with adrenal tumours. We should remember the association of this disorder and adrenal carcinoma and take it in consideration during follow up in patients with diagnosis of Li Fraumeni Syndrome.

Paraganglioma of the prostate: a case report

Mehdi Kalthoum, Faten Hadjkacem, Mouna Elleuch, Dorra Ghorbel, Nadia Charfi, Manel Naifer & Mohamed Abid
CHU hedi Chaker, Sfax, Tunisia.

Introduction
Extra-adrenal paragangliomas are neoplasms arising from cells of neural crest origin anywhere along the distribution of the sympathoadrenal neuroendocrine system. Nearly 85% are intra-abdominal, 12% are intrathoracic, and 3% are cervical. 1 Some of the unusual sites for paragangliomas include the kidney, urethra, urinary bladder, prostate.
Case report
A 27-year old man presented with sever hypertensive crisis. He had a medical history of high blood pressure since the age of 15 years old. The patient had recurrent crises of three classic symptoms of pheochromocytoma: headache, swatting and heart palpitation in association with markedly elevated blood pressure (220/100 mmHg). These crises are consistent and sever after ejaculation, associated with tremors weakness and abdominal pain. On exam the patient was 175 cm tall and weighed 94 kg. He had no signs of neurofibromatose type1, MEN type 2 or Von Hippel-Lindau syndrome. Laboratory data showed elevated metanephrines in 24-h urine collection for three consecutive days (20.94 µmol/l >4 times the upper limit of normal). NSE level was high 54.1 ng/ml (12.5–25). MRI of the body showed normal size prostate with a nodule on the right side measuring 9 mm, T_2 hyperintense with microcalcification. Adrenal glands were normal and no other lesions were seen on the rest of the body. MIBG sintigraphy showed no uptake (physiologic uptake in the urinary tract). Prostatectomy was indicated after medical therapy preparation. Unfortunately surgery was refused by the patient.
Conclusion
Prostatic paragangliomas are very rare tumors, with no more than ten cases reported in the literature. Because of the nonspecific clinical symptoms, it is difficult to give a definite diagnosis preoperatively. Biochemical studies can confirm the diagnosis of pheochromocytoma. However topographic diagnosis remains a challenge in ectopic pheochromocytomas.

A new gene – TMEM127 – in familial pheochromocytoma/ paraganglioma syndromes

Mara Ventura, Isabel Paiva, Miguel Melo, Adriana Lages, Diana Oliveira, Diana Martins, Nelson Cunha, Lúcia Fadiga, Diana Catarino & Francisco Carrilho
Department of Endocrinology, Diabetes and Metabolism, Centro Hospitalar e Universitário de Coimbra, Coimbra, Portugal.

Introduction
Pheochromocytomas are catecholamine-producing tumors originated from the chromaffin cells of the adrenal medulla. Although usually sporadic, this tumors could be associated with germline mutations in about 40% of cases. TMEM127 has recently been identified as a novel gene conferring increased susceptibility to pheochromocytoma.

Case report
A 42-year-old woman was referred to our Hospital to perform a right adrenalectomy for pheochromocytoma. Months before she had hemoptysis, chest pain and arterial hypertension (180/120 mmHg) and performed a chest computed tomography that revealed a 6.5 cm right adrenal nodule with a density similar to liver parenchyma. During hospitalization, she presented several hypertensive peaks and performed an iodine-123MIBG Whole Body Scan that revealed increased uptake in the right adrenal gland. Urinary metanephrines and vanilmandelic acid were normal. She underwent phenoxybenzamine therapy and was submitted to right adrenalectomy by laparotomy. The histological exam confirmed the presence of a pheochromocytoma with probable aggressive biological behavior, proliferation index (Ki67) of 5% and preservation of the adrenal cortex. After the surgery, she presented normalization of blood pressure, normal values of urinary metanephrines and vanilmandelic acid and a slight elevation of chromogranin A, norepinephrine and 5-hydroxyindoleacetic acid. During the biochemical and imaging follow-up, the patient showed no signs of recurrence or new extra-adrenal foci and remains in regular surveillance without evidence of disease 7 years after surgery. A gene panel analysis was performed (SDHAF2,SDHB,SDHC,SDHD,VHL,MAX,TMEM127) and the c.202delG mutation in TMEM127 gene was found. A molecular study was carried out on first-degree relatives and two asymptomatic carriers (father and sister) were identified.
Discussion and conclusion
An increasing number of genes have been associated with familial pheochromocytomas/paragangliomas and are associated with different manifestations/risk of malignancy. Pheochromocytoma associated with this mutation is unilateral in 70% of cases and may be associated with the risk of extra-adrenal locations. We report the clinical case of a patient with familial pheochromocytoma with identified mutation in TMEM127 gene, present in heterozygosity. To the best of our knowledge, this is the first mutation in this gene described in the Portuguese population. The present case identifies an adrenal lesion with typical manifestations, with a histology suggestive of aggressive behavior, without manifestations of disease to date in the other two mutation carriers. These data emphasize the need for molecular study of a large panel of genes in patients with apparently sporadic pheochromocytoma.

Bilateral adrenal mass revealing a pheochromocytoma and an adrenocortical adenoma in a young women: a case report

Sara Atraki, Siham ElAziz & Asmaa Chadli
Endocrinology, Diabetology and Metabolic Diseases Department Ibn Rochd University Hospital of Casablanca, Morocco, Neurosciences and Mental Health Laboratory Faculty of Medicine and Pharmacy, University Hassan II, Casablanca, Morocco.

A 44-year-old women without personal or familial pathological history, presented 8 months before her admission a paroxystic symptomatology made of palpitations, headache and profus sweat associated with major abdominal pain, evolving in a context of alteration of the general state. Clinical examination objectified high blood pressure and tachycardia. Laboratory testing confirmed the diagnosis of pheochromocytoma. A computed tomography of the abdomen revealed a bilateral adrenal mass. The patient was treated with blood pressure treatment, specifically nicardipine and beta blockers, and surgical excision of the masses. Anatomopathological study objectived a right pheochromocytoma and left adrenocorticaladenoma. This case displays an atypical clinical presentation of bilateral adrenal masses.

Cushing's syndrome in a patient with systemic lupus erythematosus

Ifigenia Kostoglou-Athanassiou, George Spiliotis[2], Lambros Athanassiou[3] & Ioannis Myriokefalitakis[2]
[1]Department of Endocrinology, Asclepeion Hospital, Voula, Athens, Greece; [2]Department of Rheumatology, Asclepeion Hospital, Voula, Athens, Greece; [3]1st Department of Medicine, Asclepeion Hospital, Voula, Athens, Greece.

Introduction
Systemic lupus erythematosus is a systemic autoimmune disease, which often necessitates the administration of corticosteroids for its treatment. Cushing's syndrome is a disorder characterized by the endogenous hypersecretion of cortisol.
Aim
The aim was to describe the case of a patient who had systemic lupus erythematosus, was on therapy with corticosteroids and developed Cushing's syndrome.
Case description
A patient, female, aged 34, had systemic lupus erythematosus and was on therapy with corticosteroids. While on therapy with corticosteroids she developed depression, extreme fatigue, amenorrhea, face plethora and a buffalo's hump. Subsequently, she presented with a spontaneous fracture of the pubic rami, which she suffered while walking. The fracture was managed conservatively. Thereafter, the patient suffered a fracture of the left 5th metatarsal bone. A year later, she suffered a spontaneous rib fracture. Bone densitometry revealed a T-score of -2.5 in the lumbar spine. Corticosteroids were discontinued. Further laboratory evaluation revealed urinary cortisol 235 μg/24 h (normal range 3.5–45 μg/24 h), morning cortisol 17.7 μg/dl and ACTH 1.2 pg/ml (normal range 7.2–64 pg/ml). An MRI of the abdomen revealed the presence of an adenoma measuring 3×2 cm in her left adrenal. The adenoma was surgically excised. A month later laboratory evaluation revealed low morning cortisol and hydrocortisone was administered. Menses recommenced and face plethora was no more evident. Systemic lupus erythematosus was managed by azathioprine. A year later bone densitometry revealed a T-score of -2.2 in the lumbar spine.
Conclusions
In conclusion, the case of a patient with systemic lupus erythematosus is presented who developed Cushing's syndrome. Cushing's syndrome was due to the presence of an adrenal adenoma. In the case presented Cushing's syndrome manifested with amenorrhea, fatigue and spontaneous osteoporotic fractures in a very young patient. The diagnosis was masked by the therapeutic administration of corticosteroids. In a young patient spontaneous fractures should prompt a diagnostic evaluation for endocrine causes of osteoporosis.

Searching for the cause of high HCG in a man

Tejhmal Rehman, Ali Hameed & Gul Bano
St George's University Hospitals NHS Trust, London, UK.

Beta-human chorionic gonadotropin (β-hCG) is normally produced by syncytiotrophoblasts of the placenta and may also be secreted by germ cell neoplasms. An increase of serum hCG concentration in a male patient often suggests malignant neoplasms with a trophoblastic element. Common examples include classic seminoma with syncytiotrophoblast-like giant cells, combined germ cell tumour, and choriocarcinoma. Non-gestational choriocarcinomas typically arise from gonadal organs but they may originate in extragenital sites such as the mediastinum, retroperitoneum, pineal gland, liver, gallbladder, and urinary tract. Ectopic secretion of β-hCG is associated with a poorer prognosis. We present a 50 year old man who was referred to endocrine clinic with painful gynaecomastia of 3 months duration. He was waiting hip replacement. He had history of a lump in his left breast 9 years ago. He had USS and FNA. He was treated with some tablets for a month and discharged from breast clinic. He had no other past medical history. He worked as a physical trainer to metropolitan police. He did not smoke or drink and was on no medication. He had never used recreational drugs. His BMI was 26 kg/m^2. Examination and USS confirmed bilateral gynaecomastia. USS of the testes was normal with a small hydrocele on the left side. His blood tests showed FSH of <0.1 (1–10 IU/l), LH <0.1 (2–9 IU/l), testosterone 36.2 nmol/l (6.68–25.70), oestradiol 354 pmol/l (99–192), SHBG 44 noml/l (20.6–76.7) and his HCG was 250 IU/L (0–2). CT thorax, abdomen and pelvis was reported to be normal. His whole body bone scan was normal. His Repeat HCG in 6 weeks was 1265 and subsequently in 3 months increased to 3756. He underwent NM Whole body FDG PET CT which raised suspicion of an aggressive lesion in the anterior mediastinum with metastatic deposits in the lung. Mediastinal biopsy showed no unequivocal evidence of malignancy and a panel of immunohistochemical stains was not contributory. He had elective left anterior mediastinotomy +-VATS. Anterior mediastinal mass biopsies confirmed choriocarcinoma.

Syndrome carney-stratakis, new mutation report: SDH B: D138Y (c.412>T)

Ana Ruiz Serrano[1], Alessandra Gabillo Ciccia[1], Francisca Martínez Madueña[2], Salomé Martínez González[3], Josep Oriola Ambròs[4], Inmaculada Simón-Muela[1,5], Joan Vendrell Ortega[1,5], Silvia Näf Cortes[1,5], Theodora Michalopoulou Alevras[1] & Ana Megia Colet[1,5]
[1]Department of Endocrinology and Nutrition, Joan XXIII University Hospital, Tarragona, Spain; [2]Sant Joan of Reus University Hospital, Reus, Spain; [3]Pathological Anatomy Service, Joan XXIII University Hospital, Tarragona, Spain; [4]Hospital Clínic, Barcelona, Spain; [5]CIBERDEM, Tarragona, Spain.

Introduction
The Carney-Stratakis syndrome (CSS) is an inherited condition caused by germline mutations in succinate dehydrogenase (SDH) subunits B, C or D that predispose to gastric stromal tumors (GIST) and multicentric paraganglionas (PGL). SDH acts as a tumor suppressor gene, and enzyme activity reduction is known to be oncogenic. Since 2002 there has been some scarce reports. We present a new case of CSS associated with a germline unknown significance mutation in exon 4 of the gene that encodes SDH complex subunit B.
Case presentation
In July of 2016, a 52 year old women was referred to study a 94×97 mm abdominal mass in hepatic hilum. She had a past medical history of multiple PGL. In 1995 at 31 years old, underwent a retroperitoneal hyperfunctional PGL resection and since then she had performed subsequent clinical controls with annual catecholamines/metanephrines and bi-annual cervical and thoraco-abdominal examinations. Gene analysis revealed a germline mutation (c.412> T) in SDHB. The familial gene analysis showed that her mother and son were unaffected carriers. At the 2012 control CT, a 7 × 6 mm nodular lesion was detected in the left carotid bifurcation suggestive of PGL. Surgical therapy was discarded due the small size of the tumor. Neither increase nor new cervical PGL were observed during close follow-up and catecholamines and metanephrins remained negative. First, the patient was admitted to another hospital in context of abdominal and dorsal pain and an enhanced CT evidenced a pseudonodular hepatic image 94 × 77 mm in size with intrahepatic and extrahepatic portal thrombosis up to the head of the pancreas. The patient was referred to our hospital and a diagnostic study was started. NMR revealed an infiltranting intra-abdominal mass, with intraportal dissemination and a negative MIBG; Chromogranin A was elevated and neurospecific enolase and other tumor markers were Negative; Eco-endoscopy transgastric-PAAF was diagnostic of GIST (Positive to Vimentin, CD34, CD117, WT1; Ki-67 of 60%; Absence of mutations of the KIT gene). Final diagnosis and treatment: GIST T3N1M1 Stage IV. A 6 months partial response was observed with Imantinib, but it had to be suspended at 8th month because of morphometabolic worsening. Sunitinib was introduced and discontinued at second month of therapy for upper gastrointestional bleeding and liver function deterioration. Then palliative treatment with corticosteroids was started with clinical improvement and radiotherapy localized to hepatic hilium showed partial response; so it is decided to initiate Regorafenib.

Challenges in the diagnosis and treatment of GEP NEN: a case report

Kamil Stępiński[1,2], Paulina Gorzkowska[3], Michał Wrotyński[4] & Anna Jodkowska[2]
[1]Department of Nuclear Medicine and Endocrine Oncology, Maria Skłodowska-Curie Institute, Oncology Center, Gliwice Branch, Gliwice, Poland; [2]Department and Clinic of Internal and Occupational Diseases, Hypertension and Clinical Oncology, Wrocław Medical University, Wrocław, Poland; [3]Wrocław Medical University, Wrocław, Poland; [4]First Department of Cardiology, Poznań University Hospital of Lord's Transfiguration, Poznań, Poland.

Introduction
The GEP NEN (gastroentero-pancreatic neuroendocrine neoplasms) are 70% of all neuroendocrine tumors, but are rare in general population – constituting only 2% of the gastrointestinal tract neoplasms. Carcinoid stands for 50% of GEP NEN, most often located in the appendix and/or ileum. Although the detection of NEN is rising, their prevalence is still likely underestimated. The clinical presentation is not characteristic at the early stages of the disease, it varies among patients, what may make the diagnosis difficult to establish. We present a case of a man with certain clinical characteristics of carcinoid. Specific points suggesting a GEP NEN and critical to the clinical practice are discussed.
Case report
A 65-year-old man with the previous history of hypertension, atrial fibrillation with tricuspid valve insufficiency, DM2 and a few small liver haemangiomas discovered in 2013, was referred to internal diseases department in Wroclaw in 2016. He actually complained of poor hypertension controll, sporadic diarhoea, not significant weight loss. Performed abdominal CT scans revealed multiple large liver lesions both with enlarged regional lymph nodes of suspected metastastatic origin. Other CT scans and endoscopic investigations found no primary tumor, except few gastric erosions, diverticulosis coli and benign rectal polyp. On account of the patient's slight recurrent flushes reported in a deepened interview and echocardiography revealing endocardial fibrosis with advanced degeneration of the tricuspid valve (regurgitation), the GEP NEN was suspected. Performed Tectrotide somatostatin receptor scintigraphy SPECT CT Tc99m was negative, CgA concentration was 425ng/ml and finally liver biopsy material with immunohistochemistry confirmed metastatic NEN G1. Next PET CT 18F-FDG scan revealed metabolically active lesion in the ileum, which was confirmed in Galium 68 PET(neoplasm with high expression of somatostatin receptors of the smal intestine from dissemination to mesenteric lymph nodes and liver). Due to advanced heart failure the primary tumor of the ileum was not treated surgically. The patient receives chronically Sandostain LAR, he underwent also 177Lu Dotatate therapy in Oncology Center, Gliwice. The size and number of the liver lesions are under controll.
Conclusion
Carcinoid diagnosis needs various imaging techniques and histopathological evaluation, but clinically accuracy is of greatest importance. Incidental occurrence of liver lesions suggests the need for the GEP NEN screening, at least evaluation of CgA and/or CT control, especially in the case of accompanying the right heart valve abnormalities. Early treatment is crucial to avoid dissemination of the disease and life-threatening complications.

Ectopic adrenocorticotropic hormone syndrome: clinical features, diagnosis, treatment and long-term observation. Impact of bronchial carcinoid tumors

Vadim Krylov[1], Ekaterina Dobreva[2], Sergey Kharnas[1], Vladimir Parshin[1], Leonid Ippolitov[1], Nikolay Kuznetsov[2] & Georgy Polunin[1]
[1]Sechenov University, Moscow, Russian Federation; [2]Endocrinology Research Centre, Moscow, Russian Federation.

Objective
Ectopic adrenocorticotropic hormone (ACTH-ectopic) syndrome (EAS) is a rare cause of ACTH-dependent endogenous hypercortisolism. The objective of this study was to analyze the clinical, biochemical, and radiological features, management, and treatment outcome of patients with EAS.
Methods
It was a retrospective case-record study of 47 patients with EAS. Clinical, biochemical, and radiological features and response to therapy and survival rate were measured.
Results
The median follow-up was 7 yrs. (range, 1–13 yrs.). None of the dynamic tests achieved 100% accuracy. Imaging correctly identified the lesion at first investigation in 80.9% of cases. Bronchial carcinoid tumors were the most common cause of EAS ($n=27$; 57.5%), followed by other neuroendocrine tumors ($n=11$, 23.4%). In 19.1% (9) of patients, the source of EAS was never found. Octreotide scintigraphy and whole-body venous sampling were of limited diagnostic value. Surgical attempt at curative resection was successful in 81% (38 out of 47) of all patients; 9 (19.1%) responded generally well to bilateral adrenalectomy by vital indication. Tumor histology and the presence of distant metastases were the main predictors of overall survival ($P<0.05$).
Conclusions
Bronchial carcinoid tumors is the main cause of ACTH-ectopic syndrome. No single test was capable of finding the source of EAS correctly. Despite a variety of tests and imaging studies for the correct diagnosis of the EAS, up to 19% of cases present as occult EAS syndrome. These cases require a prolonged follow-up, review, and repetition of diagnostic tests and scans, but, in severe cases, bilateral adrenalectomy is performed.

Effect of ^{177}Lu-dotatate on severe, life-threatening, and refractory hypoglycemia associated with malignant insulinoma

Pedro Iglesias[1], Alberto Martínez[2], Pablo Gajate[3], Teresa Alonso[3], Teresa Navarro[2] & Juan José Díez[1]
[1]Department of Endocrinology, Hospital Ramón y Cajal, Madrid, Spain; [2]Department of Nuclear Medicine, Hospital Ramón y Cajal, Madrid, Spain; [3]Department of Medical Oncology, Hospital Ramón y Cajal, Madrid, Spain.

Malignant insulinoma is an extremely uncommon tumor (5–10% of insulinomas). It is accompanied by severe hypoglycemia and a short life expectancy (survival at 10 years <10%). Its clinical management is complex and constitutes a real therapeutic challenge. So far, the experience of radionuclide treatment in these tumors is scarce. We report the case of a 51-year-old woman diagnosed with pancreatic neuroendocrine tumor (pNET) in January 2013. Pre-surgical imaging study by abdominal CT scan showed a hypodense image in the tail of the pancreas with multiple liver metastases and large (up to 14 cm) ovarian masses. She underwent surgery on 09/01/2013 by exploratory laparotomy performing bilateral adnexectomy with pathological result of large cell neuroendocrine carcinoma (Ki-67 60%). The post-surgical [111In] DTPA-octreotide scintigraphy (Octreoscan) revealed hypercaptant lesions in the pancreatic tail, beginning treatment with lanreotide autogel 120 mg/28 days and sunitinib 37.5 mg/day, achieving a stabilization of the pancreatic and hepatic lesions. After tumor progression, she received six cycles of chemotherapy (cisplatin-etoposide) with partial response (50% size reduction) of the pancreatic lesion and stabilization of the liver metastases. After the 3rd cycle, she began to have severe and repeated hypoglycemic episodes with neuroglycopenic symptoms and frequent loss of consciousness even with seizures. Despite treatment with everolimus (10 mg/day for 3 months) and later with steroids (methylprednisolone, 32 mg/day), diazoxide (150 mg/day) and octreotide long-acting release (LAR) (30 mg/2 wk) the patient continued with frequent severe hypoglycemia (blood glucose 20 mg/dl, serum insulin 132 mU/ml and serum peptide C 18.7 ng/ml). On 21/07/2017, a first dose (177 mCi) of ^{177}Lu-DOTATATE was administered. After 10 days, the patient reported a clear clinical improvement, disappearing symptoms of hypoglycemia, showing an adequate control of capillary blood glucose throughout the day. In her last clinical visit in January 2018, after three doses of ^{177}Lu-DOTATATE (total dose 577 mCi), the patient continued without symptoms of hypoglycemia without the need to take diazoxide. The only treatment at this time was glucocorticoid replacement therapy and SSA (octreotide long-acting release LAR, 30 mg/2 wk). With this medication analytical study showed a blood glucose level of 115 mg/dl with normal serum insulin (20.3 mU/ml) and C-peptide (5 ng/ml) levels. In conclusion, ^{177}Lu-DOTATATE effectively and early controls severe hypoglycemia associated with malignant insulinoma. Therefore, we suggest its use in early stages of symptomatic disease not controlled with medication.

Morphological changes of the adrenal glands with hypertension with a crisis current

Victoriya Chobitko, Olga Maksimova, Marina Orlova & Arina Frolova
Saratov State Medical University Named V.I. Razumovsky, Saratov, Russian Federation.

Assess the morphology of focal lesions of the adrenal glands after adrenalectomy, compare the results with the nature of the course of hypertension, the level of blood pressure, age, sex of patients.
Materials and methods
Forty-four medical maps of patients operated on for focal formations of the adrenal glands were analyzed. The clinical symptoms, the hormonal activity of adrenal gland tumors - the level of cortisol, aldosterone, potassium, sodium, renin activity of blood, metabolites of catecholamines were analyzed.
Results
Thirty-two patients (72.7%) had adrenal hypertension, 12 (27.3%) had no hypertension. In the group of patients with adrenal hypertension, women predominated - 26 (81.3%) and 6 men (18.7%), mostly of working age (50.5 $\pm$ 5.2 years). The reason for visualization of the adrenal glands in patients with hypertension was its crisis course, resistance to antihypertensive drugs. The reason for visualization of the adrenal glands in patients without hypertension was a diverse somatic pathology. All patients underwent unilateral adrenalectomy. In 87.5% of patients with adrenal hypertension, of which women predominated (78.6%) older (53.1 $\pm$ 3.2 years) than men (44.4 $\pm$ 4.7 years; $P<0$, 05), hormonally active adrenal tumors were diagnosed: pheochromocytoma in 50%, adrenocorticosteroma and aldosteroma in 35.7% and 14.3% of cases, respectively. The remaining 12.5% had hormonally inactive adrenal formations, hence there was essential hypertension. These patients were significantly older than patients who had hormonally active adrenal formations: 65.1 $\pm$ 2.4 and 51.5 $\pm$ 5.1 years ($P<0.05$), and the blood pressure level was lower: 160/100 $\pm$ 10/15 against 196.4/100 $\pm$ 20/10 mm Hg. ($P<0.05$). The results of a histological study of adrenal removed adrenal glands in patients without hypertension revealed "dumb" tumors of chromaffin tissue in 16.7% of cases. The obtained results testify to the necessity of searching for secondary hypertension of adrenal genesis in all patients with hypertension characterized by a crisis current.
Conclusions
1. In most cases (87.5%), the course of hypertension in patients operated on for focal formation of the adrenal gland is due to a hormone-active tumor.
2. Hormonal-active tumors of the adrenal glands in patients with a crisis course of arterial hypertension are represented in 50% of cases by pheochromocytoma, in 35.7% by adrenocorticosteroma, in 14.3% by aldosterome.
3. The creeping flow of arterial hypertension of the adrenal genesis is more often diagnosed in middle-aged women, accompanied by higher figures of arterial pressure.

Atypical manifestation of adrenocortical carcinoma – case series

Karolina Nowak[1], Agnieszka Lebek-Szatanska[1], Radoslaw Samsel[2], Andrzej Cichocki[2], Katarzyna Roszkowska-Purska[3], Wojciech Zgliczynski[1] & Lucyna Papierska[1]
[1]Department of Endocrinology, Centre of Postgraduate Medical Education, Warsaw, Poland; [2]Department of Surgery Clinic of Oncology Memorial M. Sklodowska-Curie Cancer Institute, Warsaw, Poland; [3]Department of Pathology Memorial M. Sklodowska-Curie Cancer Institute, Warsaw, Poland.

Adrenocortical carcinoma (ACC) is a rare malignancy. Authors present three cases of even less commonly encountered manifestation of ACC. Case 1: A 39-year-old male, with decompensated hypertension, was admitted to Department of Endocrinology due to a large tumor of the left adrenal gland (65 mm) revealed in the CT of the abdomen. Non-contrast attenuation was 35HU. After performing MRI with chemical shift, tumor was classified as non-adenoma as there was no significant loss of signal in out-of-phase sequence. Excess of cortisol and aldosterone was excluded, but urine metoxycatecholamines remained in upper limit of the norm. Scintigraphy with iodine-123-meta-iodobenzylguanidine and somatostatin receptor revealed increased uptake of radiotracers in left adrenal gland. The patient was diagnosed with pheochromocytoma and after two weeks of alfa-blocker intake he underwent surgery. The pathology report revealed ACC. Case 2: A 54-year-old woman, with hypertension and incidentalomas of both adrenal glands diagnosed in 2011 was referred to Department of Endocrinology in 2017. In 2011, due to anaphylactic reaction to iodine in medical history, only single-phase CT was performed which revealed a tumor of left adrenal gland (25 mm) of density 16 HU. Hormonal activity was excluded and the patient was diagnosed with lipid poor adenoma. One year later, CT was repeated and there was no tumor growth so the follow-up was ended. In 2017 the tumor was classified as non-adenoma based on MRI with chemical shift (very low lipid content) and the possible autonomous cortisol secretion was revealed during hormonal work-up. There was non-specific accumulation in left adrenal gland in somatostatin receptor scintigraphy and the patient underwent adrenalectomy. The pathology report, revealed myelolipoma together with ACC infiltrating the fat tissue. Case 3. A 50-year-old male reported to the emergency room due to severe hypertension, hypokalaemia and tumor in right adrenal gland (32 mm). In CT attenuation before contrast was 29HU and absolute contrast enhancement washout was 57%, so lipid poor adenoma was diagnosed. Hormonal evaluation excluded hypercortisolemia, aldosterone concentration was 123 pg/ml, PRA 0,12 ng/ml/h, therefore ARR was high $=102$. The primary hyperaldosteronism was confirmed in saline infusion test and lateralization in adrenal venous sampling. Patient underwent laparoscopic adrenalectomy. The pathology report revealed ACC.
Conclusion
Though ACC is rare, it should be taken into consideration in every case of non-adenoma phenotype in imaging examinations. Thorough meticulous evaluation in imaging is necessary to identify all cases of ACC, regardless of hormonal activity.

Are there any clinical predictor for malignancy in malignant pheochromocytoma?

Agustina Pia Marengo[1], Paula García-Sancho[1], Fernando Guerrero Pérez[1], Inmaculada Peiró[2], Elisa Santacruz[3], Andrés Ortiz Flores[3], Juan José Diez[3], Pedro Iglesias[3] & Carles Villabona[1]
[1]Hospital Universitario de Bellvitge, L'Hospitalet de Llobregat, Barcelona, Spain; [2]Institut Catalá d'Oncologia (ICO), L'Hospitalet de Llobregat, Barcelona, Spain; [3]Hospital Universitario Ramón y Cajal, Madrid, Spain.

Introduction
Malignant pheochromocytoma (MPheo) is diagnosed by the presence of invasion of adjacent structures or distant metastasis. Predictive factors of malignancy for pheochromocytoma (Pheo) are not well known.
Material and methods
We retrospectively analyzed clinical, biochemical, radiological characteristics as predictors for malignancy in patients with Pheo in two Spanish tertiary hospitals during the past 35 years. We also evaluated time of recurrence, most frequent locations of metastatic lesions, and surgical and other therapeutic modalities.
Results
We reviewed 80 patients diagnosed with Pheo (8 MPheo, 10%). Metastatic disease/invasion of adjacent structures was present in 4/8 at the time of diagnosis, and become evident in 4/8 after surgical removal of the primary tumor, within 7 years (range 1–8). Age at diagnosis was similar in both groups (MPheo 52.1yrs; range 15–73 vs Pheo 51.5yrs, range 13–76; ($P=0.481$)). Males comprised 62.5% versus 40.8% of the MPheo and Pheo group, respectively. ($P=0.216$). Prevalence of hypertension was similar in both groups [MPheo, 3/8, 3/8 (37.5%) and non-MPheo 32/72 (44.4%); $P=0.109$]. All 8 MPheo patients had elevated catecholamines (urinary and/or plasma) with an average of 5.6 times the reference value. MIBG imaging was performed in 4/8 patients, and all of them had positive scans. MPheo was unilateral in 7/8 patients; the patient with bilateral MPheo was diagnosed of MEN2a. Tumor size was significantly higher in MPheo than in non-MPheo patients (10.1 vs 5.7 cm, $P=0.038$). Metastatic lesions were found in the liver ($n=4$), bone ($n=3$), vascular ($n=3$), and distant lymph node ($n=2$). Resection of the primary mass was performed in 2 out of 4 patients with initial metastatic disease. 2/8 MPheo patients underwent surgery of metastatic lesions. Non-surgical treatment was also implemented in 6/8 (75%), 5/6 received high-dose MIBG and 1/6 chemotherapy (vincristine, dacarbazine and cyclophosphamide). Evaluation of the best overall response according to the RECIST1.1 Criteria was conducted in 6 out of 8 MPheo. Complete response was achieved in 2/6 patients (one treated with chemotherapy and another with high-dose MIBG; cumulative dose of 600mCi). Partial response was found in 1/6, and tumor progression was assessed in 3/6. Mean follow-up was 6 years.
Conclusion
No association was found regarding age or sex on the development of MPheo. The only clinical difference between MPheo and non-MPheo was the greater tumor size at diagnosis in the former. Due to the absence of clear predictors for malignancy in Pheo, long-term follow-up after surgery is mandatory in these patients.

New cancer drug targets identified in adrenocortical carcinoma through gene expression profiling

Raimunde Liang[1], Isabel Weigand[1], Barbara Altieri[1,2], Stefan Kircher[3], Sonja Steinhauer[1], Silviu Sbiera[1], Matthias Kroiss[1,4], Andreas Rosenwald[3], Martin Fassnacht[1] & Cristina Ronchi[1,5]
[1]Division of Endocrinology, University Hospital of Wuerzburg, Wuerzburg, Germany; [2]Division of Endocrinology, Catholic UNiersity of the Sacred Heart, Rome, Italy; [3]Department of Pathology, University of Wuerzburg, Wuerzburg, Germany; [4]Comprehensive Cancer Center Mainfranken, Wuerzburg, Germany; [5]Insitute of Metabolism and System Research, University of Birmingham, Birmingham, UK.

Adrenocortical carcinomas (ACC) are associated with heterogeneous prognosis and limited treatment options for advanced stages. Until now no efficient targeted therapies have been identified. This study aims to identify possible new molecular drug targets for a future personalized therapeutic approach. We isolated good quality RNA from 40 formalin-fixed paraffin-embedded tumor samples (33 from primary surgery, 5 from local recurrences and 2 from distant metastasis) of ACC patients (26F&14M, median age 46 yrs). Gene expression of 84 known cancer drug targets was evaluated by RT^2 Profiler PCR Array (Qiagen). Fold change (FC) was calculated with the 2^(-DDCT) formula using 5 housekeeper genes and 5 normal adrenal glands (NAG) as reference (overexpression by FC$>$2.0). The expression of selected candidates was validated at the protein level by immunohistochemistry in the same series. The 6 most frequently overexpressed genes were *TOP2A* (100% of cases, median FC$=$16.5), *IGF2* (95%, FC$=$52.9), *CDK1* (80%, FC$=$6.7), *CDK4* (62%, FC$=$2.9), *PLK4* (60%, FC$=$2.8) and *PLK1* (52%, FC$=$2.3). Several members of AURK and HDAC gene families (e.g. the) were also overexpressed. mRNA expression of *AURKA, CDC25A, CDK1, CDK2, HDCA2* and *TOP2A* positively correlated with ki67 proliferation index (all $P<0.05$). CDK1, CDK4, PLK1 and TOP2A were selected as candidates for validation by immunohistochemistry. Interestingly, nuclear staining of CDK1, CDK4 and PLK1 significantly correlated with mRNA expression ($R=0.64$, $R=0.52$ and $R=0.55$, respectively, all $P<0.005$). In conclusion, we identified by gene expression profiling interesting targetable genes that might serve as basis for personalized therapy in advanced ACC. The expression of these candidates might be investigated by immunohistochemistry in the clinical practice. For instance, *CDK4* is overexpressed in several cancers and can be targeted by CDK/CDK6 inhibitors (e.g. palbociclib) that are currently tested in numerous clinical trials on solid tumors. Validation and functional studies on ACC cell lines are ongoing to confirm present results.

Outcome of adjuvant mitotane therapy in patients with adrenocortical carcinoma: the experience of San Luigi Gonzaga Hospital

Soraya Puglisi[1], Anna Calabrese[1], Vittoria Basile[1], Paola Perotti[1], Anna Pia[1], Paola Berchialla[2], Marco Volante[3], Giuseppe Reimondo[1] & Massimo Terzolo[1]
[1]Internal Medicine, Department of Clinical and Biological Sciences, University of Turin, Orbassano, Italy; [2]Statistical Unit, Department of Clinical and Biological Sciences, University of Turin, Torino, Italy; [3]Pathology Unit, Department of Oncology, University of Turin, Orbassano, Italy.

Background and objectives
The role of adjuvant mitotane therapy after radical surgery for adrenocortical carcinoma (ACC) is still debated. The aim of our study is to assess the effects of adjuvant mitotane on recurrence free survival (RFS) and overall survival (OS) in non-metastatic ACC patients and to evaluate prognostic factors in adjuvant setting.
Methods
Retrospective data were collected from 152 patients affected by ACC (stage I-III) referred to our center from 1988 to 2015. One hundred patients underwent adjuvant mitotane therapy (mitotane group), while 52 patients did not receive any treatment after surgery (control group). The following potential prognostic factors were investigated with univariate and multivariate analysis: age at diagnosis, endocrine activity of the tumor, ENSAT tumor stage, R status, Weiss score, mitotic count, Ki-67, plasma mitotane levels.
Results
Although the patients on mitotane had a worse prognostic profile (higher Weiss score, mitotic count and Ki-67), we observed a significant increase in RFS of the mitotane group (median 37 [4–199] vs 21 months [4–180], HR 2.79 [1.58–4.91], $P<0.001$), while OS was not significantly different between the two groups (median 58 [8–199] vs 50 months [4–231], HR 1.22 [0.61–2.42]). In multivariate analysis hormonal secretion, Weiss score, mitotic count and Ki-67 were negative prognostic factors for RFS. The same factors with tumor stage were associated with a shorter OS.
Conclusions
Adjuvant mitotane therapy was associated with prolonged RFS in ACC patients. An effect on OS was not apparent but a longer follow-up is likely needed to evaluate any treatment-related difference.

Adrenocortical carcinoma – characteristics and outcome of patients treated at Helsinki University Hospital during the last 15 years

Iiro Kostiainen[1], Liisa Hakaste[1], Pekka Kejo[2], Helka Parviainen[3], Tiina Laine[4], Mirkka Pennanen[5], Johanna Arola[5], Caj Haglund[2], Ilkka Heiskanen[2] & Camilla Schalin-Jäntti[1]
[1]Endocrinology, Abdominal Center, University of Helsinki and Helsinki University Hospital, Helsinki, Finland; [2]Department of Surgery, Helsinki University Hospital and University of Helsinki, Helsinki, Finland; [3]HUS Medical Imaging Centre, Radiology, Helsinki University Hospital, University of Helsinki, Helsinki, Finland; [4]Children's Hospital, Helsinki University Hospital and University of Helsinki, Helsinki, Finland; [5]Department of Pathology, University of Helsinki and HUSLAB, Helsinki, Finland.

Background
Adrenal cortical carcinoma (ACC) is a rare malignancy known to be highly aggressive, with few specific treatment options. The objective was to evaluate clinicopathological features and outcome in patients treated at Helsinki University Hospital
Methods and patients
We included all patients diagnosed with adrenocortical carcinoma (Weiss score $\geq$4) at Helsinki University Hospital during the years 2002 through 2017. Patients were identified from our electronic patient records using ICD-10 codes C74.0 and 74.9 and from the Pathology register. Data on presentation, surgical and medical treatments were retrieved from patient records. Radiologic and histopathological characteristics were re-evaluated.
Results
Forty-two patients were diagnosed and treated for ACC, five of which were children. Of the adult patients, 23 (62%) were women, mean age at diagnosis was 56 years (18–84). Median follow-up was 41 (1–199) months. Twenty-seven (75%) of the tumours were found incidentally. Abdominal pain was the most common symptom, occurring in 11/36 (31%) of the patients, 6/36 (17%) presented with hirsutism, 5/36 (14%) had bruises, and 2/23 (9%) menstrual disturbances. Fifty-four percent (19/35) had biochemically verified hypercortisolism, 19% (5/27) hyperaldosteronism and hyperandrogenism was confirmed in all the 11 females (48%) that were investigated for hyperandrogenism. According to ENSAT staging, 6/36 (17%) had stage I, 13/36 (37%) stage II, 8/36 (22%) stage III and 9/36 (25%) stage IV disease. Mean tumour size was 95 mm (20–196 mm) and, in 67% (24/36) the origin was the left adrenal. Mean Hounsfield units were 33 HU (21–45), mean Ki67 17% (1–40%), mean Weiss score 7.1 (4–9) and Helsinki score 24 (4–48). Thirty-three (89%) patients underwent primary surgery, metastases were resected in 4. Thirty (81%) received adjuvant mitotane therapy, therapeutic concentrations were reached in 18 (60%) in a mean of 334 days (78–1055), with a mean cumulative dose of 1030 g (168.5–1847.5). Treatment was discontinued in 9 (30%) patients because of adverse effects. Further oncological treatments were given to 35% (13/37). The 5-year survival rate was 67%.
Conclusion
To date, ACC often presents as an incidental finding. In contrast to benign incidentalomas, ACC is always characterized by a high HU ($>$ 20) on non-contrast CT. Of the patients, 31% presented with abdominal pain and 54% had biochemically verified hypercortisolism. In this cohort, 83% had at least stage II disease and the 5-yr survival rate of 67% was better than in most previous reports.

Comparative study between familial and sporadic pheochromocytoma

Paula Garcia-Sancho[1], Agustina P. Marengo[1], Fernando Guerrero[1], Inmaculada Peiró[2], Elisa Santacruz[3], Juan José Diez[3], Pedro Iglesias[3] & Carles Villabona[1]
[1]Department of Endocrinology, Hospital Universitari Bellvitge, Hospitalet de Llobregat, Barcelona, Spain; [2]Clinical Nutrition Unit, Insitut Catala d'Oncologia (ICO), L'Hospitalet de Llobregat, Barcelona, Spain; [3]Department of Endocrinology, Hospital Universitario Ramon y Cajal, Madrid, Spain.

Introduction
Pheochromocytomas (Pheo) may appear sporadically (SPheo) or as an autosomal dominant inherited disease, named as familial PHEOs (FPheo). The latter are present in younger patients, and usually with multiple tumors, but may occur in patients with apparently simple sporadic tumors with no other syndromic features.
Material and methods
Clinical data of all consecutive patients underwent surgery for Pheo over 35 years in two tertiary referral centers were collected. We compared clinical features, diagnosis, methods, type of surgery, complications and tumor behaviour between SPheo and FPheo patients.
Results
We reviewed 76 patients who underwent surgical resection of Pheo. Fourteen patients (18.4%; 7F) had FPheo and 62 patients (81.6%; 37F) had SPheo. The distribution of FPheo patients was as follows: MEN2A ($n=6$), NF-1 ($n=5$), VHL ($n=2$), and MEN2B ($n=1$). Age at diagnosis was significantly lower in FPheo than in SPheo patients (42.1$\pm$17.2 vs 53.6$\pm$14.5 yr; $P=0.014$). Persistent hypertension was more prevalent in SPheo than in FPheo patients (21.4% vs 51.6%; $P=0.041$). No differences were found in relation of the presence of Pheo classic triad (headaches, palpitations, and sweating) between both groups. Multiple Pheo were significantly more common in FPheo than in SPheo patients (35.7% vs 3.2%; $P=0.001$). We did not found significant differences in the percentage of patients with elevation of plasma and/or urinary catecholamine levels (81.8% in FPheo vs 72.5% in SPheo; NS). All SPheo were adrenal tumors whereas one FPheo was adrenal and abdominal ($P=0.034$). The tumor size was significantly lower in FPheo than in SPheo (4.0$\pm$2.0 cm vs 5.5$\pm$2.4 cm; $P=0.047$). There were no complications in FPheo patients compared to 16 (27.1%) SPheo patients ($P=0.040$). 7 SPheo patients suffered tachycardia, five hypertensive crisis, one stroke, one acute pulmonary edema, one laceration, one died due to renal arterial injury and another one due to hypotension. Tumor recurrence rate was similar in both groups of patients (15.4% in FPheo and 11.3% in SPheo; NS)
Conclusion
FPheo usually appears in young patients with hypertension and family history of Pheo. In our series, FPheo was more frequently associated with MEN2A, with a multiple tumor presentation and smaller size compared to SPheo. Perioperative complications and recurrence rate seem to be similar in both groups. Genetic testing should be considered in all patients, especially in patients with a Pheo family history, young age, multifocal, bilateral and/or extra-adrenal tumors.

Clinical features, management and outcomes of adrenocortical carcinoma: a case series analysis

Andreu Simó-Servat[1], Sara Alonso[2], Fernando Guerrero[1], Paurla García-Sancho[1], Agustina P. Marengo[1], Pedro Iglesias[2], Juan José Díez[2], Inma Peiró[3] & Carles Villabona[1]
[1]Department of Endocrinology. Hospital Universitari de Bellvitge, L' Hospitalet de Llobregat, Barcelona, Spain; [2]Department of Endocrinology. Hospital Ramón y Cajal, Madrid, Spain; [3]Clinical Nutrition Unit, Institut Català d'Oncologia (ICO), L'Hospitalet de Llobregat, Barcelona, Spain.

Background
Adrenocortical carcinoma (ACC) is a rare and aggressive neoplasm with a 5-year survival rate $<$30%. Survival depends mainly on the stage at diagnosis, being surgery the only curative treatment.
Objective
To report the clinical features, management and outcomes of a series of ACC in two Spanish tertiary hospitals.
Material and methods
All patients with pathological diagnosis of ACC between 2000 and 2017 were included in this study. We herein report on data from clinical features, hormonal functionality, imaging, European Network for the Study of Adrenal Tumors (ENSAT) staging at diagnosis and response to treatment.
Results
We evaluated 28 patients (15 women, 53.6%) with a median age of 54.8 years [36–80]. Median tumor size was 12.1 cm [4–26]. Ten patients (35.7%) had hormonal overproduction: androgens in 10 patients, cortisol in 8 and mineralocorticoid in one. At diagnosis there were 16 patients (57.1%) in stage

IV, 8 (28.6%) in stage III, 8 (28.6%) in stage III and 4 (14.3%) in stage II. Four patients presented vena cava thrombosis. Surgery was performed in 26 patients, 20 of them with a complete resection. Twenty-four patients received mitotane (9 patients with concomitant chemotherapy, mainly cisplatin/etoposide, and one with concomitant chemoradiotherapy). Thirteen patients (54.2%) in stage IV, 7 (29.2%) in stage III and 4 (16.6%) in stage II. Thirteen out of 24 that received mitotane had disease progression and 9 died (8 in stage IV and one in III). Median daily dosage of mitotane was 2 g/day [1–10], with median treatment duration of 16 months [0–116]. Eleven patients (45.8%) suffered some adverse effect due to treatment and in 2 cases mitotane was withdrawn. Plasma mitotane levels were measured in 16 patients (66,7%). Appropriate therapeutic levels of mitotane were achieved in 57.9% of the measurments in 11 patients. Median follow-up of the patients was 27 months [0–316]. Eleven patients died: 9 in stage IV and 2 in III (6 of them with hypercortisolism). Two patients were lost for follow-up. In the group of the 15 surviving patients, 5 were in stage II at the diagnosis (one developed metastasis), 6 in III and 4 in IV.

Conclusions

One third of our ACC series were hyperfunctional, most of them multisecretory. Hypercortisolism could be a bad prognostic factor as well as the stage at the diagnosis. Mitotane can be a useful tool, but is mandatory to monitor plasma levels in order to get an effective response.

A case of multiple endocrine neoplasia type 1 (MEN1) with non-insulinoma pancreatogenous hypoglycemia syndrome (NIPHS) responding to medical treatment with diazoxide

Elif Gunes, Soner Cander, Ozen Oz Gul, Canan Ersoy & Erdinc Erturk
Uludag University, Bursa, Turkey.

Introduction

The non-insulinoma pancreatogenous hypoglycemia syndrome (NIPHS) identifies a group of hyperinsulinemic hypoglycemic patients with unique clinical, diagnostic, surgical, and pathologic features. A selective arterial calcium stimulation test (SACST) with hepatic venous sampling can be performed to distinguish between a focal abnormality (insulinoma) and a diffuse process (islet-cell hypertrophy/nesidioblastosis). In patients with insulinoma, the response is positive in one artery alone unless the tumor resides in a "watershed" area fed by two arteries or the patient has multiple insulinomas scattered throughout the pancreas. In contrast, in patients with islet-cell hypertrophy, positive responses are usually but not always observed after injection of multiple arteries.

Case

A 50-year-old female previously had a parathyroid surgery and total gastrectomy; pathology revealed gastric neuroendocrine tumor (G-NET). The diagnosis was multiple endocrine neoplasia type 1 (MEN-1). She was admitted to our hospital for hypoglycemia. Her low fasting plasma glucose level (22 mg/dl), high insulin level (8.4 μU/ml), c-peptide level (2.3 ng/ml) were consistent with the possible presence of insulinoma. But an abdominal CT revealed no pancreatic tumor, and angiography of splenic artery showed no definite tumor stain within the pancreas, negative endoscopic ultrasound, negative octreotide scan and negative ^{18}F-DOPA PET. SACST was performed due to negative noninvasive imaging. Arterial stimulation and venous sampling showed an abnormal insulin response from superior mesenteric, gastroduodenal and splenic artery. The final diagnosis was adult-onset nesidioblastosis. The long-term therapeutic approaches for persistent hyperinsulinemic hypoglycemia may be accomplished pharmacologically or surgically. Pharmacologic interventions, although frequently unsuccessful, always should be tried before surgery. However, our case treatment with diazoxide at a starting dose of 200 mg/day dosage was gradually increased finally dose 400 mg/day resulted in amelioration hypoglycemia.

Discussion

Nesidioblastosis is a condition that can be seen in the majority of MEN1 patients with pancreatic involvement. Endogenous hyperinsulinemia may be due to single or more insulinoma, or it may also be due to diffuse hyperplasia, as seen in our case. The primary goal of therapy in nesidioblastosis is the prevention of acute neurologic symptoms (eg, seizure, lethargy, coma) and long-term sequelae (eg, cognitive deficits) of prolonged and/or recurrent hypoglycemia. The therapeutic strategies in nesidioblastosis include pancreatectomy and /or medical treatment. The initial treatment consists of nutritional management and use of diazoxide. This case report suggests that diazoxide may be effective for nesidioblastosis with MEN1 syndrome.

A case of benign insulinoma successfully treated with endoscopic ultrasound guided radiofrequency ablation

Pierre Gueneau de Mussy, Faiza Lamine, Sebastien Godat, Laura Marino, Sara Di Giorgi, Elena Gonzalez Rodriguez, Nicolas Desmartines & Nelly Pitteloud
CHUV, Lausanne, Switzerland.

Background

Insulinoma is a rare pancreatic neuroendocrine tumor but a life-threatening condition if untreated. Surgical resection is the standard of care with a high cure rate for benign insulinomas but complications can occur in nearly 30% of cases. New non-surgical mini-invasive ablative therapies can be considered in patients with benign insulinoma who are either unfit for surgery or refuse it, although current data are scarce and long-term outcomes are unknown.

Aim

We describe the case of a benign and small insulinoma successfully treated with endoscopic ultrasound (EUS) guided radiofrequency ablation (RFA).

Case description

A non-diabetic 69 year old woman presented with a 5 months history of recurrent episodes of sweating, tremor and refractory focal seizures despite levetiracetam therapy. During one of these episodes, a low capillary glucose level of 2.9 mmol/l was found with rapid normalization following glucose infusion. The patient was admitted to our hospital for a fasting test which confirmed the diagnosis of insulinoma based on the following laboratory findings: symptomatic low plasma glucose level of 2.5 mmol/l (normal range 3–5.6) within 28 hours of fasting, high plasma insulin and C-Peptide levels of 13.8 mU/l (3–13) and 2.6 ug/l (1.0–3.1) respectively. Screening for both sulphonylurea hyoglycaemic agents and circulating insulin antibodies was negative. Abdominal MRI and ^{68}Ga-DOTATATE PET CT were inconclusive. The EUS guided fine needle aspiration confirmed a 12 mm well differentiated G2 (Ki 67 $<$ 2%) neuroendocrine tumor located on the pancreas body. Symptoms of hypoglycemia were controlled with diet therapy. A multidisciplinary committee with the hepatobiliary surgery unit agreed to assess a minimally invasive endoscopic technique as an alternative to surgery. EUS-guided RFA of the pancreatic tumor was carried out using EUSRA^{TM} needle (19G, Teawoong). Apart from a mild transient fever that occurred 3 days after the procedure and treated with antibiotics, outcomes were favorable. The patient achieved symptomatic relief and biochemical normalization, and remained euglycemic during a follow-up of 2 months as confirmed by continuous glucose monitoring system.

Conclusion

This report adds to the emerging evidence of benign insulinoma being successfully treated by EUS-RFA, which may represent a potential alternative to surgery in selected cases. Further studies including larger patient samples are warranted to establish the safety and long-term efficacy of EUS-RFA in this setting.

Careful selection of patients with primary aldosteronism using combination of age, serum potassium and CT adrenal glands can avoid the need for adrenal venous sampling prior to adrenalectomy.

Yun Ann , Chin , & Du Soon Swee
Singapore General Hospital, Singapore, Singapore.

Introduction
Adrenal venous sampling (AVS) is considered the reference standard to select patients with unilateral aldosterone producing adenoma for adrenalectomy. Recent studies debated the "mandatory" need for AVS before adrenalectomy. We report our experience from a tertiary hospital in Asia on the treatment outcomes of patients with primary aldosteronism (PA) who underwent adrenalectomy without AVS compared to those who had successful AVS.
Methods
A retrospective review of patients with PA who underwent adrenalectomy from February 2008 to July 2017 in Singapore General Hospital was conducted. All patients had positive case detection as defined by screening plasma aldosterone concentration (PAC): plasma renin activity (PRA) or active renin (DRC) of >20 or >3.8 respectively. They were further confirmed with intravenous salt loading test, with post infusion PAC >10 ng/dl (277 pmol/l). All patients with confirmed PA underwent adrenal CT scan. Clinical characteristics, CT findings and AVS results were analysed.
Results
In the entire cohort, 63.9% of patients had hypertension, 72.2% had hypokalemia and 16.7% had adrenal incidentaloma. Twenty three patients (63.9%) who underwent adrenalectomy had successful AVS while 13 patients (36.1%) were based on CT findings. The patients who underwent adrenalectomy based on AVS were older compared to those who did not have AVS, with mean age of 50.8 years and 45.9 years respectively. There was no significant difference in the level of hypokalemia in the AVS compared to the non-AVS group (2.7 mmol/l vs 2.9 mmol/l, $P=0.709$). Non-AVS based adrenalectomy group had an overall larger adrenal adenomas compared to the AVS based adrenalectomy group (2.23 cm vs 1.36 cm, $P=0.013$). There was no significant difference in the number of antihypertensive medications required prior to adrenalectomy in the non-AVS vs the AVS group (1.69 vs 2.17, $P=0.991$). When comparing between the non-AVS and the AVS-based adrenalectomy group, there was no significant difference in the patients who had complete resolution of hypertension (66.7% vs 45.5%, $P=0.678$) nor any difference in the reduction of anti HTN medications (45.5% vs 36.4%, $P=0.079$). In the non-AVS group, the factors associated with improvement in hypertension, were age <45 years ($P=0.014$), adrenal adenoma size ≥ 1.3 cm with contralateral normal adrenal gland on CT scan ($P=0.028$) and K <3.2 mmol/L ($P=0.028$). Among those did not experience improvement in hypertension after adrenalectomy, all were $>$ 45 years old.
Conclusion
Where access to expert AVS is limited, adrenal CT combined with specific clinical and biochemical features can potentially safely select patients for adrenalectomy.

DOI: 10.1530/endoabs.56.P122

P123

Hormonal secretion prevalence in a series of subjects with adrenal tumors incidentally discovered in clinical practice

Carmen Gabriela Barbu[1,2], Adrian Teodor Pienary[1], Alice Albu[1,2], Sorina Martin[1,2], Anca Sirbu[1,2], Suzana Florea[2] & Simona Fica[1,2]
[1]Carol Davila University, Bucuresti, Romania; [2]Elias Hospital, Bucuresti, Romania.

The objective of the study was to evaluate the prevalence of secreting profile among a series of subjects with incidental discovered adrenal tumors. Subjects. 139 subjects (112 women and 27 men) diagnosed with adrenal tumors between 2010 and 2015 in our department.
Methods
Medical records were retrospectively analysed for demographic data, routine tests, specific adrenal hormones measurements, associated diseases.
Results
Regarding the tumor localisation, 46.5% of the subjects had left adrenal tumors, 31.5% on the right adrenal gland and the other had bilateral tumors. Forty out of all subjects (28%) had a positive test for an adrenal hormonal secretion according to diagnosis tests criteria for either cortisol, cathecolamines or aldosterone: 87% for cortisol, 8% for cathecolamines and 5% for aldosterone. Measurements of the adrenal hormones were not done routinely in all subjects, presence of high blood pressure in a young patient beeing a selection criteria in the majority of the cases. On the other hand cortisol secretion evaluation was the most affordable and accesible measurement in the studied clinical setting; thus it was done in all the subjects. Cathecolamines and aldosterone secretion was evaluated in less than 20% of the subjects.The secretory characteristic of the tumors was significantly correlated to bilateral tumors (85% vs 68% on right or 47% on the left). A significantly increased diameter of the tumor (2.7 cm) was found in secretory ones vs non secretory (2.2 cm, $P<0.05$) No significant correlations were found between positive hormonal secretion of the tumors and gender, localisation, BMI, age, associated diseases. Conlcusion. Twentyeight percent of the patients with and incidental discovered adrenal tumor had a positive secretory profile wich was associated to a greater diameter of the tumor and bilateral localisation. The most frecvent found secretion was cortisol, finding which is most probable biased by a more available measurement.

Genetic background as a predictive factor of pheochromocytoma and paraganglioma presentation

Adriana De Sousa Lages[1,2], Isabel Paiva[1], Luís Cardoso[1,2], Patrícia Oliveira[1], Dírcea Rodrigues[1,2], Carolina Moreno[1,2], Diana Martins[1,2], Diana Oliveira[1,2], Mara Ventura[1,2], Nelson Cunha[1], Bernardo Marques[3], Diana Catarino[1], Lúcia Fadiga[1] & Francisco Carrilho[1]
[1]Coimbra Hospital and University Center, Coimbra, Portugal; [2]Faculty of Medicine, Coimbra University, Coimbra, Portugal; [3]Portuguese Institute of Oncology of Coimbra FG, Coimbra, Portugal.

Introduction
Pheochromocytoma (Pheo) and paragangliomas (PGL) are rare catecholamine-producing tumors.Near 35% of patients have disease-causing germline mutations.10% are malignant although the malignancy rate differs accordingly to the genetic background.
Purpose
This study aims to characterize the sample of patients followed on a tertiary Portuguese Center and associate the presence of genetic mutation with clinical presentation.
Materials and Methods
Were included patients followed until November 2017 with proven histological diagnose.Statistical analysis was performed with SPSS v.25 –Fischer test: nominal variables and U de Mann-Whitney test: ordinal variables. Results with $P<0.05$ were considered statistically significant.
Materials and Methods
*Results:*We included 67 subjects (65 with disease; 2 asymptomatic carriers of exon 2 mutation of *TMEM127* gene). From the 65 patients, 60 had Pheo, 3 head-and-neck PGL and 2 abdominal PGL. In 12.3% of the patients (8/65) evidence of metastatic disease was reported, of which 87.5% (7/8) identified at diagnose. The most frequent local of metastatic disease was bone (71.4%).7 patients died during follow-up (10.8%), 2 with previously known metastatic disease (1 Pheo;1 parapharyngeal PGL).Our sample was divided in 3 groups: negative genetic test (GT) ($n=30$; 28 Pheo); positive GT ($n=17$; 14 Pheo) – cluster 1 genes: 4 patients (*VHL*−3; *SDH* gene-1) and cluster 2 genes: 13 patients (*RET*-7; *TMEM127*−4; *NF*-2); unavailable GT ($n=20$; 10 Pheo). Compared with patients with negative GT, patients with positive GT were significantly associated to larger tumors (66.62 ± 35.8 mm vs. 44.57 ± 20.0 mm; $P=0.031$), bilateral disease (6 (40%) vs. 1 (3.3%); $P=0.003$), earlier age at diagnose ($<$ 40 years: 9 (60%) vs. 6 (20%); P 0.017) and positive familiar history (8 (53.3%) vs. 1 (3.3%); $P<0.001$). Regarding to recurrence, the mean time (months) elapsed was lower in the positive GT group (4.40 ± 15.5 vs. 7.53 ± 23.5) without reaching a statistically significant difference ($P>0.05$). There were no significant differences on clinical presentation, suggestive imagiological characteristics on anatomical (CT or MRI scan) or functional techniques (^{123}I-mIBG scan) ($P>0.05$).
Conclusions
In our sample, 1/3 of patients with history of Pheo/PGL presented a positive GT and near 12% showed metastatic disease, similarly to the data published in the literature. From the positive GT group, 93.3% were Pheo cases accordingly to the most frequent gene mutations identified – cluster 1: 3 patients with *VHL* mutations and cluster 2:13 patients. In this group, we also found a stronger association to bilateral disease, manifestation $<$40 years of age, positive familiar history and larger tumors.

Heterogeneous genetic background of Hungarian patients with pheochromocytoma/paraganglioma requires gene panel testing

Balázs Sarkadi[1], Sára Zakariás[1], István Likó[2], Vince Kornél Grolmusz[1,2], Henriett Butz[1,2,3], Miklós Tóth[1], Nikolette Szücs[1], Péter Igaz[4] & Attila Patócs[2,3,4]
[1]2nd Department of Medicine, Semmelweis University, Budapest, Hungary; [2]Lendület" Hereditary Endocrine Tumours Research Group, Hungarian Academy of Sciences – Semmelweis University, Budapest, Hungary; [3]Department of Laboratory Medicine, Semmelweis University, Budapest, Hungary; [4]Molecular Medicine Research Group, Hungarian Academy of Sciences – Semmelweis University, Budapest, Hungary.

Introduction
Pheochromocytomas and paragangliomas (Pheo/PGL) are rare neuroendocrine tumours arising from the adrenal medulla or the symphathetic paraganglia, respectively. Germline mutations are present in ~40% of the patients. To date, at least 16 genes have been demonstrated to be involved in the genetic background of Pheo/PGL. Prioritization in order of genes tested can be applied, but if the probability of a disease-associated germline mutation exceeds 10% the testing of all susceptibility genes is recommended. Using next generation sequencing (NGS) based methods for genetic testing of Pheo/PGL associated genes progressively becomes part of the routine diagnostics.
Objective
To assess the genetic background of Hungarian patients with Pheo/PGL and to develop a NGS based gene panel assay for analysis of Pheo/PGL susceptibility genes.
Methods
We examined 131 patients with the diagnosis of Pheo/PGL diagnosed and nursed at the 2nd Department of Medicine, Semmelweis University. The prevalence of the germline mutations of Pheo/PGL genes was determined using conventional methods. Genotype-phenotype correlations were evaluated. A gene panel covering 15 genes (*RET*, *VHL*, *NF1*, *EPAS*, *EGLN1*, *KIF1B*, *SDHA*, *SDHB*, *SDHAF2*, *SDHC*, *SDHD*, *FH*, *MAX*, *TMEM127*, *MEN1*) was developed and analytical sensitivity was evaluated on 36 patients with known genetic background. Library preparation was performed using SeqCapEZ capture platform with our probe design. Illumina MiSeq instrument was used for sequencing. Sequencing data were analysed with GATK workflow. Variant annotation was performed with SNPeffect.
Results
Germline mutations of Pheo/PGL genes were present in at 34% of the patients: 10 (7.6%) *SDHB*, 9 (6.9%) *RET*, 5 (3.8%) *VHL*, *TMEM127*, *MDH2*, 4 (3%) *NF1*, 3 (2.3%) *SDHD*, 2 (1.5%) *SDHC* and *KIF1B*. 5 of 10 *SDHB* mutation carriers developed malignant disease. Homozygous form of a *MDH2* variant was associated with malignancy. Among the 10 patients with bilateral adrenal Pheo 4 *RET*, 2 *TMEM127* and 1 *VHL* mutations were identified. The coverage of genes in our panel was higher than 150 reads in all regions and all known mutations were correctly identified.
Discussion
Our findings regarding the prevalence of germline mutations in the development of Pheo/PGL are in accordance with the literature. No founder mutation occurred in our population as we could detect mutations in 9 genes, underlining the need of novel methods for mutation analysis in everyday clinical practice. Our NGS-based gene panel performed accurately, however two recently identified genes (*MDH2*, *GOT2*) were not covered.

Gastroenteropancreatic neuroendocrine tumors are predictive for a positive *MEN1* germline mutation test: evidence from Hungarian MEN1 cohort

Annamária Kövesdi[1,2], Katalin Balogh[1], Miklós Tóth[1], Nikolette Szücs[1], Beatrix Sármán[1], Péter Pusztai[1], Péter Reismann[1], Anikó Somogyi[1], Katalin Borka[3], Annamária Erdei[4], Veronika Deák[5], Zsuzsanna Valkusz[6], Péter Igaz[1,7], Attila Patócs[2,7,8] & Vince Kornél Grolmusz[1,2]
[1]2nd Department of Medicine, Semmelweis University, Budapest, Hungary; [2]"Lendület" Hereditary Endocrine Tumours Research Group, Hungarian Academy of Sciences – Semmelweis University, Budapest, Hungary; [3]2nd Department of Pathology, Semmelweis University, Budapest, Hungary; [4]1st Department of Medicine, University of Debrecen, Debrecen, Hungary; [5]Kaposi Mór County Hospital, Kaposvár, Hungary; [6]1st Department of Medicine, University of Szeged, Szeged, Hungary; [7]Molecular Medicine Research Group, Hungarian Academy of Sciences – Semmelweis University, Budapest, Hungary; [8]Department of Laboratory Medicine, Semmelweis University, Budapest, Hungary.

Objective
Multiple endocrine neoplasia type 1 (MEN1) is a rare heritable tumor syndrome caused by germline mutations of *MEN1* gene affecting mainly the parathyroid, pituitary and pancreas. Phenotype varies widely, even in first-degree relatives. Recently it has been shown that functionally active gastroenteropancreatic neuroendocrine tumors (GEP-NETs), initially frequently diagnosed as sporadic cases, lead to MEN1 diagnosis. Non-functioning tumors are increasingly recognised due to advanced imaging modalities such as endoscopic ultrasound and thus became the most common GEP-NET in MEN1 patients. Contrary to sporadic GEP-NETs, MEN1-associated cases are diagnosed 10 years earlier and their penetrance is as high as 80-90%, reaching nearly that of the parathyroid adenomas. Mutation analysis enables early tumor detection, thus the possibility to prevent serious, even life-threatening morbidities associated with malignant GEP-NET. Our aim was to identify phenotype features predictive for a positive *MEN1* genetic test, and by comparing mutation-positive and mutation-negative patients to evaulate the role of *MEN1* mutations in phenotype modulation.
Design and methods
Of the 104 probands who fulfilled the criteria of *MEN1* mutation analysis, 36 patients with GEP-NET were enrolled in this study. Mutation screeening of the *MEN1* gene by Sanger sequencing was performed at our national reference laboratory. Clinical data were studied together with laboratory, imaging and histological results. Multiple ligation probe amplification analysis of *MEN1* gene and Sanger sequencing of *CDKN1B* were carried out in clinically suspicious but *MEN1*-negative cases.
Results
Of 36 GEP-NET patients mutation analysis demonstrated disease-causing mutation in 19 patients. GEP-NET developed significantly earlier in mutation-positive patients; more than half of them appeared under 30 years of age. The prevalence of GEP-NET was also significantly higher at initial presentation in mutation carriers compared to mutation negative patients. The presence of GEP-NET under 30 years best predicted a positive *MEN1* genetic test. Its prevalence remained significantly higher among mutation carriers during the follow-up. In addition, probands with high-impact mutations (frameshift, nonsense, large deletions), predicted to affect menin function significantly, developed GEP-NETs more frequently compared to low-impact (inframe and missense) mutation carriers.
Conclusions
GEP-NETs appear significantly earlier and more frequently in *MEN1*-positive patients and best predicted a positive genetic test. MEN1 patients with high-impact mutations were more likely to develop GEP-NETs, revealing a possibly important prognostic consequences regarding genetic counseling.

Adrenocortical cancer – the effectiveness of mitotane therapy depending on the time of therapy and the therapeutic dose

Kamil Stępiński, Beata Jurecka-Lubieniecka, Barbara Michalik, Sylwia Szpak-Ulczok, Przemysław Soczomski & Barbara Jarzęb
Department of Nuclear Medicine and Endocrine Oncology. Maria Skłodowska-Curie Institute – Oncology Center, Gliwice Branch, Gliwice, Poland.

Introduction
Mitotane-o'p-DDD belongs to insecticides (DDT pesticide contamination), it is the only drug registered by the FDA in treatment in adrenocortical carcinoma (ACC). Treatment effect is controled by mitotane concentration in the blood.
Aim
The aim of the study is to evaluate the effectiveness of mitotane treatment in patients with adrenocortical cancer.
Material and methods
We retrospectively reviewed data on ACC patients ($n=204$) treated with o,p′DDD ($n=117$) between 2002 and 2017. Finally, a total number of 55 patients was included in the study. In these patients, we analysed a graph of mitotane concentrations during the course of therapy. Therapeutic window of mitotan was set according to the characteristics of the medicinal product (FDA) at 14-20 mg/l. Patients were divided into two groups. For the study group, the inclusion criterion was to maintain the concentration window of mitotane in the plasma least at 50% of the treatment time. The study group included 17 people (31% of patients) The comparative group group consisted of those who did not reach the therapeutic window, 38 patients (69%). We observed patients from both groups in time one year intervals after the inclusion of mitotane therapy. In the evaluation of the effectiveness of the therapy, we based on the comparison of subsequent CT and MR results according to RECIST criteria. Average duration of treatment was up to 40 months in the first group of patients Average duration was of treatment was up to 28 months in the second group of patients.

Results
After a year 60% exhibited the stable disease. In the study group of patients, we observed stable disease in 82% of patients who is 23% ($N=4$) of patients had regression of the disease ($P<0,05$). In comparative group – stable disease was observed in only 50% of patients.
Conclusion
In conclusion, our data confirm the value of o,p′DDD plasma monitoring with ACC patients. Furthermore, our results suggest additional benefit of a targeting the o,p′DDD in terapetic window which has to be confirmed in a prospective study. In view of the limited possibilities of other therapies, the discussion on the use of mitotane remains open.

Ghrelin is overexpressed in adrenal cancers and stimulates proliferation and migration of ACC cell line.

Hanna Komarowska[1], Marcin Ruciński[2], Marianna Tyczewska[2], Nadia Sawicka-Gutaj[1], Marta Szyszka[2], Aleksandra Hernik[1], Anna Klimont[1], Paulina Milecka[2], Laura Migasiuk[1], Mateusz Biczysko[3], Ilona Idasiak-Piechocka[4], Marek Karczewski[5], Agata Czarnywojtek[1] & Marek Ruchała[1]
[1]Department of Endocrinology, Metabolism and Internal Medicine, Poznan University of Medical Science, Poznań, Poland; [2]Department of Histology and Embryology, Poznan University of Medical Science, Poznań, Poland; [3]Department of General, Endocrinological and Gastroenterological Surgery, Poznan University of Medical Science, Poznań, Poland; [4]Department of Nephrology, Transplantology and Internal Medicine, Poznan University of Medical Science, Poznań, Poland; [5]Department of General and Transplantation Surgery, Poznan University of Medical Science, Poznań, Poland.

Purpose
Adrenal cancers are relatively rare, but they have poor prognosis. IGF2 has been confirmed as a factor of adrenal tumors development. Recent data indicate that ghrelin may be an essential factor in cancerogenesis. The aim of our study was to assess ghrelin expression in adrenal tumors, and to investigate the relationship between ghrelin, IGF2 and the clinicopathological characteristics. We also investigated the influence of ghrelin on adenocarcinoma cell line proliferation in *in vitro* analysis.
Materials and methods
The study group included 77 patients diagnosed with adrenal tumors, qualified for adrenalectomy. All patients underwent physical examination, laboratory testing, and computer tomography scan before the operation. Expression of ghrelin and IGF2 in adrenal tumors: 30 adenoma, 12 hyperplasia, 8 myelolipoma, 20 pheochromocytoma, 7 carcinoma and 7 unchanged adrenal glands were estimated with RT qPCR. All parameters were compared in examined groups and correlations between them were estimated. H295R cell line was stimulated by ghrelin to assess proliferation and migration.
Results
We found ghrelin overexpression in adrenal cancers, while the lowest level of ghrelin expression was observed in the control group. Ghrelin expression was 21 times higher in carcinoma ($P=0.017$); 2.4 times higher in adenoma ($P=0.029$). There were no statistical differences between myelolipoma ($P=0.093$) and pheochromocytoma ($P=0.204$) in relation to control. Ghrelin was statistically higher in carcinoma compared to adenoma ($P=0.049$). The positive correlation between ghrelin and IGF2 expression was observed only in myelolipoma ($P=0.001$). Ghrelin in concentrations of 1×10^{-6} M and 1×10^{-8} M significantly stimulated proliferation and migration in the H295R cell line.
Conclusion
Ghrelin may be involved in adrenal tumors development.

The effect of temozolomide on pancreatic neuroendocrine tumours and role of MGMT and MMR system in temozolomide resistance

Anela Blazevic, Fadime Dogan-Oruc, Mehtap Dedeci, Peter M. van Koetsveld, Richard A. Feelders, Wouter W. de Herder & Leo J. Hofland
Erasmus MC, Rotterdam, Netherlands.

Background
Temozolomide (TMZ) has been suggested as a treatment option for patients with pancreatic neuroendocrine tumours (PNETs). The tumour response to TMZ has been linked to expression levels of O6-methylguanine-DNA methyltransferase (MGMT) and components of the mismatch repair (MMR) system. However, there is no *in vitro* data on TMZ sensitivity and the expression of MGMT and MMR components in PNETs. Moreover, the effect of TMZ exposure on chemosensitivity and expression of MGMT and MRR components in PNET cell lines is unknown.
Methods
Two PNET cell lines, BON-1 and QGP-1, were used to determine TMZ sensitivity. TMZ resistance was induced by exposing cells to three 24-hour challenges with increasing doses of TMZ, each followed by a two week drug-free period. The effect of TMZ on cell growth, transcription of *MGMT* and MMR components (*MLH1, MSH2, MSH6, PMS2*), apoptosis induction and cell cycle was assessed.
Results
BON-1 were more sensitive to TMZ, compared to QGP-1, as reflected by a lower IC50 value of TMZ on cell growth ($P<0.001$). After a 24-hour exposure to 1x IC50 dose of TMZ, BON-1 cells develop TMZ resistance and maintain this phenotype. TMZ resistance was associated with increased *MGMT* expression and a decrease in TMZ-induced apoptosis and cell cycle arrest. In contrast to BON-1, the less TMZ sensitive QGP-1 cells have a higher base-line *MGMT* expression. Moreover, exposure of QGP-1 to TMZ did not result in increased resistance. In both cell lines, there was comparable expression of MMR components and exposure to TMZ was not associated with a shift in expression levels.
Conclusion
We demonstrated that TMZ sensitivity in human PNET cells is associated with the expression of *MGMT*. Furthermore, a single, short-term exposure to TMZ can induce sustained resistance in TMZ sensitive cell lines which is associated with increased *MGMT* expression.

Treatment with (177Lu)-dotatate in patients with advanced metastatic somatostatin receptor-positive tumors

Antonio Ballesteros Martín-Portugués[1], María Isabel del Olmo García[1], Pilar Bello Arques[2], Ángel Segura Huerta[3], Juan Antonio Méndez García[3] & Juan Francisco Merino Torres[1]
[1]Endocrinology and Nutrition Department, Hospital Universitari i Politècnic La Fe, Valencia, Spain; [2]Nuclear Medicine Department, Hospital Universitari i Politècnic La Fe, Valencia, Spain; [3]Medical Oncology Department, Hospital Universitari i Politècnic La Fe, Valencia, Spain.

Introduction
The NETTER 1 trial resulted in markedly longer progression-free survival (PFS), with preliminary evidence of an overall survival benefit. We report the results of PFS and safety of (177Lu)-DOTATATE in patients treated in our hospital between 2014 and 2017.
Methods
Transversal and descriptive study of 22 patients with advanced, progressive, somatostatin receptor-positive tumors who had received previous treatments. All of them were treated with (177Lu)-DOTATATE. Results are expressed in average(SD) or percentage (%). SPSS version 2.2 was used for statistical analysis.
Results
59.1%(13) were women, with an average age of 53.32(15.2). Histological classification was: 16(72.7%) well-moderate differentiated neuroendocrine tumors (NETs) (8 pancreatic, 4 midgut, 2 lung and 2 unknown primary), 5(22.7%) paragangliomas and 1(4.5%) follicular thyroid carcinoma. At the time of administration of (177Lu)-DOTATATE, 21 patients were in metastatic stage, and one had unresectable bilateral neck paragangliomas. The localization of the metastasis was: liver 68.2%(15), bone 45.5%(10), lymph nodes 27.3%(6) and lungs 9.1%(2). All patients had received previous treatments: 2 underwent surgery exclusively, 4 were treated with somatostatin analogues (SA), 4 with SA and surgery, and the rest of patients with another systemic therapies in addition to SA and surgery: tyrosine-kinase inhibitors, mTOR inhibitors, and standard chemotherapy. 177Lu-DOTATATE was infused every eight weeks. 16 patients have already finished the treatment: 14 patients received 4 doses (59.1%), 2 received only 3 due to the excellent response. Three patients have not received yet complete treatment, and finally 3 remaining patients died during the treatment. At the data-cutoff date PFS was of 12.86(12.43) months. Ten (45.5%) patients had adverse events related to the treatment: 1 asthenia, 4 self-limited nausea, vomiting or abdominal pain, and 5 haematologic events (3 mild-moderate anemia, 2 pancytopenia, one of them with fatal ending). During the follow-up, 5 patients have died.

Conclusions
In real world practice, treatment with (177Lu)-DOTATATE not only shows benefit in advanced intestinal NETS but also in other patients with metastatic disease, previous treatments, and positive somatostatin-receptor expression. 177Lu seems to have favorable results attending to PFS and safety.

Severe impairments in health-related quality of life in patients with small intestine neuroendocrine tumors

Niina Matikainen[1], Noora Karppinen[1], Riikka Lindén[2], Harri Sintonen[3], Maija Tarkkanen[4], Risto Roine[5,6], Ilkka Heiskanen[7] & Camilla Schalin-Jäntti[1]
[1]Endocrinology, Abdominal Center, Helsinki University Hospital and University of Helsinki, Helsinki, Finland; [2]Radiology, HUS Medical Imaging Centre, Helsinki University Hospital, Helsinki, Finland; [3]Department of Public Health, University of Helsinki, Helsinki, Finland; [4]Comprehensive Cancer Center, Helsinki University Hospital, Helsinki, Finland; [5]Group Administration, University of Helsinki and Helsinki University Hospital, Finland, Helsinki, Finland; [6]Department of Health and Social Management, Research Centre for Comparative Effectiveness and Patient Safety, University of Eastern Finland and Kuopio University Hospital, Kuopio, Finland; [7]Endocrine surgery, Abdominal Center, Helsinki University Hospital, Helsinki, Finland.

Background
The prevalence of small intestine neuroendocrine tumors (SI-NETs) is increasing. Disease progression is often slow, treatment options and long-term survival rates have improved. Health-related quality of life (HRQoL) is considered an important measure of patients' perception of the burden of their disease and the impact of treatment modalities. Despite this, data on whether improvements in treatment options and survival rates also translate into improved HRQoL in patients with SI-NETs are scarce.
Objective
To assess HRQoL and its predictors in carefully characterized SI-NET patients, and compare the results to that of a general population in Finland.
Design
We studied HRQoL with 15D and SF-36 questionnaires in 134 grade 1 and 2 SI-NET patients and compared 15D results to those of age- and gender-standardized general population ($n=1153$). Patients with histologically confirmed diagnosis of SI-NET treated at the Division of Endocrinology and Department of Oncology of the Helsinki University Hospital during year 2017 were included in the study. We studied whether socioeconomic factors, disease characteristics including treatment modalities, medication and/or comorbidities predicted HRQoL.
Results
Mean disease duration was 81 (4–468) months, 91% had metastatic disease and 79% received somatostatin analog treatment. Hepatic tumor load was 0% in 44.8%, <10–25% and >25% in 44% and 11.2%, respectively. Ki-67 was 3.7 (0.5–15) %. Mean fP-CgA and S-5HIAA concentrations were 15 (1.3–250) and 344 (24–7470) nmol/l, respectively. Overall HRQoL was significantly impaired in patients compared to controls (total 15D scores 0.864 ± 0.105 vs 0.905 ± 0.028, $P<0.001$). SI-NET patients scored worse on 9 of 15 dimensions (sleep, excretion, depression, distress, vitality, sexual activity ($P<$ 0.001), breathing, usual activities and discomfort and symptoms ($P<$ 0.01–0.05). SF-36 dimension scores correlated highly with total 15D score ($P<0.001$). Patients with low 15D score in excretion dimension (impaired excretion, $n=85$) had significantly impaired HRQoL compared to those ($n=49$) without impaired excretion (0.828 vs 0.933, $P<0.001$). Diarrhea, depression and number of medications independently predicted impaired HRQoL. In contrast, age, gender, educational level, Ki67 index, hepatic tumor burden, S-5HIAA, cardiovascular or diabetes comorbidity, somatostatin analog or interferon therapy or peptide receptor radionuclide therapy did not predict HRQoL.
Conclusions
Overall HRQoL is severely impaired in SI-NET patients. The most affected dimensions are excretion, sleeping, depression, distress, vitality and sexual activity. Improved treatments of diarrhea and depression are warranted.

Role of GLUT-2 expression and MGMT methylation for streptozotocin clinical response in adrenocortical carcinoma

Silviu Sbiera[1], Alfred Maukner[1], Matthias Kroiss[1,2], Marcus Quinkler[3,4], Felix Beuschlein[5,6], Andreas Rosenwald[7], Sabine Herterich[8] & Martin Fassnacht[1,2,8]
[1]Division of Endocrinology and Diabetes, University Hospital of Würzburg, Würzburg, Germany; [2]Comprehensive Cancer Center Mainfranken, University of Würzburg, Würzburg, Germany; [3]Department of Endocrinology, University Hospital Charite Berlin, Berlin, Germany; [4]Endokrinologie Praxis am Stuttgarter Platz, Berlin, Germany; [5]Klinikum der Universität München, Endocrine Research, Munich, Germany; [6]Klinik für Endokrinologie, Diabetologie und Klinische Ernährung, UnviersitätsSpital Zürich, Zürich, Switzerland; [7]Institute for Pathology, University of Würzburg, Würzburg, Germany; [8]Clinical Chemistry and Laboratory Medicine, University Hospital Würzburg, Würzburg, Germany.

Introduction
Streptozotocin (SZ) is an active drug for the treatment of advanced adrenocortical carcinoma (ACC) in a minority of patients with an objective response rate of <10%. It has been reported that expression of glucose transporter-2 (GLUT-2) is essential for SZ to enter tumor cells and that high activity of O-6-methylguanine-DNA methyltransferase (MGMT) counteracts the alkylating effect of SZ. Therefore, we aimed to clarify the role of GLUT-2 and MGMT in the response of ACC to SZ.
Methods
GLUT-2 membrane protein expression was analyzed by immunohistochemistry in paraffin embedded tissue sections from 78 ACC patients (28 SZ responders and 50 with progressive disease). Methylation status of the promoter regions of MGMT and DNA mismatch repair (MMR) genes MLH1, 3, MSH2, 3, 6; PMS2 was assessed by multiplex ligation–dependent probe amplification (MLPA) using corresponding tumor and germ line DNA and compared with methylation of the same promoter in 6 normal adrenal glands.
Results
Membrane-located GLUT-2 protein was detected in all patients with objective response after SZ treatment and in 46/50 (92%) of the non-responders, without significant difference in average expression levels. Analysis of the samples with GLUT-2 membrane expression for promoter hypermethylation revealed significantly higher MGMT promoter methylation in responders than in non-responders ($P=0.02$) while other MMR gene promoters showed higher methylation in non-responders ($P=0.03$). MGMT hypermethylation was strongly associated with improved progression free survival during SZ (unmethylated: 3.9 ± 1.7 months; hypermethylated: 5.1 ± 0.8 months, $P=0.06$) while hypermethylation of MMR gene promoters was strongly associated with progression-free survival independent of treatment (unmethylated: 8.79 ± 2.3 months; hypermethylated: 19.23 ± 8.2 months, $P=0.05$).
Conclusion
These data demonstrate that GLUT-2 expression is necessary but not sufficient for therapeutic response to SZ in ACC. MGMT promoter hypermethylation is strongly associated with clinical efficacy of SZ, while hypermethylation of 6 other MMR gene promoters is associated with less aggressive tumors. This may be related with their role in creating neo-antigens similar to other solid cancers.

Pancreatic neuroendocrine tumors (panNETs) are the second most common neoplasm of the pancreas. panNETs arise from cells of the pancreatic islets and

comprise a diverse and heterogeneous group of neoplasms. This hampers their systematic study, and the identification of common molecular signatures that might facilitate a better diagnosis of the disease, and the development of efficient therapeutic approaches. Indeed, there are no clinical, biochemical, anatomopathological, immunohistochemical or molecular features capable to predict either tumor prognosis or postsurgical treatment for panNETs. Current evidence indicate that certain regulatory systems composed of G-protein coupled receptors and their ligands could play a crucial role in the development and/or progression of different endocrine-related tumors. In this line, several studies have shown that the KiSS/KiSSR system is present in certain tumor types where it exerts antitumoral actions. Accordingly, the goal of this study was to determine the presence of this system in human panNET tissue samples by qPCR ($n=46$, including tumor and non-tumor adjacent regions) and to analyze its relationship with several tumor distinctive clinical features related to tumor prognosis. In addition, we sought to study the potential functional role of this regulatory system in panNETs using BON1 cell line. Firstly, we found that expression levels of KiSS were higher and of KiSSR lower in panNET tissues compared to its adjacent non-tumor tissues. Moreover, KiSS expression appeared to be upregulated in panNET samples from patients harboring metastatic disease, whereas KiSSR expression was significantly lower when compared to samples from non-metastatic patients. In addition, functional assays demonstrated that kisspeptin10 significantly modulated both cell proliferation and migration processes in BON1. Interestingly, blockade of KiSSR using a KiSS1R-antagonist (kisspeptin234) evoked a significant increase in the proliferation rate of panNET cells after 24 and 48 h, while did not change cell migration capacity. Finally, combined administration of kisspeptin10 and KiSS1R-antagonist significantly reduced BON1 cell proliferation and migration after 24 h exposure, suggesting that KiSS1R-antagonist did not counteract the antitumoral action of KiSS1 in this experimental setting. Ongoing analyses indicate that the antitumor actions of KiSS1 on panNET cell line involve the modulation of various signaling pathways and different molecular mechanisms. Altogether, our results provide original evidence for the presence and functional activity of the KiSS/KiSSR system in panNETs, suggesting its potential role in the development and/or progression of this pathology, and paving the way to explore its value as a novel biomarker and/or therapeutic target in panNETs.

Introduction
Adrenocortical carcinoma (ACC) is a rare, aggressive tumour with unsatisfactory treatment options in advanced disease. Activation of epithelial to mesenchymal transition (EMT) has been described as causative of metastatic spread in a variety of human cancers. Accordingly, new drugs were developed specifically targeting EMT with a focus on HGF/c-MET and FGF/FGFR signalling. We here asked whether EMT is a relevant mechanism in ACC.
Methods
Expression of epithelial and mesenchymal markers was assessed in 20 normal adrenal glands (NAG), 23 adrenocortical adenomas (ACA) and 27 ACC. Epithelial marker E-cadherine and mesenchymal markers SLUG and N-cadherine were analysed by IHC. Expression of FGFR1-4 was quantified in FFPE tumour tissue using RNAscope and qRT-PCR array was employed to quantify expression of 92 FGF-FGFR pathway genes. Isoform switching between isoforms IIIb (epithelial) and IIIc (mesenchymal) characteristic for EMT was assessed for FGFR 1 and 2 by qRT-PCR with specific primers. c-MET was quantified by qRT-PCR and IHC.
Results
Surprisingly, all adrenal tissues lacked E-cadherine expression while N-cadherine was present in both normal and neoplastic adrenal tissues but was significantly lower in malignant vs benign tissues (0.88 ± 0.16 vs 1.64 ± 0.19, $P=0.007$). SLUG had a uniformly high nuclear expression in all adrenal tissues. FGFR2 mRNA was expressed at lower levels in ACC compared to ACA (3.1 ± 2.1 vs 6.5 ± 2.3 mRNA copies/cell, $P=0.0005$) whereas FGFR1 (7.5 ± 5.3 vs 4.5 ± 2.9, $P=0.09$) and FGFR4 (5.1 ± 2.3 vs 2.6 ± 1.3, $P=0.002$) were higher in ACC. FGFR4 expression was higher in advanced (ENSAT stage 3 and 4) vs localized ACC (6.2 ± 1.6 vs 3.9 ± 2.7, $P=0.03$). FGF/FGFR pathway analysis confirmed differential FGFR expression and revealed decreased expression of FGF7, FGF17 and mitogen associated protein kinases in tumors compared with NAG. Surprisingly, all adrenal tissues had higher expression of IIIc vs. IIIb isoform expression of both FGFR1 and 2. c-MET expression was significantly higher in ACC compared to ACA and NAG at mRNA but not protein level.
Conclusions
Normal adrenal cortical tissue but also adrenocortical tumors exhibit consistent expression of proteins considered to reflect mesenchymal differentiation. This is probably due to their origin in the intermediate mesoderm. However, significant changes in expression of mesenchymal marker N-cadherine and FGF/FGFR system suggest their relevance in adrenocortical tumorigenesis and progression. Receptor tyrosine kinase FGFR4 may be also a suitable treatment target for advanced ACC.

Multiple endocrine neoplasia type 1: a retrospective monocenter analysis of 73 cases

Roberta Modica, Fabio Lo Calzo, Federica de Cicco, Filomena Bottiglieri, Concetta Sciammarella, Annamaria Colao & Antongiulio Faggiano
Endocrinology Unit, Department of Clinical Medicine and Surgery, 'Federico II' University, Naples, Italy.

Multiple endocrine neoplasia type 1 (MEN1) is an inherited syndrome, affecting multiple endocrine glands whose natural history remains largely unknown. Aim of this study was to assess the epidemiological and clinical profile of MEN1 in a single center. Seventy-three MEN1 patients, belonging to 30 different families, referred at the NET Center of Naples, from 2000 to 2017, were evaluated. Male/female ratio was 0.73, mean age 43 years (range 10–86). Forty-six cases (64%) were diagnosed on family screening. A MEN1 gene mutation was found in 67 cases (92%) and deletion in 1 case. Primary hyperparathyroidism (PHPT) was the most common manifestation (86%), followed by duodeno-pancreatic neuroendocrine tumor (DP-NET) (74%) and pituitary adenoma (PA) (45%). Seven subjects (10%), mean age 22.7 years (range 10-34), have not yet presented any manifestation of MEN1, whereas 26 patients (36%) developed PHPT, DP-NET and PA. DP-NET were mostly non functioning (76%), followed by gastrinoma (22%), insulinoma (2%). Metastases occurred in 7 (13%), four of whom had exon 2 frameshift mutations. Five patients (7%) died, 2 for liver insufficiency of DP-NET, 1 for renal insufficiency, 2 due to DP-NET postoperative complications. Twenty-nine DP-NET patients (54%) received therapy with somatostatin analogs. Two were treated with targeted agents. Median overall survival in DP-NET patients was not reached. Among PA, 42% were macroadenoma, 45% were prolactinoma. Adrenal hyperplasia was found in 29%, mostly hormonally silent (86%), except 1 pheochromocytoma, 1 aldosterone-producing, 1 glucocorticoid producing adenoma. Five patients (7%) developed bronchial/thymic carcinoid. These data contribute to clarify the clinical picture of MEN1. Peculiar finding of our cohort is the high prevalence of DP-NET and adrenal lesions, due to better screening methods.

Cell line derived from glioblastoma synthesizes steroid hormone. Effect of enzyme inhibitors

Luis Manuel Pinacho Garcia[1], Ricardo A Valdez[1], Araceli Navarrete[1], Marisa Cabeza[2], José Segovia[1] & Marta C Romano[1]
[1]Depto. De Fisiología, Biofísica y Neurociencias. CINVESTAV del IPN, ciudad de Mexico, Mexico; [2]Depto. De Sistemas Biológicos, Universidad Autónoma Metropolitana-Xochimilco, ciudad de Mexico, Mexico.

Glioblastoma (GB) is the most aggressive primary brain tumor, the survival rate is low because of a high prevalence of recidives. The incidence of GB in the adult

population is 50% higher in men than in women, which suggest a role of steroid hormones in it is development. Information on GB as a steroidogenic tissue is poor. The objectives of this study were: 1, to investigate the capacity of a human GB cell line to synthesize sex steroids and corticosteroid metabolites, and 2, to know the effects of two enzymatic inhibitors of 5-alpha reductase, finasteride and dutasteride, on the hormonal metabolism of the tumoral cells. U87GB cells line were cultured with DMEM, antibiotics and 10% FBS. Thereafter media were replaced by fresh culture media without FBS. Tritiated steroid precursors, progesterone (^{3}H-P4) or androstenedione (^{3}H-A_4), were added to the media and cells cultured in the presence or absence of three concentrations of finasteride or dutasteride. Culture media were collected after 24 or 48 h, and extracted with ether. The resulting steroids were separated by thin layer chromatography (TLC). Data were expressed as percent transformation of the tritiated precursors ± S.E. Results showed that the U87 cells incubated with ^{3}H-A_4, synthesized significant quantities of testosterone after 24 h. The synthesis decreased by 48 h, but the production of its metabolites, dehidrotestosterone (DHT) and androsterone increased. After 48 h finasteride inhibited the production of DHT, dehidroandrosterone (DHA), androsterone and androstanedione. After 48h of culture dutasteride significantly inhibited the synthesis of the testosterone metabolites DHT, DHA, androsterone and androstanedione. The incubation of U87 cells with ^{3}H-P4 for 24 and 48 h lead to the time-dependent synthesis of the corticosteroid metabolites 17-hydroxyprogesterone (17-OHP4), deoxycortisol (DCLS), deoxycorticosterone (DOC), cortisol (CLS), corticosterone (CNE) and aldosterone. The addition of dutasteride to the culture media caused the inhibition of the synthesis of CLS, DCLS, aldosterone, allocorticosterone, and dehidrocorticosterone (DHC) with a significant accumulation of DOC after 48h of culture. In conclusion, U87 cells have the capacity to synthesize sex steroid hormones and corticosteroids, with a remarkable abundance of androgens. 5-alpha reductase inhibitors significantly reduced the synthesis of androgenic metabolites. In addition, dutasteride blocked the 5-alpha reductase action on the corticosteroid pathway, affecting the metabolite synthesis. Therefore, 5-alpha reductase inhibitors may possibly have a role in the control of GB.

Unraveling the incidence and clinical patterns of neuroendocrine neoplasms in Greece, through the experience of multipotent, specialized clinical centers.

Olga Papalou[1], Eleni Kandaraki[1], Georgios Papadakis[2], Georgios Nikou[3] & Evanthia Diamanti-Kandarakis[1]
[1]Department of Endocrinology and Diabetes, Hygeia Hospital, Athens, Greece; [2]STEPS Stoffwechselzentrum, Biel/Bienne, Switzerland.
[3]Medical School of Athens, Athens, Greece.

Introduction
Neuroendocrine neoplasms (NENs) are a heterogeneous group of tumors arising from neuroendocrine cells in the endocrine and central nervous system, the natural history of which remains inadequately understood. Large epidemiological studies are gradually emerging from different countries worldwide, which contribute to the establishment of a spherical view about these tumors. The purpose of this study is to evaluate the epidemiological, clinical and pathological characteristics of patients with NENs that have visited the specialized, multipotent medical center of a University Hospital in Athens, Greece.
Methods
311 patients with NENs were recruited at the specialized, outpatient Medical Center of Neuroendocrine Tumors of the Endocrine Department of 'Sotiria' University Hospital in Athens, Greece, during the period from September 2013 till the end of 2014. Anthropometric, clinical, laboratory, imaging and pathologic data were obtained from every patient.
Results
55.9% of patients with NENs were female and 44.1% were male. The mean age at the time of diagnosis was 52.77 ± 16.7 years old. The majority of NENs were detected in the gastroenteropancreatic system. The most common primary site was stomach (23.8%), followed by pancreas (19.6%) and appendix (12.9%). In 31 patients (10%) the primary tumor remained unknown. Over half of NENs were regional at the time of diagnosis, 18.6% of patients had locally extended disease, while 25.4% of NENs, involving mostly NENs of unknown origin, pancreas and small intestine, were metastatic. Simultaneously, most of them displayed a Ki-67 index of ≤2%, while G3 classification, with a high proliferation index was only observed in pancreatic, rectal and rare NENs. Laboratory data revealed that CgA can predict whether a NEN is metastatic or not, but cannot predict how aggressive its behavior can be. On the contrary, NSE cannot be used as prognostic marker both in disease extent and grading of NENs. Finally, it was observed that patients with CgA levels in the highest quartile (CgA > 237 ng/ml) displayed 8 times higher risk for being metastatic at the time of diagnosis (OR = 8.643, 95% CI = 2.576–9.0).
Conclusions
This is one of the first large, epidemiological studies in Greece, evaluating the natural course of NENs through the experience of a specialized medical center. NENs of the gastroenteropancreatic system were most common, mainly regional at the time of diagnosis and with a Ki-67 index of ≤ 2%. CgA can be a useful marker in predicting disease extent of NENs.

Evaluation of neurofibromatosis type 1 and gastroenteropancreatic neuroendocrine tumors.

Juan Carlos Percovich, José Atencia, Rogelio García, Marcel Sambo, Montserrat Blanco, Amanda Rotger, Dolores López, Yoko Olmedilla, María Picallo, Marián Vélez, Javier Agreda, Noemí Brox & Susana Monereo
Hospital General Universitario Gregorio Marañón, Madrid, Spain.

Introduction
Neurofibromatosis type 1 (NF1) is an autosomal dominant condition with an incidence of 1 in 2600 to 3000 individuals. Patients with this disorder are characterized by multiple neurofibromas, caf-au-lait macules, axillary freckling, optic gliomas, iris hamartomas, and skeletal abnormalities. Overall risk of developing neoplasms is approximately 2 to 4-fold higher in patients with NF1, with a risk of malignancy estimated between 5 and 15%. Endocrinopathies are sometimes associated with this condition. Patients with NF1 usually assessed at Endocrinology consultation are those who suffer from gastroenteropancreatic neuroendocrine tumours (NET) (∼1.0%) and/or pheochromocytomas/paragangliomas (∼0.1-5.0%). Gastroenteropancreatic involvement in NF1 includes gastrointestinal stromal tumors (GIST), carcinoids, somatostatinomas, gastrinomas, insulinomas and nonfunctioning pancreatic tumors.
Methods
We identified 11 patients with NF1 who are still ongoing follow-ups at the Endocrinology Service of our Centre. Of those, two were found to be affected by NETs. We describe the demographic characteristics, the age of diagnosis, the type of tumor and its current status.
Results
Case 1. A 58-year-old woman that underwent an enucleation of a pancreatic somastotatinoma at the age of 15. She has non-specific lesions in the liver, but none with evidence of metastases and on the other hand has high chromogranin a (CgA) levels, therefore she is being treated with a somatostatin analogue.
Case 2. A 70-year-old man proceded to a pancreatoduodenectomy of a dudodenal somastotinoma at the age of 67. The tumor size was 25 mm and the average Ki67 < 5%. There is currently no evidence of metastases and CgA levels are normal.
Conclusions
Although association of gastroenteropancreatic NETs in the context of patients with NF1 is uncommon, these patients' treating physicians should be aware of such possibility. Surgical removal of the NET is the first-line therapy and is potentially curable if there is no significant delay in the diagnosis.

P139

Prevalence of undiagnosed Medullary Thyroid Carcinoma and Phaeochromocytoma in MEN2A syndrome revealed by cascade screening

Rakshit Kumar, Mamta Joshi, Anand Velusamy, Barbara Mcgowan, Jake Powrie, Louise Izatt & Paul Carroll
Guy's and St Thomas' NHS Foundation Trust, London, UK.

Mutations in the RET gene are responsible for Multiple Endocrine Neoplasia type 2A (MEN2A), characterised by Medullary Thyroid Carcinoma (MTC) and Pheochromocytoma (PCC). It is well recognised that there is a genotype-phenotype correlation regarding likelihood of endocrine tumour development. The American Thyroid Association (ATA) has published predictive grading to guide clinical management of patients with RET mutations.
Aim
In this study, we aim to assess the prevalence of MTC and PCC in asymptomatic patients, diagnosed with a RET mutation as a result of cascade screening of a proband relation.

Method
Review of electronic records, notes and clinical material collected from patients referred to NET (Neuro Endocrine Tumors) MDM and regional genetics referral centre over last 15 years. The database revealed 30 patients with confirmed MEN 2A, of which 20 were diagnosed after cascade genetic screening. Data from 18 patients was included in the study.
Results
There were 12 males, 6 females with mean age of 32.4 ± 22.5 years (mean ± S.D.). 8/18 asymptomatic patients (44.4%) had endocrine tumours diagnosed at or within 12 months of screening (mean age at MEN 2A diagnosis 41.3 ± 16.7 years). 100% (8/8) patients had histologically confirmed MTC, although serum calcitonin was elevated in only in 6/8 (range 16.9–3900 ng/l). 3 of these 8 patients (17%) also had PCC at diagnosis (with elevated catecholamines/ metanephrines), 2 bilateral and 1 unilateral (13 × 7 cm). In patients with tumour, the most frequent ATA Class was B (7 patients) followed by Class C (1 patient). The most common mutations were of codon C609Y and codon C620R in Exon 10 in 3 patients each, followed by C609R and C634R in 1 each. All 3 patients with synchronous PCC and MTC at presentation had ATA Class B mutations (C620R: 2 patients and C609Y) in Exon 10. In this cohort, mutations were found in Exon 10 in 88% and in Exon 11 in 12%.
Conclusion
Our study revealed the prevalence of previously undiagnosed tumours with cascade screening as 44% for MTC and 17% for PCC. This information is helpful in counselling during cascade screening. These findings emphasise that all patients with MTC should have RET mutation screening.

Introduction
Multi-modal therapy for adrenocortical carcinoma (ACC) includes surgery, therapy with the adrenolytic agent mitotane and systemic chemotherapy. Achievement of therapeutic mitotane concentrations (≥ 14 mg/l) has been related to improved outcomes.
Aim
To evaluate the effectiveness of a defined* high dose protocol mitotane therapy in patients with advanced ACC (stages III and IV).
Methods
Review of patients presenting to KCH with stage III or IV ACC and the mitotane concentration achieved through the Lysosafe monitoring service.
Results
$N = 57$ patients were referred and first diagnosed with ACC (2008-17) of whom 44 patients had stage III or IV disease at diagnosis and were managed actively with surgery and/or mitotane therapy. 40/44 patients underwent surgical resection of the primary tumour;11/22 patients with stage IV disease subsequently received systemic chemotherapy [10 patients received a combination of etoposide, doxorubicin and cisplatin (EDP) and 1 patient received a combination of carboplatin and etoposide]. 38/44 patients were initiated on mitotane therapy. The median overall survival of patients with stage IV disease was 25.3 months. The median survival for stage III has not been reached. An additional 9 patients had prior management, including surgery, elsewhere and were referred for mitotane initiation. A total of 47 patients were therefore included in the mitotane pharmacokinetic analysis. Six patients were excluded: 3 patients died shortly after mitotane initiation, 1 patient withdrew due to a severe reaction and 2 patients had not completed 12 weeks therapy at the time of submission. Of the remaining 41 patients, 33 commenced the 'high dose' protocol and the remainder the 'low dose' protocol. For patients on the high dose protocol, 25/33 (76%) reached a mitotane concentration ≥ 14 mg/l within 12 weeks of initiation of therapy, compared to 3 patients from the low dose protocol group ($P = 0.084$). In the high dose protocol group, 21 patients (84%) maintained therapeutic drug concentrations in ≥ 50% of the subsequent follow-up samples and 12 patients (48%) maintained therapeutic drug concentrations in ≥ 75% of subsequent samples.
Conclusion
The use of high dose protocol mitotane therapy is a successful strategy to achieve and maintain therapeutic drug concentrations when treating patients with advanced ACC (stages III and IV). In combination with an assertive surgical approach and optimal chemotherapy, this has resulted in outcomes that compare favourably (median OS 25.5 months in stage IV disease) with previously published series which describe a median OS < 12 months.

Patients with metastatic bone disease and neuroendocrine neoplasms: the experience of a multi-center study

Krystallenia Alexandraki[1], Marina Tsoli[1], Inbal Uri[2], Tristan Page[3], Michail Pizanias[4], Dimitrios Thomas[1], Chen Sheng Low[3], Vasiliki Mavroeidi[1], Olu Adesanya[3], Denise Kolomodi[1], Srirajaskanthan Rajaventhan[4], Simona Grozinsky-Glasberg[2], Martin Weickert[3] & Gregory Kaltsas[1,3]
[1]Endocrine Unit, 1st Department of Propaedeutic Medicine, Laiko University Hospital, Medical School, National and Kapodistrian University of Athens, Athens, Greece; [2]Neuroendocrine Tumor Unit, Endocrinology and Metabolism Department, Division of Medicine, Hadassah-Hebrew University Medical Center, P.O.B. 12000, 91120, Jerusalem, Israel; [3]The ARDEN NET Centre, University Hospitals Coventry and Warwickshire NHS Trust, Coventry, UK; [4]Institute of Liver Studies, King's College Hospital, London, UK.

Introduction
Neuroendocrine neoplasms (NENs) have variable biological behavior but the majority exhibits a slow progression. Metastatic bone disease (mBD) in NENs is relatively uncommon and not well described albeit associated with an increased mortality.
Methods
Seventy-four [37 males (50%), aged(± S.D.) 60.2 ± 19.3] patients with NENs and bone metastases were recruited from 4 centers.
Results
Seventy-three (98.6%) patients had sporadic disease while 1(1.4%) had MEN-1. The primary disease sites were: pancreas: 22(29.2%); small bowel: 18(24.3%); unknown origin: 12(16.2%); lung: 11(14.9%); sigmoid: 4(9.5%), thymus: 2(2.7%), breast: 1(1.4%) and caecum 1(1.4%). Four (5.4%) had functional syndrome, 2 ACTH-ectopic syndrome and 2 carcinoid syndrome. Thirty-four (46%) patients had synchronous diagnosis of NEN and mBD, while in the remaining the time to mBD since first diagnosis was 27.9 ± 56.7(0-383) months. Metastatic deposits were found as following: liver 48(64.9%), lymph nodes 24(32.4%), adrenal gland 4(5.4%), lymph nodes 11(14.9%), retroperitoneal and pelvic implantation 2(2.7%), mediastinum 2(2.7%), orbital brain 2(2.7%), brain 1(1.4%), parotid gland 1(1.4%), ovaries and uterus 1(1.4%), pancreas 1(1.4%). Sixteen (28.1%) patients had Ki-67 ≤ 2% (grade 1), 27(47.4%) 3-20% (grade 2), 25(15.8%) > 20% (grade 3) for gastro-intestinal NENs and for lung and thymus all 9(15.8%) had atypical NENs. The treatment for mBD included bisphosphonates in 40 (74%), peptide receptor radionuclide therapy (PRRT) 29(39.2%), denosumab 13(17.6%), and RT 13(17.6%). The imaging studies dentified mBD as following: 45/54(83.3%) bone scan, 21/35(60%) MRI, 36/67(53.7%) CT, 35/54(64.8%) octreoscan, 11/21(52.4%) PET-FDG and 28/30(93.3%) gallium-68 positron emission tomography (Ga-PET). The mBD therapy resulted in improvement in 6.3%, stable disease in 45.3%, and deterioration in 37.5% while 10.9% of patients passed away before the evaluation of treatment response. No difference was seen after treatment with an intensified bishphosphonate scheme (4 mg of zoledronic acid monthly for 2 consecutive years) versus a conventional scheme. Overall, 30(40.5%) patients succumbed because of their disease with an overall survival 67.1 ± 76(1-447) months since the NEN diagnosis.
Conclusion
The present multicentre registry of patients with NENs and mBD highlights the validity of Ga-PET for mBD identification and implies that there is no need of an intensified treatment at least for bisphosphonates despite the higher mortality rate of this subgroup of patients with NENs.

Clinical features of 'dedifferentiation' in advanced pancreatic neuroendocrine neoplasms: the experience of two centers of excellence

Krystallenia Alexandraki[1], Simona Grozinsky-Glasberg[2], Maria Kaltsatou[1], Georgios Kyriakopoulos[3], Chrysovalantis Vergadis[4], Paris Pappas[4], Vasiliki Mavroeidi[1], Marina Tsoli[1], Georgios Nikolopoulos[1], Anna Angelousi[1], Akrivi Kostopoulou[5], Theodosia Choreftaki[5], Dimitra Rondogianni[3], Johanna Kassiani Delladetsima[6] & Gregory Kaltsas[1]
[1]Endocrine Unit, 1st Department of Propaedeutic Medicine, Laiko University Hospital, Medical School, National and Kapodistrian University of Athens, Athens, Greece; [2]Neuroendocrine Tumor Unit, Department of Endocrinology, Hadassah-Hebrew University Medical Center, Jerusalem, Israel; [3]Department of Pathology, Evangelismos Hospital, Athens, Greece; [4]Department of Radiology, Laiko General Hospital, Athens, Greece; [5]Department of Pathology, 'G. Gennimatas' General Hospital, Athens, Greece; [6]First Department of Pathology, Medical School, National and Kapodistrian University of Athens, Athens, Greece.

Introduction
Neuroendocrine neoplasms (NENs) exhibit significant heterogeneity in growth rates. Clinical and histopathological dedifferentiation has been documented but their clinical characteristics have not been described.
Aim of the study
The identification of clinical features of a series of pancreatic NENs (pNENs) that developed dedifferentiation during their course.
Methods
Fourteen patients (eight males) with mean age($\pm$S.D.): 54.8$\pm$12.4 years were recruited from two centers. Patients with documented disease progression were submitted to a new biopsy. Dedifferentiation was defined as histologically proven higher Ki-67 (%) able to increase the grade of neoplasm. Immunohistochemical analysis (IHC) for p53, β-catenin and E-cadherin were studied as markers of aggressive behavior.
Results
Twelve (85.7%) patients with a $>$10% change in Ki-67 had sporadic pNENs and 2 with $<$10% had pNEN in the context of MEN-1. At presentation, 1 (7.1%) patient had a NEN stage I, another stage III, 12(85.7%) had stage IV; 5 (35.7%) patients had a grade 1 NEN, 8 (57.1%) had a grade 2 NEN, and 1 (7.1%) had a low grade 3 (Ki-67:25%). After dedifferentiation 2 patients had low grade 2 (Ki-67$<$10%), 1 high grade 2, 3 (21.4%) had low grade 3(Ki-67$<$50%), and 8 (57.1%) had high grade 3 (Ki-67$\geq$50%); metastatic sites included, only liver:6, liver and bone:1, liver and lymph node:4, liver, lymph node, peritoneal implants:1. All patients had a positive octreoscan; 5 had functional syndrome (two gastrinoma, one carcinoid syndrome, one insulinoma, one VIPoma). The time of dedifferentiation, five patients were under molecular-targeted treatment (everolimus or sunitinib) with or without somatostatin analogs, four chemotherapy, three peptide receptor radionuclide therapy (PRRTs), one chemotherapy and PRRTs and one follow-up only. Eight lines of treatment were registered. At the last follow-up, 6 (42.9%) patients were alive with an overall survival 81.1$\pm$72.2 (9.46–263.3) months. The progression free-survival (PFS) for 1st line treatment was the only factor to predict time to dedifferentiation. No factor studied predicted mortality or the magnitude of Ki-67 increase. IHC for p53 was abnormal in 80% (4/5) cases all after dedifferentiation while β-catenin and E-cadherin had unaltered pattern of expression.
Conclusions
Dedifferentiation of NENs is associated with a more aggressive behavior and worse overall survival. More studies are needed to clarify if p53 may be used as immunohistochemical marker of dedifferentiation.

Clinical features of a gastric neuroendocrine neoplasms type 1 series

Vasiliki Mavroeidi[1], Marina Tsoli[1], Aggeliki Karapanagioti[1], Dimitrios Thomas[1], Panagiotis Moschouris[1], Charikleia Christakou[1], Maria Chrysochoou[1], Stavros Sougioultzis[2], Ioannis Karoumpalis[3], Maria Kaltsatou[1], Georgios Nikolopoulos[1], Gregory Kaltsas[1] & Krystallenia Alexandraki[1]
[1]Endocrine Unit, 1st Department of Propaedeutic Medicine, Laiko University Hospital, Medical School, National and Kapodistrian University of Athens, Athens, Greece; [2]Gastroenterology Division, Department of Pathophysiology, 'Laikon' General Hospital, University of Athens, Athens, Greece; [3]Department of Gastroenterology, Athens General Hospital 'Georgios Gennimatas', Athens, Greece.

Background
The aim of the study was to assess the clinical features of gastric neuroendocrine neoplasms type 1 (GNEN1).
Methods
We have analyzed the clinical data of the first 73 patients with GNEN1 from our registry.
Results
The mean age($\pm$S.D.) of the patients (51 (68.9%) females) and the mean follow-up were 55$\pm$12.3 years and 28.8$\pm$42.2months, respectively. All patients had sporadic tumors and all were not functional. At diagnosis gastrin levels were 1086.4$\pm$946.7 pg/ml ($<$110). Anti-parietal cell antibodies (APCA) were positive in 91.1% (51) of the patients, autoimmune thyroid disease was found in 56.8%, and another autoimmune disease was reported in 21.9%. Median value of Ki-67 was 2 (interquantile range, IQR: 2, $<$1–20); 58.2% (39) patients had Ki-67$\leq$2% and 41.8% (28) had Ki-67$\leq$20% no neoplasm had Ki-67 $>$20%. The immunohistochemical analysis showed positivity for ghrelin in 3(4.1%), serotonin 2(2.7%), neuron specific enolase in 2, vasoactive intestinal peptide in 1 specimen and evidence of some ulceration (micro- or macro-) in 13 (17.8%) patients. Three (4.1%) patients had metastasis (two in liver and one in lymphnodes). Somatostatin receptor scintigraphy (SRS) was performed in 24 patients and was positive in 4 (16.7%). Regarding treatment, 16 patients received somatostatin analogues, 1 received everolimus, 12 (16.4%) patients were submitted in gastrectomy (total, partial or antrectomy). In the first year follow-up in 53.84%(21/39) GNEN-1 recurred [28.9% (6/21), Ki-67$>$2%], in the second year follow-up 56.3%(9/16) (12.5%(1/8), Ki-67$>$2%), in the fifth year follow-up 33.3%(4/12) (all Ki-67$\leq$2%), while following years all cases had Ki-67%$<$2% that 2 (one with 5% and the other 3%). No death was reported in the studied population.
Conclusion
Our study showed that despite the fact that the prevalence of grade 2 GNEN1 is higher than previously, GNEN1 remains a benign disease.

Female fertility in congenital adrenal hyperplasia

Imen Gargouri[1], Fatma Mnif[1], Rihab Ajili[1], Faten Hadjkacem[1], Salwa Sessi[2], Mahdi Kammoun[1], Mouna Mnif[1] & Mohamed Abid[1]
[1]Endocrinology Department, Sfax, Tunisia; [2]Regional Hospital f Kerkennah, Sfax, Tunisia.

Introduction
Congenital adrenal hyperplasia (CAH) is a genetic disease with autosomal recessive inheritance. The deficit in 21-hydroxylase (21-OH) is by far the most common enzyme deficiency CAH, since it represents 95% of the cases. Fertility in wome is found to be reduced due to hormonal, mechanical and psychological factors.
Patients and methods
It is about a descriptive and prospective study conducted in 15 patients collected in the endocrinology department of Sfax University hospital center. Fertility was evaluated by realising hormonal assessment of FSH, LH, testosterone, prolactin, estradiol and AMH. Pelvic ultrasound was also practiced in search of polycystic ovaries aspect.
Results
At the end of this report we concluded to a hypogonadotropic hypogonadism in a patient and a drop in the AMH hormone in four patients (33.3%). Pelvic ultrasound revealed micropolycystic ovaries in five patients. Referring to 2003 Rotterdam criteria, polycystic ovary syndrome was retained in six patients (40%). Five spontaneous pregnancies happened in three patients resulting in three abortions and the birth of two newborns with unambiguous female phenotype.
Conclusion
The prognosis of fertility in the CAH remains a priority for women in their fertile years. Genetic counseling in this case, is necessary.

Non-functional duodenal neuroendocrine carcinoma- a rare cause of diabetes mellitus

Chad Bisambar[1], Andrew Collier[1] & Fraser Duthie[2]
[1]NHS Ayrshire and Arran, Ayr, UK; [2]NHS Glasgow and Greater Clyde, Glasgow, UK.

Case history
We present a 40 year old female admitted with hyperglycaemia, polyuria, polydipsia and weight loss of 6 kg over a 1 month period. She had no night sweats or change in bowel habit. There was no personal or family history of malignancy or diabetes mellitus. She denied any alcohol, cigarette or illicit drug use. She took no prescription or OTC medication. On examination, she was jaundiced with pale mucous membranes. The rest of systemic examination was normal. Capillary glucose was 23.1 mmol/l.
Investigations
FBC, LFT, U and E, HbA1c, Urinary ACR, blood film, fasting gut hormone profile, CT- chest, abdomen and pelvis, duodenoscopy and biopsy, MRI liver, Octreotide scan, Endoscopic Ultrasound and biopsy, Screen for MEN 1 syndrome
Results and treatment
Hb – 64, Wcc – 8.4, platelet count – 346, lab glucose – 21.8 mmol/l, T -bili 48, Alp 687, Ast – 96, Alt – 117, Urea – 2.5, Cr – 52, Na – 136, k – 4.6, HbA1c – 79 mmol/mol, Blood film – iron deficiency anaemia, Urinary ACR – 5.4, pituitary profile, calcium and PTH normal
Fasting gut hormones
Vip – 4 (<30 pmol/l), pancreatic polypeptide – 12 (<3000 pmol/l), gastrin – 8 (<40 pmol/l), glucagon – 14 (0–50 pmol/l), Somatostatin – 174 (0–150 pmol/l), chromogranin A – 78 (0–60 pmol/l), chromogranin B – 49 (0–150 pmol/l). Duodenoscopy and biopsy- flat velvet like lesion in anterior wall of 2nd part of duodenum around ampulla. Biopsy – tubovillous adenoma with low grade dyplasia, CT chest, abdomen, pelvis – significant dilatation of intra and extra hepatic biliary tree including pancreatic duct. Periampullary 30 mm mass lesion projecting into lumen of duodenum. Enlarged nodes around superior mesenteric artery. Confirmed on MRI liver. EUS and biopsy mass in medial wall duodenum. Suspicious node over SMA. Fine needle biopsy of duodenal wall and lymph node in keeping with grade 1, well differentiated neuroendocrine tumour NM octreotide whole body scan and Spect CT- no uptake Treatment-BD mixed insulin, transfused to Hb>8 g/dl whipples pancreatico-duodenectomy R0 pT3 pN1 well differentiated neuroendocrine carcinoma arising in duodenum grade G1 (Ki 67: 0.5%) venous invasion present involvement of 4 of 17 lymph nodes.
Conclusions and points for discussion
Duodenal NET with main pancreatic duct obstruction can present with hyperglycaemia and cause diabetes. This is in the absence of gluconeogenic hormones such as somatostatin and glucagon. There was complete resolution of diabetes post Whipple's procedure and patient is now off insulin. Her last HBA1C was 31 mmol/mol.

Preliminary study of *POU1F1* (Pit1) gene expression in lactotroph and thyrotroph neuroendocrine tumours

Araceli García-Martínez[1], Johana Sottile[1], Carmen Fajardo[2], Rosa Cámara[3], Cristina Lamas[4], María Eugenia Torregrosa[5], Ignacio Aranda[6] & Antonio Picó[7]
[1]Research Support Laboratory, General University Hospital of Alicante-ISABIAL, Alicante, Spain; [2]Endocrinology Service, University Hospital La Ribera, Alzira, Spain; [3]Endocrinology Service, University and Politechnic Hospital La Fe, Valencia, Spain; [4]Endocrinology Service, General Hospital of Albacete, Albacete, Spain; [5]Clinical Analysis Service, General University Hospital of Alicante, Alicante, Spain; [6]Pathology Service, General University Hospital of Alicante, Alicante, Spain; [7]Endocrinology Service, General University Hospital of Alicante-ISABIAL, Alicante, Spain.

Introduction
The last World Health Organization (WHO) 2016 classification of Pituitary Tumours recommends the determination of transcription factors. During the last few years, silent variants of the main pituitary tumours (PTs) have been described. The mechanisms of silencing of these tumors are still unknown. *POU1F1* (Pit1) encodes a member of the POU family of transcription factors that has a relevant role in the differentiation, proliferation and survival of three pituitary cell types: somatotroph, lactotroph and thyrotroph lineage. It regulates the expression of GH, PRL and TSH-beta in the anterior pituitary gland.
Aim
To analyze the gene expression of *POU1F1* in a series of lactotroph and thyrotrophtumours, both functioning and silent, in order to observe if there are differences between the functioning and silent variants in both subtypes.
Material and methods
We selected 24 samples of PTs (seven functioning lactotropinomas (FLT), five silent lactotropinomas (SLT), three functioning thyrotropinomas (FTT) and nine silent thyrotropinomas (STT)) from our collection of 258 PTs. The tumours were previously molecularly identified on the basis of the expression of gene expression. Silent tumours were defined when the gene expression of PRL or TSHβ in the correspondent subtypes were similar to the respective functioning tumours, but without symptoms. The gene expression of *POU1F1* was performed using qRT-PCR with TaqMan probes. The data are expressed as the mean and S.D. of the Fold Change (FC). The ANOVA test was used to analyze differences between functioning and silent tumours in both subtypes.
Results
There were no significant differences in the expression of *POU1F1* between LT and TT subtypes in the overall series (2.87 ± 2.11 vs 2.00 ± 1.11, $P=0.266$) and between their respective silent or functioning tumours (1.39 ± 1.45 vs 1.91 ± 1.26, $P=0.797$; 3.94 ± 1.89 vs 2.27 ± 0.48, $P=0.267$). FLT but not FTT expressed more *POU1F1* than their silent variants (FLT vs SLT:3.94 ± 1.89 vs 1.39 ± 1.45, $P=0.036$); FTT vs STT (2.27 ± 0.48 vs 1.91 ± 1.26, $P=0.983$).
Conclusions
The lower expression of *POU1F1* in the silent variant of functioning lacto and thyrotropinomas could contribute to the silencing of these tumours. The absence of statistical significance in TT could be attributed to the short number of analyzed tumours.

Ectopic cushing's syndrome: Six cases description

Nerea Egaña Zunzunegui, Ismene Bilbao Garay, Maite Perez de Ciriza Cordeu, Izaskun Olaizola Iregi, Maite Aramburu Calafell, Leire Agea Diaz, Cristina García Delgado, Alfredo Yoldi Arrieta & Miguel Maria Goena Iglesias
Hospital Universitario Donostia, Donostia- San Sebastian, Spain.

Introduction
Ectopic Cushing's syndrome (ECS) is due to ACTH secretion of no pituitary neuroendocrine tumors and represents around 5–10% of all cases of ACTH dependent Cushing's syndromes.
Methods
Six cases of ECS diagnosticated from 2008 to 2017 were studied. Patients' age ranges from 36 to 69 years (mean 53), four females and two males. Three had pancreatic tumors, two small cell lung carcinomas and one pheocromocytoma. At diagnosis, in 83% disease was disseminated. Hypercortisolism was diagnosed before neoplasic process in five cases. All patients presented rapid clinical evolution except for patient with pheocromocytoma. Weakness, hyperpigmentation, edema, hypertension and diabetes mellitus were the most important signs and symptoms. two patients presented severe psychotic disorders. Hypokaliemia was observed in five cases (mean potassium level 2.35 mEq/l) and metabolic alkalosis in 4. Bioquimical parameters were: cortisol 73 μg/dl (29.2–136.6), ACTH 561.1 pg/ml (46–1884), urinary cortisol 6596.9 μg/24 h (226–2,3247), nugent 60.5 μg/dl (26.9–135). All patients were treated to control the hypercortisolism, one with ketoconazole, two with metopirone, two with combination of ketoconazole and metopirone and one with mifepristone. No bilateral adrenalectomy were performed, only one adrenal embolectomy. Surgical removal of primary tumor was performed in two pancreatic tumors and pheocromocytoma, and four were treated with chemotherapy. Five patients died few months after diagnosis, pheocromocytoma is cured and one patient with lung carcinoma is under control but is suffering tumor progression.
Conclusions
Any neuroendocrine tumor may be associated with ECS. Survival depends on primary tumor histology, presence of metastases and severity of hypercortisolism.

This is why a multidisciplinary approach is required for the correct diagnostic and therapeutic management.

Metastatic meduller thyroid cancer patient with MEN 2B who developed acute leukemia

Goknur Yorulmaz[1], Aysen Akalin[1], Toygar Kalkan[1], Ilknur Ak Sivrikoz[2], Eren Gunduz[3] & Ozgur Ceylan[4]
[1]Eskisehir Osmangazi University Division of Endocrinology, Eskisehir, Turkey; [2]Eskişehir Osmangazi University Department of Nuclear Medicine, Eskisehir, Turkey; [3]Eskisehir Osmangazi University Division of Hematology, Eskisehir, Turkey; [4]Eskisehir Osmangazi University Department of Internal Medicine, Eskisehir, Turkey.

Introduction
Multiple endocrine neoplasia type 2B (MEN 2B) is an aggressive disorder characterized by medullary thyroid cancer (MTC) and pheochromocytoma. Peptide receptor radionuclide therapy (PRRT) with 177Lu-DOTATATE is an effective new treatment for inoperable or metastatic neuroendocrine tumors (NETs). Hematologic problems, myelodysplastic syndrome or leukemia can be seen after alkylating agent and peptide receptor radionuclide therapy treatments. We present metastatic meduller thyroid cancer patient with MEN 2B who developed acute leukemia after treatment with 177 Lu-labeled peptide receptor radionuclide.
Case
28-year-old female was diagnosed with MEN 2B (thyroid medullary carcinoma, bilateral pheochromocytoma, and mucosal neurinoma) in 2015. Bilateral adrenalectomy and bilateral thyroidectomy with neck dissection was performed. The patients RET gen mutation was heterozygote positive. Liver biopsy for a liver mass showed metastasis of medullary thyroid carcinoma. F18-FDG-PET-CT revealed metastases in liver, lungs, and bone therefore she received alkylating chemotherapy of 6-cycles. ^{68}Ga-labeled somatostatin analogue PET/CT was revealed progression in metastatic lesions(somatostatin receptor positive) and increase in calcitonin levels after 12 months from the last cycle of chemotherapy. Six doses of Lu-177 DOTATATE was administered. After 9 months from the last dose of Lu-177 DOTATATE treatment progression in metastatic lesions and increase in calcitonin levels occurred and a new treatment was planned. However, her blood count revealed pancytopenia and bone marrow aspiration revealed promyelocytic cells. Genetic tests and flow cytometry analysis was consistent with acute promyelocytic leukemia (AML M3). Chemotherapy was planned for leukemia after ATRA treatment.
Conclusion
A decrease in bone marrow reserve, more rarely myelodysplastic syndrome (MDS) and leukemia may occur after PRRT. As with our patient, the risk of MDS increases when alkylating agents and PRRT are used together. Researchers state that acute leukemia (AL) occurred after a median follow-up of 55 months after first therapy (range 32–125 months). In our patient, acute promyelocytic leukemia occurred 18 months after the first PRRT treatment.

Diagnostic difficulties, management and treatment in neuroendocrine tumors

Mirela Claudia Nechita[1], Anca Georgiana Tudurean-Olteanu[1], Anamaria Hrisca[1], Cipriana Stefanescu[1,2], Cati Raluca Stolniceanu[1], Alexandru Florescu[2] & Maria Christina Ungureanu[1,2]
[1]'St Spiridon' Clinical Emergency Hospital, Iasi, Romania; [2]'Grigore T. Popa' University of Medicine and Pharmacy, Iasi, Romania.

Introduction
Diagnosis of NETs (neuroendocrine tumors) is based on clinical manifestations, peptide and amine secretion, specialized radiological and nuclear imaging, secured by detailed histology and immunohistochemistry, which should be obtained whenever possible. Biomarkers are still the mainstay in the diagnosis and follow-up of patients with NETs.
Case report
We present the case of a 36-year-old patient with no significant pathological personal history, diagnosticated in 2015 with amesenteric tumor/jejunal GIST (gastrointestinal stromal tumor) and lymphadenopathies adjacent to the II–III jejunal branches. Surgery was performed, with good postoperative evolution. The histopathological exam shows malignant proliferation with solid and cordial architecture, areas of intratumoral necrosis and multiple images of vascular invasion; five lymph nodes present tumor metastasis. Immunohistochemistry assays decelerate synaptophysin, CD99 positive in most tumor cells, rare positive NSE and negative cromogranin; Ki67 positive in 10% of tumor cells. The final diagnosis was neuroendocrine tumor (NET G2). The patient met the criteria for inclusion in somatostatin analog therapy, but it was schedule on demand. Between 2016 and October 2017: chromogranin A, serotonin and 5-hydroxy indolacetate were negative, no recidives on CT scan. In November 2017, the patient was admitted for weight loss, abdominal pain, nausea. Biologically, the carcinoembryonic antigen was over the upper limit, with anemia and important inflammatory syndrome. CT scan describes adenopathies in the left flank, with central necrosis and tendency to confluence, and three new hepatic nodular lesions, suspected of secondary dissemination. Surgically reintervention with the excision of the hepatic formations and the lymph node was performed; immunohistochemistry detects synaptophysin, CD56, NSE positive in the hepatic lesions with negative cromogranin; negative synaptophysin, cromogranin and CD99, with positive CD56, NSE in lymph nodes and Ki67 20% in both sites. SSTR2 and SSTR5 receptors were also positive. A Tektrotyd (Technetium 99mTc-HYNIC-Tyr3-Octreotide) scan confirmed the presence of the radiopharmaceutical pathological capture in the hepatic VI and III segment, grade Krenning 3, with a limited tumor dissemination score. Considering the aggressive progression of the disease, the dissemination rate, the Ki67 increase from 10% to 20% in a short time, we opt for somatostatin therapy and PRRT treatment initiation, the patient fulfilling the inclusion criteria (Krenning score $>$ 2).
Conclusions
The diagnosis delay, the trap of negative usual neuroendocrine markers and the refusing of the specific treatment, lead to unfavorable disease progression, aggressive growth of Ki67, which together can lead to therapeutic failure.

Through five hospitals and 800 km, a long way from emergency department to insulinoma operation

Renata Budzyńska-Nosal[1], Marta Węgrzyn-Bęk[1], Janusz Strzelczyk[2,3], Krzysztof Gutkowski[4], Beata Kos-Kudła[2,3] & Krzysztof Marczewski[1,5]
[1]Pope John Paul II Regional Hospital, Zamość, Poland; [2]Department of Endocrinology and Neuroendocrine Tumors Medical University of Silesia, Katowice, Poland; [3]Department of Pathophysiology and Endocrinology, Medical University of Silesia, Katowice, Poland; [4]Department of Gastroenterology and Hepatology with Internal Disease Unit, Teaching Hospital No 1 in Rzeszow, Rzeszów, Poland; [5]Faculty of Medical Science Lublin University Of Economy and Innovations, Lublin, Poland.

Introduction
Urgent conditions, as first symptom of endocrine disease, are rather rare in a hospital emergency department. Emergency medicine doctors work in difficult conditions, often under time pressure, they must also be guided by the likelihood of linking symptoms to the disease. Unfortunately, this makes it difficult to diagnose rare diseases. Therefore, without criticising doctors of other specialties, we would like to present our patient's long journey from the emergency department to an effective operation.
Case
A 33-year-old woman was brought to a hospital emergency department in a district hospital due to an acute psychotic episode. In the absence of a response to the treatment, she was transported to a psychiatric hospital, where initially her condition improved slightly. Unfortunately, in the further course convulsions appeared and with suspected state of epilepsy she was transported to the neurology department, where despite intensive pharmacotherapy and mechanical ventilation her condition did not improve. A dramatic improvement occurred when the consultant internist ordered blood glucose control (29 mg/dl) and subsequently glucose infusion. In the endocrinology ward during the hunger test,

hypoglycaemia was found, but with not very high insulin levels, which did not allow unambiguous diagnosis of insulinoma. In the gastrology clinic, extended imaging diagnostics with MRI and an EUS were performed combined with a biopsy of the 29×15 mm "nodula" adjacent to the head of the pancreas. However, the result of the biopsy did not confirm the diagnosis of insulinoma. Meanwhile, the patient 'disappeared" from observations of endocrinologists from the first hospital, but after 2 months "was found" in a clinic of endocrinology 400 km away. In this time the values of insulin and C peptide during spontaneous hypoglycaemia met the criteria for insulinoma diagnosis, which was also confirmed by the histopathological examination after surgical removal of the nodule. The patient in good general condition remains under the control of the endocrinology clinic. From the psychotic episode in the hospital emergency department 105 days have passed to the operation and from the first discrete symptoms 13 months.

Conclusion

Diagnosis of insulinoma in department of emergency is practically impossible, However, adherence to the principle of blood glucose testing in each patient in department of emergency probably slightly shortens the path to proper diagnosis and effective treatment.

A rare association of neuroendocrine tumors

Raluca Cristina Pascu[1], Iulia Soare[2], Liliana Mazalu[1], Anca Elena Sirbu[1,2] & Simona Fica[1,2]

[1]Elias University Hospital, Endocrinology, Diabetes and Nutrition Diseases Department, Bucharest, Romania; [2]Carol Davila University of Medicine and Pharmacy, Elias' Endocrinology Department, Bucharest, Romania.

Background

The occurrence of multiple endocrine tumors in the same patient is not always typical and cannot always be classified into a multiple endocrine neoplasia (MEN) type, McCune-Albright syndrome or the Carney complex. Schwannomas are mesenchymal tumors that originate from Schwann cells of peripheral nerve fibers that can associate in some syndromes. 90% cases are benign, involving usually the head, neck and extremities. They are rare in the retroperitoneal region (1–3%).

Case report

We report the case of a 49-year-old female patient, Caucasian, non-smoker, who was previously diagnosed (in 2008) with ACTH-independent Cushing's syndrome due to a cortisol secreting adenoma of the right adrenal gland (30/25mm). She had undergone right adrenalectomy (histopathologic exam and immunohistochemistry confirmed the diagnosis) and received one year of hydrocortisone replacement. In 2016, due to recurrence of malignant hypertension, the CT scan revealed in the right adrenal lodge a multilobulated, well-defined, heterogeneous mass, measuring 50/23 mm, that was compressing the superior vena cava and also a small adenoma (0.7/1 cm) on the left adrenal gland and left renal cysts. The patient had only a mild discomfort in the right flank. Adrenal function evaluation results were normal, excluding recurrent Cushing's syndrome, pheocromocytoma or primary aldosteronism. Pituitary function was also normal. Further testing revealed hypercalcemia (11.3 mg/dl), elevated parathormone level (103 pg/ml), insufficient level of 25-OH-Vitamin D (17.02 ng/ml), normal renal function (CKD-EPI eGFR = 97.02 ml/min per 1.73 m^2 and normal calcitonin (excluding medullary thyroid cancer). The anterior cervical ultrasonography showed a hypo-echogenic nodule (1.23/1.6 cm), suggestive for parathyroid adenoma. The patient was then referred to surgical service in order to remove the retroperitoneal mass of unknown origin by laparoscopic approach. The histopathologic and immunohistochemistry (S100, SYN, Melan A and VIM diffusely positive) exams indicated an ancient schwannoma. The patient is scheduled for sestamibi parathyroid scintigraphy. Further on, depending on the scintigraphy result, the patient will be advised to undergo parathyroidectomy and will be periodically screened for other occurrences.

Conclusion

The association between ACTH-independent Cushing's, schwannoma finding in the same adrenal lodge after adrenalectomy and recently discovered primary hyperparathyroidism, is very rare and it may be genetically determined in the context of MEN or other syndromes, but can also be sporadic. Also, retroperitoneal ancient schwannomas are very rare, and the occurrence of it after adrenalectomy has not yet been reported, so we cannot know for sure if there is a connection with these endocrine conditions.

Head and neck paragangliomas: genetic mutation and location of the tumors

José-María Recio-Córdova[1], Cecilia Higueruela[1], Rocío Cáceres[1], María García-Duque[1], Rogelio González-Sarmiento[2], José-Manuel Miralles[1], Juan-José Corrales-Hernández[1] & Ángel Muñoz-Herrera[3]

[1]Service of Endocrinology and Nutrition, University Healthcare Complex of Salamanca, Salamanca, Spain; [2]Service of Genetics, University Healthcare Complex of Salamanca, Salamanca, Spain; [3]Service of Otolaryngology, University Healthcare Complex of Salamanca, Salamanca, Spain.

Introduction

Tumors derived from the paraganglionic system are rare. 90% of them are located on the adrenal gland, and the remaining 10% are extra-adrenal. Within this last group, 85% are located in the abdomen, 12% in the thorax, and 3% in the head and neck region (HNPG). Its proximity to important structures represents a great difficulty for resection. This makes it necessary to refer these patients to reference centers with multidisciplinary teams and specific surgical training.

Objectives

To determine whether there is a correlation between the genetic mutation of the head and neck paragangliomas, their location and the presence of metastasis.

Methods

Retrospective study. Inclusion criteria: patients with head and neck paragangliomas (HNPG) treated in our hospital between the years 2000 and 2016. In total, 97 patients were included, 65 women (66%) and 32 men (33%), with an age range of 14–84 years (mean age: 49 years). All of them were surgically removed. The SDHB, C and D genes were studied.

Results

Ninety-eight percent of the tumors were nonfunctional (normal metanephrines in urine after 24 h). Out of the 97 patients, 24 (23%) showed genetic mutations. Within this group, 9 patients had the *SDHB* mutation (41%); 8 patients had the *SDHC* mutation (37%); and 5 patients had the *SDHD* mutation (20%). There was no correlation between the genetic mutation and the location of the tumor. In the patients with *SDHB* mutation, 11% had a metastasis on diagnosis, compared with 3% in the group with sporadic tumors. Vagal HNPG represented 11% (10 patients) and had a higher malignacy rate: 15% of the cases.

Conclusions

In the HNPC in our series, the most frequently found mutation was *SDHB*, which was not associated with the location and which showed shorter survival in cases with metastasis.

Bilateral neck paragangliomas in a patient with a family history and chronic hypoxemia

Cecilia Higueruela, Rocío Cáceres, María García-Duque, Cristina Robles, Myriam Beaulieu, Rosana Iglesias, Ana Herrerro, Manuel Delgado & José María Recio-Córdova

Service of Endocrinology and Nutrition. University Healthcare Complex of Salamanca, Salamanca, Spain.

Introduction

Tumors derived from the extra-adrenal paraganglionic system are rare (incidence: 0.8/100,000 people/year). In this group, 85% are located in the abdomen, 12% in the thorax, and 3% in the head and neck region (HNPC).

Case report

A 46-year-old man, ex-smoker, with a personal history of arterial hypertension, multifactorial secondary polycythemia (obesity, OSA syndrome, hypertrophic cardiomyopathy). Family history: one brother with paraganglioma. The patient presented symptoms of asthenia and neck pain.

Complementary tests

Laboratory: Hb: 20.5 g/dl; Hct: 59.6%; Ca: 12.7 mg/dl; PTH: 353 pg/ml; Calc. urine: 398 mg/24 h; Normetanephrines in urine: 599 mcg/24 h.

Neck CT scan: Bilateral laterocervical masses on both carotid bifurcation. The mass on the right side is 2.4x1.7x3.9 cm and the mass on the left side is 6.5x3.2x7.5 cm.
Scintigraphy (octreotide): laterocervical masses which express somatostatin receptors. The lesion on the right side shows more metabolic activity.
Diagnosis: Bilateral HNPG, clinically silent, which does not extend beyond the cervical region.
Evolution: The patient was operated to treat the HNPG.
Genetic study: Exons 1 to 8 of the SDHB gene, exons 1 to 6 of gene SDHC and exons 1 to 4 of gene SDHD were studied with PCR and BigDye sequencing. No pathogenic mutations or variants of unknown origin were found in the regions analyzed.
Discussion
In this patient is probably a familial paraganglioma syndrome (bilateralism and one brother with a similar condition). The genetic study performed did not come to any final conclusion on the origin of the disease (it did not analyze the SDHAF2 gene, whose mutation is typical in HNPG). The pathogenesis of HNPG is not completely known. The mutation of some specific genes (HID, SDH and VHL) create a similar effect to the stimulation of paraganglionic cells due to chronic hypoxia. Mutations of VHL and SDH are related to these routes of cell hypoxia, and the tumors present associated angiogenesis and a decrease of oxidative metabolism. It is important to mention that HNPG lack histological or molecular markers for malignancy. Up to 50% of all malignant HNPG can be initially classified as benign. Currently, the only clinical predictors for the appearance of metastasis are the presence of the SDHB mutation and a tumor size over 5 cm. Our patient meets the second condition, and therefore will be subject to strict monitoring.

The first experience of using of ultrasound with multimodal imaging technology for the diagnosis of pancreatic insulinoma

Tatjana Soldatova, Marina Yukina, Ekaterina Troshina & Nurana Nuralieva
Endocrinology Research Centre, Moscow, Russian Federation.

Introduction
Topical diagnosis of insulinoma is an actual problem due to the low detection rate of tumors (about 75%) and conflicting data about its localization in pancreas (more than 50%) when using different imaging techniques. This is partly due to the subjectivity of visualizing diagnosis specialists when describing the location of tumor. We assumed that multimodal imaging Fusion will improve the accuracy of topical diagnosis of insulinoma.
Aim
To determine the feasibility of Fusion technology for localization of insulinoma.
Materials and methods
We include 12 patients with laboratory confirmed hypoglycemic syndrome and autonomous insulin secretion aged 31-65 years. All patients underwent standard initial imaging examination for localization of insulinomas – computer tomography (CT), magnetic resonance imaging (MRI) and ultrasonography (US). In addition, we used the Smart Fusion (S-Fusion) intelligent program for synchronization real-time ultrasonography images and CT images, as well as MRI images. We created magnetic field next to the US machine and mounted magnetic sensors at the US transducer. Then we loaded data of CT (or MRI) and displayed image with tumor on the screen of US machine. The same section was obtained using the US transducer. Then we established anatomical landmarks on CT (MRI) and US images and synchronized them. In accordance with data obtained by combining the images we made topical diagnosis in all patients and then performed surgical treatment of insulinoma.
Results
There was a discrepancy in topical diagnosis, according to the standard initial imaging examination, in 5 patients (42%). The intelligent program S-Fusion helped us to clarify the tumor localization in these patients. This study also allowed to obtain more accurate information on the location of tumor (including in relation to vessels) in those patients in whom topical diagnosis was not doubt ($n=7$). The duration of ultrasound with the application of S-Fusion technology increased by only 5 minutes, and the cost was not changed. Intraoperative revision in all patients (100%) confirmed the presence of tumor of pancreas in accordance with the established topical diagnosis: in the head ($n=3$; 25%), body ($n=3$; 25%), tail ($n=6$; 50%). Microscopic examination confirmed the immunomorphological characteristics of insulin-producing tumors in all patients. In the postoperative period none of the patients had hypoglycemia.
Conclusions
Fusion technology eliminates the subjectivity of visualizing diagnosis specialists and provides more accurate information on the location of tumor. Advantages of this method are: non-invasiveness, absence of ionizing radiation, low cost and low duration of the study.

Body composition and concentration of 25-OH vitamin D as metabolic syndrome indicators in patients with non-functioning adrenal incidentalomas

Joanna Kowalska[1], Iwona Zieleń-Zynek[1], Justyna Nowak[1], Karolina Kulik-Kupka[1], Agnieszka Będkowska-Szczepańska[2] & Barbara Zubelewicz-Szkodzińska[1,2]
[1]Department of Nutrition-Related Disease Prevention, School of Public Health in Bytom, Medical University of Silesia, Katowice, Bytom, Poland; [2]Department of Endocrinology, Piekary Medical Center, St. Luke's Local Hospital in Piekary Śląskie, Piekary Śląskie, Poland.

Abstract
Up to 96% of changes detected in adrenal glands are non-functioning adrenal incidentalomas. Adrenal masses are associated with increased risk of metabolic syndrome (MS). Studies demonstrate that new anthropometric parameters can be useful indicators of disturbances in glucose and lipid metabolism in various diseases. The purpose of the study was to determine antropometric parameters and its relationship with MS factors according to the criteria of the International Diabetes Federation among patients with non-functioning adrenal incidentalomas. 120 patients hospitalized in Endocrinology City Hospital in Piekary in 2013-2017 with non-functioning adrenal incidentalomas were included to the study. Exclusion criteria were adenomas producting hormones, vitamin D supplementation, liver or kidneys failure. Biochemical parameters were obtained during routinely performed tests in the hospital and taken from the patient's medical record. Anthropometric parameters were measured in the morning. The results were used to calculate the anthropometric indicators (BMI, BAI, VAI, WHR, WHtR). The data were statistically analyzed by STATISTICA 12. $\alpha=0.05$. The average BMI was 29.5 ± 5.3 kg/m^2, WHR(women) 0.9 ± 0.2, WHR(men) 1.0 ± 0.1, WHtR 0.6 ± 0.1, BAI (women) 35.1 ± 6.2, BAI(men) $26.1\pm3.0\%$, VAI 2.1 ± 0.3. The average systolic pressure was 142 ± 18 mmHg, diastolic pressure 83.2 ± 9.5 mmHg. The mean concentration of $25(OH)D_3$ was 18.6 ± 7.7 ng/dl, total cholesterol (TC) 205.7 ± 44.9 mg/dl, HDL cholesterol(women) 66.2 ± 20.6 mg/dl, HDL cholesterol(men) 49.8 ± 16.7 mg/dl, LDL cholesterol 116.3 ± 40.3 mg/dl, triglycerides (TG) 135.9 ± 75 mg/dl, fasting glucose 112.3 ± 33.5 mg/dl, HBA1C% 6.3 ± 0.9. Possitive correlation ($p\leq0.05$) was observed between VAI and TC ($r=0.06$), VAI and LDL cholesterol ($r=0.34$), VAI and TG ($r=0.83$), WHR and TG ($r=0.08$), WHtR and TG ($r=0.04$). Systolic pressure was statistically higher ($p\leq0.05$) in patients with higher BMI ($r=0.11$), BAI ($r=0.06$), WHR ($r=0.09$;), WHtR ($r=0.14$). Fasting glucose correlated possitively ($P\leq0.05$) with BAI ($r=0.05$), BMI ($r=0.11$), VAI ($r=0.03$), WHR ($r=0.13$), WHtR ($r=0.16$), HBA1C% ($p\leq0.05$). Patients with higher $25(OH)D_3$ concentration had statistically lower HBA1C%, TC and LDL cholesterol ($p\leq0.05$). There were negative correlations ($p\leq0.05$) between HDL cholesterol and VAI, WHR, WHtR. Low $25(OH)D_3$ concentration may indicate lipid disorders in patients with non-functioning adrenal incidentalomas. BMI, BAI, VAI, WHR and WHtR are good inditators of metabolic syndrome in studied group of patients with non-functioning adrenal adenomas.

Pediatric adrenal insufficiency: experience from a Tertiary Hospital Center

Mara Ventura[1], Rita Cardoso[2], Joana Caetano[2], Isabel Dinis[2], Miguel Melo[1], Margarida Bastos[1], Francisco Carrilho[1] & Alice Mirante[2]
[1]Department of Endocrinology, Diabetes and Metabolism, Centro Hospitalar e Universitário de Coimbra, Coimbra, Portugal; [2]Department of Paediatric Endocrinology, Diabetes and Growth, Hospital Pediátrico de Coimbra, Coimbra, Portugal.

Introduction
Adrenal insufficiency is a life-threatening disease caused by primary adrenal failure or secondary adrenal failure due to an impairment of hypothalamic-pituitary axis that affects adrenal cortisol synthesis. It is characterized by deficient production of glucocorticoids and may be associated with mineralocorticoid and androgens deficiency. Prompt diagnosis and management are essential and may even be life-saving.
Methods
We retrospectively collected and analysed clinical, laboratorial and radiological data from patients with adrenal insufficiency observed over a period of 34 years (January 1984–December 2017) in a Pediatric Endocrinology Department of a Tertiary Care Hospital.
Results
Seventy patients with adrenal insufficiency were identified:41 with primary adrenal insufficiency and 29 with central adrenal insufficiency. Primary adrenal insufficiency patients were mainly males (56%), with a mean age at diagnosis of 2 ± 4 years, followed for about 11 ± 6 years. Thirty-five patients (85%) had classic adrenal congenital hyperplasia, mainly due to 21-hydroxilase deficiency ($n = 33$), 3 patients had Addison disease, 1 had X-linked adrenoleukodystrophy, 1 had Pearson disease and 1 had bilateral adrenal haemorrhage. At the presentation, 73% of the patients had hyponatremia and more than half had mucocutaneous hyperpigmentation, asthenia, anorexia, weight loss, nauseas and vomiting; 46% presented with genital ambiguity.Mean ACTH level at diagnosis was 631 ± 449 pg/mL (reference range < 46.0) and mean cortisol level was 7 ± 5 µg/dL (reference range 5.0-25.0). All the patients were treated with hydrocortisone (mean dose 9 ± 5 mg/day) and 90% were also on fludrocortisone (mean dose 60 ± 20 µg/day). During the follow-up, one patient died for unknown causes. Regarding patients with central adrenal insufficiency, the majority were females (52%), with a mean age at diagnosis of 6 ± 5 years, followed for 9 ± 6years. Craniopharyngeoma was present in 31% of the patients,pituitary hypoplasia in 24% and 10% had a hypothalamic tumour. Besides corticotropin, the most common hormone insufficiencies were thyrotropin (93%), growth hormone (63%) and antidiuretic hormone (52%) deficiencies. The most frequent presenting clinical features were hypoglycemia (35%), nausea and vomiting (28%) and infectious diseases (28%) .93% of the patients were treated with hydrocortisone (mean dose 9 ± 8 mg/day). During the follow-up, 2 patients died due to cardiorespiratory complications.
Conclusions
Despite medical advances, the diagnosis and management of adrenal insufficiency remains a challenge, particularly in the paediatric population owing to their special characteristics. Raising awareness and knowledge in medical teams and population about adrenal insufficiency is of crucial importance to improve clinical outcomes and to reduce disease morbidity and mortality.

MicroRNA profile after octreotide treatment in neuroendocrine tumor cell line

Gyu-pil Lee[1], Han-hee Jo[1], Da-yeong Ryu[1] & Misu Lee[1,2]
[1]Division of Life Science, College of Life Science and Bioengineering, Incheon National University, Incheon, Republic of Korea; [2]Department of Nuclear Medicine, Severance Hospital, Yonsei University College of Medicine, Seoul, Republic of Korea.

Abstract
Somatostatin analogs (SSAs) constitute first-line treatment for patients with neuroendocrine tumors. Somatostatin receptors (SSTRs) are the most common therapeutic, radiotherapeutic, and imaging targets of SSAs. Some G-protein-coupled receptors, including SSTRs, regulate their responsiveness to continuous drug exposure with different degrees of receptor internalization. Thus, SSTR internalization seems to play an important role in predicting the response to SSAs in patients with neuroendocrine tumors. The present study aimed to regulate SSTR internalization via miRNA profiling after SSA (octreotide) treatment in the rat pancreatic beta cell line INS-1. INS-1 cells were treated with octreotide at various incubation times (0–60 min) to confirm SSTR internalization via immunofluorescence staining. Internalization of SSTR2 in INS-1 cells was induced after 5 min of SSA treatment. Hence, we analyzed the changes in microRNA expression between 0 and 5 min after octreotide treatment. Using a greater than two-fold change in cut-off for miRNA expression, 49 probe sets were up-regulated at 5 min versus at 0 min of incubation, and 75 were down-regulated. Interestingly, miRNA involved in ubiquitination, such as rno-miR-504, rno-miR-99a-5p, and rno-miR-466b-3 were up-regulated. In conclusion, we identified miRNAs responsible for SSTR2 internalization. To modulate SSTR internalization by miRNA in tumor cells of a patient, treatment with SSAs would be clinically relevant, as this could improve the response to therapy or for tumor detection.

Gender differences in delays to diagnosis of acromegaly: data from the Swedish National Patient Register

Daniel Granfeldt[1], Åse Björstad[1], Marlow Tom[1], Anthony Berthon[2], Jérôme Dinet[2], Peter Myrenfors[3], Eva Lesén[1], Ingela Björholt[1], Daniel S. Olsson[4,5] & Gudmundur Johannsson[4,5]
[1]Nordic Health Economics, Gothenburg, Sweden; [2]Ipsen, Boulogne-Billancourt, France; [3]Ipsen, Stockholm, Sweden; [4]Department of Internal medicine and Clinical Nutrition, Institute of Medicine, Sahlgrenska Academy, University of Gothenburg, Gothenburg, Sweden; [5]Department of Endocrinology, Sahlgrenska University Hospital, Gothenburg, Sweden.

Acromegaly is a complex disease with an insidious onset and diagnosis can be delayed. The aim of the study was to investigate the diagnostic delay (DD), for patients with acromegaly due to a pituitary tumour in Sweden. Data were obtained from the Swedish National Patient Register. Patients diagnosed between January 1, 2011 and December 31, 2013 in Sweden were included ($n = 135$, 69 men, 66 women). For these patients, the occurrence of pre-defined relevant comorbidities was assessed from 1987 and onwards. DD was defined as the time between the first diagnosis (outpatient or inpatient visit) of a relevant comorbidity and the date of acromegaly diagnosis. The median (95% CI of the median) overall DD for all patients included in the analysis was 52.4 (33.4–74.3) months. The median (95% CI of the median) DD for patients diagnosed during 2011 was 57.6 (27.4–80.5) months while corresponding numbers for 2012 and 2013 was 49.3 (13.6–74.3) and 47.7 (4.2–86.8) months, respectively. During the entire study period, there were 39 patients (29%) diagnosed within 6 months while 21 patients (16%) had a DD of more than 120 months. Patients with a first symptom diagnosis categorized as hypertension had a median (95% CI of the median) DD of 17.8 (2.6–120.9) months while corresponding numbers for patients with a first symptom diagnosis categorized as a cardiac diagnosis were 108.8 (1.6–150.8) months. The median (95% CI of the median) DD for men was 21.7 (4.2–53.3) months while it was 76.7 (55.0–89.2) months for women ($P = 0.0182$ using Log rank test). Hazard ratio (95% CI) with women as reference category was 1.50 (1.06–2.11). This analysis focused on a small population, but the reported DD was in line with previous published data. A limitation of this analysis is that data on primary care visits are not included in the registry; therefore, time between first primary care visit and diagnosis of a relevant comorbidity in secondary care is not captured in the DD calculated. During the short time frame of this study no changes in the DD for patients diagnosed during the different years can be detected. There are patients with very long DD, approaching the total follow-up time. This underlines previous findings that acromegaly has an insidious onset and that diagnosis can be complex. In this study, men were diagnosed 3.5 fold faster than women, indicating that women are not correctly diagnosed to the same extent as men.

Direct costs after diagnosis of acromegaly: Data from Swedish nationwide registries

Daniel Granfeldt[1], Åse Björstad[1], Tom Marlow[1], Anthony Berthon[2], Jérôme Dinet[2], Peter Myrenfors[3], Eva Lesén[1], Daniel S Olsson[4,5], Gudmundur Johannsson[4,5] & Ingela Björholt[1]
[1]Nordic Health Economics, Gothenburg, Sweden; [2]Ipsen, Boulogne-Billancourt, France; [3]Ipsen, Stockholm, Sweden; [4]Department of Internal medicine and Clinical Nutrition, Institute of Medicine, Sahlgrenska Academy, University of Gothenburg, Gothenburg, Sweden; [5]Department of Endocrinology, Sahlgrenska University Hospital, Gothenburg, Sweden.

Acromegaly and comorbidities incur large costs in the Swedish health care system. The aim of the study was to describe direct costs since time of diagnosis, for patients with acromegaly due to a pituitary tumour in Sweden. Data were obtained via linkage of nationwide registers. Patients diagnosed between 1 July 2005 and 31 December 2007 in Sweden and with a follow-up of at least 6 years were included ($n=105$). Direct costs due to use of health care resources and pharmacological treatments (somatostatin analogues [SSA], growth hormone receptor antagonists [GHRA], and dopamine agonists [DA]) were assessed. The mean total direct costs per patient were highest for year 1 after diagnosis (€18 108 [95%CI 15 952–20 265]) with surgical interventions being the main contributor (54%). For subsequent years, the mean (95%CI) costs ranged from a maximum of €8,770 (6733–10 807) (year 2) to a minimum of €6686 (4943–8429) (year 4), with acromegaly drug costs as the largest part. The share of direct costs due to acromegaly amounted to 95% (remaining 5% due to comorbidities) for the first year after diagnosis and fell to 86% (comorbidities 14%) during year 6. SSAs (lanreotide and octreotide) were the main contributors to drug costs (>86% throughout the study period). Costs for drugs for the treatment of acromegaly increased every year and rose from 15% during year 1 to 77% for year 6 with GHRA (47%), lanreotide (44%), and octreotide (9%) costs as contributors. DA costs decreased over time but were overall negligible. Over the follow-up period, the number of patients treated with lanreotide rose from 12 (11%) to 20 (19%) patients while corresponding numbers for octreotide fell from 26 (25%) to 13 (12%) patients. During year 1 and 2, no patients were treated with GHRA but this increased to eight (8%) patients during year 6. When the mean direct costs per patient using each drug were analysed, lanreotide costs increased 31% from year 1 to year 6. The corresponding increase for octreotide was 135% while the increase from year 3 to 6 for GHRA (pegvisomant) was 186%. Real world evidence from national registers allows detailed monitoring of changes in direct costs after diagnosis of acromegaly. Surgical interventions are a main contributor (54%) to the total direct costs during the first year after diagnosis, but pharmaceutical treatments become more important over time with SSA and, to some extent, GHRA as the main contributors.

Introduction
Primary adrenal insufficiency (PAI) leads to a drastically reduced production of steroids from the adrenal cortex, but a few patients may keep some residual adrenal steroid secretion that may simplify replacement therapy and prevent adrenal crisis. Irrespectively, the conventional glucocorticoid (GC) replacement therapy, using thrice-daily oral hydrocortisone, does not restore the patients' physiological cortisol profile.
Objective
The primary objective was to study enzyme activity related to GC action, synthesis and degradation in patients with PAI and GC replacement by assessing urinary steroid profile. The secondary aim was to analyze if any residual adrenal function can be detected in patients with long-standing PAI.
Methods
Case-control study comparing patients with PAI >6 months after diagnosis, under stable thrice-daily hydrocortisone replacement (20-40mgs/day) with healthy controls. Urinary steroid profile was measured using gas chromatography/mass spectrometry. Activity of enzymes involved in synthesis and metabolism of steroid hormones was evaluated by calculation of ratios (substrates/products).
Results
Fifty PAI patients (22 females, mean age 47 years (range 19-71)) were compared with 124 healthy controls (73 females, mean age 48 years (range 20-81). Urinary cortisol (F) ($P<0.001$) and cortisone (E) ($P<0.001$) excretion were higher in patients compared to controls. In contrast, urinary metabolites of F (5α-THF and 11β-OH-etiocholanolone) and E (THE, 11-oxo-etiocholanolone) were similar in patients and controls. The urinary THF+5αTHF/THE ratio reflecting 11βHSD1 activity and the urinary F/E ratio reflecting 11βHSD2 activity was higher in patients than in controls ($P<0.001$ and $P<0.01$ respectively). The F/5αTHF ($P<0.001$), THB/αTHB ($P<0.001$) and androstenedione/etiocholanolone ($P=0.023$) ratios were higher in patients suggesting a lower 5α-reductase activity. Similarly, ratios evaluating 5β-reductase, 20αHSD and 20βHSD indicated a lower activity in patients. Androgens, mineralocorticoids and their precursors as well as the GC precursors were drastically decreased in patients, although residual secretion of one or more steroids was detected in 9 patients.
Conclusion
The urinary steroid metabolome showed that activity of important enzymes involved in the modulation of corticosteroid action and metabolism was markedly abnormal in PAI patients treated with conventional hydrocortisone therapy. This results in an abnormal cortisol metabolite profile that may contribute to adverse metabolic effects. Production of androgens, mineralocorticoids and GCs is markedly reduced in PAI patients, although 18% of them exhibited residual steroid secretion.

Steroid profile using gas chromatography tandem mass spectrometry (GC-MS/MS) in search for a steroid which correlates most with subclinical hypercortisolism

Václav Hána jr.[1], Mikuláš Kosák[1], Václav Hána[1] & Martin Hill[2]
[1]3rd Department of Internal Medicine, 1st Faculty of Medicine, Charles University and General Teaching Hospital in Prague, Prague, Czech Republic; [2]Institute of endocrinology, Prague, Prague, Czech Republic.

Introduction
Gas chromatography tandem mass spectrometry (GC-MS/MS) quantitatively detects a large number of steroids at one time in a single serum sample. Most studies of subclinical hypercortisolism in adrenal incidentalomas have focused on detection of a few steroids like cortisol, DHEA/S, androstenedione, testosterone. We used GC-MS/MS to quantify 91 steroids in patients with adrenal incidentalomas to search for the most reliable marker of subclinical hypercortisolism.
Methods
Steroid profiles consisting of 91 steroids measured by GC-MS/MS from sera of 54 patients with unilateral ($n=29$) and bilateral ($n=25$) adrenal incidentalomas were compared. Suspected subclinical hypercortisolism was defined as cortisol >50 nmol/l (1.8 μg/dl) in 1 mg overnight dexamethasone (DXM) test. Sensitivity and specificity was calculated for urinary free cortisol >208 nmol/24 h, ACTH< 10 ng/l (2.2 pmol/l), midnight serum cortisol >149 nmol/l as sole criterion. Logistic regression and ROC curves were used to select steroids that best reflect non suppressibility in 1 mg dexamethasone test and ROC curves with sensitivity and specificity were calculated.

Results
Out of 54 patients 13 had suppressed cortisol in 1 mg DXM test under 50 nmol/l. Remaining 41 (21 unilat., 20 bilat.) had post DXM cortisol ranging from 51 to 381 nmol/l. UFC > 208 nmol/24 h showed 34% sensitivity and 76% specificity. ACTH < 10 ng/l had 17% sensitivity and 100% specificity. Midnight serum cortisol >149 nmol/l had 60% sensitivity and 84% specificity. DHEAS had sensitivity 71% and 85% specificity with cut off value =876 nmol/l, AUC= 0,800 and Z-score=3.07. Androsterone sulphate showed sensitivity 76% and specificity 69% with cut off value=539 nmol/l, AUC=0.780 and z-score=3.33. Androstenediol had 78% sensitivity 77% specificity with cut off value= 0.69 nmol/l, AUC 0,740, z-score=2.46. Other measured steroids had lower predictive values.
Conclusions
Non-suppressibility in dexamethasone test correlates with the suppression of DHEAS in most cases. Other steroids like androsterone sulphate, androstenediol and other show similar sensitivity and specificity but are difficult to measure in routine conditions. Diagnosis of subclinical hypercortisolism needs to be evaluated by a combination of parameters, which cannot be replaced by a sole criterion.

Clinical aspects of the schmidt's syndrome: a 14 years retrospective monocentric study

Taieb Ach, Asma Ben Abdelkarim, Yosra Hasni, Safa Khaldi, Amel Maaroufi, Maha Kacem, Molka Chaieb & Koussay Ach
Endocrinology and diabetology, University hospital Farhat Hached de Sousse., sousse, Tunisia.

Introduction
Schmidt's syndrome also known as autoimmune polyglandular syndrome type 2 (APS type 2) is a rare endocrine disorder defined by the combined occurrence of Addison disease with autoimmune thyroid disease. The rarity of the condition and the atypical presentation of adrenal insufficiency and hypothyroidism often lead to misdiagnosis with life-threatening consequences for the patient. In this study we report an exhaustive monocentric analysis of 22 patients diagnosed with a Schmidt's Syndrome.
Patients and methods
We carried out a retrospective study of all the patients diagnosed of a Schmidt syndrome or APS type 2 in the Department of Endocrinology and Diabetology of University Hospital Farhat Hached of Sousse, over a period from 1999 to 2013. Adrenal insufficiency was diagnosed with a basal cortisol level<40 ng/ml or peak <180 ng/ml after Synacthen. Autoimmune Hypothyroidism was diagnosed with a T4 <7 pg/ml and TSH >10 mUI/l associated with the positivity of anti-Peroxydase antibodies. We analyzed clinical and biological aspects of these patients with SPSS ver. 23.0 software.
Results
We reported 22 cases, with a mean age of 31.77±11.26 years old, with 36.3% between 20 and 39 years old ($P=0.02$) and a predominance for female sex with a sex ratio=0.22 ($P<10^{-3}$). The mean age of discovery of Addison's disease was 32.5±9.2 with extremes ranging from 12 to 58 years. According to the age of discovery compared to hypothyroidism, Addison disease was diagnosed significantly before the diagnosis of Hashimoto's disease in 59% ($P=0.03$), concomitant in 27.2% and posterior in 13.6%. Clinical symptoms made of melanodermia and hypoglycaemia suggested the diagnosis in 47% of all patients. An acute adrenal insufficiency was triggered by the hormonal thyroxin substitution in one case. Other autoimmune diseases were found in 27.2%, as a celiac disease (8%), type 1 diabetes (8%), Biermer anemia (7%) and autoimmune ovaritis in 4.2%.
Conclusion
Schmidt's Syndrome is more likely to be associated with the female sex and young age. In our study, Hashimoto's hypothyroidism was the first autoimmune disease discovered. The presence of at least one component of the APS type 2 must lead to the autoimmune screening of the other diseases. This screening could avoid the triggering of an adrenal insufficiency in thyroid hormonal substitution.

Sentinel lymph node biopsy of jugulo-carotid regions in medullary thyroid microcarcinomas after methylene blue dye mapping – A single institution experience

Nada Santrac[1], Ivan Markovic[1,2], Merima Goran[1], Marko Buta[1,2], Gordana Pupic[3], Ognjen Zivkovic[3] & Radan Dzodic[1,2]
[1]Surgical Oncology Clinic, Institute for Oncology and Radiology of Serbia, Belgrade, Serbia; [2]Medical Faculty, University of Belgrade, Belgrade, Serbia; [3]Department of Pathology, Institute for Oncology and Radiology of Serbia, Belgrade, Serbia.

Introduction
Management of lymph nodes (LN) in medullary thyroid carcinoma (MTC) is an ongoing debate. Unpredictable behavior of MTCs, regardless the serum calcitonin levels and preoperative examinations of regional LNs, has led many surgeons to do prophylactic lateral neck dissections (LND). The aim of this study was to analyze usefulness of sentinel lymph node biopsy (SLNB) of jugulo-carotid regions, after methylene blue dye (MBD) mapping and frozen section analysis, for selecting true positive patients in clinically N0 (cN0) group of micro-MTCs for one-time LND.
Methods
In a 10-year period, 17 cN0 patients were operated by our surgical team due to micro-MTCs ($\leq$10 mm), with serum calcitonin <1000 pg/ml. In all patients, sentinel-LN mapping was performed by injecting 1%-MBD subcapsullary in both lobes. As a standard surgical treatment, along with total thyroidectomy and prophylactic central neck dissection, all patients had SLNB of jugulo-carotid regions (*Dzodic's original method for LN staging in thyroid carcinomas*, published in *World J Surg, 2006*), since blue-stained LNs in central compartment are routinely dissected. After exploration of levels II-III bilaterally, sentinel-LNs were extirpated and examined by frozen section. If sentinel-LNs were benign, additional surrounding non-sentinel-LNs were extirpated and sent to standard pathohistology (sPH), with no further LND. If sentinel-LNs were malignant, one-time LND was performed.
Results
One patient with calcitonin level of 221 pg/ml had hereditary, bilateral micro-MTC, positive central-LNs and sentinel-LNs on both sides, so bilateral LNDs were performed. Metastases were found in non-sentinel-LNs, as well, thus sentinel-LNs were predictive for non-sentinel-LNs status. Remaining 16 patients had sporadic, unilateral micro-MTCs, without metastases in central-LNs, sentinel-LNs or additional LNs from levels II-III on both sides. None of the patients had allergic reactions to MBD. Frozen section and sPH were 100% match. Accuracy of *Dzodic's method for LN staging* was 100%.
Conclusions
This study is the first reported experience with SLNB of jugulo-carotid regions in MTCs using MBD, focusing on the subgroup of microcarcinomas. The *Dzodic's method for LN staging* in thyroid carcinomas can be precisely used for intraoperative assessment of lateral-LNs and optimizing initial surgery of micro-MTCs. cN0 patients with proven sentinel-LN metastases in lateral regions on frozen section can receive one-time LND, while those without LN-metastases benefit from less extensive surgery. All patients can benefit from lower complication rate, since MBD injection facilitates central neck dissection and diminishes the possibility of accidental removal of parathyroid glands (that remain non-colored), even in less experienced surgeons' hands.

Influence of the levels of vitamin D on T-score in HIP measured by DXA of colombian postmenopausal women

Richard Buendia[1,2], Santiago Cardenas[1,2], Monica Zambrano[2,3], Andres Buendia[4], Maria De Los Angeles Varon[2], Heidy Carolina Mier[2], Alejandra Morales[2], Adriana Alejo[2] & Diego Sanchez[2]
[1]Pontificia Universidad Javeriana, Bogota D.C., Colombia, USA; [2]Colsubsidio, Bogota D.C., Colombia, USA; [3]Hospital De La Samaritana, Bogota D.C., Colombia, USA; [4]Fundacion Universitaria De Ciencias De La Salud (FUCS), Bogota D.C., Colombia, USA.

Introduction
The 25hydroxyvitamin(OH)D deficiency has been linked to the risk of postmenopausal fractures and osteoporosis. In Colombia, the prevalence of 25(OH)vitaminD deficiency is high, reaching more than 53% of the total population. It can be stated that hip fracture is one of its most feared complications, with a high risk of mortality and morbidity, which can affect even osteopenic patients. The objective of this study is to assess modifications in hip T-score (using dual-energyX-ray absorptiometry(DXA)), that are related and influenced by changes in 25(OH)vitaminD levels in Colombian postmenopausal women.
Methodology
This study is a cross-sectional analysis that uses linear regression to determine the changes of hipT-score value (standard deviation(SD)) according to vitaminD levels, it is adjusted to serum calcium, phosphorus, paratohormone levels and age. To establish the validity of the model: the homocedasticity and normality of the residues were exhibited; Cook's distance <2 and colinearity was ruled out (VIF $<$ 10). VitaminD deficiency was defined as a value of 25(OH)vitaminD below 20 ng/ml (50 nmol/l), and vitaminD insufficiency as a value between 21 and 29 ng/ml(3).
Results
124 Postmenopausal women were included at mean age of 66.07 ± 11.28 years; with average levels of serum calcium:9.53 ± 0.60 mg/dl; mean of paratohormone:57.06 ± 27.14 pg/ml; mean vitamin25(OH)D:25.69 ± 9.22 ng/ml; mean serum phosphorus: 3.62 ± 0.61 mg/dl; mean hip T-score: $-1{,}92 \pm 1{,}18$; mean hip Z-score:$0{,}058 \pm 0{,}80$; hip bone mineral density:$0{,}833 \pm 0{,}095$;g/cm^2; 22.08% of patients had a deficiency of 25(OH)vitaminD and 53.25% had insufficiency of 25(OH)vitaminD; 31% of patients had osteoporosis and 53% osteopenia. The linear regression model found that a 25 (OH) vitamin D change of 0.042 ± 0.20 ng/ml (95% CI 0.012–0.083, $P=0.04$) produces a change of 1 (one) standard deviation in hip T-score; adjusting to levels of paratohormone, serum calcium, serum phosphorus and age; constant value -6.34.The linear regression equation would be:HipT-score $= 6.34 + 0.042$(25(OH)vitaminD). The model explains 22% of the changes in the T-score, the residuals were homocedastic and normal ($P=0.70$); there was no collinearity (average VIF $= 1.11$) and distance of cook $=$ 0.064.
Conclusion
This study tries to demonstrate how very small variations in the levels of 25(OH) VitaminD, can significantly influence changes of up to 1(one)SD in hip T-Score of postmenopausal women.

Potential extension of frax algoritm and probability of bonefracture

Aikaterini Andreadi[1], Barbara Capuani[1], Donata Sabato[2], Maria Romano[2], Angelica Galli[2], Flavio Pozzi[2], Marco Cerilli[2], Alfonso Bellia[1,2], David Della Morte[1] & Davide Lauro[1,2]
[1]University of Rome Tor Vergata, Department of Systems Medicine, Rome, Italy; [2]UOC of Endocrinology, Diabetology and Metabolic Diseases, Foundation Policlinico Tor Vergata, Rome, Italy.

Osteoporosis is a pandemic chronic non communicable disease, with worldwide expansion. This condition and the resulting bone fracture are a maor cause of disability and mortality for millions of people worlwide. Frax is an algoritm that relies on a questionnaire for the prediction of bonefracture. This algoritm it is called Frax and it's estimates the probability in % to have a fracture in the following 10 years. The aim of the study was to evaluate whether patients lifestyle and dietary habits may be considered as additional risk factors for new bone fracrtures and evaluate how its correlates to the degree of osteoporosis, Furthermore we analysed if obesity can be associated with reduced levels of bone mineral density (BMD). IN tha last year we have enrolled 1132 patients at the Unit of Endocrinologia, Diabetes and Metabolic Diseases at the University Hospital of TOr Vergata, Rome, Italy. All subjects underwent to evaluation of anthropotric data (weight, BMI, height), bone densitometry with DEXA Hologic QDR 4500 Delphi series, Food frequency questionnaire to access dietary habits during a week and Frax questionnaire. From 1132 subjects, the media of the age was 63.3 (± 9.5 s.d.); from wich 1086 were women (63.3 years ± 9.4 s.d.) and 45 men (63.8 years ± 11.6 s.d.). The food questionnaire data when divided considering the T-score in three groups, 210 subjects normal (-0.29 s.d. $\pm$ 0.636/0.818 g/cm^2/± 0.07), 712 with osteopenia (-1.74 ± 0.42/0.649 g/cm^2 $\pm$ 0.05) and 210 with osteoporosis (-2.86 ± 0.38/0.515 g/cm^2 ± 0.04), confirming that patients with osteoporosis, consume less foods that contains calcium and vitamin D (p value 0.01). Patients were also divided according the body mass index (BMI). From 1132 people the 0.79% were underweight (9 subjects), 34.8% (395 subjects) have normal weight, 36.7% (416 subjects), overweight (27.2 ± 1.4) and 27.5% (312 subjects) were obese (33.7 ± 3.7). It is important to consider that the prevalence of oveweight and obesity in our population was 64.2%. if then we analyze the patients that were overweight and obese, the majority of the sample (80%) presents osteopenia of osteoporosis; this result is controversy from the supposed protective role of adipose issue on bone mineral density.

A case report: FGF23-related tumor-induced osteomalacia in a patient with pulmonary adenocarcinoma

Hiroshi Arai[1,2], Yugo Kanai[2], Yuji Nakamoto[3], Hiroki Nagai[4], Yuichi Sakamori[4], Akihiro Yasoda[2] & Nobuya Inagaki[2]
[1]Kyoto Institute of Technology, Kyoto, Japan; [2]Department of Diabetes, Endocrinology and Nutrition, Kyoto University Graduate School of Medicine, Kyoto, Japan; [3]Department of Diagnostic Imaging and Nuclear Medicine, Kyoto University Graduate School of Medicine, Kyoto, Japan; [4]Department of Respiratory Medicine, Kyoto University Graduate School of Medicine, Kyoto, Japan.

Tumor-induced osteomalacia (TIO) is a rare paraneoplastic syndrome caused by the abnormal production of fibroblast growth factor 23 (FGF23) in the tumor. Here we report a case of TIO with pulmonary adenocarcinoma. A 61-year old woman was referred to our hospital. She was suffering from severe polyarthralgia and bilateral limb weakness. Her blood chemistry revealed high alkaline phosphatase, low phosphate, low calcium, and low 1,25-$(OH)_2D_3$. Bone-scintigraphy revealed multiple accumulations in femoral neck, sacrum, 1st rib, sacroiliac joints and many other joints, suggesting small fractures and systemic arthritis. Endocrinological analyses exhibited elevated iPTH and markedly high FGF23 level of 3900 pg/ml (reference: 14.7–40.5 pg/ml). These findings suggest that the FGF23-producing tumor of uncertain location induced osteomalacia in this patient. DOTATOC-PET/CT showed a major uptake in a nodular lesion of the left lung and several minor uptakes in the supraclavicular, hilar and mediastinal lymph nodes. An ultrasound-guided fine needle aspiration biopsy of the left supraclavicular lymph node was performed and the histological diagnosis was metastatic adenocarcinoma. PNA-LNA PCR clamp analysis of the biopsy specimen detected a mutation in Exon19 of the EGFR gene. She was diagnosed as stage IVA (cT1cN3M1b) pulmonary adenocarcinoma, and the chemotherapy with afatinib maleate (EGFR tyrosine kinase blocker) was started. At the same time, alfacalcidol was prescribed for osteomalacia. After 5 months, the primary tumor and metastatic lesions are gradually shrinking. The bone metabolism is almost normalized, and FGF23 level is markedly decreased (42 pg/ml). At present, the arthralgia is ameliorated and controlled with minimal dose of analgesics. This is a rare case of TIO associated with pulmonary adenocarcinoma. The DOTATOC-PET/CT was an effective modality for diagnosis.

Features of distal forearm fracture in persons 50 years old and older

Olga Iurova[1] & Larisa Marchenkova[2]
[1]CM-Clinica, Moscow, Russian Federation; [2]National Medical Research Center for Rehabilitation and Balneology of the Ministry of Health, Moscow, Russian Federation.

Objective
To identify the prevalent fracture risk factors in the group of persons 50 years and older. Assess their impact on BMD in patients with a distal forearm fracture (DFF-fracture of the radius) over 50 years at low injury.
Materials and methods
A comparative study among patients with DFF in the age group 50 years and older. Study based on medical records of city hospital traum depatment. Analised period 2009–2012. All patients underwent R-densitometry on the unit DTX-200, provided by Nicomed Takeda in the framework of the program 'Russian Osteoscreening'.
Results
Hospital records of patients 50 years and older who suffered from low-energy fracture of the distal forearm were analyzed retrospectively for the period of 2009–2012. 791 patients were interviewed using standardized questionnaires 'Osteoscreening Russia'. According to the survey the metabolic syndrome (MS) diagnosed in 70.8% (560 persons). It included type 2 diabetes mellitus (T2DM) −14.8% (117 persons), prediabetes −22.9% (181 people) – (Impaired glucose tolerance (IGT) and impaired fasting glucose (IFG)), obesity (33.1%) – an isolated cohort of patients with overweight and obesity without disrupting glycemic indices. All patients had DFF that occurred at a low injury. Among the investigated cohort of patients with highnormal bone mineral density (BMD above −1.0 standard deviation (S.D.))we revealed 66.0% of patients with MS; 64.1% – with obesity; 65.4% – with the presence of pre-diabetes; 65.3% – with a history of type 2 diabetes. BMD−1.0–2.5 S.D.: 20.6% with MS; obesity, 20.2%; prediabetes, 19.7%; type 2 diabetes −19.5% BMD below 2.5 standard deviations (S.D.): MS at 13.5%; obesity, 15.7%; prediabetes, 14.7%; Type 2 DM −15.3%. Patients with low-energy DFF with a history of metabolic syndrome differed from the group of patients without this disease by its high and highnormal % normal BMD. Almost 2/3 (70.8%) of patients with metabolic syndrome have normal BMD.
Conclusion
The prevalence of low BMD in patients of investigated groups has not been established. Proposed mechanism of fracture is focused not on the performance of T-score (BMD) but the bone quality due to changes caused by abnormality of bone metabolism. Suppression of medullary osteoblastogenesis by adipocytes of bone marrow and stimulation of proinflammatory cytokines synthesis leads to increased bone fragility without decreasing BMD.

Effect of surgery vs observation: 6-Year skeletal outcomes in primary hyperparathyroidism

Laura Ramos[1], Maria Piedra[1], Pedro Muñoz[2], Luis Vazquez[1] & Jose Antonio Amado[1]
[1]Marqués De Valdecilla Hospital, Santander, Spain; [2]Servicio Cantabro De Salud, Santander, Spain.

Background and aims
Primary hyperparathyroidism (PHPT) often presents without classical symptoms such as overt skeletal disease or nephrolithiasis. Treatment strategies have been widely discussed. The objective of our research was to study the effect of parathyroidectomy (PTX) compared to observation (OBS) on skeletal outcomes such as bone mineral density (BMD).
Subjects and methods
A retrospective observational study was conducted between 1991 and 2014. 170 patients with PHPT who had baseline dual energy x-ray absorptiometry (DXA) and at least another one after 2 years of follow-up were included. Mean follow-up time was 6 years. PHPT was diagnosed when persistent hypercalcemia occurred with the presence of elevated or inappropriately normal parathyroid hormone levels. Clinical features were registered. Area based BMD was measured by at the lumbar (L2–L4) spine (LS), femoral neck (FN), total hip, and forearm at the radius 33% (Rad33).
Results
112 patients were treated with PTX and 58 patients were under OBS. Patients under OBS were older than PTX group, mean age 68.8±12.1 years and 62.5±11.3 years respectively ($P<0.005$). More than 85% of patients in both groups were women. DXA after two years of surgical intervention showed a mean BMD change of 4.37% in LS, 3.9% in FN, and 2.72% in the total hip. Significantly higher than those presented at 2 years in the observation group (1.59% in LS, −0.19% FN, 0.14% CT) ($P<0.005$). In Rad33, BMD remained stable in the PTX group and decreased in OBS group ($P=0.583$). At 4 and 6 years, a positive effect of PTX was still observed with statistically significant improvements in the LS and FN ($P<0.05$). In total hip and Rad33, improvement was observed with PTX and worsening in the OBS group, but these differences were not statistically significant. It is important to note that 58% of patients in PTX group and 63.8% of patients in OBS group received treatment with drugs with bone activity, mainly bisphosphonates according to the criteria of their physician. Anyway it may have reduced, but not increased, the difference between groups.
Conclusions
In conclusion, PTX improves BMD and OBS leads to a small, but statistically significant decrease in BMD in FN. The surgical intervention does not involve significant changes in Rad33 BMD. Thus, bone health appears to be a clinical concern with long-term observation in patients with mild PHPT.

Association between Serum FGF21 levels and bone mineral density in healthy postmenopausal Korean women

Mi-Seon Shin[1], Eun-Hee Cho[2], Mi Young Lee[3], Ji Yun Jeong[4] & Jung Min Kim[5]
[1]Hanil General Hospital, Seoul, Republic of Korea; [2]School of Medicine, Kangwon National University, Chuncheon, Republic of Korea; [3]Yonsei University Wonju College of Medicine, Wonju, Republic of Korea; [4]Soonchunhyang University, Gumi, Republic of Korea; [5]Sanggye Paik Hospital, Inje University College of Medicine, Seoul, Republic of Korea.

Objective
Despite beneficial effect of FGF-21 on metabolic disease, there were concerns about adverse effect on bone metabolism, supported by animal studies. However, a recent human study showed the positive association between FGF-21 and bone mineral density (BMD) in health premenopausal women. This study was undertaken to examine the association between FGF-21 and BMD in healthy postmenopausal Korean women who are susceptible to osteoporosis.
Methods
We used data of 115 participants from healthy postmenopausal women cohort (>50 years old) to examine the correlations between FGF-21 levels and BMD. Participants had provided information regarding their clinical characteristics, and underwent blood testing and serum FGF-21 testing. BMD and T scores of lumbar spine, femur neck and total hip area were used in analyses.
Results
The subjects' mean age was 60.2±7.2 years old and mean BMI was 24.4±3.5 kg/m^2. The prevalences of osteoporosis were 19.6%. There were two patients with a history of lumbar fractures and none had a history of hip fractures. Serum FGF-21 level showed inverted correlation with BMD and T scores at all three areas; however, there were no statistical significances. Multivariate analyses with adjustment for age and BMI also did not show significant associations of FGF-21 level and BMD and T scores. Additionally, FGF-21 level also showed no correlation with CTX and osteocalcin.
Conclusions
In our study, serum FGF-21 level showed no significant correlation with BMD and T scores.

Bone geometry is correlated with arterial stiffness in overweight older adults with vitamin D insufficiency

Alexander Rodriguez[1], Cecilia Xu[1], Lachlan McMillan[1], Velandai Srikanth[2], David Scott[1] & Peter Ebeling[1]
[1]Bone & Muscle Health Research Group, Monash University, Melbourne, Australia; [2]Stroke and Ageing Research Group, Monash University, Melbourne, Australia.

Background
Vitamin D deficiency/insufficiency and adiposity have deleterious effects on skeletal health and can increase arterial stiffness. Additionally, low bone mass is associated with increased arterial disease, but little is known about the association of bone geometry with arterial disease.
Objective
To determine the association between bone geometry and arterial stiffness in overweight (body mass index >25 kg/m^2], older adults [50–80 years] with vitamin D insufficiency [<50 nmol/l].
Methods
Cross-sectional analysis. Demographics and clinical history were obtained via questionnaires and anthropometric data were obtained using standard protocols. Tibial bone geometry in the tibia at the 4% and 66% sites was assessed via peripheral quantitative computed tomography [XCT3000, Stratec, Germany]. Blood pressure and measures of arterial stiffness were determined by an oscillometric device [Mobil-o-Graph, IEM, Germany]. These measures included pulse wave velocity [velocity at which arterial pulse propagates throughout the vasculature], augmentation index [proportion of blood pressure waveform attributable to the reflection wave] and pulse pressure [difference between systolic and diastolic blood pressure]
Results
Thirty individuals were recruited [mean age: 57.7 ± 6.3; women: $n=15(50\%)$]. Mean systolic blood pressure was high-normal [128.6 ± 13.5 mmHg]. In age and BMI adjusted models, there was an inverse correlation between trabecular area at 4% site [$r=-0.80$; $P<0.001$]; trabecular volumetric bone mineral density [$r=-0.58$; $P=0.003$]; cortical area at 66% site [$r=-0.55$; $P=0.008$]; fracture load(x) [$r=-0.47$; $P=0.028$]; fracture load(y) [$r=-0.69$; $P<0.001$] with augmentation index. Additionally, there was an inverse correlation between trabecular area at 4% site [$r=-0.42$; $P=0.027$] and cortical area at 66% site [$r=-0.449$; $P=0.018$] with pulse pressure. Bone marrow density correlated positively with pulse pressure [$r=0.448$; $P=0.021$]. In multivariate regression analyses adjusting for age, BMI and sex, trabecular area was inversely associated with augmentation index [$\beta=-5.67$; 95% confidence interval: -8.81, -2.43].
Conclusion
Poorer bone geometry was strongly negatively related with augmentation index, a measure of systemic arterial stiffness. This provides further evidence for an association between bone loss and changes in arterial stiffness that act to increase vascular risk. A randomised trial is now required to determine if an intervention to reduce underlying adiposity and correct vitamin D deficiency will improve these outcomes.

Effects of acromegaly on plasma microRNA levels relevant to bone metabolism.

Tatiana Grebennikova[1], Zhanna Belaya[1], Alexey Nikitin[2], Alexander Solodovnikov[3] & Galina Melnichenko[1]
[1]Federal State Institution 'The National Research Center for Endocrinology', Moscow, Russian Federation; [2]Federal Research and Clinical Center for Specialized Medical Assistance and Medical Technology, Moscow, Russian Federation; [3]Ural State Medical Academy, Ekaterinburg, Russian Federation.

Molecular basis of the bone disorders in patients with acromegaly are largely unknown.
Objective
To investigate microRNAs (miRNA) expression profiles that regulate bone metabolism in plasma samples from patients with acromegaly.
Materials and methods
Fasting plasma samples were taken from consecutive subjects with biochemically confirmed active acromegaly and healthy volunteers matched by age, sex and BMI. IGF1 was measured by an electrochemiluminescence assay on a Liaison. Total RNA isolation from plasma samples with on-column digestion of the genomic DNA was carried out with miRNeasy Mini Kit on the automatic station 'QIAcube'. Reverse transcription was carried out using a TaqMan Advanced miRNA cDNA Synthesis Kit. MicroRNA expression analysis was performed by Real-Time PCR on StepOnePlus instrument with TaqMan Advanced miRNA Assay.
Results
22 subjects with acromegaly mean age 40 (CI 95% 36–44) years old, 17 females and 5 males, BMI – 28 (CI 95% 25–31) kg/m^2 were enrolled along with 18 healthy control subjects (17 females, 1 male) matched by age $P=0.205$ and BMI $P=0.253$. Mean IGF-1 in subjects with acromegaly – 752 (CI 95% 577–926) ng/ml was higher as compared to healthy control – 195 (CI 95% 139-251) ng/ml ($P<0.001$). Among the 28 miRNAs studied, expression of miRNA-320a 12.2 (CI 95% 4.3 – 20.2, $P=0.056$) was increased in patients with acromegaly as compared to healthy volunteers. The revealed change negatively affects the level of β-catenin and Runt-related transcription factor 2 (RUNX2) and promotes suppression of chondrogenesis. However, after applying the correction of multiple comparisons, the change in the level of miRNA-320a was statistically insignificant ($q=0.605$), which is most likely due to the insufficient sample size.
Conclusion
Plasma miRNA-320a can be considered as a potential diagnostic marker of osteoporosis.

Is FGF23 a key factor in primary hyperparathyroidism?

Alina-Andreea Gatu[1], Cristian Velicescu[1], Dan Ionut Repede[2], Stefana Bilha[1], Alexandru Florescu[1], Anca Matei[1] & Dumitru Branisteanu[1]
[1]Gr T Popa University of Medicine and Pharmacy, Iasi, Romania; [2]Emergency County Hospital Sf Pantelimon, Focsani, Romania.

Published data regarding the role of FGF23 in primary hyperparathyroidism and its prognostic applicability are scarce and discordant.
Aims
To assess FGF23 profile in patients with primary hyperparathyroidism undergoing surgery.
Matherials and methods
Longitudinal study involving 48 patients aged 30–80 years with primary hyperparathyroidism caused by solitary parathyroid adenoma, submitted to parathyroidectomy. We evaluated FGF23, PTH, 25(OH)D3, calcium and phosphorus at admission, immediately after parathyroid adenoma excision in all patients, and at 3, 6 months and one year after surgery in 13 patients. Differences were considered significant for $P<0.05$.
Results
FGF23 was within the reference ranges (120 ± 80 pg/ml, normal values specific for carboxyterminal FGF23, dosed in this study), with initial mean values of 75.55 ± 22.74 pg/ml. Preoperative FGF23 was negatively correlated with PTH ($r=-0.397$; $P=0.015$) and calcium ($P=0.04$). We observed no change in postoperative FGF23 or at distance from cure (80.57 ± 27.07 pg/ml 1 year postoperative, NS). Mean FGF23 did not show significant differences in patients with osteoporosis, renal lithiasis or fractures, neither preoperatively, nor 1 year after surgery.
Conclusions
FGF23 levels of patients with primary hyperparathyroidism are in the normal range and do not change significantly after surgery seeming therefore to have no practical prognosis application. The negative correlation of FGF23 with preoperative PTH seems to be an epiphenomenon and suggests that FGF23 regulating role may be largely replaced by PTH in primary hyperparathyroidism.

Long-term monitoring of echinococcal cyst as a cause of increased lumbar bone mineral density

Miro Cokolic & Ursa Ksela
Department of Endocrinology and Diabetology, Internal Clinic, University Clinical Centre Maribor, Maribor, Slovenia.

An 82-year old female with known osteoporosis was reassessed for bone mineral density (BMD) measurement. Her baseline BMD and lumbar spine T-score (L1-L4) measured in 2004 was 0.699 g/cm^2, –3.5 SD, total left hip T-score was 0.618 g/cm^2, –2.7 SD. She was treated with alendronate 70 mg, cholecalciferol 7000 IE per week and calcium supplements for some years. On follow-up in 2013

DXA of lumbar spine and hip, BMD of lumbar spine L1-L4 was 0.910 g/cm^2, T-score was –1.2 SD. BMD and lumbar vertebrae T-scores for a single lumbar vertebra were: L1 1.384 g/cm^2, +4.2 SD; L2 0.667 g/cm^2, –3.3 S.D.; L3 0.654 g/cm^2, –3.9 S.D.; L4 0.785 g/cm^2, –3.0 S.D. The BMD and T-score of the neck were 0.463 g/cm^2, –3.5 S.D. and of the total hip 0.590 g/cm^2, –2.9 S.D. The images revealed a calcified mass in the L1 vertebral projection. The DXA scan analysis was repeated and the calcified formation in the L1 vertebra was excluded. BMD of analyzed lumbar spine (L2–L4) was 0.701 g/cm^2, T-score was –3.4 S.D. BMD and T-scores were: L2 0.614 g/cm^2, –3.8 S.D.; L3 0.642 g/cm^2, –4.0 S.D.; L4 0.785 g/cm^2, –3.0 S.D. In 2018, BMD of analyzed lumbar spine (L3–L4) was 0.911 g/cm^2, T-score was –1.7 S.D. BMD and T-scores were: L3 0.976 g/cm^2, –1.0 S.D.; L4 0.845 g/cm^2, –2.5 S.D., superposition of calcified formation was on L1 + L2. Abdominal CT scans revealed a 3 cm large calcified Echinococcal cyst (EC) that was unnoticed in 2004. 2013 DXA scans show the EC projected to the L1 and those made in 2018 EC is seen on L1 + L2 + L3 because of the development of kyphosis, and consequently due to height reduction of 9 cm over the period of 14 years. Hip BMD was stable; the 10-year fracture risk for major osteoporosis fracture was 16% and 7.5% for hip fracture. Discussion. The study showed that calcium carbonate pills and bra wires positioned lateral to the spine can change BMD. Several medical conditions, such as osteoarthritis, ankylosing spondylitis, vertebral fractions, osteophyte formation, and aortic calcifications can also increase BMD. In our case, the patient's hip BMD decreased by –1.8% and increased by 51.3% in L1-L4 without corrections on account of EC in the period of 14 years.

Acromegaly patients with vertebral fractures, have lower trabecular bone score despite no difference in bone mineral density, than non-fractured patients and healthy controls

Martin Kužma[1], Peter Vaňuga[2], Ivana Ságová[3], Dušan Pávai[2], Peter Jackuliak[1], Zdenko Killinger[1], Neil Binkley[4], Harry Genant[5] & Juraj Payer[1]
[1]Comenius University Faculty of Medicine, 5th Department of Internal Medicine, University Hospital, Bratislava, Slovakia; [2]National Institute of Endocrinology and Diabetology, Lubochňa, Slovakia; [3]Comenius University Jessenius Faculty of Medicine, 1th Department of Internal Medicine, University Hospital, Martin, Slovakia; [4]Department of Medicine, University of Wisconsin, Madison, WI, USA; [5]University of California San Francisco, San Francisco, CA, USA.

Introduction
Patients with acromegaly, despite normal or even high bone mineral density (BMD), have prevalent vertebral fractures (VFs). HR-pQCT studies in acromegaly have proposed that impaired trabecular bone microarchitecture possibly plays a role in fragility fracture development. As such, we hypothesized that trabecular bone score (TBS) would be low in patients with acromegaly.
Aim of the study
To compare BMD and TBS in acromegaly patients with and without VFs and healthy controls.
Methods
This cross-sectional study compared patients with acromegaly to age- and BMI-matched healthy controls. Study group was recruited from all acromegaly patients who came to a University Endocrinology clinic for follow-up from 6/2016 – 8/2017 and controls consisting of healthy subjects. In all subjects a single measurement of pituitary axis hormone levels, P1NP,CTx, BMD, (total hip [TH] and lumbar spine [LS]) and trabecular bone score (TBS) was performed. Vertebral fractures were identified by DXA VFA. These images were interpreted by an expert musculoskeletal radiologist (H. Genant) using a semi-quantitative approach.
Results
One-hundred six patients with acromegaly (mean age 56.6 years, mean BMI 30.2 kg/m^2) and 104 control subjects (mean age 54.06 years, mean 28.4 BMI kg/m^2) were included. There was no difference in TH BMD, CTx and plasma cortisol between study groups. Patients with acromegaly had lower LS BMD (1.002 ± 0.16 vs 1.049 ± 0.15; $P < 0.05$) and TBS (1.19 ± 0.13 vs 1.33 ± 0.14; $P < 0.0001$). higher levels of IGF-1 (244.5 ± 189.2 vs 115.2 ± 37.7 ng/ml; $P < 0.0001$) and P1NP (55.69 ± 34.3 vs 45.47 ± 18.6 ng/l; $P < 0.05$). In total, 13 patients and 4 control subjects had VFs identified using IVA. Among acromegaly patients those with VFs had lower TBS (1.11 ± 0.12 vs 1.20 ± 0.13; $P < 0.05$) and P1NP (32.06 ± 16.9 vs 58.5 ± 34.9 ng/l; $P < 0.05$) levels than non-fractured. No difference in BMD (both measured sites), CTx or IGF-1 was observed.
Conclusions
In this study, acromegaly patients had lower TBS and LS BMD than healthy controls. Additionly, those with VFs had lower TBS, and P1NP, but not BMD (both measured sites) than non-fractured acromegaly subjects. Thus, it could be suggested that VFs in acromegaly subjects are associated with impaired trabecular microarchitecture. We suggest using TBS, rather than BMD, to identify acromegaly patients at high VF risk.

Atypical femoral fracture-a possible complication in long term use of bisphosphonates (case report)

Alexandru Florescu[1,2], Vasile Lisnic[3] & Corina Galesanu[1,2]
[1]University of Medicine and Pharmacy 'Grigore T. Popa', Iasi, Romania; [2]Department of Endocrinology 'Sf.Spiridon' Emergency Clinical Hospital, Iasi, Romania; [3]Department of Orthopaedics 'Sf.Spiridon' Emergency Clinical Hospital, Iasi, Romania.

One of the clinical complications associated with the long term use of bisphosphonates treatment in osteoporosis is the atypical femoral fracture (AFF).Even the absolute risk is low and acceptable compared with the number of fractures prevented, there are still reasonable concerns due to the wide prescription of bisphosphonates and the existence of several case series proving that bisphosphonates have a strong association with this unique fracture type. We present a case of a 81 year old woman who was admitted in our clinic two and a half years ago right after she was treated for left femoral fracture in the orthopedic department.She had no history of recent trauma or low energy trauma,no corticotherapy, smoking or alcohol intake,no previous fractures.For the past 13 years she was continously treated with various type of bisphosphonates without any therapeutical pause or medical control.At that moment an association between bisphosphonates long term use and the occurence of atypical femoral fracture has been suggested.This diagnostic has also been supported by the X-ray with all the major features of AFF.Therapy with strontium ranelate and vitamin D supplements was initiated right after surgery with fully recover of the mobility and an increase in the quality of life. While concrete evidence based recommandations canot be provided, strict surveillance,overall awareness of prodromal thigh pain,radiological findings and bisphosphonates usage records are recomanded for prevention.For most people with osteoporosis the proven fragility-fracture risk-reduction benefits of bisphosphonates outweigh the risks of AFF.

Malignant hypercalcemia induced by denosumab discontinuation in a patient with primary hyperparathyroidism

Chiara Camponovo[1] & Elena Gonzalez Rodriguez[2]
[1]Service d'Endocrinologie, Diabétologie et Métabolisme, Lausanne, Switzerland; [2]Service d'Endocrinologie, Diabétologie et Métabolisme, CHUV, Lausanne, Switzerland.

Context
Denosumab, a fully human monoclonal antibody that inactivates receptor activator of nuclear factor k-B ligand (RANKL), is used for osteoporosis treatment because of its potent anti-resorptive properties. Due to its reversible mode of action, bone resorption increases rapidly after its discontinuation and is accompanied by a quick loss of bone mineral density. Spontaneous vertebral fractures at this period have been recognized as secondary to the rebound of bone resorption. Three cases of rebound-linked hypercalcemia have also been

described, one of moderate hypercalcemia following denosumab discontinuation given for osteoporosis, and 2 cases of malignant hypercalcemia in children receiving oncologic doses of denosumab.
Case report
We report the case of an osteoporotic 86-year-old woman treated with denosumab 60 mg subcutaneously every 6 months from 2013 to October 2016 (last injection). She is also known for a primary hyperparathyroidism (PTH 24.2 pmol/l, NV 1.3-9.3), with serum corrected calcium (CCa) at 2.82 mmol/l (NV 2.15-2.5) in April 2017, at the end of denosumab efficacy. Treatment by 30 mg/day cinacalcet lowers CCa to 2.51 mmol/l one month after. In July 2017, she is hospitalized due to weight loss (5 kg,15% body weight), malnutrition and bad health status. Clinical evaluation concludes to malignant hypercalcemia (CaC 3.53 mmol/l) despite lower PTH (10 pmol/l). Initial treatment by hydration and intranasal calcitonin only partially corrects CCa to 2.95 mmol/l. Very high values of bone resorption markers (B-crosslaps 1777 ng/l, NV $<$573; creatinine 97 umol/l) suggest a rebound effect due to denosumab discontinuation. An X-ray shows new multiple vertebral fractures. After injection of 60 mg denosumab, CCa rapidly lowers to 2.63 mmol/l, and bone resorption markers dramatically decrease (122 ng/l B-crosslaps).
Conclusion
This critical case suggests that hypercalcemia is an underappreciated side effect of denosumab discontinuation, which can become a severe complication when other causes of hypercalcemia, like primary hyperparathyroidism, are present.

An extremely high risk of recurrent fractures in an elderly patient, identified with the implementation of Fracture Liaison Service (FLS) in a trauma hospital.

Diliara Rizina[1] & Leonid Farba[2]
[1]Sechenov University, Moscow, Russian Federation; [2]City Hospital No. 13, Moscow, Russian Federation.

Introduction
Osteoporosis is a serious problem all over the world. The presence of low-energy fractures increases the risk of repeated fractures twice. Each new fracture increases the risk of a fatal outcome in the future. Globally, the most effective model of re-fractures preventing in patients with osteoporosis is a Fracture Liaison Service (FLS). FLS main objectives are identification of patients, assessment of re-fractures risks, diagnosis and initiation of osteoporosis therapy. In our hospital, this service has been operational since 2017.
Clinical case
Woman, 72 years old, with a fall from the height growth, suffered a fracture of the left proximal shoulder. She was hospitalized in the trauma department of the City Clinical Hospital No. 13. This fracture in the patient is not the first. In 2015, she underwent several compressive vertebral fractures. Currently, anti-osteoporotic drugs do not take. Also, suffers from rheumatoid arthritis. The onset of menopause in 50 age. When examining: there is curvature of the spine by type 'widow's hump'. Growth of 146 cm (decreased by 10 cm in height), 46 kg of BMI 21.6 kg/m^2. According to laboratory tests: vitamin D deficiency was found to be 8.4 ng/ml ($<$20-deficiency), an increase in the level of alkaline phosphatase 179 (0–120) U/l. The rest of the laboratory parameters were within norms: calcium 2.26 (2.15–2.55) mmol/l, phosphorus 1.38 (0.81–1.45) mmol/l, parathyroid hormone 82.4 (12.0–88.0) pg/ml, creatinine 46 (44–80) umol/l. The result of densitometry (DEXA): severe systemic osteoporosis with a very significant loss of bone mineral density. (T-score L1-L4 -4.5, neck of the left hip -4.4). But the worst result was in calculating the risk of repeated fractures with the FRAX® Calculation Tool, which showed a more than 50% chance of recurrent fractures and a 32% chance of a hip fracture (this is an extremely high risk). In connection with this, the patient began to take the prescribed pathogenetic anti-osteoporotic therapy and supplements of calcium and vitamin D immediately, in the hospital. We hope that the treatment started will reduce such high risks and protect against the most dangerous fracture of the hip.
Discussion
The introduction of the FLS into the practice of the City Hospital in Moscow is real and justified. This will help identify patients with the highest risks and will allow timely initiation of anti-osteoporotic therapy, thereby reducing the risks of fractures in the future.

The comparison of parathyroid neoplasms mappings evaluated by using gray scale ultrasound images and histopathological whole slide images

Aylin Kilic Yazgan[1], Oya Topaloglu[2], Fatma Neslihan Cuhaci Seyrek[2], Didem Ozdemir[2], Afra Alkan[3], Mehmet Kilic[4], Reyhan Ersoy[2] & Bekir Cakir[5]
[1]Department of Pathology, Ataturk Education and Research Hospital, Ankara, Turkey; [2]Department of Endocrinology and Metabolism, Yildirim Beyazit University School of Medicine, Ankara, Turkey; [3]Department of Biostatistics, Yildiri Beyazit University School of Medicine, Ankara, Turkey; [4]Department of General Surgery, Yildirim Beyazit University School of Medicine, Ankara, Turkey; [5]Department of Endocrinology and Metabolism, Yildirim Beyazit University School of Medicine, Ankara, Turkey.

Aim
The aim of this study is to correlate the histopathological cell types and morphologic features of parathyroid neoplasms with ultrasound(US) images and laboratory findings, and also gain more information about the clinical importance of these results.
Materials and methods
The parathyroid lesions of 57 patients who were operated for hyperparathyroidism were sampled on saggital plane. The slides were scanned on high resolution and digital whole slide images were formed. The system was consisted of motorized microscope, motorized table, robotic slide loader, and a high resolution camera. The slide on the motorized table was automatically scanned with the chosen objective and a high resolution image was formed. This image was opened with the help of an interface and then examined. These images can be archived. The US and the slide images were matched by the manufacturer software program.
Results
Forty three patients were female (73.7%). The ages of the patients were between 21–48 years and the median was 53. The study population had 47 adenomas, 7 atypical adenomas, 2 carcinomas. The median of parathormone (PTH) was 194 pg/ml (min–max: 53–2800), median of the tissue area was 96.29 (min–max: 16.01–576.05). Hypoechogenic areas on ultrasound(US) were matched with chief cells in 21 (55.3%), oncocytic cells in 2(5.0%), cyctic morphology in 8(20.0%) cases. There were less chief cells and more connective tissue in hyperechogenic areas ($P<0.05$). Hyperechogenic areas had less clear cells than isoechoic areas ($P<0.05$). Lipoic tissue ratio was significantly less in hypoechoic areas than hyperechoic areas ($P<0.05$). There was no significant difference between echogenicity, oncocytic cells, and haemorrhagia. There was a significant positive correlation between PTH and total neoplasm area ($r=0.377$, $P=0.004$). There was no significant difference between cyctic area ratio and chief cell amount in atypical and other cases($P>0.05$). A moderate positive lineer relationship was found between serum calcium levels and cyctic area ratio and percentage ($r=0.416$, $P=0.048$).
Conclusion
The morphologies of parathyroid neoplasms taken from the digital whole slide images were compared to US projections in the study. However, hypoechogenic areas of US images were matched with chief cells, hyperechogenic areas were compatible with connective and adipose tissues in histopathology. The positive lineer relationship between serum calcium levels and cyctic areas was open to new researches. Results of this study may guide the evaluation of the clinic outcomes of detailed morphometric studies with digital whole slide method.

Evaluation of bone mineral density and vertebral fracture incidence in a group of kidney transplant recipients

Dilek Gogas Yavuz, Arzu Kahveci, Onur Bugdaycı & Serhan Tuglular
Marmara University School of Medicine, Istanbul, Turkey.

Kidney transplant patients are prone to metabolic bone diseases. In this descriptive clinical study we aimed to evaluate the incidence of osteopenia osteoporosis, vertebral fractures in our group of renal transplant patients.
Methods
Eighty seven patients (25 males and 62 females) aged from 20 to 67 years, who had undergone kidney transplantation 1 to 20 yrs. previously included in the study. Bone mineral densitometry was performed using dual-energy X-ray absorptiometry, Thoracolumbar lateral vertebral X-ray evaluated for fracture according to Genant classification. Serum parathormone (PTH), 25OH vitamin D, calcium, phosphate, Luteinizing hormone (LH) and Follicular stimulating hormone (FSH) levels were measured.
Results
The incidence of osteoporosis was 26% (23 of 87 patients).and osteopenia was 52.8% (46 of 87 patients). Vertebral fracture was observed in 28.8% of the patients in thoracolumbar lateral vertebral X-ray evaluation. Serum Ca and P levels were in normal range while PTH levels were elevated and 25OH vitamin D levels were in deficient range. Vertebral fractures mostly observed in patients with osteopenia (17.2%). A negative correlation with post-transplantation duration with serum PTH levels (r: -0.16 $P<0.05$) and femur neck BMD (r:-0.24, $P<0.03$) was observed. Femur and lumbar 1-4 BMD levels were negatively correlated with serum LH and FSH levels ($P<0.001$).
Conclusion
Vertebral fractures observed more frequently in osteopenic group of renal transplant patients. Besides the BMD evaluation, vertebral fracture evaluation may help to make a proper therapy decision for metabolic bone disease in kidney transplant receipents

PTH correlates with bone turnover serum markers in patients with end stage renal disease

Roxana Dusceac[1], Dan Alexandru Niculescu[1], Madalina Cristina Dragne[2], Ramona Dobre[2], Cristiana David[3], Cristian Tacu[4] & Catalina Poiana[1]
[1]Department of Endocrinology, Carol Davila University of Medicine and Pharmacy, Bucharest, Romania; [2]Department of Pituitary and Neuroendocrine Disorders, C. I. Parhon National Institute of Endocrinology, Bucharest, Romania; [3]Department of Nephrology, Carol Davila University of Medicine and Pharmacy, Bucharest, Romania; [4]Diaverum Nephrology Clinic, Bucharest, Romania.

Background
End stage renal disease is usually associated with high serum parathyroid hormone (PTH) and increased bone turnover. The aim of our study was to correlate serum PTH with serum markers of bone turnover in patients with end stage renal disease (ESRD).
Methods
We measured serum PTH, osteocalcin, procollagen type 1 n-terminal propeptide (P1NP) and beta-crosslaps in 64 (32 men) consecutive pacients, median (25, 75 percentile) age 61 (49.5, 65.5) years, on permanent hemodialysis.
Results
Median (25, 75 percentile) PTH, osteocalcin, P1NP and beta-crosslaps were 246.1 (128, 487.9) pg/mL, 233.9 (96.7, 300) ng/mL, 287.1 (169.9, 810.7) ng/mL and 2.25 (1.63, 3.25) ng/mL, respectively. 90.6%, 96.8% and 93.7% of osteocalcin, P1NP and beta-crosslaps results respectively were higer than the upper limit of normal. We found a positive correlation between serum PTH and bone formation markers osteocalcin ($r=0.6136$, $P<0.001$) and P1NP ($r=0.6898$, $P<0.001$). There was no correlation between PTH and bone resorbtion marker beta-crosslaps ($r=-0.1520$, $P=0.23$).
Conclusion
Bone turnover is increased in end stage renal disease. Beside PTH, osteocalcine and P1NP could also be associated with osteitis fibrosa of ESRD.

Rapid washout in primary, secondary, and tertiary hyperparathyroidism and utility of dual radiopharmaceutical acquisition with ^{99}Tc-sestamibi-^{123}I for localization of parathyroid adenomas

Yevgeniya Kushchayeva[1], Sergiy Kushchayev[2], Sri Harsha Tella[3], Douglas Van Nostrand[4] & Kanchan Kulkarni[4]
[1]National Institutes of Health, Bethesda, MD, USA; [2]Mercy Catholic Medical Center, Darby, PA, USA; [3]University of South Carolina School of Medicine, Columbia, SC, USA; [4]MedStar Washington Hospital Center, Washington, DC, USA.

^{99m}Tc-Sestamibi (SeS) is a standard tool for localization of adenomas/hyperplasia (PA) in hyperparathyroidism (HPTH), designed on the difference between thyroid and parathyroid tissue radiotracer washout on early and late scintigraphy phases. However, PA have been reported to washout as fast as normal thyroid tissue ('rapid washout', RW), which may lead to diagnostic failure. The aim of the study was to determine a correlation of RW of SeS from parathyroid glands and types of hyperparathyroidism (HPTH). The utility of dual isotope radiopharmaceutical acquisition with ^{123}I/SeS subtraction imaging (SS) for detection of PA with RW was also investigated.
Methods
An IRB approved retrospective review of cases with HPTH referred to nuclear medicine and had subsequent parathyroid surgery was performed. Pre-, post-surgical and biochemical workup of HPTH, surgical pathology reports were analyzed. Correlative imaging with ^{123}I/SeS subtraction imaging was performed on selective patients. Group comparison was performed using paired t-test, ANOVA, and Brown–Forsythe tests.
Results
135 HPTH patients after parathyroidectomy with available dual phase SeS, pathology report, pre- and post-surgical biochemical HPTH workup were analyzed. Ninety-six (71%) patients had primary (p-HPTH), 29 (21%) had secondary (s-HPTH) and 10 (7%) had tertiary (t-HPTH) HPTH. 87/103 (84%) in p-HPTH, 53/94 (56%) in s-HPTH, and 16/23 (69%) in t-HPTH glands were positive on late SeS. RW was identified in 27% (28/103) p-HPTH, 15% (14/94) s-HPTH, 4% (1/23) t-HPTH ($P<0.0001$). Glands that were positive on late SeS phase were large being 1.7 (IQR: 1.4–2.3) vs 1.45 (IQR: 1–2) cm ($P=0.0036$). Median PTH levels for p-HPTH, s-HPTH, and t-HPTH were 142 (IQR:110–240.3), 955 (IQR:1865–2448), 1394 (IQR: 949–2613) pg/ml respectively ($P<0.0001$). High PTH levels were associated with early SeS phase positivity ($P=0.024$) but not with late SeS phase positivity ($P=0.26$). There was no significant difference in preoperative levels of calcium on retention of SeS radiotracer on early and late phases ($P=0.545$). Correlative imaging with dual isotope was performed in 17 patients and ^{123}I uptake was positive in 88% of PA with RW.
Conclusion
Higher rates of RW were seen in p-HPTH followed by s-HPTH and t-HPTH and was dependent on PA size but neither on PTH nor calcium levels. Pre-operative PTH levels and size of the gland were major determinants of 99mTc-sestamibi positivity on early SeS phase whereas size is an independent predictor of late SeS phase positivity. SS scintigraphy might be a useful tool in suspected cases of RA.

Trabecular bone score in patients with active acromegaly

Timur Tsoriev, Zhanna Belaya, Natalia Sasonova, Tatiana Chernova, Galina Melnichenko & Ivan Dedov
The National Research Centre for Endocrinology, Moscow, Russian Federation.

Introduction
In previous studies, it was noted that increased serum growth hormone (GH) and insulin-like growth factor-1 (IGF-1) lead to the increased vertebral fractures risk in patients with acromegaly. This may be explained by the altered quality of bone rather than bone mineral density (BMD) loss. Trabecular bone score (TBS) is an easily available tool to obtain some surrogate information on bone micro-architecture from a routine DXA.
Objective
To evaluate trabecular bone score (TBS) and standard dual-energy X-ray absorptiometry (DXA) measurements in patients with acromegaly (compared to the healthy controls).

Methods
32 patients with confirmed active acromegaly and 35 healthy volunteers were enrolled into the study. Standard DXA with simultaneous calculation of TBS L1-L4 was performed using GE iDXA, TBS iNsight software v2.1 (Medimaps, Merignac, France). Serum insulin-like growth factor-1 (IGF-1) in patients with acromegaly was measured by the immunochemiluminescence assay, reference range (60–280 ng/ml).
Results
The groups were matched by sex (in total 21 men and 46 women) $P=0.657$; age 45.1 (95% CI 41.3–48.9) in patients with acromegaly and 44.7 (95% CI 42.7–46.7) $P=0.225$ and BMI 28.5 (95% CI 27.1–29.9) kg/m^2 in patients with acromegaly vs 26.7 (95% CI 25.3–28.1) kg/m^2 $P=0.065$. Mean IGF-1 level in patients with acromegaly was 703.79 ng/ml (95% CI 595.37–812.20). In patients with acromegaly there were not revealed significant differences in any DXA measurements compared to the control group: BMD L1-L4 1.162 g/sm^2 (95% CI 1.100–1.225) vs 1.221 g/sm^2 (95% CI 1.149–1.293); BMD T-score L1-L4 −0.28 s.d. (95% CI −0.79 to 0.23) vs 0.24 s.d. (95% CI −0.36 to 0.83); BMD Z-score L1-L4 −0.29 s.d. (95% CI −0.75 to 0.18) vs 0.12 s.d. (95% CI −0.40 to 0.63) ($P=0.221$, 0.192 and 0.245 respectively). TBS L1-L4 in patients with acromegaly was 1.408 (95% CI 1.358–1.458) vs 1.463 (95% CI 1.424–1.501) in controls ($P=0.080$). Statistically significant correlation between IGF-1 and TBS L1-L4 was not identified (as well as between IGF-1 and BMD, T- and Z-scores): $r=0.313$, 0.296, 0.274 and 0.092 respectively ($P=0.098$, 0.119, 0.150 and 0.635 respectively).
Conclusion
Acromegaly does not affect TBS or BMD in the value to be diagnostics in the individual subjects or in a small patient groups.

Gut and bone connection: celiac disease presented as hypertrophic osteoarthropathy
Darin Ruanpeng & Tasma Harindhanavudhi
University of Minnesota, Minneapolis, MN, USA.

A 52-year-old postmenopausal woman was referred to endocrinology clinic for evaluation of persistent isolated elevation of alkaline phosphatase during routine check-up. Her past medical history was notable for hypothyroidism and vitamin D deficiency. She denied history of fractures or kidney stone. She denied using over the counter supplement, alcohol, smoking or drug use. Family history was suggestive of autoimmune disease, including celiac disease, type 1 diabetes, rheumatoid arthritis, and thyroid disease. Her physical examination was completely unremarkable. Initial laboratory investigation revealed elevated alkaline phosphatase (ALP) of 159 U/L (reference range: 40–150), with normal transaminase level. Subsequent labs were rechecked with further elevation of ALP to 177 U/L at 6 months and 212 U/L at 1-year follow-up. Additional labs revealed mild hypocalcemia with corrected calcium of 8.4, normal TSH, GGT, hepatitis B and C panel, ESR and CRP. Liver ultrasound revealed a 1.2 cm benign appearing hemangioma and no apparent culprit for abnormal enzymes. Further evaluation of persistent elevation of ALP revealed a fractionated bone alkaline phosphatase of 42.2 μg/L (reference range: 7–22.4 for postmenopausal woman). Subsequent nuclear bone scan demonstrated linear tram-like increased uptake in the bilateral tibia without focal areas of abnormal radiotracer uptake within the skeleton. Because of the patient's and family history of autoimmune disease as well bone scan finding, further work-up revealed a positive serum transglutaminase IgA indicated celiac disease. She was ultimately started on gluten-free diet with complete normalization of ALP. Periostosis is a radiographic hallmark of hypertrophic osteoarthropathy (HOA) which manifests along the shafts of tubular bones. HOA can also present as digital clubbing or synovial effusions. It is characterized by abnormal skin proliferation at the distal parts of the extremities as well as periosteal proliferation of the long bones. HOA is commonly associated with pulmonary disease but it could also be related to a variety of conditions involving different organ systems such as infection, inflammatory bowel disease, thyroid disease or hematologic malignancy. Herein, this case highlights HOA as a rare presentation of celiac disease.

The main bone mass predictors in healthy young and middle-aged men: lean mass and estradiol
Stefana Catalina Bilha[1], Maria-Christina Ungureanu[1], Petru Cianga[1], Catalin Buzduga[1], Alina Gatu[1], Adrian Aancute[2], Valentin Zaharia[2], Daniela Constantinescu[1], Adrian Covic[1] & Dumitru Branisteanu[1]
[1]'Gr. T. Popa' University of Medicine and Pharmacy, Iasi, Romania; [2]'St. Spiridon' Hospital, Iasi, Romania.

Introduction
Despite the high burden of osteoporotic fractures, bone evaluation in men is not without flaws, being frequently undervalued. We aimed at investigating the role of body composition, adipokines and classic bone determinants (sex hormones) as predictive factors for bone mass parameters in healthy young and middle-aged men.
Materials and methods
Anthropometric, bone mineral density (BMD) (assessed by Dual X-Ray Absorptiometry;DXA) and body composition parameters (assessed by DXA) and also the serum levels of C-terminal telopeptide of type I collagen (CTx), adipocytokines (leptin, resistin), total testosterone (free testosterone was calculated using mass action equations), total estradiol and sex hormone-binding globulin (SHBG) were determined from 30 healthy male volunteers aged 20-65 years old. Correlation analysis and also multivariable and hierarchical regression analyses were performed.
Results
BMD at various sites significantly correlated with body mass index (BMI), lean mass (LM), trunk fat mass, leptin, resistin, total estradiol and SHBG in the initial correlation analysis. When multiple regression analysis was performed, only LM and total estradiol remained independent significant predictors of BMD in men (together explaining 49% of whole-body BMD variance, $P<0.001$), while there were no independent predictors found for CTx. In the hirerchical regression analysis, the beta coefficient for BMI became non-significant when LM was added to the model.
Conclusions
LM and estradiol are the main BMD predictors in healthy young and middle-aged men. LM largely mediates the bone effects of the BMI. These parameters may find their place for fine tuning the male bone evaluation algorithms.

Teriparatide treatment in a patient with atypical femoral fractures associated with long-term bisphosphonate therapy
Nagihan Bestepe[1], Cevdet Aydin[2], Berna Evranos[1], Oya Topaloglu[2], Reyhan Ersoy[2] & Bekir Cakir[2]
[1]Ataturk Education and Research Hospital, Department of Endocrinology and Metabolism, Ankara, Turkey; [2]Ankara Yildirim Beyazit University School of Medicine, Department of Endocrinology and Metabolism, Ankara, Turkey.

Introduction
Bisphosphonates are the most commonly used drugs for the treatment of osteoporosis and have been shown to improve bone mineral density and reduce fractures. However, approximately a decade ago, atypical femoral shaft fractures were found to be a rare complication of bisphosphonate treatment. Atypical Femoral Fractures (AFF) represent fractures located between the lesser trochanter and the supracondylar flare of a femur. An increasing pool of evidence supports

their association with the prolonged use of bisphosphonates, even though a direct correlation has not been proven yet. In this report, we describe a patient who developed atypical femoral fractures after prolonged use of bisphosphonates.
Case
A 42-year-old man was referred to our out-patient clinic after operation for bilateral femoral fractures by orthopedists. The patient had the history of mild trauma. Her medical case history revealed that, for the past 6 years, he had received 70 mg/week alendronate as treatment for osteoporosis. Plain radiographs showed a transverse fracture in the bilateral femur, and cortical thickening was observed at the fracture site. His bone mineral densities (BMD) at the baseline dual-energy X-ray absorptiometry (DEXA) scan were as follows; femoral neck: 0.76 g/cm^2 (T score −1.2), femoral total: 0.79 g/cm^2 (T Score −1.6), and lumbar total: 0.70 g/cm^2(T Score −3.7). Blood tests indicated that his serum calcium, phosphate, and alkaline phosphatase levels were in the normal ranges. Any reason for secondary osteoporosis was not determined. The patient was diagnosed as bilateral atypical femoral fractures. The patient discontinued his alendronate regimen. The patient was treated with teriparatide 30 μg/day for osteoporosis for 18 months. After this treatment, lumbar total T-score was reduced to −2.9 (0.77 g/cm^2).
Conclusion
Bisphosphonates are one of the most widely prescribed drugs for the treatment osteoporosis and the reduction of fracture risk. In this report, we presented a patient with atypical fractures associated with long-term bisphosphonate treatment. The correlation between the long-term bisphosphonate use and atypical fractures has not been conclusively established. However, the drug holiday is suggested to reduce the risk of atypical fracture after prolonged bisphosphonates use. This case confirmed that teriparatide had a rapid bone anabolic effect on unhealed atypical fractures associated with chronic bisphosphonate use.

Detection of pulmonary metastases with 18F-Fluorocholine PET/CT and treatment of refractory hypercalcemia with denosumab in a patient with long term parathyroid carcinoma

Nagihan Bestepe[1], Oya Topaloglu[1], Cigdem Soydal[2], Nilufer Yildirim[3], Reyhan Ersoy[1] & Bekir Cakir[1]
[1]Yildirim Beyazit University School of Medicine, Department of Endocrinology and Metabolism, Ankara, Turkey; [2]Ankara University Faculty of Medicine, Department of Nuclear Medicine, Ankara, Turkey; [3]Ataturk Education and Research Hospital, Department of Nuclear Medicine, Ankara, Turkey.

Introduction
Parathyroid carcinoma (PC) mediated hypercalcemia is often severe and more resistant to medical treatment. 18F-Fluorocholine PET/CT is a new technique used for determining the localization of parathyroid lesions. Denosumab, novel antiresorbtive agent, has been shown to have a useful role in hypercalcemia treatment. We report a male patient in long-term follow-up of PC who had refractory hypercalcemia due to pulmonary metastases revealed with 18-Fluorocholine PET/CT and who was successfully treated with denosumab.
Case
A 49-year-old man with recurrent PC initially presented in July 2007 with diffuse bone pain at lower extremities and hypercalcemia A neck ultrasound and CT scanning revealed a 3.9×3×3.5 cm solid lesion adjacent to the lower pole of the left thyroid lobe that was shown to represent a single hyperfunctioning parathyroid lesion on 99mTc-sestamibi (MIBI) parathyroid scintigraphy. The patient underwent a left parathyroidectomy along with en-bloc left thyroid lobectomy and left lateral lymph node dissection. Histological examination revealed parathyroid carcinoma. Due to postoperatively increased calcium and PTH levels, the patient was re-operated two times during the follow-up period for local recurrences. Afterwards, local radiotherapy was applied. One year later, laboratory investigations showed significantly raised calcium and PTH levels. Intravenous bisphosphonate as zolendronic acid 4 mg/28 days was started. For last 3 years, he did not take the medication due to social problems. He had admitted to our department with severe hypercalcemia 10 years later the initial operation at June 2017. He had hypercalcemia (16.8 mg/dl). He was screened for local recurrence or metastases. In 18F-FDG PET/CT diffuse nonhomogeneous hypermetabolism in medullary bones mostly associated with metabolic bone disesase was detected. His serum calcium levels were not decreased to <14 mg/dl levels with standard therapy such as aggressive saline rehydration, intravenous bisphosphonate, hemodialysis, oral cinacalcet. He had also acute pancreatitis in hospitalised period. For detection of local recurrence, 18-Fluorocholine PET/CT which revealed high uptake on pulmonary nodules was performed. Subcutaneous denosumab of 60 mg/28 days was given. After 3 doses of denosumab, total calcium was measured as 11.4 mg/dl.
Conclusion
As in this case, imaging with 18F-fluorocholine PET/CT is feasible in recurrent/metastatic parathyroid carcinoma. In our patient, 18F-fluorocholine PET/CT seems superior to FDG-PET/CT for detection of metastases. Denosumab is a good choice in treatment of hypercalcemia in patients who are resistant to other therapies such as hemodialysis, bisphosphonates and calcimimetics.

Bone mineral density decline following denosumab discontinuation might not be attenuated with previous bisphosphonate therapy

Miha Japelj[1], Gaj Vidmar[2], Antonela Sabati Rajic[3], Marija Pfeifer[1] & Tomaz Kocjan[3]
[1]Medical Faculty Ljubljana, Ljubljana, Slovenia; [2]University Rehabilitation Institute, Ljubljana, Slovenia; [3]University Medical Centre Ljubljana, Ljubljana, Slovenia.

Objective
Limited data suggest that the rebound increase in bone resorption and rapid bone mineral density (BMD) decline following sudden interruption of denosumab therapy can be avoided in patients previously treated with bisphosphonates. We aimed to compare BMD changes in osteoporotic patients after denosumab discontinuation regarding their previous bisphosphonate (BP) therapy.
Material and methods
There were 14 women (age 69 years, BMI 23.1 kg/m^2 on average) with postmenopausal osteoporosis who had been treated between 2011 and 2015 with denosumab for 2.8 (1–4) years at our outpatient clinic and were not prescribed with another antiresorptive after denosumab discontinuation. Before starting denosumab ten patients were on BP therapy, while the others were treatment naïve. One patient had a history of multiple vertebral fractures and two patients had sustained nonvertebral fractures. There were no fractures during denosumab therapy. BMD was measured at lumbar spine (LS), total hip (TH) and femoral neck (FN) by DXA when denosumab was stopped and 12 to 18 months later. The data were analyzed using exact nonparametric tests.
Results
At the time of denosumab discontinuation 5 patients (36%) were vitamin D sufficient (25OH vitamin D > 75 nmol/l). BMD decreased on average statistically significantly at all sites, (marginally at LS and most clearly at FN). There were no statistically significant differences in average BMD decrease with respect to previous BP therapy. However, there was statistically significantly lower decrease at LS on average among the vitamin D sufficient patients. Off denosumab, one treatment naïve patient and one former BP user sustained five and four vertebral fractures, respectively. Fractures were confirmed with MRI and occurred approximately 13 months after last denosumab dose. The estimated proportion of patients with fractures (adjusted Wald method) was 19% (95% CI 3–41%).
Conclusion
After stopping denosumab BMD similarly decreased in all patients, regardless of previous BP use.

Novel heterozygous mutation of tissue-non-specific alkaline phosphatase (TNSALP) gene causing late-onset hypophosphatasia

Rosaria Maddalena Ruggeri[1,2], Rosaria Certo[2], Vito Guarnieri[3], Salvatore Giovinazzo[1,2], Francesco Ferraù[1] & Salvatore Cannavò[2,4]
[1]Department of Clinical and Experimental Medicine University of Messina, Messina, Italy; [2]Unit of Endocrinology, AOU G. Martino, Messina, Italy; [3]IRCCS Casa Sollievo della Sofferenza Hospital, San Giovanni Rotondo, Foggia, Italy; [4]Department of Human Pathology of Adulthood and Childhood, University of Messina, Messina, Italy.

Background
Hypophosphatasia (HPP) is a rare metabolic, inherited disease of bone metabolism, caused by loss-of-function mutations within the gene coding for TNSALP, that result in a decrease in serum ALP concentrations and consequent accumulation of ALP substrates outside of the cell, including inorganic pyrophosphate which inhibits bone mineralization. HPP leads to a variety of clinical manifestations across all ages and its prognosis is conditioned principally by the skeletal complications, which generally reflect patient age at presentation.
Case report
We report the case of a 60-year-old woman presenting with chronic kidney disease stage 4 due to progressive nephrocalcinosis and recurrent renal calculi. Starting from the age of 37 yr, when a fracture of distal ulna occurred, the patient had experienced multiple fractures, including bilateral atypical subtrochanteric femoral fractures, and increasing pain, which had resulted in a decrease in her mobility from fully mobile to bed-bound. On physical examination the patient was 145 cm tall and weighed 45 kg. Examination of the lungs, heart and abdomen was unremarkable. ECG and EGA were normal. An ultrasonographic study of abdomen revealed kidneys reduced in volume with irregular profile; bilaterally absent hydronephrosi. Chest radiographs showed severe sclerosis with marked dysmorphism of the scapulae, the humerus and the clavicles. Laboratory evaluation revealed low serum ALP levels (11 UI/l; n.v. 40–150) and high values of Vitamin B6 (33.5 μg/dl; n.v.8.7–27.2), consistently with a diagnosis of HHP. Serum PTH was high (94.20 pg/ml; n.v. 8–76) and 25OH-vitamin D low (9.9 μg/dl; n.v. >30), with total calcium 10.2 mg/dl. Mutation analysis revealed a novel heterozygous mutation in the TNSALP gene (c.1415A$>$G, p.His472Arg). The mutation identified in this patient's TNSALP gene have never been previously identified as causing HPP.
Conclusion
We report a novel missense mutation of TNSALP gene, causing late-onset HHP. Up to date over 300 mutations have been identified, which result in a variable loss of function in the enzyme and a consequent decrease in serum ALP concentrations. A clear correlation genotype-phenotype has not been recognized yet.

Orthopedic patient with hearing impairment and dizziness due to the undiagnosed Paget's disease of bone

Sintija Sausa[1,2], Sandra Steina[2] & Valdis Pirags[1,2]
[1]University of Latvia, Riga, Latvia; [2]Pauls Stradins Clinical University Hospital, Riga, Latvia.

A 67-year-old female patient with a more than five-year history of symptomatic treatment of bilateral hip joint arthrosis, lumbar spine spondiloarthrosis as well as progressive hearing impairmen and dizziness was referrred by orthopedic surgeon to the endocrinology ward for diagnostic workup of metabolic bone disease. From the family history it was known that her mother had similar complains by the age of 60, which rapidly led to disability to walk, but she was never properly investigated. Patients plasma calcium (2.24 mmol/l) and phosphorus (1.48 mmol/l) were within the normal range, but parathyroid hormone (1294 U/l, 12.2 pmol/l) and alkaline phosphatase (1294 U/l) were significantly elevated. The skull radiography revealed areas of increased density and fibrous cortical layer, and similar changes were observed in left thigh and pelvic bones, both hip joint surfaces were narrowed, sclerotic and thickened. The skull CT scan indicated that the cause of the bilateral sensoneural hearing loss was a diffuse and uneven hyperostosis leading to compression of the auditory nerves. Magnetic resonance imaging of lumbosacral, lower thoracic vertebrae revealed degenerative spondylarthrosis. All these findings indicated that patient had the Paget's bone disease. Patient received a high dose vitamin D therapy followed by a single 5-mg dose of intra venous zoledronate injection and long term calcium and vitamin D substitution that led to an increase of the bone mineral density. After 6 months the knee joint replacement with endoprosthesis was performed.
Discussion
Our case report is showing importance of measurement of the alkaline phosphatase within the endocrinological investigation for metabolic bone disease in patients complaining of hearing loss, vertigo and osteoarthritis. Paget's disease of bone is a chronic disorder of bone remodelling that begins with excessive bone resorption followed by an increase in bone formation. Mostly it manifests in the 5th decade of life and diagnosed in the sixth decade. Disease commonly affects the pelvis and spine, the sacrum, the skull, and the femur. Skull involvement results in headaches, impaired hearing, vertigo and tinnitus.

Tumor-induced osteomalacia associated with mesenchymal tumor: a challenging case report

Milda Daneliene[1], Aurelija Krasauskiene[1], Lina Barsiene[1], Saulius Lukosevicius[2] & Birute Zilaitiene[1,3]
[1]Department of Endocrinology, Hospital of Lithuanian University of Health Sciences Kauno Klinikos, Kaunas, Lithuania; [2]Department of Radiology, Hospital of Lithuanian University of Health Sciences Kauno Klinikos, Kaunas, Lithuania; [3]Institute of Endocrinology, Lithuanian University of Health Sciences, Kaunas, Lithuania.

Introduction
Tumor-induced osteomalacia (TIO) or oncogenic hypophosphatemic osteomalacia (OHO) is a rare paraneoplastic syndrome characterized by renal phosphate wasting leading to hypophosphatemia and secondary osteomalacia. TIO was first described in 1947 by Robert McCance and only 500 of cases have been reported in literature since then, approximately 200 of cases during this decade.
Case report
In 2014, a 32-year-old female presented with waist pain, myalgia, muscle weakness. The patient felt unhealthy after second childbirth. In June 2015 MRI scan revealed bilateral acute sacroiliitis. Treatment with sulphasalazine, methylprednisolone, methotrexate and later with etanercept was started, but was ineffective. In May 2016 repeated MRI showed bilateral avascular femoral head necrosis of unknown origin. Plain radiography showed osteoporosis at thoracic, lumbar vertebrae, hip bone and femur, fracture of superior ramus of pubis, compressive fractures in Th8-Th9. Dual energy x ray absorptiometry (DXA) scans confirmed low bone mineral density at the spine 0.516 g/cm^2 (Z-score -4.8), hip neck 0.507 g/cm^2 (Z-score -2.9) and hip total 0.496 g/cm^2 (Z-score -3.6). Other causes of secondary osteoporosis were excluded and the antiosteoporotic treatment with denosumab was started. The patient was first seen by an endocrinologist in October 2016 because of progressing symptoms. Biochemical evaluation revealed hypophosphatemia 0.3 mmol/l (n: 0.78–0.153) and low 24-h urine phosphorus excretion 8.78 mmol/24 h (n: 12.9–42.0). Hypophosphatemia was treated with phosphate supplements but where was no improvement. In September 2017 patient noticed a soft lump in the right groin. Right leg ultrasound and MRI revealed $1.5\times1.8\times2.0$ cm size tumor between sartorius and adductor longus muscles. Whole-body MRI and bone scintigraphy showed no metastasis or other tumors. In October 2017 the whole-body scintigraphy with somatostatin analogues 99mTC-tektrotyd showed intensive uptake of radiotracer at the tumor. Tumor biopsy was performed and the result confirmed giant cell tumor of soft tissue (GCT-ST). FGF-23 values were found increased eightfold and being 867 U/l (n: 26–110). With strong prediction of TIO, in January 2018 the patient underwent tumor removal surgery. One week after surgery serum phosphate reached normal range. Histopathology examination is still in process.
Conclusion
A stepwise approach to tumor localization with functional and anatomic imaging for the diagnosing TIO is essential. Patients should first be assessed with a thorough physical examination. Removal of the tumor successfully cures this debilitating disease.

Osteoprotegerin and bone metabolism markers in postmenopausal women with primary hyperparathyroidism

E.V. Brutskaya-Stempkovskaya[1], A.P. Shepelkevich[1], N.V. Karlovich[1,2], A.V. Yurenia[2], A.S. Kazlova[2], A.V. Sosedkova[2] & Y.A. Hostina[3]
[1]Belarusian State Medical University, Minsk, Belarus; [2]Minsk City Dispensary of Endocrinology, Minsk, Belarus; [3]Minsk Consulting and Diagnostic Centre, Minsk, Belarus.

Objective
To study relationship between osteoprotegerin (OPG) and bone metabolism markers in postmenopausal women with primary hyperparathyroidism (PHPT) compared postmenopausal women without PHPT.
Materials and methods
We studied 30 postmenopausal women with PHPT, average age 62.5 ± 6.12. The control group were 16 postmenopausal women without PHPT, mean age 59.7 ± 6.28 in physiological menopause. We analyzed anthropometric data and history of fractures. Examination: total calcium, Ca^{++}, phosphorus, albumin, creatinine, alkaline phosphatase, PTG, OPG, crosslaps, osteocalcin.
Results
The were no differences in the age ($U=138.5$, $P=0.052$), height, m ($U=216.5$, $P=0.99$), weight, kg ($U=202.5$, $P=0.72$), BMI kg/m^2 ($U=196.5$, $P=0.61$), duration of menopause, years ($U=146.5$, $P=0.08$). Calcium total was 2.75 (2.69-2.82) mmol/l in postmenopausal women with PHPT vs 2.44 (2.31-2.50) mmol/l in the control group, $U=4$, $P=0.001$; Ca^{++}1.27 (1.26-1.36) mmol/l vs 1.04 (0.98-1.14) mmol/l in the control group, $U=4.24$, $P<0.0001$; phosphorus 0.94 (0.80-1.06) mmol/l vs 1.36 (1.32-1.40) mmol/l in the control group, $U=0.001$, $P=0.029$; alkaline phosphatase 122.0 (89.0-146.0) mmol/l vs 84.0 (72.0-84.0) mmol/l in the control group, $U=4.0$, $P=0.126$; PTG 111,1 (88.5-144.3) pg/ml vs 54.7 (35.4-55.3) pg/ml, $U=0.001$, $P<0.0001$; osteocalcin 32.33 (21.95-40.33) ng/ml vs 19.9 (16.0-27.8) ng/ml, $U=23$, $P=0.07$; crosslaps 0.60 (0.37-0.79) vs 0.46 (0.33-0.54), $U=16$, $P=0.2$. Significant differences were detected in calcium total, Ca^{++}, phosphorus, PTG in postmenopausal women with PHPT compared control group, there were no differences in alkaline phosphatase, osteocalcin, crosslaps. We detected negative correlation between OPG level and calcium total $r_s=-0.6$, $P<0.05$, $r_s=-0.7$, $P<0.05$, PTG $r_s=-0.6$, $P<0.05$.
Conclusion
The results of the study confirmed high bone metabolism in postmenopausal women with PHPT compared control group. The results may indicate association between PTG, calcium level and OPG.

Endocrine osteoporosis characteristics (about 177 cases)

Fatima Zahra Iftahy[1,2,3], Siham El Aziz[1,2,3] & Asma Chadli[1,2,3]
[1]Endocrinology, Diabetology and Metabolic Diseases Department Ibn Rochd University Hospital of Casablanca, Morocco, CASABLANCA, Morocco; [2]Neurosciences and Mental Health Laboratory, CASABLANCA, Morocco; [3]Faculty of Medicine and Pharmacy- University Hassan II- Casablanca-Morocco, CASABLANCA, Morocco.

Background
Osteoporosis is a not uncommon complication of endocrine disease. It may even be accompanied by endocrinopathy. The aim of study was to determine mineral bone density profile of patients with endocrinopathy and define the osteoporosis and osteopenia prevalence in these patients.
Materials and methods
Descriptive study included 177 patients followed for endocrinopathy (hypercorticism, hyperparathyroidism, prolactinoma and hypogonadism) in Endocrinology and Diabetology department of Ibn Rochd University Hospital of Casablanca, from 2011 to 2017. Each patient had a phosphocalcic balance, a vitamin D test and bone densitometry. Several variables were studied such as age, gender, fracture antecedant. Statistical analysis performed by the software SPSS.16.
Results
Mean age of our patients was 38 (16-73) years, with a female predominance (sex ratio: 0.3). The etiologies were represented by hyperparathyroidismin 65 patients, hypercorticismin 61 patients, prolactinoma in 12 patients and hypogonadism in 39 patients. An abnormal bone density was found in 85% of patients. Osteoporosis prevalence was 68% with predominance of the spine localization during hypercoticism (45%) and hypogonadism (38%) with an average T-score of -1.98 ± 1 among patients with hyperparathyroidism. Osteoporosis predominated in the forearm in 35% of patients. Osteopenia was found in 37% of patients with femoral predominance. Vitamin D deficiency was found in 74% of our patients. These bone density abnormalities were revealed by endocrine pathology in 75% of patients, 18% of whom were at the stage of complications such as bone fractures.
Conclusion
This work shows a high incidence of osteoporosis and osteopenia in patients treated for endocrine diseases especially who followed for hypercorticism and hypogonadism and drove us to place the interests of systematically seek an abnormal bone density before any endocrine disorder which can cause rheumatic disorder.

Osteoprotegerin and distal radius bone mineral density in postmenopausal women with primary hyperparathyroidism

E.V. Brutskaya-Stempkovskaya
Belarusian State Medical University, Minsk, Belarus.

Objective
To study relationship osteoprotegerin (OPG) and distal radius bone mineral density (BMD) in postmenopausal women with primary hyperparathyroidism (PHPT) compared postmenopausal women without PHPT.
Materials and methods
We studied 30 postmenopausal women with PHPT, average age 62.5 ± 6.12. The control group were 16 postmenopausal women without PHPT, mean age 59.7 ± 6.28 in physiological menopause. We analyzed anthropometric data and history of fractures. Examination: total calcium, phosphorus, albumin, creatinine, PTG, OPG, vitamin D, BMD measurements in the lumbar spine, femoral neck, total hip, and distal 1/3 radius by DXA (T-score$_{33\%}$, BMD$_{33\%}$ g/cm^2).
Results
The were no differences in the age (U = 138.5, $P=0.052$), height, m (U = 216.5, $P=0.99$), weight, kg (U = 202.5, $P=0.72$), BMI kg/m^2 (U = 196.5, $P=0.61$), duration of menopause in both group, years (U = 146.5, $P=0.08$). Osteoporosis of distal 1/3 radius was founded in 33% (10 cases), osteopenia in 43% (13 cases) in postmenopausal women with PHPT(T-score$_{33\%}$ = –2.3 (–3.2 –1.5, BMD$_{33\%}$ = 0.67 (0.59–0.75) g/cm^2), and low distal radius BMD was no founded in the control group (T-score$_{33\%}$ = −0.3 (−0.7 –0), BMD$_{33\%}$ = 0.87 (0.82–0.9) g/cm^2). Significant differences was detected in the distal radius BMD in postmenopausal women with PHPT compared postmenopausal women without PHPT ($U_{\text{T-score33\%}}=22.0$, $P<0.0001$, $U_{\text{BMD33\%}}=20.5$, $P<0.0001$). We detected correlation between OPG level and distal radius BMD: $r_{\text{sT-score33\%}}=0.7$, $P<0.05$, $r^2_{\text{s33\%g/cm}}=0.64$, $P<0.05$.
Conclusion
The results of the study confirmed reduced BMD in cortical bone, particularly at the distal radius, in postmenopausal women with PHPT compared control group. The results may indicate association between OPG level and low distal radius BMD.

Cystic fibrosis-related bone disease in young adults affected with cystic fibrosis awaiting lung transplantation for end-stage respiratory failure

Elisa Cairoli[1,2], Cristina Eller-Vainicher[1], Alice D'Adda[3], Federica Briganti[3], Maria Pappalettera[3], Paolo Tarsia[3], Maura Arosio[1,2] & Iacopo Chiodini[1]
[1]Unit of Endocrinology, Fondazione IRCCS Ca' Granda Ospedale Maggiore Policlinico, Milan, Italy; [2]University of Milan, Deparment of Clinical Science and Community Health, Milan, Italy; [3]Unit of Broncopneumology, Fondazione IRCCS Ca' Granda Ospedale Maggiore Policlinico, Milan, Italy.

Background
Cystic fibrosis-related bone disease (CFBD) is an emerging complication of cystic fibrosis (CF), especially in CF-lung transplant candidates for end-stage disease.

Objectives
The assessment of vitamin D levels, bone mineral density (BMD) and morphometric and clinical prevalent fragility fractures in a cohort of young adults affected with CF awaiting lung transplantation for end-stage respiratory failure.
Methods
In 42 CF-patients (24 females, age 33.7 ± 8.3 years), who were consecutively referred as lung transplant candidates to our Hospital, we evaluated the parameters of calcium metabolism, including 25-OH vitamin D (25OHVitD) levels, BMD by dual-energy x-ray absorptiometry and vertebral fractures by spinal radiograph.
Results
Mean 25OHVitD levels (22.0 ± 10.4 ng/mL) were below the reference range and hypovitaminosis D (25OHVitD <30 ng/mL) was found in 34 patients (81%) despite vitamin D supplementation in the majority of patients. Even mean daily calcium intakes (615.5 ± 266.8 mg/day) were lower than that recommended (1000 mg/day). BMD FT Z-scores were inversely correlated with prednisone cumulative exposure ($r=-0.383$, $P=0.015$) and BMD FN and FT Z-scores were directly correlated with albumin-adjusted calcium ($r=0.387$, $P=0.020$ and $r=0.346$, $P=0.039$ respectively) and 25OHVitD levels ($r=0.508$, $P=0.001$ and $r=0.554$, $P=0.0001$ respectively). In particular, no patients with normal 25OHVitD levels showed FT Z-scores <-1.0. A BMD below the expected range for age (Z-score <-2.0) was found in 22 patients (52.4%) and at least one prevalent fracture in 18 patients (45.2%). In patients with a BMD Z-score <-2.0 the prevalence of fragility fractures tended to be higher (59.1%) than in patients with a BMD within the range of age (30.0%, $P=0.059$), whereas these two groups were comparable as far as age, gender, body mass index, familiar history of fracture, glucocorticoid exposure, daily calcium intake and vitamin D supplementation, prevalence of main CF-related comorbidities, albumin-adjusted calcium and 25OHVitD levels.
Conclusions
Despite the improvement of CF-care, CFBD is still highly prevalent in young adults awaiting lung transplantation for end-stage CF. In order to optimize bone health of CF population approaching lung transplantation, glucocorticoid use should be minimized whenever possible, optimal calcium intake ensured and hypovitaminosis D adequately corrected.

Recurrent vertebral fracture after denosumab discontinuation in a male patient with severe osteoporosis

Panagiotis Anagnostis[1], Stavroula Paschou[2], Michael Potoupnis[3], Eleftherios Tsiridis[3] & Dimitrios Goulis[1]
[1]Unit of Reproductive Endocrinology, First Department of Obstetrics and Gynecology, Medical School, Aristotle University of Thessaloniki, Thessaloniki, Greece; [2]Division of Endocrinology and Diabetes, "Aghia Sophia" Hospital, Medical School, National and Kapodistrian University of Athens, Athens, Greece; [3]Academic Orthopaedic Unit, Aristotle University Medical School, General Hospital Papageorgiou, Thessaloniki, Greece.

Introduction
Discontinuation of denosumab may rarely lead to rebound fractures, although the evidence is low, since available data have derived from case reports and post-hoc analyses.
Case presentation
A 45-year old Caucasian male was presented at the outpatient clinic in February 2016 for evaluation and management of severe osteoporosis, which had been complicated with multiple vertebral low energy fractures at the 10 th to 12th thoracic vertebrae (T10-T12) and at the 1st (L1), 2nd (L2), 4th (L4) and 5th lumbar vertebrae (L5). These fractures were diagnosed in 2013 after continuous back pain following a mild injury and weight-bearing activities. Severe osteoporosis was diagnosed and the patient was initially treated with teriparatide (for 24 months) showing significant improvement in physical activity. Bone mineral density (BMD) values after teriparatide treatment were 0.861 mg/cm^2 (T-score: –3, Z-score: –2.5) for lumbar spine, 0.78 mg/cm^2 (T-score: –2.2, Z-score: –1.4) for neck and 0.783 mg/cm^2 (T-score –2.4. Z-score: –1.7) for total hip. Evaluation for causes of secondary osteoporosis was negative. He was also receiving calcium supplementation (1000 mg/d) and cholecalciferol 800 IU/d (25-hydroxy-vitamin D concentrations: 29 ng/ml). After three injections of denosumab (March 2017), the patient's lumbar spinre BMD increased to 0.882 mg/cm^2 (T-score: –2.8, Z-score: –2.2). However, he was complaining of continuous musculoskeletal pain since denosumab injections and he omitted the fourth one. The patient attended the outpatient clinic in September 2017 complaining of a new severe back pain after mild physical activity. Spine magnetic resonance imaging (MRI) revealed a new vertebral fracture in L4 and concomitant biconcave deformation of T11 and T12. After excluding other causes of low bone mass, denosumab was re-initiated.
Conclusions
This is the first case of a male patient having sustained a new vertebral fracture, nine months after his last denosumab dose. The possibility of a rebound fracture, although low, should always be taken under consideration after denosumab discontinuation, especially in patients at high fracture risk, not previously being treated with bisphosphonates.

Microindentation in the study of bone properties for type 1 diabetes mellitus patients

Sílvia Ballesta, Juan José Chillarón, Robert Güerri, Alfonso Díez, Sabina Herrera, Nicolás Ascoeta, Anna Güell & Juana Antonia Flores-Le Roux
Hospital del Mar, Barcelona, Spain.

Background and aims
Patients with T1D present some predisposing factors to fractures. The aim of the present study is to analyse the bone tissue quality in T1DM women and healthy controls by bone microindentation, as well as their relationship with bone mineral density (BMD).
Materials and methods
Cross-sectional study including 45 women with T1D at least with one year of duration and 21 healthy controls adjusted by age and BMI. Women with osteoporosis or previous pathologic fractures, presence of diseases that predispose to the development of osteoporosis, and patients who did not consent to participate in the study were excluded. Anthropometric variables were collected using standardized methods. T1DM-related variables were collected. NCEP-ATP III modified criteria was used to define metabolic syndrome (MetS). A blood analysis was performed in all subjects, including fasting glucose, lipid profile, calcidiol, calcium and iPTH. In T1DM patients, glycated hemoglobin and albumin/creatinine ratio was also determined. BMD was measured in lumbar column, femoral neck and total femur in all subjects by dual energy x-ray absorptiometry. BMS was obtained by microindentation technique.
Results
No differences between T1D patients and healthy controls were observed in BMS, BMD nor in calcium, iPTH or calcidiol (Table 1). Among T1D patients, mean HbA1c was 7.52% + 1.0 and mean time since diagnosis was 22.6 + 12.2 years. 8 patients (17.7%) met the MetS criteria, and in 12 patients (26.7%) microvascular complications were present. A trend towards a lower BMS was observed in parallel to an increase of the number of Metabolic Syndrome criteria (79.2 + 8.5 vs 75.1 + 7.9, P 0.273, 1 vs3 or more MetS criteria, respectively) and in patients with microangiopathy (78.3 + 10.8 vs 80.5 + 7.6, P 0.447, in patients with and without microangiopathy, respectively).
Conclusion
T1DM women show bone tissue properties comparable to controls. Microangiopahy and MetS seems to affect negatively to BMS.

Table 1

Characteristic	Control	T1D	P
n	21	45	
Age (y)	38.4 + 9.9	39.3 + 10.3	0.729
BMI (Kg/m^2)	24.7 + 4.5	25.3 + 4.9	0.617
T-score, lumbar	−0.10 + 1.2	−0.50 + 1.1	0.296
T-score femoral neck	−0.5 + 0.9	−0.67 + 1.0	0.624
BMS	80.3 + 7.1	79.9 + 8.5	0.825
Calcium (mg/dL)	9.54 + 0.3	9.61 + 0.4	0.653
iPTH (pg/mL)	36.2 + 14.6	44.3 + 28.1	0.542

Relationships between hormonal parameters, body fat distribution and bone mineral density in women with menstrual disorders

Małgorzata Syrenicz[1], Elżbieta Sowińska-Przepiera[2], Elżbieta Andrysiak-Mamos[2], Bartosz Kiedrowicz[2], Anna Sieradzka[2] & Anhelli Syrenicz[2]
[1]Department of Propedeutics of Children's Diseases, Pomeranian Medical University, Szczecin, Poland; [2]Department of Endocrinology, Metabolic Diseases and Internal Diseases, Pomeranian Medical University, Szczecin, Poland.

Available evidence suggests that unfavorable changes in the distribution of body fat resulting from hormonal imbalance associated with ovarian insufficiency may exert detrimental effects on bone mineral density (BMD). The aim of this study was to verify if densitometrically determined volumes of visceral (VAT), female (FAT) and android (AAT) adipose tissue influence BMD in women with menstrual disorders, and if these relationships are modulated by endocrine factors. The study included 293 Caucasian women (mean age 26.7 ± 4.4 years) with at least 6-month history of secondary amenorrhea. Volume of fat in all analyzed regions correlated positively with BMD in lumbar spine (VAT: $R = 0.277$, FAT: $R = 0.345$, AAT: $R = 0.336$) and entire skeleton (VAT: $R = 0.453$, FAT: $R = 0.527$, AAT: $R = 0.529$). Moreover, BMD in the lumbar spine and entire skeleton correlated positively with body mass index ($R = 0.380$ and $R = 0.599$, respectively) and free androgen index values ($R = 0.150$ and $R = 0.279$), and showed inverse correlations with sex hormone-binding globulin ($R = -0.191$ and $R = -0.326$). None of the above mentioned parameters turned out to be an independent predictor of BMD. These findings imply that distribution of adipose tissue is only one of many determinants of BMD in women with ovarian insufficiency and therefore, should not be considered as a single risk marker for bone mass deficiency. Due to their specific metabolic and hormonal profile, physiological functional differences between subcutaneous and visceral adipose tissue in women with menstrual disorders seem to be blurred. As a result, determination of body fat distribution in patients with ovarian insufficiency is probably of lesser clinical importance.

Long term follow up of patients with hypophosphatemic rickets in a Public Institution in Brazil

Júlia Vieira Oberger Marques, Caio Cervi Lagana, Neudir Frare Junior, Patrícia Oliboni Do Amaral, Débora Besen, Marcela Robl, Victoria Zegbi Cochenski Borba & Carolina Aguiar Moreira
Endocrinology and Metabolism Service of Paraná (SEMPR), Curitiba, Brazil.

Introduction
Hypophosphatemic rickets comprehends a group of hereditary diseases characterized by hypophosphatemia and defective bone mineralization. The most common form is X-linked, with a prevalence of 1:20.000.
Objectives
Describe the follow up of patients with hypophosphatemic rickets in a public center in Brazil.
Methods
Patients with hypophosphatemic rickets were selected from a database of Endocrinology and Metabolism Service of Paraná (SEMPR). Medical records were revised to collect clinical and laboratory evaluation.
Results
Twenty-two patients were included, being 15 women. The median follow up was 11 years (1 month – 27 years), with a median age at diagnosis of 105 months (13 – 384 months). All patients presented with bone deformity, 11 (50%) patients with genus varus, 10 (45%) patients with genus valgus and 1 (4%) patient with both. Other bone deformities present were: 6 (27%) lordosis, 6 (27%) scoliosis, 5 (22%) bone deformity with frontal bossing and 12 (54%) epiphyseal enlargement. Median initial laboratory results were as follows: calcium 9.1 mg/dL (8.3–9.9 mg/dL), phosphorus 2.18 mg/dL (1.3–3.0 mg/dL), alkaline phosphatase 848 U/L (19.26–2109 U/L), parathormone 122 pg/mL (6–523 pg/ml), total reabsorption of phosphorus of 43%. Initial X-rays showed 12 (54%) patients with typical rickets findings, 3 (13%) patients with reduced bone mineral density and 2 (9%) patients with fractures. Fanconi syndrome was diagnosed in 5 (22%) patients. Treatment consisted of phosphorus supplementation in 14 (63%) patients with a median dose of 1.7 gr/day, calcitriol in 13 (59%) with a median dose of 0.32 mcg/day and combined treatment in 9 (40%). During follow up showed fractures in 8 (36%) patients, most frequently in femur (7) 41% and tibia (4) 23%. Eight patients were evaluated DEXA and all of them showed increased BMD in all sites. Nine patients were evaluated with hand x-ray for bone age and all showed with delay, with a median of 19 months (12-84 months). Alkaline phosphatase after treatment went down to a median of 236 U/L (decrease of 72%) and creatinine went up by a median of 37%. Calcium, phosphorus and parathormone didn't show significant alterations. Kidneys were assessed by ultrasonography in 17 (77%) patients, and showed nephrocalcinosis and nephrolithiasis in 3 (17%) and renal parenchymal disease in 4 (23%). Secondary hyperparathyroidism was observed in 1 (4%) patient.
Conclusion
Phosphorus and calcitriol induced bone mineralization leading to symptom improvement and increased bone mineral density. Then, overtreatment could possibly lead to renal complications, as shown in 40% of patients.

Genetic polymorphisms may modulate bone and energy metabolism of mountain cycling ultramarathon athlete's

Isanete Alonso[1,2,3], Andreia Matos[1,4,5,6], Ricardo Ribeiro[1,5,6], Ângela Gil[1,4,7], Carlos Cardoso[8] & Manuel Bicho[1,4]
[1]Laboratory of Genetics and Environmental Health Institute, Faculty of Medicine, University of Lisbon, Lisbon, Portugal; [2]Department of Nutritional Science, Atlântica University, Barcarena, Portugal; [3]CESOB – Center for Studies in Social Sciences, Business, Health and Welfare, Atlântica University, Barcarena, Portugal; [4]Institute of Scientific Research Bento of Rocha Cabral, Lisbon, Portugal; [5]i3S, Institute for Research and Innovation in Health, University of Porto, Porto, Portugal; [6]INEB, Institute of Biomedical Engineering, University of Porto, Porto, Portugal; [7]Department of Clinical Pathology, The Coimbra Hospital and Universitary Centre, Coimbra, Portugal; [8]Clinical Chemistry Laboratory, Joaquim Chaves Group, Lisbon, Portugal.

Introduction
The interaction between bone and energy metabolism may be enhanced in high demanding physical activities. We hypothesize that genetic background may modulate the exercise-associated bone and energy responses of athletes participating of a mountain cycling ultramarathon.
Methods
Fifty-five non-professional athletes (mean age 44.8 ± 7.1 years) participating in a 9-day mountain cycling ultramarathon (TransPortugal) were evaluated. Before and immediately after the race were determined the following parameters: insulin, glucose, uric acid and creatinine by standard methods; IL-6-plasma and carboxyglutamic acid residues of osteocalcin (Gla-OC)-plasma by ELISAs. The genetic polymorphisms of leptin-*LEP-rs1137101,* βeta-2 adrenergic receptor-*ADRβ2-rs1042713,* Osteocalcin-*BGLAP-2274911* were determined by PCR-RFLP. Δ% represents values adjusted for plasma volume. Body composition was evaluated by BIA-Quantum-X. Participants were also categorized according to the number of courses completed (<9 or 9 courses).
Results
The genotype's frequencies of polymorphisms analyzed were: *LEP* (homozygous G 0.29, heterozygous 0.51, homozygous A 0.20), *ADRB2* (homozygous Gli 0.51, heterozygous 0.25, homozygous Arg 0.07) and *BGLAP* (homozygous T 0.60, heterozygous 0.31, homozygote C 0.09). The athletes with *LEP* polymorphism AA + AG genotypes (*versus* GG) had a favorable predisposition to: complete 9 courses, adjusting for age, gender, average speed, % fat mass and waist circumference (OR = 5.0 [1.1–22.5], $P = 0.036$) and to finish the race faster, adjusting for age, fat mass percentage in the pre-test, pre-run waist circumference and all stages (OR = 8.0 [1.1–61.1], $P = 0.044$). For this model, the *LEP*-A carriers presented higher Δ% uric acid ($P = 0.041$) and Δ% Gla-OC ($P = 0.037$). In 9-courses completers, *LEP*-A carriers presented a gain increase in Δ% IL-6 ($P = 0.012$). For the *ADRB2* polymorphism, athletes with AG + GG genotypes

(*versus* AA) presented lower levels of post-race: insulin, HOMA-IR and HOMA-B ($P<0.05$). For *BGLAP* polymorphism, athletes with CC+CT genotypes (*versus* TT) had higher post-race levels and Δ% of HOMA-IR and HOMA-B ($P<0.05$). Covariance analysis showed a significant effect of *LEP*-A carriers on Δ% glucose ($F=4.712$, $P=0.036$), controlling for Δ% Gla-OC, Δ% IL-6, age, average speed and completers. Other covariance analysis showed significant effect of basal skeletal muscle mass on the Δ% Gla-OC ($F=4.650$, $P=0.037$), controlling for Δ% uric acid, creatinine, glucose, age, average speed and completers.

Conclusion

The *LEP*, *ADRβ2* and *BGLAP* polymorphisms, related to bone and energy metabolism, may modulate the performance of athletes. This work supports a hypothesis of the influence of a co-modulatory action between genetic factors and mediators released during long-term exercises.

May polymorphisms of DHFR, CBS and MTHFR genes modulate metabolic and bone remodeling parameters associated with reduced bone mineral density?

Joana Freitas[1,2], Carla Carvalho[1,2], Carolina Ribeiro[1,2], David Sarmento[2,3], Ana Paula Barbosa[2,4,5], Mário Rui Mascarenhas[2,4,5] & Manuel Bicho[1,2]
[1]Institute for Scientific Research Bento Rocha Cabral, Lisbon, Portugal; [2]Environmental Health Institute, ISAMB_FMUL, Lisbon, Portugal; [3]Institute for Scientific Research Bento Rocha Cabral, Lisboa, Portugal; [4]Clinic of endocrinology, diabetes and metabolism, Lda., Lisbon, Portugal; [5]Department of endocrinology, diabetes and metabolism, HSMaria-CHLN, Lisbon, Portugal.

Objectives

To study the association of functional polymorphisms at DHFR, CBS and MTHFR genes with bone mineral density (BMD) and metabolic parameters of bone remodeling.

Materials and methods

BMD (g/cm2) was measured by DEXA in 391 subjects: 174 with normal BMD (137F 37M; age=48.79±12.99 years; BMI=29.61±5.22 kg/m2), 62 with osteopenia (48F 14M; age=56.06±12.96 years; BMI=27.64±4.94 kg/m2) and 154 with osteoporosis (119F, 35M; age=64.17±11.04 years; BMI=27.48±4.56 kg/m2). Metabolic bone remodeling parameters were analyzed: LDL, HDL, total cholesterol, triglycerides, HOMA, parathormone (PTH), alkaline phosphatase (AP), bone fraction of alkaline phosphatase (AP_BF) and osteocalcin. Genetic polymorphisms were evaluated by PCR and PCR-RFLP. Statistical analysis by SPSS 23.0. Statistical significance for $P<0.05$.

Results

The three studied groups differ in age and BMI being those with osteoporosis the oldest and with the lower BMI. Individuals with reduced BMD (osteopenia and osteoporosis) showed higher PTH and osteocalcin. Those with osteoporosis also showed higher AP. Individuals with allele C of MTHFR_C677T polymorphism (CC or CT) showed a 2.194 risk for the development of reduced BMD ($P=0.024$; OR=2.194; CI95% [1.109–4.342]) when adjusted for age and BMI. For the studied polymorphisms at DHFR and CBS genes we did not find association with the susceptibility for osteopenia or osteoporosis. When we compared metabolic bone remodeling parameters within genotypes of the studied polymorphisms, we found: For DHFR we did not find statistical differences when we included the all studied population. Although, we found lower AP, AP_BF and total cholesterol for DHFR_ins/ins genotype in normal BMD individuals. For CBS we did not find statistical differences when we included the all studied population. Although, we found lower AP and AP_BF for CBS_-/- genotype in osteoporotic individuals. For MTHFR we found higher AP and AP_BF and lower HDL for CC individuals, and higher osteocalcin for Individuals with allele C (CC or CT) when we included the all studied population. When we separated individuals according to their BMD, we found lower HDL and total cholesterol and higher osteocalcin for osteoporotic individuals carrying allele C (CC or CT).

Conclusion

MTHFR_C677T polymorphism seems to confer susceptibility for reduced bone mass, either directly or by modulating metabolic bone remodeling parameters. On the other hand, genetic polymorphisms of DHFR and CBS seem to play and important role in modulating metabolic bone remodeling parameters associated with reduced bone mineral density.

Vitamin D levels in two ethnic groups of patients with diabetes

Georgios Papadakis[1], Thomas Zambelis[2], Kostas Konstantopoulos[3] & Stylianos Chatzipanagiotou[4]
[1]STEPS Stoffwechselzentrum, Biel/Bienne, Switzerland; [2]Neurology Department Aeginition Hospital, Medical School, University of Athens, Athens, Greece; [3]Department of Haematology, Laikon University Hospital, Medical School, University of Athens, Athens, Greece; [4]Medical Biopathology Department, Aeginition Hospital, Medical School, University of Athens, Athens, Greece.

Introduction

- Vitamin D deficiency is thought to impair insulin action and glucose metabolism.
- Migrants who live in Western countries seem to have lower 25(OH)VitD levels, not only from their white counterparts but also from their native populations in their country of origin.

Objectives

- We investigated a cohort of predominantly white Greek Caucasian and Bangladeshi immigrant patients with diabetes mellitus in order assess the differences in 25(OH)VitD.

Methods

- A total of 165 patients from Bangladesh and 118 patients from Greece with diabetes were assessed for diabetes and 25(OH)VitD status.
- All measurements of 25(OH)VitD were categorized into two halves of the year: the first period from mid-October until mid-April: winter period; and second period from mid-April until mid-October: summer period.
- The prevalence of vitamin deficiency (<20 ng/ml), insufficiency (20-<30 ng/ml) and sufficiency (≥30 ng/ml) was estimated.

Results

- A total of 76 Bangladeshi patients (65 men and 11 women) and 43 (36 men and 7 women) Greek patients were recruited over the winter period and 83 (80 men and 3 women) Bangleshi patients and 71 (61 men and 10 women) Greek patients over the summer period.
- Patients from Bangladesh were younger than Greek patients (43.96±8.1 vs. 48.78±9.3 years old).
- Patients from Bangladesh had slightly worse glycemic control as compared with Greek patients (HbA1c=7.76±1.5% vs. 7.57±1.7%, $P=0.3$).
- The 25(OH)VitD levels of Bangladeshi patients were significant lower compared to Greek patients (12.42±5.86 vs. 23.06±12.36, $P<0.001$).
- The same pattern also occurred regarding the seasonal periods. In Bangladeshi patients, the mean level of 25(OH)VitD in winter and summer periods was 11.28±5.53 and 13.68±6.04 ng/ml, respectively. In Greek patients the mean level of 25(OH)VitD in winter and summer periods was 21.97±13.18 and 24.19±12.32 ng/ml, respectively.
- The prevalence of 25(OH)VitD deficiency, insufficiency and sufficiency differ significantly in two groups of patients and in Bangladeshi patients was 90.0%, 8.6% and 1.2%, respectively, while in Greek patients, the rates were 43.2, 32.2 and 24.57%, respectively.

Conclusions

- The prevalence of vitamin D deficiency is very high amongst patients with diabetes but immigrants are at greater risk. Vitamin D supplementation could be valuable mostly during the winter period for patients with diabetes.

Effects of steroid hormone on Calbindin-D_{9k} expression in rat cerebellum

Seon Young Park, Bonn Lee, Duc Viet Ly, Thi Bich Thuy Vo, Yeong-Min Yoo, Eui-Man Jung & Eui-Bae Jeung
Chungbuk National University, Cheongju, Republic of Korea.

Introduction
Calbindin-D_{9k} is a 9 kDa polypeptide expressed in the mammalian intestine, uterus, and pituitary gland. Calbindin-D_{9k} increase Ca^{2+} absorption by buffering intracellular Ca^{2+}. The intracellular concentration of calcium is regulated by calcium related proteins such as calbindin-D_{9k}, TRPV1 and PMCA1. The regulatory effect of steroid hormones and glucocorticoids on calbindin-D_{9k}, TRPV1 and PMCA1 expressions in the cerebellum are currently unknown. In this study, we investigate the expressions of calbindin-D_{9k}, TRPV1 and PMCA1 by sex steroid hormones and glucocorticoids in rat cerebellum.
Methods
To investigate the effect of sex steroid hormones and glucocorticoids to the cerebellum calbindin-D_{9k}, TRPV1 and PMCA1 expressions, 14 days old rat were administered 40 ug/kg of E2, 20 mg/kg of P4, 10 mg/kg of ICI 182,780 and 13 weeks old rat were administered 10 mg/kg of Dexamethasone (Dex), 50 mg/kg of RU486.
Results
Transcriptional level and localization of Calbindin-D_{9k}, TRPV1, PMCA1 were examined in the cerebellum. mRNA and protein level of Calbindin-D_{9k} was increased by Dex, but not by E2 nor P4. Immunofluorescence shows that calbindin-D_{9k} were mainly localized in the purkinje cell. Like the expression of calbindin-D_{9k}, mRNA levels of TRPV1 and PMCA1 only increased in response to Dex treatment.
Conclusion
These results are correlated with calbindin-D_{9k}, TRPV1 and PMCA1 expressions were regulated by glucocorticoids in cerebellum. Especially, the localization and regulation of calbindin-D9k in purkinje cell could indicate that glucocorticoids can bring functional changes in the purkinje cell.

Effects of glucocorticoid on mucin secretion by calcium-related proteins in mouse lung

Jin Yong An, Duc Viet Ly, Bo Hui Jeon, Thi Hoai Thu Nguyen & Eui-Bae Jeung
Chungbuk National University, Cheongju, Republic of Korea.

Calcium is important for physiological functioning in many tissues and is essential in mucus secretion and muscle contraction. Intracellular concentrations of calcium are regulated by calcium-related proteins such as TRPV4, TRPV6, CaBP-9k, NCX1, and PMCA1. In this study, the relationship between secretion of pulmonary mucus and calcium regulation was investigated. To confirm the effect of steroid hormones, immature mice were injected with estrogen (E2) or progesterone (P4) and mature mice were injected with dexamethasone (DEX). Subsequently, the location and expression of TRPV4, TRPV6, CaBP-9k, NCX1, and PMCA1 in lung tissue were examined. PAS staining was performed to investigate functional aspects of the protein expressions. There were no significant differences in calcium-related gene expressions in E2- and P4-treated mice, but TRPV4, NCX1, and PMCA1 were increased in DEX-treated mice and were recovered by RU486 treatment. This regulation is via the glucocorticoid receptor and is involved in the mucus secretion in the lung. TRPV4, TRPV6, CaBP-9k, NCX1, and PMCA1 were specifically expressed in Clara and alveolar type 2 cells of mouse lung. CC10, a marker of Clara cell, was decreased by DEX. In addition, mucin secretion, which is a functional aspect of this cell, was also decreased by DEX treatment. Control of calcium-related gene expression may affect the control of mucus secretion in the lung. Such a control mechanism can form the basis of studies into diseases such as inflammation due to mucus secretion abnormalities, coughing, and respiratory disorders and distress.

Effect of endocrine disrupting chemicals on the calcium channel and implantation during implantation period

Dinh Nam Tran, Seon Young Park, Jae-Hwan Lee, Bonn Lee, Thi Bich Thuy Vo & Eui-Bae Jeung
Chungbuk National University, Cheongju, Republic of Korea.

Miscarriage is a very common occurrence in humans, in which blastocyst implantation failure in naturally-occurring and assisted human reproduction occurs in up to 2/3 of all cases. Calcium (Ca^{2+}) has been showed to involve in many cellular signal transduction pathways as well as regulation of cell adhesion, which is necessary for the physiology process of endometrial epithelial cell transformation and stromal cell decidualization during embryo implantation. Previous studies have been reported that EDC can regulate the expression of genes associated with calcium transport in during pregnancy period such as TRPV6, PMCA, TRPV5, NCX1 and CaBP-D9k. Additionally, exposure to EDs during early gestation results in disrupt intrauterine implantation, uterine receptive, leading to implantation failure. In this study, BPA, OP, E2 and/or ICI 172,80 (antagonist) were inject by subcutaneous from 1 to 3 day post coitus. The number of implantation sites were significant decreased in OP group and no implantation site was observed in EDC + ICI groups. There was different in the expression of Ca channel between maternal uterine and implantation. The level of TRPV6, TRPV5 mRNA in uterus were significantly increased by EDC and/or ICI treatment. In contrary, their expressions are significantly decreased by OP- and BPA- treated in implantation site. The expression of NCX1 and PMCA1 mRNA level were significantly decreased in OP and BPA groups than that in the VE group. The expression of Muc-1 mRNA, a major epithelial apical surface glycoprotein expressed significantly decreased by OP-treated in implantation site. The mRNA level of E-cadherin, a group of cell surface glycoproteins responsible for maintaining adhesion between epithelial cells using a calcium-dependent mechanism was also significantly decreased in implantation site by BPA and OP treatment. Taken together, BPA and OP regulate the expression of calcium channel during early pregnancy period, throughout induce the loss numbers of implantation via reduce the uterine conceptive and implantation adhesion and invasion.

Clinical, paraclinical, etiological and therapeutic particularities of severe hypercalcemia: A comparative study

Ibtissem Oueslati[1], Amal Rached[2], Madiha Mahfoudhi[2], Hayet Kaaroud[2], Karima Khiari[2], Sami Turki[2], Néjib Ben Abdallah[2] & Taieb Ben Abdallah[2]
[1]Department of Endocrinology, La Rabta Hospital, Tunis, Tunisia;
[2]Department of Internal Medicine A, Charles Nicolle Hospital, Tunis, Tunisia.

Background
Severe hypercalcemia, defined as a serum calcium concentration $\geq$ 3.5 mmol/l or $>$ 3 mmol/l associated with symptoms and signs of acute calcium intoxication, is a rare but a potentially life threatening condition. The aim of this study was to assess clinical, paraclinical, etiological and therapeutic features of severe hypercalcemia and to determine its outcome.
Methods
It was a retrospective, descriptive and comparative study conducted in the department of internal medicine, Charles Nicolle hospital of Tunis, and including 32 patients with severe hypercalcemia (group 1) and 39 patients with non-severe hypercalcemia (group 2). Clinical, paraclinical, etiological and therapeutic characteristics were determined.
Results
Although demographic characteristics including age and gender were similar in both groups, an age $\leq$45 years was significantly associated with severe hypercalcemia (Hazard Ratio (HR) =4.69, P=0.02). This condition was identified with symptoms of hypercalcemia or a complication in 75% of cases (HR=5.35, P=0.001). Weakness (HR=5.04, P=0.01), anorexia (HR=2.7, P=0.04), nausea, vomiting and epigastric pain (HR=5.14, P=0.01), dehydration (HR=31.29, $P<0.001$) and renal failure (HR=4.26, P=0.01) were significantly associated with severe hypercalcemia. Its main etiologies were malignancy (43%), primary hyperparathyroidism (30%), medications (20%) and sarcoidosis (7%). The management of severe hypercalcemia involved both intensive medical and etiologic treatment. Saline rehydration, furosemide, calcitonin, bisphosphonate and hemodialysis were prescribed in 81%, 34%, 81%, 25%, 25%, 9% and 3% of cases, respectively. An immediate significant decrease of serum calcium level ($P<0.001$) was obtained in all patients with a normalization in 17% of cases. The mortality rate was 12% in group 1 and 13% in

group 2. The severity of hypercalcemia was not a predictive factor of mortality in our study.
Conclusion
Severe hypercalcemia is a therapeutic emergency including various symptoms. This condition can occur in multiple etiologies. Therefore plasma calcium should be measured at the slightest suspicion in order to perform an immediate and optimal management.

Genetic characteristics of sensitivity of vitamin D and prevalence of vitamin deficiency among patients of polyclinics

Alena Poluektova[1], Yuri Poteshkin[2] & Polina Polevyanova[1]
[1]Russian National Research Medical University named after N.I. Pirogov, Moscow, Russian Federation; [2]Atlas Clinic, Moscow, Russian Federation.

Introduction
Vitamin D deficiency is a global problem worldwide.
Purpose of the study
To investigate the incidence of vitamin D deficiency and genetic sensitivity to it among patients in the polyclinic.
Materials and methods
A retrospective study was conducted, 6034 medical charts were analyzed, of those who were tested for vitamin D, the study included 567 patients (374 women, 193 men, women average age 40.7 ± 14.1 years, men – 41.3 ± 12.7 years). The following were analyzed: total calcium, creatinine, LDL, parathyroid hormone, urine protein. A genetic test was performed on the sensitivity of the receptors to vitamin D by sequencing HiSeq2000 on DNA chips (Illumina). An interpretation was made of the genetic characteristics of sensitivity to vitamin D: a predisposition to a decrease in receptor sensitivity; with a predisposition to high receptor sensitivity. The statistical analysis of the data was carried out with the help of the package of applied programs Statistica 10.0.1011.0. The critical level of reliability of the null hypothesis was assumed to be 0.05.
Results
Deficiency of vitamin D (25%, mean – 16.2 ± 3.4 ng/ml), moderate vitamin D deficiency (37%, mean – 24.9 ± 2.5 ng/ml), normal vitamin D concentration (38%, mean – 39.7 ± 9.6 ng/ml). A weak negative correlation was found between vitamin D and LDL ($P < 0.05$, $r = -0.16$). In the pairwise comparison (t-tests), significant differences in the seasons of the year were revealed for vitamin D levels: in winter groups (mean – 24.9 ± 9.97 ng/ml) and summer (mean – 31.2 ± 13.42 ng/ml), as well as in the autumn groups (mean – 29.8 ± 10.18 ng/ml) and spring (mean – 26.9 ± 10.9 ng/ml) ($P = 0.00003$ and $P = 0.01$ respectively). In the case of a pair comparison (t-tests), significant differences were detected by the level of total calcium and significantly differ in groups with stage 1 CKD (mean – 2.33 ± 0.1 mmol/l) from stage 2 CKD (mean – 2.38 ± 0.09 mmol/l) and from stage 3 CKD (mean – 2.53 ± 0.13 mmol/l) ($P = 0.017$ and $P = 0.0009$ respectively). In a pair comparison (t-test), significant differences in the level of vitamin D in groups with a predisposition to a decrease in receptor sensitivity (mean – 34.6 ± 10.54 ng/ml) and a predisposition to high sensitivity of receptors (mean – 28.3 ± 11.42 ng/ml) ($P = 0.015$).
Conclusions
The concentration of vitamin D by the genetic test is related to the sensitivity of the receptors.

A Curious phenomenon of Post radioiodine therapy induced hypocalcemia in Graves' disease: Case series

Ramakanth Bhargav Panchangam[1], B Ramesh[2], B Rajesh[2], N Vimaladevi [1], B Rajkiran Reddy[3], M Venkateshwara Reddy[2], D Vignesh[2] & B Chakrapani[4]
[1]Endocare Hospital, Vijayawada, India; [2]VMC, Kurnool, India; [3]SMART Sunshine Hospital, Hyderabad, India; [4]Neuro Hospital, Nizamabad, India.

Introduction
Graves' disease (GD) is often treated with radioiodine therapy for cure. While, post external irradiation and post-radioiodine therapy (RAI) induced hyperparathyroidism after many years of latency is a well known phenomenon, there are only anectodal reports of post-radioiodine hypocalcemia. The factors contributing to this are poorly understood. In this context, we evaluated our own series to look deeper in to this issue.
Material and methods
This retrospective study was conducted on 65 surgically managed GD patients. Diagnosis of GD was based on clinical picture, thyroid function tests, radionuclide scanning and histopathology. Exclusion criteria were subjects with vitamin D deficiency (20 ng/dl), chronic renal, hepatic or inflammatory disease or drugs interfering with calcium metabolism. All subjects were normocalcemic preoperatively (8.5–10 mg/dl). Hypocalcemia was treated with calcium supplements and vitamin D. Parameters such as severity of Graves' disease, Statistical analysis was performed by SPSS 20.0 version. Descriptive statistics, t test and Chi-square tests were performed.
Results
6/65 patients (9.3%) developed hypocalcemia. Average follow-up duration of subjects was 18.4 ± 4.5 months (14–24). Average onset of clinical and/or biochemical hypocalcemia was at 4.2 ± 1.5 months (2–7). Serum calcium level during first detection of hypocalcemia was 6.9 ± 1.5 mg/dl (5.6–8.2). Corresponding serum parathyroid hormone level was 35 ± 14 pg/ml (25–65). Hypocalcemia resolved after treatment for 2 months on an average. No further hypocalcemic episodes during follow-up period. Range of RAI dosage was 7–12 mCi. None of factors such as severity of hyperthyroidism, duration of hyperthyroidism, goiter size, age of patient, serum parathyroid hormone level and sex had statistically significant influence on occurrence of hypocalcemia on correlation and multivariate analysis.
Conclusions
Our study shows that post RAI hypocalcemia is a frequent morbidity. Further it is independent of any physiological or disease related factors. The exact cause of this curious phenomenon appears to be enigmatic, but we hypothesize that collateral damage caused by radiation causes temporary parathyroid stunning. More studies are needed to unravel this mystery, but active watch at followup post RAI therapy is recommended in routine management of GD.

Primary hyperparathyroidism in the elderly

Hadar Duskin-Bitan[1,2], Nina Nemirovsky[3], Ilana Slutzky-Shraga[1,2], Eyal Robenshtok[1,2], Talia Diker-Cohen[1,2,4], Ilan Shimon[1,2], Dania Hirsch[1,2] & Gloria Tsvetov[1,2]
[1]Institute of Endocrinology, Diabetes and Metabolism, Rabin Medical Center, Petah-Tikva, Israel; [2]Sackler Faculty of Medicine, Tel Aviv University, Tel-Aviv, Israel; [3]Medicine F, Rabin Medical Center, Petah-Tikva, Israel; [4]Medicine A, Rabin Medical Center, Petah-Tikva, Israel.

Introduction
Primary hyperparathyroidism (PHPT) is the third most common endocrinopathy. Data on PHPT in the elderly are scarce.
Objective
To characterize elderly patients with PHTP, clinically and biochemically.
Patients
A total of 216 patients (73.6% females) aged ≥ 75 years were diagnosed and followed at a single tertiary medical center for PHPT.
Results
Mean follow-up was 11.3 ± 5.5 years. Age at diagnosis was 70.9 ± 7.2 years, and at last follow-up, 82.3 ± 5.2 years. Maximal serum calcium and maximal PTH were 11.6 ± 0.7 mg/dl and 3 ± 2.7 X upper limit of normal (UNL), respectively. Mean urinary calcium and vitamin D levels were 208 ± 130 mg/24 hours and 51.9 ± 19.1 nmol/l, respectively. Serum creatinine was 0.9 ± 0.5. Osteoporosis was diagnosed in 135 patients (62.5%; 92 with fractures, 75 after PHPT diagnosis), and nephrolithiasis, in 50; only 49 patients (22.7%) had neither. Thirty-six patients underwent parathyroidectomy: they were younger than the non-operated patients at diagnosis (67.4 ± 9.5 vs 71.6 ± 6.3 years) and had higher serum and urinary calcium levels. Patients ≥ 70 years at diagnosis ($n = 128$), compared to younger patients, had significantly lower levels of calcium (10.2 ± 0.7 vs 10.4 ± 0.8 mg/dl, $P = 0.05$) and PTH (1.7 vs 2.1 X UNL, $P = 0.05$) at last follow-up. The younger patients had more nephrolithiasis (29.9% vs 18.8%). In the whole cohort, serum and urinary calcium significantly ($P = 0.001$) decreased and vitamin D level significantly increased at last visit (10.3 ± 0.47, 172.5 ± 116, 68.6 ± 23, respectively) compared with levels at diagnosis (10.6 ± 0.7, 237 ± 148, 51.5 ± 19, respectively). Thirty-nine patients died during follow-up: they were significantly ($P = 0.001$) older than the remaining patients at diagnosis (75.2 ± 6.1 vs 70.2 ± 6.1 years) and last follow up (85.3 ± 5.9 vs 81.6 ± 4.8 years), with no differences in laboratory variables.

Conclusions
Most elderly patients with PHPT had at least one indication for parathyroidectomy, but only 17% were operated. Serum and urinary calcium levels decreased during follow-up.

Edentulous jaw and Primary HyperParathyroidism

Sabaretnam Mayilvaganan[1], Sapana Bothra[1], Aromal Chekavar[1], Amit agarwal[1] & PrK Bhargav[2]
[1]Sanjay Gandhi Postgraduate Institute of Medical Sciences, Lucknow, India; [2]Endocare Hospital, Vijayawada, India.

Introduction
Primary Hyperparathyroidism usually presents as bone disease, renal or with Gastro Intestinal Symptoms. Dental Symptoms as primary or presenting manifestations are rare. We report two patients who presented with edentulous jaw in young age, which resulted in investigations leading to the diagnosis for primary hyperparathyroidism.
Material and methods
We report two patients operated in a tertiary referral Centre from Jan 2017–Dec 2017 for PHPT with Edentulous jaw. We describe the clinical case and surgical findings of these two patients.
Results
First patient was a 30 year old lady had loosening and falling all teeth suddenly within 2 months, investigated had hypercalcemia of 13 mg/dl and had concordant Left Inferior parathyroid adenoma on USG and MIBI Scan. She underwent uneventful focused parathyroid with IOPTH monitoring and on follow up norm calcemic. Second patient was a 45 year old lady who had loosing and falling of most of the teeth with bone pains, investigated and found to have hypercalcemic crisis of 17 mg/dl. She had an aorta pulmonary window parathyroid Adenoma on functional and anatomic imaging. She was treated with hydration, Calcitonin and bisphosphonates and operated in the same admission and underwent sternotomy and focused parathyroidectomy with IOPTH monitoring and on follow up normocalcemic.
Discussion
Dental manifestations are rare but can be the first symptom of PHPT. Severe osteoporosis can manifest as falling of teeth when resorption of jaw occurs due to osteoporosis and tooth become loose and fall off.

P211

Coeliac Disease complicating Autoimmune Hypoparathyroidism with Recalcitrant Hypocalcaemia

Christopher Philbey, Najeeb Shah, Kamrudeen Mohammed & Hiba Ibrahim Hull Royal Infirmary, Hull, UK.

We present the case of a 57 year old male that presented to a tertiary centre with a week's history of lethargy, muscle cramps and peri-oral paraesthesia. He was otherwise fit and well. His examination revealed no evidence of Chvostek's, Trousseau's or tetany. His reflexes were not assessed. Initial electrolyte screening confirmed a hypocalcaemia with a serum adjusted calcium of 1.47 mmol/l (2.2–2.6), his phosphate was elevated at 1.64 mmol/l (0.8–1.5) and a serum magnesium was below target range at 0.67 mmol/l (0.7–1.0). Serum PTH was 0.2 pmol/l (1.3–9.3). Vitamin D level was normal. Haematinics revealed a folate deficiency. USS of the neck identified no masses. Despite adequate parenteral replacement of Calcium, Magnesium, oral alpha calcidol and high doses of Vitamin D, his calcium levels remained low. As a work up for malabsorption, an IgA antibody screen returned positive and he was commenced on a gluten-free diet and treated for concurrent coeliac disease. Idiopathic hypoparathyroidism (IH) occurs with atrophic, infiltrative or autoimmune mediated destruction of the parathyroids. Injury must be severe as there is adequate reserve in a single parathyroid gland for normal function. It is distinct to the more common acquired hypoparathyroidism that occurs mostly after surgery and at a permanent incidence between 0.4 to 33% depending on the centre. The autoimmune hypoparathyroid patient load has been estimated via population studies at 3 per 100,000. The condition is recognised to be strongly associated with both adrenal antibodies (26%) and thyroid antibodies (12%), such that combinations of these contribute to the Autoimmune polyglandular syndrome type 1. APS1 has been associated with malabsorption in up to 15% of patients. However, despite epidemiological reviews recognizing the existence of coeliac disease as a co-morbid state sparse work has been done on the immunological factors underpinning it. Thus, Saha et al examined the co-presentation of this in 2016 and in a particular patient group of confirmed IH, found co-existing Coeliac Autoimmunity is present at 6.4% and biopsy proven coeliac disease at 1.2%. This is not significantly different from the incidence in the general population. These are small numbers when taken as per head of population, but they do present a confounding variable in the face of recalcitrant hypocalcaemia independent of copper or magnesium levels. The authors would therefore recommend anti-tissue transglutaminase antibody with total IgA levels to screen all similar patients as in our case, who can affirm compliance to medication.

The prevalence of Vitamin D deficiency in a Greek and a Cypriot population sample

Souzana Eirini Xyda[1], Kalliopi Kotsa[1], Argyrios Doumas[1], Manolis Papanastasiou[1], George Samoutis[2,*] & Alexandros Anastasios Garyfallos[1,*]
[1]Aristotle University, Thessaloniki, Greece; [2]St George Medical School UK, University of Nicosia International Department, Nicosia, Cyprus.
*Both authors have contributed the same

Introduction
The results of this epidemiological study demonstrate the burden of 25-hydroxyvitamin D deficiency in two sunny Mediterranean countries Greece and Cyprus- and some of the related risk factors. These two populations were examined together due to their common phylogenetic origin. Up until now there are no available data for the mean Vitamin D levels of the Cypriot adult population. An early identification of vitamin D deficiency is now considered as the cornerstone of preventive medicine.
Materials and methods
Vitamin D levels for 8780 Greek and 2594 Cypriot subjects were blindly collected from the hospitals' laboratory information systems over a 5-year time period. Sex, age, the month at which the blood sample was drawn, and accompanying diseases (recorded just for 870 patients in the Greek database) were also collected. These data were obtained respectively from the tertiary health care center AHEPA in Thessaloniki, Greece (latitude; N40.7°, longitude; E22.9°) and AGIOS LOUKAS a primary health care center in Nicosia, Cyprus (latitude; N35.1°, longitude; E33.3°). In order to examine the relationship between potential risk factors and vitamin D levels univariate analysis and multivariate linear regression analysis were performed.
Results
73.07% of the Greek and 69.28% of the Cypriot subjects of the sample had inadequate levels of vitamin D. The mean 25(OH)D value for the Greek subjects was found 25.08 ng/ml and for the Cypriots 25.37 ng/ml. The highest levels in both databases were recorded for the month September. For, both databases the multivariate linear regression models demonstrated that age and month were significantly associated with 25(OH)D levels. Sex was significantly associated only in the Greek database ($P<0.0001$). In the second multivariate linear regression model- which included just the subgroup of patients with a recorded disease- the month was not associated with 25(OH)D levels ($P=0.235$). Amongst the recorded diseases growth retardation, hypercalcemia, sickle cell anemia, polyneuropathy (all $P<0.01$), mental retardation and MS (both $P<0.05$) were related with 25(OH)D levels.
Conclusions
The prevalence of vitamin D deficiency is extremely high in both population samples and particularly in subjects with chronic diseases. However, the cross-sectional design of the study cannot prove causality and further prospective studies in healthy subjects are necessary.

Epidemiology of primary hyperparathyroidism in Santander, Spain

Laura Ramos[1], Pedro Muñoz[2], Maria Piedra[1], Luis Vazquez[1] & Jose Antonio Amado[1]
[1]Marqués De Valdecilla Hospital, Santander, Spain; [2]Servicio Cantabro De Salud, Santander, Spain.

Background and aims
Primary hyperparathyroidism (PHPT) is a common endocrine disorder with different epidemiological patterns among countries. The incidence of PHPT is unknown in Spain. The aim of our study is to assess the prevalence and incidence of diagnosed PHPT in adults between 1970 and 2014 in Santander, a population of 290.000 inhabitants, located in the north of Spain.
Subjects and methods
All patients diagnosed with primary hyperparathyroidism from 1970 to 2014 were included. PHPT was diagnosed when persistent hypercalcemia occurred with the presence of elevated or inappropriately normal parathyroid hormone levels. Prevalence and incidence density adjusted for age and sex were calculated for each 5-year period.
Results
We identified 709 patients (82.3% females) diagnosed with PHPT by the end of 2014. Females were older than males at baseline (median age 67.6 years (57.8–75.9) and 63.7 years (52.1–74.2) respectively) ($P<0.05$). Prevalence of PHPT was higher in females, and the female preponderance increased with age. In the mid-1990s the incidence rate in women was 3.72/100.000 person-years and doubled in the period 1995-1999, with an incidence rate of 8.38/100.000 person-years. Incidence increased in the following years, and in the period from 2005 to 2009, it doubled again from 12.08/100.000 person-years in 2000 to 2004 to a maximum level of 24.52/100.000 person-years in the period from 2005 to 2009. In the last period of study, from 2010 to 2014, the incidence in women decreased up to 21.44/100.000 person-years. The increased incidence is progressive and less flashy in males than females. The incidence in the period from 1995 to 1999 was 2.75/100.000 person-years and doubled in the period from 2010 to 2014, becoming 5.20/100.000 person-years. The prevalence of diagnosed PHPT in Santander increased from 0.01 per 1000 population in the period from 1980 to 1984 to 0.38 per 1000 population in the period from 2010 to 2014.
Conclusions
The incidence of PHPT in Santander continues its remarkable rise. The incidence of diagnosis is greater in females than in males and increases with age. The overall increase in incidence may be the result of more frequent plasma calcium measurements, periods of increasing medical interest or environment factors. However, the most likely explanation is the bias of the selective detection of PHPT in patients who are being evaluated for osteoporosis.

Human Chorionic Gonadotrophin (hCG) as a diagnostic test to differentiate between Parathyroid Carcinoma, Primary Benign Hyperparathyroidism and Secondary Hyperparathyroidism.

Hernan Valdes-Socin[1], Daniela Betea[1], Adrian Daly[1], Pierre Delanaye[1], Jean-Claude Souberbielle[2], Albert Beckers[1] & Etienne Cavalier[1]
[1]CHU de Liège, Liège, Belgium; [2]CHU Necker, Paris, France.

Introduction
Parathyroid carcinoma (PCa) is a rare presentation of primary hyperparathyroidism (PHPT), accounting for less than 1% of cases. Differentiating parathyroid cancer from benign hyperparathyroidism is clinically challenging. Some previous work suggest that there is a paraneoplastic hCG production in parathyroid cancer (Stock et al 1987, Rubin et al 2008). In this study, we aimed to investigate whether the hCG+β kit from Roche Diagnostics could distinguish PCa patients from primary and secondary hyperparathyroidism. Additionally, we validate hCG levels according to renal function and determine hCG test sensibility and specificity to diagnose parathyroid cancer.
Material and methods
We studied a series of eight patients suffering from advanced PCa, referred to the CHU de Liege. A group of 20 PHPT patients and 25 patients with secondary hyperparathyroidism (SHP) due to chronic renal failure were used as controls. hCG+β kit on Cobas (Roche Diagnostics) uses 2 monoclonal antibodies that recognize holo-hCG, nicked hCG, β-core fragment and free β-subunit. Limits of hCG detection and quantification are <0.1 and <0.6 mUI/ml. In non pregnant and postmenopausal women and in men, hCG (p95) is <1 (5.3), <7 mUI/ml (8.3) and <2 (2.6) mUI/mL, respectively.
Results
The 8 PCa patients (3 women) presented high serum hCG values at: 1.29, 3.46, 5.7, 24.2, 31.2, 34.1, 36.5 and 164 UI/l. Values of 1.29 and 3.46 were obtained in 2 postmenopausal women. The lowest value was presented by the only still alive patient who had hormonal and biochemical normalization and tumor shrinkage induced by anti-parathyroid hormone immunotherapy (Betea et al. 2004). In cancer patients, there was a significant correlation ($r=0.786$; $P<0.05$) between hCG and PTH whereas median hCG (5.7 UI/l) was significantly higher than in PHP (1.25 UI/l) and SHP (0.97 UI/l). hCG test sensitivity was 75% and specificity was 94% to detect parathyroid cancer, with a cutt-off of hCG of more than 5.68 UI/l.
Conclusions
These results suggest that serum hCG might have the potential to discriminate between parathyroid adenomas and carcinomas, with a sensibility of 75% and a specificity of 94%. The only patient still alive who underwent a PTH immunotherapy, presented the lowest hCG values. If hCG could be predictive of PCa survival needs to be studied in a larger series of patients. A future area of research revealed by this data is to test hCG immunotherapy in parathyroid cancer.

Reliabilty of serum Calcium to Phosphorus (Ca/P) ratio as an accurate and inexpensive toolto define disorders of Ca-P metabolism: preliminary data

Sara De Vincentis[1,2], Maria Laura Monzani[1,2], Elda Kara[2], Giovanni Guaraldi[3], Vincenzo Rochira[1,2] & Bruno Madeo[2]
[1]Unit of Endocrinology, Department of Biomedical, Metabolic and Neural Sciences, University of Modena and Reggio Emilia, Modena, Italy; [2]Unit of Endocrinology, Department of Internal Medicine, Endocrinology, Metabolism, and Geriatrics, Azienda Ospedaliero-Universitaria di Modena, Ospedale Civile di Baggiovara, Modena, Italy; [3]Multidisciplinary Metabolic Clinic, Unit of Infectious Diseases, University of Modena and Reggio Emilia, Modena, Italy.

Background
Primary hyperparathyroidism (PHPT) is the third most common endocrine disorder. The Ca/P ratio is an accurate tool to differentiate patients with PHPT (>3.5 if Ca and P are expressed in mg/dl) from healthy subjects [1]. The reliability of this index is based on the fact that serum Ca and P are inversely related together. However, other disorders of the Ca-P metabolism, such as hypophosphoremia (HypoP), might impair the Ca/P ratio.
Aim
To validate the accuracy of Ca/P ratio in the diagnosis of Ca-P metabolism disorders, including also patients with documented HypoP.
Methods
A single-center, retrospective, case-control study was carried out, including 130 patients with documented PHPT and 300 patients with HypoP, compared with 120 controls. HypoP patients were enrolled among HIV-infected patients on HAART treatment from the large Modena cohort. The main outcome measures were: serum Ca, P, parathyroid hormone (PTH), 25-OH vitamin D, albumin and creatinine.
Statistical analysis
Comparisons among groups were performed by the nonparametric Kruskal-Wallis, followed by the Dunn's post hoc test. The diagnostic accuracy of Ca/P ratio was investigated by receiver operator characteristics (ROC) curves in order to define cut-off points (with the highest sensitivity and specificity).
Results
The Ca/P ratio was significantly higher in the group of PHPT together with HypoP, compared to controls ($P<0.0001$). Also Ca and PTH were significantly different among groups, in particular they were higher ($P<0.0001$) in PHPT than both controls and HypoP, as expected. At ROC curves analysis, the cut-off of 3.6 for Ca/P ratio was able to identify patients with PHPT and HypoP (sensitivity 91%; specificity 93%). Among patients with Ca/P ratio above 3.6, the thresholds of 10.2 mg/dl for serum Ca (sensitivity 91%; specificity 98%) and of 83.6 pg/ml for PTH (sensitivity 92%; specificity 93%) were defined for the specific diagnosis of PHPT.
Conclusions
In this study we confirm the role of serum Ca/P ratio as a reliable index to diagnose a Ca-P metabolism disorder, especially PHPT and HypoP. In clinical practice, when a Ca/P ratio above 3.6 is found, the presence of serum Ca >10.2 mg/dl or PTH >83.6 pg/ml is able to discriminate patients with PHPT from those with HypoP.

Secondary hyperparathyroidism after obesity surgery is associated with serum levels of 25-hydroxyvitamin D and ionized calcium

Stephen Hewitt[1,2], Jon Kristinsson[1], Erlend Aasheim[2], Ingvild Blom-Høgestøl[1,2], Eirik Aaseth[3], Erik Fink Eriksen[1,2] & Tom Mala[1]
[1]Oslo University Hospital, Oslo, Norway; [2]University of Oslo, Oslo, Norway; [3]Innlandet Hospital, Elverum, Norway.

Background
Secondary hyperparathyroidism (SHPT) is common in obesity, and a concern after obesity surgery due to negative impact on bone. Longitudinal data is sparse, and relationships with vitamin D and calcium levels are unclear. We studied the prevalence of SHPT over five years after Roux-en-Y gastric bypass (RYGB) and investigated whether SHPT was associated with serum levels of 25-hydroxyvitamin D (25(OH)D) and ionized calcium (iCa).
Methods
347 of 568 (61%) patients attending a 5-year follow-up visit after a RYGB at Oslo University Hospital in the years 2004-2008 were eligible for study inclusion. We excluded 14 patients with missing data, four with primary hyperparathyroidism and 10 with elevated serum creatinine. We defined SHPT as PTH >7.0 pmol/l and vitamin D deficiency as 25(OH)D <50 nmol/l. Low iCa refers to serum levels <1.21 mmol/l (lower tertile of reference range or below). Substitution of vitamin D3 (1000 IE/day) and calcium carbonate (1000 mg/day) was recommended.
Results
Among the 319 included patients (230 women) the prevalence of SHPT was 32% before surgery, while the prevalence was 18%, 24%, 28% and 35% after a half, one, two and five years, respectively. Vitamin D deficiency was found in 45% preoperatively, and 18%, 20%, 28% and 33% after a half, one, two and five years. The proportion with serum iCa in the lower range was: 24% preoperatively, and 29%, 35%, 44% and 49% at a half, one, two and five years. Table 1 illustrates the prevalence of SHPT by serum vitamin D and calcium levels (*illustrates $P<0.001$ between subgroups).

Table 1

	Baseline	1/2y	1y	2y	5y
25(OH)D (nmol/l)					
<50	40	34	29	45	39
≥ 50	26*	13*	20*	19*	33^{ns}
Ionized calcium (mmol/l)					
<1.21	46	21	30	35	46
≥ 1.21	26*	16*	22*	22*	23*

Discussion
The prevalence of SHPT decreased the first half year after RYGB and thereafter increased over time. SHPT was higher in vitamin D deficiency and with iCa levels in the lower range. Improved vitamin D and calcium status may potentially reduce the prevalence of SHPT both preoperatively and after obesity surgery.

The frequencies of persistent hyperparathyroidism and hypercalcemia after kidney transplantation: a single-center experience

Ayşegül Oruç[1], Canan Ersoy[2], Özen Öz Gül[2], Suat Akgür[1], Soner Cander[2], Abdülmecit Yıldız[1] & Alparslan Ersoy[1]
[1]Uludag University Medical Faculty, Department of Nephrology, Bursa, Turkey; [2]Uludağ University Medical Faculty, Department of Endocrinology and Metabolism, Bursa, Turkey.

Bone mineral disorders usually resolve after successful kidney transplantation. Serum calcium (Ca), phosphorus (P) and parathyroid hormone (PTH) levels tend to normalize within time. Serum Ca levels >10.2 mg/dL and PTH levels >150 pg/mL at 6th−12th months of transplantation is defined as persistent hypercalcemia and persistent hyperparathyroidism (PHPT) in recipients with normal graft function. Reported persistent hypercalcemia prevalence varies in wide range between 5% and 66%. This huge variation might be explained with different diagnostic criteria, heterogenic recipient population and variation in renal replacement vintage. We aimed to evaluate the prevalence of hypercalcemia and PHPT among recipients after successful kidney transplantation in our center.
Methods
We performed a retrospective study involving a total 391 (224 males, 40.6 ± 11.9 years) adult kidney transplant recipients between January 2008 and December 2014. Recipients who were underwent parathyroidectomy before transplantation were excluded. Demographic and laboratory data of 307 recipients who were followed up at least 12 months were obtained by review of electronic file system. PHPT was defined as serum corrected Ca level >10.2 mg/dl (at least twice in a 6 month period) and PTH >150 pg/ml at 6th month of transplantation. Serum creatinine, Ca levels at pre- and post-transplant 1st, 3rd, 6th, 12th months, PTH levels at pre- and post-transplant 6th, 12th months of recipients were recorded.
Results
A total 307 recipients (150 deceased, 157 living donor; 175 male, 132 female; mean age 39.4 ± 11.4 years) were enrolled the study. The mean duration of renal replacement treatment was 75.1 ± 3.3 months. Mean serum Ca levels before transplantation and at 1st, 3rd, 6th, 12th months of transplantation were 9.3 ± 0.8 mg/dl, 9.3 ± 0.7 mg/dl, 9.6 ± 0.7 mg/dl, 9.7 ± 0.7 mg/dl, 9.7 ± 0.7 mg/dl; and prevalence of hypercalcemia (>10.2 mg/dl) at 1st, 3rd, 6th, 12th months of transplantation were 10.8%, 21.2%, 21.2% and 21.2%, respectively. Mean serum PTH levels before transplantation and at 6th, 12th months of transplantation (>150 pg/ml) were 526.2 ± 474.9 pg/ml, 237 ± 334 pg/ml, 215 ± 236.9 pg/ml, and prevalence of hyperparathyroidism at 6th, 12th months of transplantation were 57.1% and 52.3%, respectively.
Conclusion
PTH levels decreased and Ca levels remained stable after transplantation within 12 months in our study. Although prevalence of hyperparathyroidism was high, persistent hypercalcemia affected fewer recipients.

Prevalence and clinico-epidemiology of vitamin D deficiency in patients with type 2 diabetes mellitus and hypertension – a Pan-India study

P G Talwalkar[1], Vaishali Deshmukh[2], M C Deepak[3], Dinesh Agrawal[4], Ishan Patel[5] & Rashmi Hegde[5]
[1]Talwalkar Diabetes Clinic,X, Mumbai, India; [2]Deshmukh Clinic and Research Centre, Pune, India; [3]R M Diabetes Educational and Research Foundation, Chennai, India; [4]Only Research, Guwahati, India; [5]Abbott India Ltd, Mumbai, India.

Introduction
Vitamin D (vitD) deficiency is a worldwide epidemic health problem, with a prevalence of about 70–100% in general Indian population. The objective of this cross-sectional, clinico-epidemiological, Pan-India study was to evaluate the prevalence of vitD deficiency in patients with Type-2 diabetes mellitus (T2DM) or hypertension (HT) or both T2DM and HT and to understand the management practices in Indian real-world setting.
Methods
Adults with a diagnosis of T2DM or HT or both (established/newly diagnosed), visiting physician for routine check-up, were enrolled. Percentage of patients with vitD deficiency in those with T2DM/HT/or T2DM + HT and prevailing management practices were assessed. VitD insufficiency and deficiency was defined as serum 25(OH)D levels 21–29 ng/ml and ≤ 20 ng/ml, respectively.
Results
A total of 1501 (99.5%) patients completed the study (T2DM:500 [99.2%]; hypertension:499 [99.6%]; both T2DM and HT: 502 [99.8%]). Mean ($\pm$s.d.) age of the study population was 52.9 ± 12.49 years. Mean age at diagnosis of vitD deficiency was 52.5 ± 10.77 years; mean vitD level at the time of diagnosis was 16.9 ± 12.78 ng/ml. Overall prevalence of patients with low vitD levels (vitD deficiency and insufficiency) was 1257 (83.7%); 1231 (82%) were newly diagnosed cases. Out of 1257 (83.7%) patients with low vitD levels, 60.9% patients had vitD deficiency and 22.9% patients had vitD insufficiency. Prevalence of low vitD levels amongst patients with T2DM ($n=500$), HT ($n=499$) and T2DM + HT ($n=502$) was 84.2%, 82.6% and 84.5%, respectively. Out of 1257 patients with low level of vitD, 84.8% received vitD supplementation. Preferred dose of vitD was 60,000IU (70.2%); route of administration was oral for majority of patients (79.6%). Preferred frequency of

dose was once in a week (76.7%). Average duration of treatment was 7.6 ± 3.49 weeks. Factors considered by physician to prescribe vitD supplements were vitD deficiency (26.9%), vitD insufficiency (34.5%), symptoms of vitD deficiency (10.4%) and co-morbid condition (1.8%). Out of 126 patients with low vitD levels and T2DM, 84.37% patients had abnormal HbA1c levels.
Conclusion
Prevalence of vitD deficiency was higher amongst newly diagnosed cases, which indicates that vitD deficiency may have been missed in a large proportion of patients with T2DM, HT, or both T2DM and HT. This study emphasizes on the magnitude of overlap between these diseases and the need for routine vitD screening and appropriate management in Indian patients with T2DM and HT.

DOI: 10.1530/endoabs.56.P218

P219

PTH threshold for hyperparathyroidism diagnosis in vitamin D deficiency

Gloria Baena-Nieto, Rosa Márquez-Pardo, Manuel Cayón-Blanco & Lourdes García-García-Doncel
Jerez Hospital, Cádiz, Spain.

Introduction
Vitamin D insufficiency is very common among Spanish adults. It is well established there is an inverse relationship between vitamin D and PTH levels. The diagnostic approach of an increased serum PTH concentration in a normocalcemic normophosphatemic patient is frequent in routine practice and the deficiency of vitamin D is the major cause of secondary hyperparathyroidism (SHPT). The aims of this study were to evaluate the prevalence of SHPT in a cohort of normocalcemic patients with elevated serum PTH levels and deficiency/insufficiency of vitamin D and to analyze the correlation between PTH and vitamin D levels.
Methods
96 patients with elevated PTH levels and a 25OHD <30 ng/ml were included. All patients were treated with vitamin D for 3–6 months and all parameters were re-evaluated. Patients with diabetes and chronic kidney disease were excluded.
Results
96 patients were included (61.3% female; 63.22 ± 12.56 median age). Baseline characteristics were: Serum calcium: 9.87 ± 0.93 mg/dl, serum phosphate: 3.08 ± 0.54 mg/dl, calciuria: 180.3 ± 123 mg/dl/24 h, PTH: 117 ± 42 and 25(OH) vitamin D: 14.86 ± 3.3 ng/dl. After treatment with vitamin D there was a significant increase of 25(OH) vitamin D levels (40.36 ± 19, $P<0.0001$) and a significant decrease of PTH levels (83 ± 40 $P<0.001$), serum calcium (9.8 ± 0.58, $P<0.037$), and calciuria (199 ± 123 mg/24 h; $P<0.032$). 12 patients were diagnosed of primary hyperparathyroidism (12.5%). Plasma 25(OH)D3 levels correlated negatively with PTH levels ($r=-0.261$, $P<0.01$). For the diagnosis of hyperparathyroidism in patients with vitamin D levels low 20 ng/ml the threshold of 108.5 pg/ml for PTH levels was obtained by means of the ROC curve analysis, with 87% of sensitivity and 58% specificity.
Conclusions
Vitamin D deficiency/insufficiency is the major cause of secondary hyperparathyroidism. To adequately assess this condition is critical to replenish levels of vitamin D. PTH threshold for hyperparathyrodism diagnosis in vitamin D deficiency must be calculated.

Vitamin D status in hospitalized chronic ill patients

Raef Botros, Mona Abdelsalam, Ahmed Bahaaeldin & Sherihan Aboelyazed
Ain Shams University, Cairo, Egypt.

Objectives
Vitamin D deficiency is rarely considered or treated in critically ill patients. Deficiency of 25-hydroxy vitamin D (25(OH) D) prior to hospital admission might be a significant predictor of short and long term all cause patient mortality in a critically ill patient. We aimed to investigate the prevalence of vitamin D deficiency in hospitalized patients and its relation to the length of stay and outcome of hospitalization.
Methods
Prospective cohort study performed on eighty patients admitted to internal medicine department, with acute deterioration of their chronic illness. Four groups of diseases were included, namely chronic liver diseases, chronic obstructive pulmonary diseases, cerebrovascular stroke and heart failure. The patients were followed up till their discharge, or transfer, or death. Patients were sampled for their vitamin D level on admission and were divided according to their vitamin D status into sufficient, insufficient and deficient. Statistical methods and analysis of the present study was conducted using SPSS V17 program.
Results
Vitamin D level had a significant inverse correlation with length of hospital stay ($r=-0.648$) ($P=<0.001$). In vitamin D deficient and insufficient groups, there was a significant difference between survivors and non-survivors as regard vitamin D levels and inverse correlation between vitamin D level and outcome of hospital admission.
Conclusions
Vitamin D deficiency and insufficiency are significantly associated with a longer hospital stay and a poor outcome of hospital admission in comparison to control.

Role of 4D–TC in Primary Hyperparathyroidism Diagnosis– case report

Catarina Ivo, Vitória Pires, David Veríssimo, João Silva, Filipa Serra, Luis Lopes, Dolores Passos, João Jácome de Castro & Mafalda Marcelino
Endocrinology Department – Armed Forces Hospital, Lisboa, Portugal.

Introduction
Primary Hyperparathyroidism (pHPT) is a calcium metabolism disease, resulting from one or more parathyroid glands hyperfunction. Ultrasonography and Technetium Sestamibi are, nowadays, the first line imaging techniques for diagnosis. Recently, a 4-dimensional computed tomography (4D-TC) protocol has emerged, presented in the last endocrine surgery guidelines. It is a dynamic imaging exam based on the parathyroid contrast uptake pattern, whose sensitivity and specificity have been shown to be superior to conventional imaging tests. 4D-TC allows a better anatomic, morphologic and functional precision for detection of parathyroid lesions either of typical or ectopic location.
Clinical case
76 years-old man, with history of arterial hypertension, renal microlithiasis and prostate neoplasm, evaluated in endocrinology department for nodular thyroid disease and osteoporosis. In routine laboratory test, it was detected hypercalcemia (11.3 mg/dl), normal phosphatemia (2.6 mg/dl), elevated parathormona (PTHi 169.2 pg/ml), normal creatinine (1.1 mg/dl) and normal 24 h urinary calcium level. Either, ultrasonography and Sestamibi were negative for parathyroid lesions. Because of the presence of three surgery criteria (hypercalcemia, osteoporosis and renal lithiasis), it was decided to perform a preoperative 4D-TC, which revealed a parathyroid adenoma in the lower third of right thyroid lobe with 9 × 20 mm. A parathyroidectomy was performed without complications and intraoperative PTHi levels vary from basal value of 164.9 pg/ml to 55 pg/ml after procedure. The histologic report confirmed parathyroid adenoma. Last analytical evaluation showed maintained normal serum values of calcium (9.4 mg/dl) and PTHi (70 pg/ml).
Discussion
This clinical case portrays a pHPT diagnosis in which only the 4D-TC, allowed the identification and location of the underlying lesion, after conventional first-line imaging tests were negative. It was our purpose, to demonstrate the potential of 4D-TC as an effective method to identify parathyroid lesions, especially in cases of difficult detection, constituting a useful tool in the preoperative evaluation. Its use, replacing conventional exams, may happen if more studies confirm its diagnostic superiority.

Severe hypomagnesaemia and hypocalcaemia: an uncommon but serious complication with proton pump inhibitor therapy

Rahat Tauni, Syed Kashif Kazmi, Unoma Chukwuma, Nida Ali & Mark Evans
Cambridge University Hospitals, Cambridge, UK.

A 73 year old man was admitted to the hospital with a multi-factorial fall. He was otherwise asymptomatic. Past medical history included stage 3 chronic kidney disease (CKD), ulcerative colitis, epidermolysis bullosa and mild cognitive impairment. Examination was unremarkable apart from unilateral leg swelling and deep venous thrombosis was excluded. Investigations showed incidental undetectable magnesium level and severe hypocalcaemia. Potassium level was normal, 25-hydroxy-vitamin D level was low and parathyroid level was appropriately raised. Electrocardiogram revealed normal sinus rhythm and high corrected QT interval. Treatment with intravenous magnesium and calcium rendered both electrolytes to normal. Medication review revealed omeprazole 20 mg once a day for more than 2 years for heartburn. He was not on diuretics and there was no suggestion of alcohol excess, diarrhoea or re-feeding syndrome. Hypomagnesaemia was attributed to the long term use of the omeprazole and the latter was replaced with ranitidine. He did not require further magnesium or calcium replacement and was commenced on cholecalciferol replacement for vitamin D deficiency. Proton pump inhibitor (PPI) induced hypomagnesaemia is rare but potentially serious complication of long term PPI use. Hypomagnesaemia is caused by reduced intestinal absorption of magnesium and seems to be a class effect seen with all PPIs. The severity of hypomagnesaemia is not linked to the dose of PPI but to the duration of use. The risk is higher in elderly population, females, people with concomitant diuretic use and with other co-morbidities especially diabetes or diarrhoea. Hypomagnesaemia can be associated with hypocalcaemia and hypokalaemia. Patients present with weakness, diarrhoea, leg cramps, paraesthesia, tetany, seizures and torsades de pointes. Physicians must recognise this potentially serious complication and switch patients from PPIs to H2-receptor blockers as the latter are not associated with abnormal magnesium absorption. Short term management involves replacement of magnesium, calcium and potassium. Cardiac monitoring in indicated especially in patients with prolonged QT interval. Risk benefit analysis should be carried out for patients in whom long term PPI therapy is being considered.

Hip fractures and vitamin D deficiency

Ifigenia Kostoglou-Athanassiou[1], Lambros Athanassiou[2], Andreas Giannakopoulos[3], Alexandros Pastroudis[3] & Panagiotis Athanassiou[4]
[1]Department of Endocrinology, Asclepeion Hospital, Voula, Athens, Greece; [2]1st Department of Medicine, Asclepeion Hospital, Voula, Athens, Greece; [3]6th Department of Orthopedics, Asclepeion Hospital, Voula, Athens, Greece; [4]Department of Rheumatology, St. Paul's Hospital, Thessaloniki, Greece.

Introduction
Vitamin D deficiency is associated with the development of osteomalacia, as it decreases intestinal calcium absorption and bone mineralization. However, severe vitamin D deficiency may also be correlated with secondary hyperparathyroidism which induces osteoporosis. In addition, it induces muscular dysfunction which along with frailty in old age it may induce falls.
Aim
The aim was to present a group of patients with severe vitamin D deficiency who developed a hip fracture.
Methods
A group of ten old frail patients, aged 82–97 years, is presented, who developed a hip fracture. Patients were successfully operated for the hip fracture. Laboratory evaluation revealed marginally low blood calcium, low urinary calcium and very low $25(OH)D_3$ levels ($25(OH)D_3$ <7 ng/ml, normal range >30 ng/ml).
Results
Cholecalciferol was administered to the patients initially in high dosage, thereafter in lower doses. The patients recovered fully. A period of six months after discharge from the hospital they were reevaluated. They had normal $25(OH)D_3$ levels and they had recovered, physical condition found to be similar to that previous to the hip fracture.
Conclusions
In the group of patients with hip fracture presented the observed severe vitamin D deficiency contributed to the development of hip fracture, whereas the administered vitamin D acted therapeutically and contributed to the postsurgical rehabilitation of the patients. Thus, it is recommended that in old patients presenting with a hip fracture vitamin D levels should be measured and the respective vitamin D deficiency should be corrected therapeutically with the administration of cholecalciferol. In frail patients who live in closed accommodation, due to inability to get out, the measurement of vitamin D should be performed. Vitamin D administration is recommended for the prevention of falls and fractures in this group of patients.

Clinical manifestation of Hypoparathyroidism in a monocentric cohort: our experience

Andrea Repaci, Paola Altieri, Francesco Dianori, Nicola Salituro, Giulia Vandi & Uberto Pagotto
Division of Endocrinology, Department of Medical and Surgical Sciences (DIMEC), University Alma Mater Studiorum, S. Orsola-Malpighi Hospital, Bologna, Italy.

Introduction
Hypoparathyroidism (HP) is characterized by low serum calcium and increased phosphate levels associated with inappropriately low serum PTH levels. Clinical manifestations of HP are tingling, muscle cramps, seizures, nephrocalcinosis, kidney stone, kidney failure, depression and anxiety.
Objective
Quantify the chronic symptoms and complications of HP in our monocentric cohort.
Material and methods
We conducted a retrospective study involving patients that attended the Endocrinology Unit of S.Orsola-Malpighi Hospital in Bologna from 1980 to 2016. HP was confirmed by hypocalcemia with a simultaneous low or inappropriately normal PTH level for at least 1 yr. We evaluated serum and urine laboratory results in association with clinical manifestation.
Results
We identified 130 permanently hypoparathyroid patients. Mean age at the end of the observation period was 61 ± 16 (range 21–94) yr, and the cohort was 83% female. The main cause of HP was neck surgery. 90.8% of patients were treated with calcium supplements (mostly carbonate) and/or calcitriol. In addition, 14.6% took thiazide diuretics and 7.7% phosphate binders. Mean serum calcium was 8.4 ± 0.8 mg/dl. Time-weighted average for calcium was between 7.5 and 9.5 mg/dl for 80.8% of patients, while 12.3% was under this target and 6.9% over the target. The average calcium-phosphate product was 38.3 ± 6.9 mg^2/dl^2, and 98.4% had a calcium-phosphate product under 55 mg^2/dl^2. Hypercalciuria was recorded in 27.7% of the cohort. Calcium urinary levels were correlated with age ($P=0.009$), serum calcium levels ($P=0.001$) and calcitriol dose ($P=0.005$). As expected, neuromuscular symptoms were inversely correlated with serum calcium levels, and only 8% of patients with calcium levels under 9 mg/dl was symptomatic. Nevertheless, 50% of patients were asymptomatic with calcium levels under 6.5 mg/dl. Symptomatic hypocalcemia and vitamin D intoxication required hospitalization in 6 and 11 occasions, respectively. Chronic kidney disease (CKD) was observed in 27.7% of the cohort. Thirty patients developed moderate CKD and six severe CKD. By multivariate Cox regression, eGFR was inversely associated with serum calcium levels ($P=0.04$; HR 1.7 CI 95% 1.0–2.9). Nephrolitiasis was detected in 14.6% and nephrocalcinosis in 2.3% of the cohort. Soft tissue calcifications were observed in 14.6% of the cohort. Bone fractures occurrred in 15.3% (20/130) of patients, while 19.3% (12/62) had a densitometric diagnosis of osteoporosis. In addition, hospitalization for cardiovascular events (20.8%), malignancy (10%), and infections (7.7%) were recorded.
Conclusions
Hyoparathyroidism and its treatment are associated with a high rate of complications, particularly kidney disease.

Primary hyperparathyroidism due to a parathyroid adenoma with cystic degeneration presenting as recurrent acute pancreatitis

Ionela Lungu[1], Cristina Alina Silaghi[2,3], Horaţiu Silaghi[3,4], Gheorghe Cobzac[5], Georgiana Nagy[3,6], Denisa Petrescu[1,3], Claudiu Ştefan Mirescu[7] & Carmen Emanuela Georgescu[1,3]
[1]Clinical of Endocrinology, County Emergency Hospital, Cluj-Napoca, Romania; [2]Department of Endocrinology, Cluj-Napoca, Romania; [3]'Iuliu Hatieganu' University of Medicine and Pharmacy, Cluj-Napoca, Romania; [4]5th Department of Surgery, Cluj-Napoca, Romania; [5]Clinic of Nuclear Medicine, County Emergency Hospital, Cluj-Napoca, Romania; [6]Ist Internal Medicine Departament, Cluj-Napoca, Romania; [7]Department of Pathology, Municipal Hospital, Cluj-Napoca, Romania.

Primary hyperparathyroidism (PHPT) is rarely associated with the development of acute pancreatitis (AP). The incidence of AP induced by hypercalcemia in PHPT varies between 1.5 and 7%. PHPT is most commonly caused by parathyroid adenoma and infrequently by parathyroid hyperplasia, carcinoma or cyst and multiple endocrine neoplasia (MEN) types 1 and 2A. The present case is a 48-year-old man referred to our service for further investigation 1 month after an acute hemorrhagic necrotic pancreatitis in context of hypercalcemia, complicated with caudal pancreatic pseudocyst, partial thrombosis of portal vein, hepatosplenomegaly, moderate anemia and acute renal failure. His history included 3 AP attacks managed conservatively throughout the last 2 years, left renal microlithiasis, essential hypertension, chronic renal insufficiency, hyperuricemia, without additional risk factors for AP like alcohol ingestion, hyperlipidemia and gallstones. Laboratory findings revealed increased serum ionized calcium (6.29 mg/dl) and total serum calcium (11.98 mg/dl), hypophosphatemia (2.06 mg/dl) associated with elevated parathyroid hormone (PTH = 320 pg/ml), high serum amylase (167 U/l), lipase (318.8 U/l), C-reactive protein (9.94 mg/dl), azotate retention (creatinine = 1.75 mg/dl, serum urea = 47 mg/dl), hyperglycemia (130 mg/dl) and moderate anemia (haemoglobin = 9.3 g/dl). Cervical ultrasonography showed a 5.8/4.04/3.74 cm, mixed, echogenic and transonic, well-defined mass located postero-inferior of the right thyroid lobe. Single photon emission computed tomography (SPECT) with technetium-99 m sestamibi combined with X ray–based computed tomography (CT) revealed a right posterior cystic parathyroid adenoma, extended in the superior mediastinum, measuring 5/3.5/4 cm. After conservative management, hydratation, forced diuresis and calcitonine, the patient underwent right inferior parathyroidectomy. Histopathological examination confirmed the diagnosis of parathyroid adenoma. Postoperatively, the patient developed mild hypocalcemia and was treated by intravenous calcium infusions, followed by oral calcium and vitamin D. Serum calcium and PTH levels returned to normal and the patient was asymptomatic at the follow-up examinations. Although hypocalcemia is expected to appear during an AP attack, identifying hypercalcemia should always raise the suspicion of either hyperparathyroidism or malignancy. High PTH helps differentiate the two. As AP can have fatal consequences, it is important to reassess calcium levels after resolution of AP, especially in patients with idiopathic recurrent AP, because early recognition and treatment prevent reappearance.

Glucose metabolism in primary hyperparathyroidism: The role of parathyroidectomy

Vasiliki Antonopoulou[1], Maria Grammatiki[1], Eleni Rapti[1], Theocharis Koufakis[1], Spyridon Karras[1], Maria Yavropoulou[1], Theodossis Papavramidis[2] & Kalliopi Kotsa[1]
[1]Diabetes Center, Department of Endocrinology and Metabolism, 1st Department of Internal Medicine, AHEPA University Hospital, Thessaloniki, Greece; [2]1st Propaedeutic Surgical Department, AHEPA University Hospital, Thessaloniki, Greece.

Background
Although primary hyperparathyroidism (PHPT) has been associated with diabetes mellitus (DM), the etiological link is not clear and the effect of parathyroidectomy is controversial.The aim of this observational study was to investigate the metabolic link between calciotropic hormones and glucose metabolism in PHPT patients before and after parathyroidectomy.
Methods
Twenty-four consecutive patients with PHPT (Group-A) without DM were included in the study. Anthropometric characteristics and medical history were recorded. Fasting plasma glucose (FPG), fasting insulin (FI), calcium, phosphorus, parathyroid hormone (PTH) and 25-hydroxyvitamin-D [25(OH)D] were measured. Homeostasis Model Assessment was used for estimating insulin resistance (HOMA-IR) and β-cell function (HOMA-B). QUICKI index for insulin sensitivity was also calculated. In a subgroup of 13 patients (Group-B) a scheduled curative parathyroidectomy was performed and all measurements were repeated after surgery. In 10 out of 13 a 75 g OGTT was performed before and 6 weeks after surgery to further evaluate glucose response, insulin response and insulin sensitivity using Matsuda Index. SPSS 22 was used for statistical analysis.
Results
Group-A had a mean age of 55 ± 10.66 years and the female:male ratio was 19:5. Pearson and Spearman correlation coefficient was used and a statistically significant positive correlation between HOMA-B and PTH ($r = 0.53$, $P = 0.008$) was identified. PTH was also correlated to waist-to-hip ratio ($r = 0.44$, $P = 0.03$) and inversely to FPG/FI ratio ($r = -0.40$, $P = 0.056$). Linear regression showed a significant linear relation between HOMA-B and PTH ($P = 0.006$), which remained significant when adjusted for age and BMI.When subjects were classified according to their 25(OH)D levels in vitamin D sufficient [25(OH)D ≥ 20 ng/dl, $n = 16$] and vitamin D insufficient ($10 < 25(OH)D < 20$ ng/dl, $n = 8$), independent samples *t*-test showed no significant difference in glucose homeostasis. In Group-B after surgery, calcium and PTH levels normalized and phosphorus increased. T-paired test and Wilcoxon signed rank test were used but no significant alterations were identified in FPG ($P = 0.56$), FI ($P = 0.73$), HOMA-IR ($P = 0.65$), HOMA-B ($P = 0.53$), QUICKI ($P = 0.90$), Matsuda index ($P = 0.10$), BMI ($P = 0.17$).The correlation between HOMA-B and PTH remained significant after surgery ($r = 0.76$, $P = 0.002$).
Conclusion
Findings of this small study indicate a correlation independent of vitamin D between PTH and indices of β-cell function and insulin sensitivity, in PHPT patients. This parallel increase of HOMA-B and PTH could be due to insulin resistance or reflect a potential direct action of PTH on β-cell. Larger studies will clarify the mechanisms and explain the inability of parathyroidectomy to reverse this effect.

Acquired Fanconi syndrome and hypophosphatemic osteomalacia in two patients treated with adefovir and tenofovir

Basak Ozgen Saydam[1], Goksel Bengi[2], Serkan Yener[1] & Abdurrahman Comlekci[1]
[1]Dokuz Eylul University Faculty of Medicine, Department of Endocrinology and Metabolism, Izmir, Turkey; [2]Dokuz Eylul University Faculty of Medicine, Department of Gastroenterology, Izmir, Turkey.

Background
Proximal tubule dysfunction in Fanconi syndrome causes impaired reabsorbtion of amino acids, glucose, urate and phosphate, which leads to hypophosphatemic osteomalcia. Adefovir and tenofovir are two nucleoside reverse transcriptase inhibitors, which are used for treatment of patients with hepatitis B infection. Although these drugs are well tolerated with few side effects, patients may rarely suffer from drug-induced Fanconi syndrome and hypophosphatemic osteomalacia.
Clinical case
Patient-1, a-63-year-old male patient, referred to Endocrinology and Metabolism Clinic suffering from right knee pain for 3 months which became bilateral in course of time. He also had pain in lomber region, in legs and feet. He has been on adefovir treatment for hepatitis B infection for 10 years. His phosphorus (P) level was 1.1 mg/dl, calcium (Ca) level was 9.05 mg/dl and ALP level was 153 mg/dl. His tubular maximum of phosphate corrected for GFR was low for his GFR, age and gender. His FGF23 level was suppressed. After treatment with calcitriol 50 μg and with 1500 mg/day phosphorus, his phosphate levels reached to normal levels with amelioration of symptoms within 1 year and dose was tapered according to clinical and laboratory assessment. Patient-2-, a 64-year-old-male patient, applied to Endocrinology and Metabolism Clinic suffering from loss of balance, difficulty in walking, bilateral hip and knee pain and general muscle pain for 4 years. He had been walking with the help of crutch for 2 years. He was on treatment with tenofovir for 5 years for hepatitis B infection. His serum Ca was 8.78 mg/dl, P was 1.2 mg/dl and ALP level was 242 mg/dl. His tubular maximum of phosphate corrected for GFR was low for his GFR, age and gender. He is on treatment with calcitriol 0.25 μg and 1500 mg/day phosphorus with normalization of calcium and phosphorus levels as well as amelioration of symptoms. Due to previous lamivudine resistance, entacavir treatment was recommended after cessation of tenofovir for treatment of hepatitis B infection.

Conclusion
Drug induced Fanconi syndrome and hypophosphatemic osteomalacia should be kept in mind in patients receiving nucleoside analogue treatment for hepatitis B who suffer from bone pain and muscle weakness.

The coexistence of primary hyperparathyroidism with different auto-antibodies and autoimmune diseases

Jovanka Novakovic-Paro[1,2], Tijana Icin[1,2], Ivana Bajkin[1,2], Bozidar Dejanovic[1], Kristina Stepanovic[1], Bojan Vukovic[1,2], Damir Benc[1,2], Dragana Tomic-Naglic[1,2], Radoslav Pejin[1,2], Andrijana Milankov[1,2] & Milica Medic-Stojanoska[1,2]
[1]Medical Faculty, Unversity of Novi Sad, Novi Sad, Serbia; [2]Clinic for Endocrinology, Diabetes and Metabolic Diseases, Clinical Center of Vojvodina, Novi Sad, Serbia.

Introduction
The coexistence of primary hyperparathyroidism with autoimmune diseases is described very rarely in the literature so far. There are only few cases of immune-mediated hyperparathyroidism, associated with anti-calcium- sensing receptor autoantibodies, frequently in context with other immune diseases. Spontaneous remission of primary hyperparathyroidism in anti-TNF therapy of psoriatic arthritis has also been described in one case. Prevalence of positive antithyroid antibodies is 10–13%, and prevalence of undiluted antinuclear antibodies is up to 20% in general population.
The aim of the study was to examine the prevalence of positive autoantibodies in patients with primary hyperparathyroidism.
Material and methods
The study was conducted on 38 patients with primary hyperparathyroidism. Data were collected from medical records. Laboratory or medical history evidence of autoimmune diseases were collected.
Results
Autoimmune thyroid disease was present in 13 (36.1%) of 36 patients. Antinuclear antibodies and antinuclear antibodies on HEP-2 were positive in 4 (22.2%) of 18 patients. Tissue transglutaminase antibodies were done in 14 patients, and were negative in all cases. Antineutrophil cytoplasmic antibodies were done in 13 patients and were negative in all cases. Anticardiolipin antibodies were negative in all 14 cases. Of all 38 patients, 16 (44,4%) of them have either an autoimmune thyroid diseases or some other proven autoimmune disease.
Conclusion
In patients with primary hyperparathyroidism, there is a higher prevalence of autoimmune thyroid disease and positive antinuclear antibodies to HEP-2 than in the general population. Also, the presence of some autoimmune disease in 44.4% of patients is surprisingly high. We propose to examine the prevalence of anti-calcium-sensing receptor autoantibodies in patients with the simultaneous presence of primary hyperparathyroidism and other autoimmune diseases.

Timely and dose assessment of serum parathormone and calcium levels by cinacalcet in patients with primary hyperparathyroidism: an individualized approach

Leonidas Duntas[1], Savvas Tanteles[2], Anastasios Boutsiadis[1] & Stergios Polyzos[3]
[1]Evgenideion Hospital, Unit of Endocrinology, Diabetes and Metabolism, Thyroid Section, University of Athens, Athens, Greece; [2]Evgenideion Hospital, Department of Radiology, University of Athens, Athens, Greece; [3]First Department of Pharmacology, University of Aristotle, Thessaloniki, Greece.

Objective
To assess the regulation of parathormone (PTH) and serum calcium (s-Ca) in patients, on follow-up over a long time period of four years, who have primary hyperparathyroidism (pHPT) and whose condition is non-operable or who are not willing to undergo surgery.
Methods
Initially, 17 patients with documented pHPT were recruited and treated with calcimimetic cinacalcet at a dose calculated according to s-Ca levels ($\leq$11 mg/dl or $>$11 mg/dl), amounting to 30–60 mg/daily ($n=8$) and 60–90 mg/daily ($n=9$). All the patients but four underwent PTH and s-Ca monitoring, firstly after 3 months and then every 6 months, together with monitoring of s-phosphorus, 25-hydroxy-vitamin D [25(OH)D] levels, and a yearly bone mineral density (BMD) check. No patients were taking other drugs, except for cholecalciferol compounds. To compensate for the small number of patients, we analyzed both mean and median values and parametric and non-parametric analysis was performed.
Results
Gr1 ($n=7$) and Gr2 ($n=6$) were matched by age 66 ± 9.2 yr vs. 69.5 ± 6.5 yr. S-Ca levels were statistically significantly (ss) higher at baseline in Gr1 (11.3 ± 0.2 mg/dl) than in Gr2 (10.7 ± 0.2 mg/dl; $P<0.002$). PTH levels were higher, though not ss, in Gr1 (262.8 ± 114.9 pg/ml) than in Gr2 (180.5 ± 17.1 pg/ml). A steep and rapid reduction of PTH was observed in Gr1 at month 3 (M3) resulting in a lower mean and median vs Gr2 for this time point as well as for the following assessments. After M24 and until M48, mean and median values for PTH were close for the 2 groups (M24: 126.6 ± 31.2 pg/ml vs. 118 ± 33.3 pg/ml; M48:95.3 ± 22 pg/ml vs.100.3 ± 9 pg/ml). A consistently increasing level of 25 (OH) D was noted throughout the study in both groups, peaking at M36. No difference in the z-score between both groups was registered. BMI tendentially decreased in both groups.
Epicrisis
Cinacalcet was effective in controlling s-Ca and reducing PTH levels in patients with moderate and severe pHPT. The effect on PTH is characterized by fluctuations and is apparently dose- and time-dependent since stabilization was achieved following several years of treatment. The steady increase of Vit D3 levels could also have contributed to PTH moderation. These results, though numerically limited, should be considered when long-term medical treatment of pHPT is applied.

Coexistence of a large functioning parathyroid cyst with papillary thyroid carcinoma: a case report

Athanasios Panagiotou[1], Panagiotis Anagnostis[1], Savvas Rafailidis[2] & Marina Kita[1]
[1]Department of Endocrinology and Diabetes, Hippokration Hospital of Thessaloniki, Thessaloniki, Greece; [2]Euromedica Kyanous Stavros, Thessaloniki, Greece.

Introduction
Parathyroid cysts constitute a rare cause of primary hyperparathyroidism (PHPT). PHPT may also rarely coexist with non-medullary thyroid carcinoma (NMTC).
Case presentation
A 70-year old woman was admitted to our department for type 2 diabetes mellitus (T2DM) management. She also reported nephritic colics due to kidney stone disease. There were no reports for fractures, symptoms of hypercalcemia or obstructive neck symptomatology. Laboratory investigation for nephrolithiasis showed elevated serum total calcium and parathyroid hormone (PTH) concentrations: 10.8 mg/dl (corrected calcium, normal range: 8.4–10.4) and 187 pg/ml (normal range: 10–53). Serum phosphorus, magnesium and 25-hydroxy-vitamin D levels were low: 2.34 mg/dl (normal range: 2.5–4.5), 1.7 mg/dl (normal range 1.9–2.5) and 9 ng/ml (sufficiency levels $>$30), respectively. Renal function was normal (estimated glomerular filtration rate (eGFR): 144.3 ml/min/1.73 m^2), as were the 24-h urinary calcium concentrations 189 mg/24-h (normal range: 50–300). Dual-energy X-ray absorptiometry (DXA) in lumbar spine was indicative of osteopenia (T-score: -2.3). Renal ultrasound was negative for the presence of kidney stones. Primary (PHPT) combined with secondary hyperparathyroidism was diagnosed and the patient underwent a neck ultrasound and parathyroid scintigraphy (Sestamibi) scan, which were indicative of a cystic mass attached to the lower pole of the right thyroid lobe with an estimated maximum diameter of 6.5 cm. Multinodular goitre was also diagnosed with some of the nodules being suspicious for malignancy. The patient underwent an uneventful right parathyroidectomy and total thyroidectomy. Post-operative corrected calcium and PTH levels were 9.3 mg/dl and 17 pg/ml. Histopathological diagnosis was also positive of a unifocal papillary thyroid carcinoma

(PTC) of follicular variant, 6 mm in diameter, without extrathyroidal extension. Due to the patient's low risk of PTC recurrence, no radioiodine was administered. The patient remains normocalcemic (with normal PTH levels and vitamin D sufficiency) and no signs of PTC recurrence two years after.
Conclusions
Functioning parathyroid cysts constitute a rare cause of PHPT. Large parathyroid cysts may be asymptomatic. PTC may rarely coexist with PHPT but it is not known if this is just a diagnosis of coincidence or a result of common pathogenetic mechanisms.

Assessment of calcium and vitamin D medications adherence in patients with hypoparathyroidism after thyroidectomy

Muhammet Cuneyt Bilginer, Cevdet Aydin, Sevgul Faki, Oya Topaloglu, Reyhan Ersoy & Bekir Cakir
Ankara Yildirim Beyazit University School of Medicine, Department of Endocrinology and Metabolism, Ankara, Turkey.

Aim
In this study, we aimed to evaluate the vitamin D and calcium treatments adherence in patients with hypoparathyroidism after surgery.
Materials and methods
To elucidate the medication adherence, we performed a questionnaire survey using the six item Morisky Medication Adherence Scale for medication of patients with postoperative hypoparathyroidism. These 6 questions were as follows; 1) Do you sometimes have problems remembering to take your medications? 2) Do you pay attention to take medications at exact time? 3) Do you sometimes leave your medication when you feel yourself well? 4) Do you stop sometimes your medication if you feel yourself bad and think that it is associated with medication? 5) Do you know long term benefits of taking your drugs? 6) Do you forget to being prescribed your medications when the prescription time comes? The answers were evaluated as Yes/No. In addition to these six questions, three more questions were added concerning to have worry about side effects of drugs.
Results
Totally 64 patients (12 men, 52 women; median age 48.6 ± 11.6 years) who had postoperative hypoparathyroidism were included in our study. Average duration from diagnosis to evaluation time was 73.0 ± 72.6 months. Average calcium and vitamin D dosages were 1388.39 ± 897.92 mg and 0.61 ± 0.39 μg, respectively. However, in evaluation of calcium usage, motivation level was low in 16 (26.2%) patients and information level was low in 12 (19.7%) patients. Moreover, for vitamin D usage, motivation and information levels were low in 8 (13.3%) and 4 (6.7%) patients, respectively. We found that motivation score of calcium usage was significantly low compared to vitamin D usage ($P<0.001$) Calcium motivation score was found as decreasing significantly with increasing disease time ($r=-0.256$ and $P=0.046$). 38 (59.4%) patients had worry about side effects of calcium treatment. Of these, 10 (15.6%) patients left medication due to this feeling. 55.5% of patients had worry about renal problems such as nephrolithiasis and renal toxicity. 21 (32.8%) of patients declared that they were using lower doses of both drugs than recommended.
Conclusion
In this study, we found that one third of the patients had low motivation for calcium usage and more than half of patients had worry about side effects. We think that these patients must be informed about side effects and convinced about regular and careful follow-up of treatment associated side effects especially in patients who are under calcium treatment.

Preoperative serumvitamin D levels in patients with breast cancer: association with histological characteristics

Grigorios Panagiotou[1], Despina Komninou[1], Sofia Triantafillidou[1], Anastasios Vagionas[1], Kalliopi Pazaitou-Panayiotou[1] & Andreas Tsakalof[2]
[1]Division of Endocrinology-Endocrine Oncology, Theagenio Cancer Hospital, Thessaloniki, Greece; [2]University of Thessaly, Faculty of Medicine, Laboratory of Biochemistry, Larisa, Greece.

Objective
Vitamin D is a multifunctional hormone with possible antitumor effects. Its exact role in breast carcinogenesis remains largely unknown. We evaluated serum vitamin D levels in female patients with recently identified benign or malignant lesions of the breast and its associations with tumor histology.
Subjects-methods
One hundred sixty women with suspicious breast masses that required surgical excision were included in this study. Body composition data were measured using bioelectrical impedance. Pre-operatively, patients provided early morning blood sample for the quantification of Vitamin D status and other biochemical parameters. Determination of vitamin D status of the patients was implemented by quantification of 25-hydroxyvitamin D3 and D2 metabolites ($25OH\text{-}D_3/D_2$) in serum samples of the patients by our previously developed and validated HPLC-DAD method (1). Surgically excised lesions were sent for histological examination and histopathological characterictics were recorded.
Results
After histological examination of the tumor specimens, 64 specimens were found with benign histology and 96 specimens had malignant characteristics. Comparisons between study groups are shown in Table 1. Cancer patients were older and had greater waist circumference. Vitamin D3 levels were similar in patients with benign lesions vs. those with malignancy. Regarding associations with histological characteristics, Vitamin D3 was associated with nodular metastasis ($\rho=0.26$, $P=0.03$) and Ki67 levels ($\rho=0.27$, $P=0.02$) but did not correlate with tumor size ($\rho=0.06$, $P=0.62$). No significant associations were found with overall TNM staging, presence of estrogen or progesterone receptors and Her-2 protein ($P>0.05$ for all).
Conclusions
Vitamin D was associated with tumor aggressiveness. Its role as a non-invasive biomarker of breast cancer prognosis warrants further investigation in longitudinal studies and/or clinical trials.

Association of vitamin D status with pulmonary function: potential mediation by physical function and inflammation

Rachida Rafiq[1], Natasja van Schoor[1], Paul Lips[1], Martin den Heijer[1], Martijn Spruit[2] & Renate de Jongh[1]
[1]VU University Medical Center, Amsterdam, Netherlands; [2]Ciro, Horn, Netherlands.

Background
Several studies have reported an association between serum 25-hydroxyvitamin D (25(OH)D) concentrations and pulmonary function in the general population. However, results remain conflicting. In addition, the underlying mechanisms by which vitamin D affects pulmonary function are unknown.
Objective
To assess the relationship of vitamin D status with pulmonary function and whether this relationship is mediated by physical function and/or inflammation. We will also examine potential effect modification of sex and smoking in this relationship.

Methods
We analyzed data from the Longitudinal Aging Study Amsterdam (LASA), an ongoing population-based, prospective cohort study in the Netherlands. Data for this study were obtained from the third cohort (2012/2013). For this study we used data of 551 participants aged between 55 and 65 years, with complete data on serum 25-hydroxyvitamin D (25(OH)D, CRP, IL-6 and pulmonary function tests (Forced Expiratory Volume in one second (FEV_1) and Forced Vital Capacity (FVC). In the regression analyses we corrected for age, sex, BMI, serum creatinine, smoking status, alcohol consumption, educational level, physical activity and season of blood collection. In addition, effect modification of sex and smoking, and mediation by physical performance, IL-6 and CRP was tested.
Results
In men, serum 25(OH)D was associated with pulmonary function: 10 nmol/L higher serum 25(OH)D was associated with 1.01% predicted higher FEV_1 (95%CI: 0.03 to 1.98) and 1.02% predicted higher FVC (95%CI: 0.26 to 1.77). In women no assocation between serum 25(OH)D and FEV_1 (B(95%CI):-0.19 (−1.17 to 0.78)) and FVC (0.12 (−0.74 to 0.97)) was found. No effect modification by smoking was found. Serum 25(OH)D had an indirect effect on FEV_1 through physical performance in women. No mediation effect of physical performance in the relationship between serum 25(OH)D and FVC was seen. In addition, CRP and IL-6 were no mediators in the relationships between serum 25(OH)D and FEV_1 and FVC.
Conclusion
Higher serum vitamin D concentrations were associated with better pulmonary function in men, but not in women. Further studies are needed to elucidate potential mechanisms underlying the difference between men and women.

Quantification of serum 25-hydroxyvitamin D: a comparison between competitive chemiluminescence immunoassay and mass spectrometry coupled to high performances liquid chromatography

Federica Saponaro[1], Sabina Frascarelli[1], Alessandro Saba[1], Concetta Prontera[2], Aldo Clerico[2], Marco Scalese[3], Claudio Passino[2], Claudio Marcocci[4] & Riccardo Zucchi[1]
[1]Laboratory of Biochemistry, Department of Surgical, Medical, Molecular and Critical Area Pathology, University of Pisa, Pisa, Italy; [2]Fondazione Toscana Gabriele Monasterio, Pisa, Italy; [3]Institute of Clinical Physiology, National Council of Research,, Pisa, Italy; [4]Endocrinology Unit 2, University Hospital of Pisa, Pisa, Italy.

Serum 25-hydroxy-vitamin D (25OHD) is considered the most reliable marker of vitamin D status. Adequate levels 25OHD of are necessary for pleiotropic effects of vitamin D, either skeletal or extra-skeletal. Traditional assays based on immunoassay often show an unsatisfactory accuracy and sensibility. A valuable alternative is Tandem Mass Spectrometry coupled to High Performances Liquid Chromatography (HPLC-MS-MS), that offers a good quantification accuracy, as the contribution of interfering compounds to the final results is limited. We enrolled 110 consecutive patients with Heart Failure, who underwent comprehensive biohumoral characterization. The analyses of 25OHD by chemiluminescence immunoassay (DiaSorin LIAISON) and HPLC-MS-MS were performed at the same moment from two aliquots of the same stored sample. 25OHD levels with LIAISON were statistically lower than with HPLC-MS-MS (17.6±8.9 ng/ml vs 18.9±9.4, $P<0.0001$). The prevalence of Vitamin D insufficiency (<50 nmol/l or 20 ng/ml) was statistically lower using HPLC-MS-MS compared to LIAISON (59% vs 63%, $P<0.0001$). The same result was found for severe Vitamin D deficiency (<25 nmol/l or 10 ng/ml; 20.9% vs 25.4%=<0.001). A good correlation ($R=0.909$, $R^2=0.824$, $P<0.001$) between 25OHD values measured with LIAISON and with HPLC-MS-MS was found. The inter-assay bias was evaluated by Bland-Altman plots: compared to the HPLC-MS-MS method, LIAISON assay demonstrated a mean relative bias of −6.54% with 95% of limits of agreement (−46.52% to +33.44%). HPLC-MS-MS technology is well correlated to the method currently used (CLIA), avoid overestimation of hypovitaminosis D and is a reliable diagnostic tool for 25OHD measurement.

Maximal foot force and plantar pressure distribution assessed by Footscan is not affected in asymptomatic primary hyperparathyroidism patients

Seda Oguz, Ugur Unluturk, Suleyman Nahit Sendur & Tomris Erbas
Hacettepe University School of Medicine, Department of Internal Medicine, Division of Endocrinology and Metabolism, Ankara, Turkey.

Background
Primary hyperparathyroidism (PHPT) is associated with various musculoskeletal complaints. It is difficult to evaluate muscle strength as it is hard to extract objective data due to lack of definite methods for measurement.
Objective
To assess the differences between PHPT patients and healthy controls regarding maximum foot force and plantar pressure distribution by using platform pressure measuring system [Footscan (RSscan)].
Methods
Twenty patients with newly diagnosed PHPT (9 F, 12 M) and 21 healthy controls (13 F, 7 M) were enrolled into the study. Static and dynamic parameters of plantar pressure were recorded using a Footscan pressure plate.
Results
Mean age of the PHPT patients and controls were 45.8±11.3 and 41.3±6.8 (p=NS), respectively. BMI were not different in PHPT patients and healthy controls (29.83±4.6 vs. 27.53±2.7, p=ns). When the measurements of four quadrants on foot (Q) taken into account, Footscan analysis revealed similar distribution of plantar pressure between groups (Q1 24.32%±4.4% vs 23.08%±3.8%, Q2 23.98%±4.3% vs 24.99%±4.51%, Q3 27.28%±5.2% vs 25.98%±5.36%, Q4 24.41%±6.0% vs 25.96%±4.7%). Maximum foot force (MaF) was investigated in ten areas of both feet as standard procedure and no statistically significant difference between groups were observed (MaF left: 1008.34±212.1 N vs 994.71±170.3 N, MaF right: 912.00±226.6 N vs 870.14±127.9 N, P=ns).
Conclusion
According to the present study, the parameters of maximum foot force and plantar pressure computed by using platform pressure measuring system were not different in PHPT patients when compared to healthy controls.

Primary hyperparathyroidism in Russian Federation: epidemiology according to the online register

Nataliya Mokrysheva, Irina Maganeva, Svetlana Mirnaya & Anna Eremkina
Endocrinology Research Centre, Moscow, Russian Federation.

Objective
Primary hyperparathyroidism (PHPT) is one of the most frequently diagnosed endocrine disorders. The Russian Registry of PHPT is an on-line web-based database created in 2016 with the aim to estimate the disease prevalence and improve the quality of health care for such patients in Russian Federation. The Endocrinology Research Centre, Moscow represents The Head organization.
Material and methods
We retrieved retrospective data submitted to the Russian PHPT registry (http://pgpt.clin-reg.ru/) between 2007 and 2017 from 10 geographical regions connected at the moment. The clinical, biochemical, radiological and histopathological characteristics of PHPT patients were analyzed for similarity and variability across the centers. There were registered 1914 patients with different forms of PHPT (hypercalcemic, normocalcemic, sporadic and hereditary cases).
Results
The median age of the all patients at the time of diagnosis (1744 women and 170 men) was 55,6±10 years. The median duration from disease onset till diagnosis was 2 years in Moscow and 5 years in other regions. According to the Registry the sporadic PHPT was the most frequent form and caused by solitary adenoma. The estimated incidence of parathyroid cancer was 2% comparable with other epidemiological studies. PHPT as a MEN syndrome component occurred in 9% of

cases. We included cases confirmed by genetic testing for mutations in the MEN-1 gene (9%) as well as cases with clinical features of MEN 1 syndrome. The most frequent components were pituitary adenoma (30%), adrenal adenoma (27%), pancreatic neoplasm (13,9%). The normocalcemic PHPT with median calcium level 2.45 ± 0.1 mmol/l was observed in 11.7%. The majority of patients were symptomatic (74%). Common clinical manifestations among all PHPT subjects were law trauma fracture and osteoporosis (20% and 8% respectively) nephrolithiasis and/or decrease in glomerular filtration rate (25%), cardiovascular complications (59%), upper gastrointestinal complications (12%). Mean serum calcium, and parathyroid hormone levels in hypercalcemic forms were 2.75 mmol/l ± 0.2 and 250 ± 300 pg/mL respectively. Surgical treatment was performed in 65% cases with recurrence rate 5.1%.

Conclusion

PHPT considerably influences the Russian healthcare system. We observed a tendency to progressive increase in disease detectability. It should be noted that compared to European countries, the symptomatic PHPT is more likely to be diagnosed, which indicates delayed diagnosis because of no routine screening of serum calcium level.

Intrathyroidal parathyroid carcinoma in a chronic hemodialysis patient: a case report

Natalya Mokrysheva, Julia Krupinova, Sergei Kuznecov, lily Selivanova & Svetlana Mirnaya
Endocrinology Research Centre, Moscow, Russian Federation.

Background

Parathyroid carcinoma (PC) is an infrequent pathology, responsible for 0.5–5% of primary hyperparathyroidism cases. Despite the high prevalence of secondary hyperparathyroidism in patients with a chronic kidney disease (CKD), PC among them is extremely rare, with less than 30 cases reported in the literature. The diagnosis of PC in CKD patients is more complex, because of using cinacalcet that reduces the level of calcium and parathyroid hormone (PTH). We report a case of intrathyroidal PC in patients with CKD that was successfully treated by en-bloc resection of the tumor.

Clinical case

A 57-year-old man who had received regular hemodialysis, applied to our center because of uncontrolled hypercalcemia and hyperphosphathemia. He had been treated with cinacalcet 120 mg and sevelamer 4800 mg per day and his laboratory findings were as follows: calcium (Ca) – 2.92 mmol/l (range 2.1–2.55 mmol/l), phosphate (P) – 1.96 mmol/l (0.74- 1.52 mmol/l), PTH – 1983 pg/ml (15-65), alkaline phosphatase – 597 u/l (50-150). Ultrasonography showed an enlarged parathyroid gland (PG) on the right upper side of the thyroid gland with uneven contours of 3.0 x 3.0 x 2.3 cm with calcinate, that was confirmed by CT-scan and 99mTc-Sestamibi scintigraphy. No other PG were identified. During a surgery, intrathyroidal parathyroid tumor was detected that had no clear boundary with the right lobe of the thyroid gland. A locally invasive tumor of the right upper PG and enlargement of the other three parathyroid glands were found during bilateral neck exploration. An en-bloc resection of the upper right PG was performed with the right thyroid lobe, surrounding tissue and paratracheal lymph nodes with subtotal parathyroidectomy of the three enlarged PG. PTH and Ca decreased down after surgery that required taking 2,5 mcg of alfacalcidol and 1,5 g of calcium carbonate per day. Intrathyroidal PC was confirmed by a histological examination that identified vascular and capsular invasion and foci of necrosis. The immunohistochemical study with PTH revealed a positive reaction and confirmed the histogenesis of the tumor from the parathyroid tissue, Ki67 was 5–7%. Three months after surgery the laboratory examination showed: Ca – 2,08 mmol/l, PTH – 117 pg/ml, P – 0.53 mmol/l.

Conclusion

Our case indicates that the use of cinacalcet can hinder the diagnosis of PC in a chronic dialysis patient. When uncontrolled hypercalcemia and/or hyperphosphathemia develop during cinacalcet administration, PC should be suspected, and the appropriate surgery should be planned.

Raloxifene has no efficacy in reducing the risk of spontaneous vertebral fractures after denosumab discontinuation

Gonzalez Rodriguez Elena[1,2], Delphine Stoll[1] & Olivier Lamy[1,3]
[1]Center of Bone Diseases, CHUV, Lausanne, Switzerland; [2]Service of Endocrinology, Diabetes and Metabolism, CHUV, Lausanne, Switzerland; [3]Service of Internal Medicine, CHUV, Lausanne, Switzerland.

Introduction

Denosumab reduces bone resorption, increases BMD, and reduces fracture risk. Denosumab discontinuation (DD) induces an increase of B-crosslaps above baseline values for two years, and a decrease of BMD values. This rebound effect is associated with spontaneous clinical vertebral fractures (SCVF) in close to 15% of patients considering a follow-up of 2 years without taking another osteoporosis treatment. Prescribing a bisphosphonate or SERMs at DD would prevent the rebound effect and the risk of SCVF.

Case report

A breast cancer was diagnosed in this 60-year-old woman. BMD T-scores were −2.9 DS at the lumbar spine and −1.9 DS at the total hip. The 10-year probability of major osteoporotic fractures assessed by FRAX® was 13%. Letrozole and denosumab were given for 5 years. At the end of the treatment, lumbar spine and total hip BMD increase significantly (+18% and +8%, respectively). Vertebral morphometry confirmed the absence of fractures. Raloxifene 60 mg daily was startet 7 months after DD. B-crosslaps were measured at 33 ng/l (normal range: 25-573 ng/l). Four months later, she experienced spontaneous low back pain. MRI revealed D11 and L5 fractures. B-crosslaps were measured at 2070 ng/l.

Discussion

Raloxifene has not been effective, neither in reducing the high bone turnover, nor in preventing SCVF. In addition, follow-up of B-crosslaps was too much apart. To minimize the high bone turnover at DD, it seems preferable to prescribe a potent bisphosphonate, alendronate or zoledronate. However, frequent measurements of bone turnover should make it possible: 1) to detect the beginning of the rebound effect; 2) to evaluate the effectiveness of the given antiresorptive treatment; and, if necessary, 3) to replace it or to adjust its dosage. However, the threshold value that determines the need for an intervention is unknown. Furthermore, a significant decrease in the high bone turnover after DD is not a guarantee to prevent bone loss and to avoid the risk of SCVF.

Conclusion

Studies are urgently needed to assess the efficacy of bisphosphonates and their optimal doses in such situations.

Prevalence of basal ganglia calcification in patients with pseudohypoparathyroidism

Laura Mazoni[1], Federica Saponaro[1], Matteo Apicella[1], Giovanna Mantovani[2], Claudio Marcocci[3] & Filomena Cetani[4]
[1]Department of Clinical and Experimental Medicine, University of Pisa, Pisa, Italy; [2]Endocrinology Unit, Fondazione IRCCS Ca' Granda Ospedale Maggiore Policlinico; Department of Clinical Sciences and Community Health, University of Milan, Milan, Italy, Milano, Italy; [3]Department of Clinical and Experimental Medicine, Pisa, Italy; [4]Universital Hospital of Pisa, Endocrine Unit 2, Pisa, Italy.

Pseudohypoparathyroidism (PHP) is group of heterogeneous disorders characterized by hypocalcemia, hyperphosphatemia and elevated paratormone (PTH) levels as a result of end-organ resistance to PTH. Basal ganglia calcification (BGC) in states of hypoparathyroidism is not uncommon. In PHP, BGC can occur up to 50%; the pathogenesis is poorly defined. The aim of our study was to evaluate the prevalence of BGC at baseline observation in a series of patients with PHP followed at a tertiary center. The diagnosis of PHP was based on clinical features and confirmed by genetic analysis. We evaluated 21 patients with a mean age of 21 ± 12 (7 males and 14 females) with a diagnosis of PHP type I (1A, $n = 5$; 1b, $n = 13$), pseudopseudohypoparathyroidism ($n = 1$). Two patients were

negative at genetic screening. Five (23.8%) subjects had familial PHP type 1A. All patients underwent brain computed tomography (CT, $n=20$) or magnetic resonance imaging (MRI, $n=1$) to detect the presence of BCG. Biochemical and clinical data were available for all patients. BGC were present in 8 (38,1%) patients (7 in PHP type 1b and one in type 1A). 37% were present in males and 62% percent in females, ($P=0.5$). The localization of BCG was pallidum in two patients, all basal ganglia in two, pallidum, cerebellum and caudatum in one, cortical-subcortical junction and caudatum in one, pallidum, striatum and cortical-subcortical junction in one and pallidum and subcortical area in one. Four (19%) patients had other cerebral calcifications, localized in cerebral falx ($n=1$), in pineal gland ($n=1$), choroid plexus ($n=1$) and soft cerebral tissue ($n=1$). Before diagnosis, two of 21 (9.5%) patients presented seizures and one (4.8%) neurocognitive alterations; none of them had BCG. Three patients had soft tissue calcification and two of them also had BCG. Eight patients (38%) presented signs or symptoms of hypocalcemia before the diagnosis, and all but one had BCG. At baseline evaluation, 6 of 21 patients were taking calcium supplements and calcitriol. Mean serum calcium, phosphate and PTH levels were 7.7 ± 1.5 mg/dl, 4.863 ± 1.8 and 440.1 ± 397 pg/ml, respectively. In conclusion, our study finds a high rate of BCG in patients with PHP, with no significant difference between gender. Calcifications were detected in different cerebral sites, usually without clinical manifestations. However, their clinical value is still unclear. Our results suggest evaluating the presence of BCG in PHP and monitoring them with CT o MRI during follow-up.

Thyroid oncocytes may complicate ^{18}F-fluorocholine PET-CT localization of parathyroid adenomas in primary hyperparathyroidism

Katerina Zajickova
Institute of Endocrinology, Prague, Czech Republic.

^{18}F-fluorocholine positron emission tomography/X-ray computed tomography (PET-CT) was carried out in our patients with primary hyperparathyroidism (PHPT) and inconclusive preoperative neck ultrasound and ^{99}Tc-sestaMIBI scintigraphy to localize abnormal parathyroid glands before surgery. The results were retrospectively evaluated and compared to postoperative histopathological findings. A total of 9 patients (1 man, 8 women) with sporadic PHPT was enrolled with a mean age of 62,2 years, mean preoperative levels of calcium 2.71 mmol/l and parathyroid hormone 124 ng/l. ^{18}F-fluorocholine PET-CT correctly localized a parathyroid adenoma in 7 patients of 9 (sensitivity 0.77). In one patient, adenoma was successfully found by a surgeon in spite of negative ^{18}F-fluorocholine imaging (false negative). In 2 patients, ^{18}F-fluorocholine PET-CT localized 3-4 foci suggestive of parathyroid hyperplasia and/or multiglandular disease. In one of them, only a single adenoma was found. In the other subject, in spite of bilateral cervical exploration with total thyroidectomy, parathyroid adenoma was not found resulting in persistent hyperparathyroidism (false positive). In the present cohort, positive predictive value of ^{18}F-fluorocholine PET-CT parathyroid imaging was lower than sensitivity due to a few false positive results (0.66). 8 of 9 patients had underlying thyroid disease (thyroid nodules and/or autoimmune thyroid disease). High uptake of ^{18}F-fluorocholine has been documented in oncocytic thyroid adenoma. In all patients (3 of 9) with inconclusive ^{18}F-fluorocholine PET-CT imaging either oncocytic thyroid cells or oncocytic metaplasia were found by aspiration cytology or postoperative histopathology. In our study sample, ^{18}F-fluorocholine PET-CT allowed to correctly localize parathyroid adenomas in 77% patients with previously inconclusive conventional imaging. Underlying thyroid pathology, in particular, thyroid oncocytes, may complicate ^{18}F-fluorocholine PET-CT parathyroid imaging. Further studies are needed to evaluate ^{18}F-fluorocholine PET-CT imaging in patients with PHPT and simultaneous thyroid disease.

Burden of illness among patients with chronic hypoparathyroidism not adequately controlled with standard therapy by self-perception

Heide Siggelkow[1], Bart L. Clarke[2], Helen Dahl-Hansen[3], Elizabeth Glenister[4], Davneet Judge[5], Nawal Bent-Ennakhil[5], Katie Gibson[5], John Germak[6], Kristina Chen[7], Claudio Marelli[6] & Jens Bollerslev[8]
[1]Department of Gastroenterology and Endocrinology, University of Göttingen, Göttingen, Germany; [2]Mayo Clinic Division of Endocrinology, Diabetes, Metabolism, and Nutrition, Rochester, USA; [3]Nordic hypoPARA Organisation, Oslo, Norway; [4]Hypopara UK, East Grinstead, UK; [5]Adelphi Real-World, Bollington, UK; [6]Shire International GmbH, Zug, Switzerland; [7]Shire Human Genetic Therapies, Inc., Lexington, USA; [8]Section of Specialized Endocrinology, Oslo University Hospital, Oslo, Norway.

Significant knowledge gaps exist regarding the humanistic effects of chronic hypoparathyroidism (HPT), a rare, debilitating condition. We provide interim results from a global survey conducted to characterise the burden associated with chronic HPT from the patient perspective. An anonymous, self-reported survey (online or paper) was conducted in patients with chronic HPT, not adequately controlled with standard therapy by self-perception, from 12 countries through physicians or patient associations. Symptoms and impact of HPT were assessed via HPT Symptom Diary, a disease-specific, patient-reported outcome tool that recorded severity of symptoms experienced in the last 7 days. Health-related quality of life (HRQoL) was evaluated by 2 validated instruments: SF-36 v2 and EQ-5D-5L. Patient demographics and clinical characteristics were also captured. Data were obtained from 226 patients (mean age, 51.6 years; 77% women; mean time since diagnosis, 7.8 years; surgery as main cause of HPT, 81%), of whom 94% had persistent symptoms despite treatment and 63% had been told by a physician that their calcium levels were poorly controlled. Most patients were receiving oral calcium (77%) and/or activated vitamin D (74%). Self-perceived overall symptom severity was reported as mild, moderate, or severe in 56 (25%), 138 (61%), and 30 (13%) patients, respectively. Per symptom diary, 98% of patients reported physical fatigue (symptom severity: mild, 22%; moderate, 42%; severe, 26%; very severe, 9%), 90% reported muscle cramps (mild, 31%; moderate, 42%; severe, 13%; very severe, 4%), and 90% reported heaviness in limbs (mild, 24%; moderate, 46%; severe, 16%; very severe, 4%). An impact on daily life, rated as 'somewhat' or 'very much', was reported by 89% of patients for ability to exercise, 85% for sleep, 80% for ability to work, and 72% for family relationships. An apparent inverse relationship was observed between scores of HPT symptom severity and both HRQoL assessments – the higher the severity scores, the lower the health status. Mean SF-36 summary scores were 44.3/36.6/28.2 (physical component summary) and 44.4/33.9/31.4 (mental health component summary) for patients reporting mild/moderate/severe HPT symptoms, respectively. Mean EQ-5D scores were 0.8/0.7/0.3 for patients reporting mild/moderate/severe HPT symptoms [$n=132$]). Findings from this interim analysis of a global survey demonstrated that there is a spectrum of symptom severity within a cohort of patients self-reporting inadequately-controlled HPT on standard therapy. The magnitude of symptom severity as reported by patients correlated with extent of impact on daily life and reduction in HRQoL.

PTH secretion dynamics in patients with chronic kidney disease stage 3 and stage 4 during 1 year of observation

Natalia Karlovich
Belarusian State Medical University, Minsk, Belarus.

Secondary hyperparathyroidism (SHPT) is common in patients with chronic kidney disease (CKD). The aim of the study was to analyze dynamics of PTH secretion during 1 year of observation of patients with CKD stage 3 and 4. We examined 40 patients, 22 f, 18 m; age 55.9 ± 14.5 years. Mean glomerular filtration rate (GFR)? Calculated by MDRD formula was 27.2 ± 15.7 ml/min; 15 patients have CKD stage 3, 25 – stage 4. Serum PTH, 25(OH)D3, calcium (Ca) and phosphorus (P) were measured initially and at the end of observation period (mean 12.4 ± 1.6 months). Initially SHPT as well as vitamin D deficiency were revealed in 80% of cases. 90% of patients with vitamin D deficiency had SHPT. We found significant negative correlation of PTH level and eGFR ($r = -0.55$), vitamin D level ($r = -0.34$). 20 patients with vitamin D deficiency (25(OH)D3 $<$20 ng/ml) were recommended to receive vitamin D supplements, 2000 IU daily. After 1 year PTH increased in 45% of patients, mean increase was 65.4 pg/ml (95%CI 27.5 – 103.3). Subgroup with increased PTH shown higher initial PTH level ($P = 0.003$) and lower eGFR ($P = 0.0008$). At the end of observation we did not found significant changes of PTH level both in patients received vitamin D and not received supplements. PTH was 168.5 ± 132.1 initially and 164.7 ± 1.6 pg/ml at the end of observation, $P = 0.578$. GFR significantly declined from 27.2 ± 15.7 to 21.3 ± 1.8 ml/min ($P = 0.0004$). At the same time in patients received vitamin D supplements vitamin D level increased from 11.6 ± 5.0 to 31.1 ± 12.3 ng/ml, $P = 0.0002$, Ca and P levels remained unchanged. In the subgroup of patients not supplemented with vitamin D serum Ca decrease from 2.46 ± 0.19 to 2.35 ± 0.15 mmol/l. We can assume that in patients with CKD stages 3 and 4 frequency of both SHPT and vitamin D deficiency is high (80%). Supplementation of vitamin D 2000 IU daily allows restoring normal vitamin D level but seems to not have significant effect on PTH, at list on its decrease. 45% of patients demonstrate PTH increase after 1 year of observation, most predictive value have initial higher level of PTH and lower GFR. Further study is required to confirm this findings and to choose the best strategy of follow-up for patients with SHPT.

Biological and endocrine features of Infra Clinical Hypoparathyroidism in Major Beta Thalassemia at adulthood in Algeria, screening and therapeutic management

Abderahman Youssouf Belazzouz[1], Ziane Khouja[2], Malha Azzouz[1], Aissa Boudiba[1] & Ahmed Nacer[2]
[1]Mustapha Pacha Hospital Diabetologia Departement, Algiers, Algeria; [2]Pierre Marie Curie Center Departement of Hematology, Algiers, Algeria.

Introduction
Major Beta Thalassemia (MBT) is a common hereditary condition in Algeria (2%) and in North Africa it requires repeated transfusions. Life expectancy has improved significantly thanks to advances in chelating treatments that will delay endocrine complications associated with secondary hemochromatosis. The hypoparathyroidism (HPT) continues to be seen (5–20%), its relation with the iron overload is not clearly elucidated.
Patients and methods
It is about 20 BTM patients of mean age 29 years (20–46) (10 Males/10 Females) hospitalized in hematology at the Pierre Marie Curie Center, Algiers. In whom an infra-clinical HPT has been researched in cases of hypocalcemia, hyper-phosphoremia or high alkaline phosphatase.
Results
The prevalence of asymptomatic HPT is 25%, normo-calcemic in 40%. Vitamin D $<$ 10 ng/ml exists in 50% of MBT. Among patient with HPT, 3 patients are diabetics. 2 patients had infra clinical hypothyroidism, only one BTM with HPT has a growth delay less than 2 deviation, and all cases have central hypogonadism except one patient. All HPT patients are under Defirasirox, the 5 cases benefited from biological check up of magnesium level and bone densitometry.
Discussion
An **annual screening** of HPT after the start of the second decade is required. Its coexistence with a frequent **hyper-calciuria** in the BTM make that the conventional preventive treatment by living D and calcium in the long course must be reviewed because of the risk of nephrocalcinose worsening the renal prognosis already altered by the renal hemosiderosis. Other therapeutic weapons such as **recombinant Parathormon** prove to be more effective both renally and on bone capital already altered by other endocrinopathies such as central hypogonadism. Exception for infra clinical HPT, in which "**wait and see**" seems to be more adequate management.

Patients	Age (years)/Sex	Calcium/ phosphorus	PAL ui/l	Parathormon pg/ml	Vit D ng/ml	Feritin ng/ml
Case 1	25/Female (F)	**84**/43 mg/l (miligrams/liter)	106	15.41	8.2	9177
Case 2	35/Male (M)	69/42 mg/l	144	16.07	8.1	1500
Case 3	26/F	57/81 mg/l	113	4.81	8.1	8620
Case 4	31/M	77/48 mg/l	Not available	22.34	12.9	5736
Case 5	28/M	**86**/54 mg/l	170	22.77	8.1	4193

Impact of vitamin D status in clinical, biochemical, radiological and pathological parameters in primary hyperparathyroidism

Paloma Iglesias[1,2], Sonsoles Gutierrez[2], Raquel Barba[2], Miguel Angel Delgado[1], Manuel Duran[2], Clotilde Vazquez[2], Guadalupe Guijarro[1] & Isabel Pavon[1]
[1]Hospital Universitario De Getafe, Madrid, Spain; [2]Hospital Rey Juan Carlos, Madrid, Spain.

To determine the effects of 25-hydroxyvitamin D (25-OHD) status on parathyroid adenoma weight, clinical, radiological and biochemical phenotype in patients with primary hyperparathyroidism (HPTP) were studied.
Methods
Eighty-two patients with pHPT who underwent surgical treatment and in whom the presence of parathyroid adenoma were confirmed histopathologically were studied retrospectively. Patients were divided into 2 groups: group A patients with 25-OHD concentrations $<$ 20 ng/ml ($n = 49$) and group B patients with 25-OHD concentrations $\geq$ 20 ng/ml ($n = 33$). Serum parathyroid hormone (PTH), albumin-corrected serum calcium, phosphate, alkaline phosphatase and urinary calcium excretion were determined. The results of preoperative imaging modalities (ultrasound, planar scintigraphy and SPECT/CT) and parathyroid adenoma weight were recorded.
Results
74% of patients presented vitamin D insufficiency ($<$ 20 ng/dl). No statistically significant differences were observed with respect to serum calcium, phosphorus, PTH, alkaline phosphatase concentrations, urinary calcium excretion and parathyroid adenoma weight between groups. The history of bone fracture was more frequent in group A (9.7% vs 1.2% $P = 0.03$). Likewise, group A presented lower values of bone mineral density at femoral site, although it did not reach statistical significance (0.67 vs 0.73, $P = 0.07$). Significant correlations were observed between 25 OHD and femoral mineral density ($r = 0.331$, $P = 0.01$), and serum PTH ($r = -0.233$, $P = 0.03$). Parathyroid adenoma weight correlated with serum calcium ($r = 0.404$, $P < 0.001$), serum phosphate ($r = -0.243$, $P = 0.03$), and PTH ($r = 0.523$, $P < 0.001$). No biochemical/pathological features were suggested to influence in the localization studies.
Conclusions
Vitamin D deficiency is a common disorder in patients with HPTP. It seems to lead to more severe bone disease. Our results suggest that there is not an effect of vitamin D deficiency on parathyroid tumor growth.

Milk alkali syndrome & soft tissue calcification in a patient with a history of cancer

Enis Mumdzic[1,2] & Zayd Merza[1]
[1]Barnsley Hospital NHS Foundation Trust, Barnsley, United Kingdom; [2]University of Sheffield, Sheffield, UK.

A 61-year-old female, with a previous history of left nephrectomy for papillary renal cell carcinoma, presented with lethargy. Her initial blood tests revealed an

adjusted calcium of 4.26 mmol/l (normal range 2.2–2.6) associated with acute renal impairment (creatinine 432 μmol/l, urea 25 mmol/l) and low PTH of 9 ng/l (normal range 20–75). Following rehydration with IV fluids and IV pamidronate administration, her adjusted calcium normalised to 2.37 mmol/l. The initial impression was that her hypercalcaemia was most likely malignancy related. Imaging including CXR, renal US, CT scan of thorax, abdomen, pelvis and MRI brain and whole spine were all unremarkable. A bone isotope scan revealed abnormal increased uptake over both hemithoraces suggestive of soft tissue calcification. On further questioning, it appeared that the patient had been taking a full packet (36 tablets) of Setlers antacid (calcium carbonate 500 mg per tablet) per day for the previous 6 weeks for indigestion indicating her hypercalcaemia was due to Milk Alkali Syndrome. The medication was stopped. Three months later, a repeat bone isotope scan, showed that the increased uptake over the right hemithorax had resolved with reduced intensity over the left hemithorax. Several months later her calcium levels remained normal. About 90% of cases of hypercalcaemia are caused by primary hyperparathyroidism or malignancy, however, this case illustrates the importance of considering less common causes of hypercalcaemia even in a patient with a history of cancer.

Management of parathyroid adenomas

Halwani Chiraz, Zoghlami Imène, Zgolli Cyrine, Akkari Khmaies & Ben Mhamed Rania
ENT Department – Military Hospital, Tunis, Tunisia.

Introduction

Preoperative localization of parathyroid adenomas still remains a problem, despite advances in imaging of the parathyroid gland. The purpose of our presentation was to present our attitude in the diagnosis and the treatment of parathyroid adenomas and in case of recurrence.

Method

Our study includes 33 cases of primary hyperparathyroidism treated in our department, during a period of 15 years (2002–2017). All patients were referred from the endocrinology department after the biological diagnosis was made and the surgical indication was discussed.

Results

The average age was 55 years old with extremes of 20–80. They were 24 women and 9 men. Patients presented with complaint of asthenia, polyuria, polydipsia associated with bone pain in 17 cases. All our patients were systematically explored by cervical ultrasonography, Thallium-Technetium scintigraphy in two cases and 99Tc-sestamibi in 31 cases. The preoperative localization of the adenoma was done in 28 cases. 99Tc-sestamimbi scintigraphy revealed parathyroid hypertrophy in 26 patients and perfectly localized them. Thallium-Tc scintigraphy was helpful in one patient, while it missed a 15 mm right superior adenoma in another patient. Cervical ultrasonography showed same result with surgery in 21 patients. Cervico mediastinal CT scan was performed in five cases and MRI in one case. Peroperatively, double localization was noted in two patients. The efficiency of surgery was confirmed by a postoperative parathyroid hormone level monitoring. Surgical revision was necessary in three cases, for persistence of elevated parathyroid hormons levels (In one case it was a 1.2 cm adenoma found in left retrovascular position, in the second case it was a 0.8 cm adenoma localized in the the tracheoesophageal groove and the last case it was an intrathymic 1.5 cm adenoma). Postoperatively, a case of chondrocalcinosis was noted in one patient, severe hypocalcemia at 1.7 mmol/l was noted in a patient with a tetany crisis.

Conclusion

In terms of parathyroid adenomas, a well detailed preoperative imaging done by an experienced radiologist is of great help for the surgeon but does not necessarily lead to a better success rate compared to conventional bilateral neck surgical exploration.

Recurrent hyperparathyroidism: parathyroid carcinoma or parathyromatosis?

Isaic Alina[1], Varcus Flore[1,2], Cornianu Maria[1], Golu Ioana[1] & Vlad Mihaela[1,2]
[1]Timisoara County Hospital, Timisoara, Romania; [2]University Of Medicine and Pharmacy, Timisoara, Romania.

Recurrent hyperparathyroidism (HPT) refers to reappearance of hypercalcemia after a normocalcemic period of at least 6 months post-parathyroidectomy. Parathyroid carcinoma is a rare cause of primary hyperparathyroidism (pHPT), accounting for 0.4–5.2% of cases. Parathyromatosis is defined as small nodules of hyperfunctioning parathyroid tissue scattered in the soft tissues of the neck and/or mediastinum. We describe two cases with recurrent hypercalcemia after surgical interventions for pHPT.

Case 1: A male patient, MI, 47 yo, had recurrent hypercalcemia despite three parathyroidectomies. At first presentation, his labs were Ca = 15.4 mg/dl, PTH = 340 pg/ml. Sestamibi parathyroid scintigraphy and MRI scan of the neck showed an upper left parathyroid adenoma. It was removed in 2012 and pathology was consistent with adenoma. He remained normocalcemic for 3 years, and then his hypercalcemia recurred. The patient underwent surgery for the second time, when unfortunately the recurrent left nerve was accidentally cut. In November 2016, he underwent a third surgical neck exploration and pathology indicated a parathyroid carcinoma. Postoperatively, the calcium was within the normal range for 3 months. At the last evaluation in 2017, Ca = 12.3 mg/dl, PTH = 219.5 pg/ml (NR:7.5–53.5). MRI scan showed two nodules: one located left paratracheal area and one behind the left sternocleidomastoid muscle. He began medical management with alendronate and the fourth surgery was scheduled.

Case 2: A male patient, IB, 45 yo, was admitted in our Clinic in May 2017, due to recurrent hyperparathyroidism. Laboratory data when patient was diagnosed with pHPT for the first time indicated Ca = 14.4 mg/dl, PTH = 2000 pg/ml due to a lower left parathyroid adenoma. He was operated in 2012 and adenoma was confirmed by pathology. After 5 years he presents with: Ca = 16.7 mg/dl, PTH = 5000 pg/ml (NR:12–65). Sestamibi parathyroid scintigraphy and ultrasound exam showed recurrence. He underwent surgery for the second time and pathology indicated a parathyroid carcinoma. Both patients were males, with benign disease after first surgery and without any renal disease. None of them presented local or distant metastasis. Regarding the origin of parathyromatosis there are three theories we took into account: it is a low-grade parathyroid malignancy, it results from seeding of the parathyroid tissue during surgery for pHPT or it is an overgrowth of an embryologic rest. In conclusion, in some cases, it should make a distinction between a locoregional metastatic parathyroid carcinoma with multiple implants and paratyromatosis.

Prenatal hypophosphatasia with severe skull bone deficits report of a case

Vassiliki Sideri[1], Feneli Karachaliou[2], Helen Kapsabeli[3], Artemis Doulgeraki[4], Anna Dakalaki[1] & Vassiliki Papaevangelou[5]
[1]Neonatology Department, Attikon University Hospital, Athens, Greece; [2]Pediatric Endocrinology Unit, Attikon University Hospital, Athens, Greece; [3]Neonatology Department, Attikon University, Athens, Greece; [4]Department of Bone and Mineral Metabolism, Institute of Child Health, Athens, Greece; [5]Pediatric University Department, Attikon University Hospital, Athens, Greece.

Hypophosphatasia (HPP) is a rare inherited disorder caused by loss-of-function mutations in the tissue-nonspecific alkaline phosphatase (TNSALP) gene. HPP B is a multisystemic B disorder with a predominantly B skeletal phenotype, with a clinical spectrum ranging from high lethality in early onset (< 6 months) HPP to mild late-onset presentations. HPP skeletal disease in utero was thought to predict a lethal outcome. However a benign prenatal form (PB HPP) with a mild postnatal course has been emphasized in several reports. We report the case of a girl born full term with absent parietal bones, severe deficits in temporal and occipital bones and widely separated frontal and lambdoid sutures. There was also absence of the nasal bone and severe hypoplasia of the clavicles. No respiratory support was required. The laboratory investigation revealed low levels of ALP (44 U/L-77 U/L, ref. range 115–460 U/L) with normal levels of calcium and phosphorus in blood and urine, normal serum magnesium, PTH and 25(OH) D levels. The TNSALP gene was analyzed by PCR and direct sequencing. A heterozygous TNSALP variant c.542C > T was detected, which has been predicted as pathogenic and has been identified in compound heterozygosity in two cases of infantile HPP and in heterozygosity in a patient with adultHPP. On re-evaluation 6 months later, there is no improvement of her bone deficits, with persistently low alkaline phosphatase and calcium levels at the upper normal range. In light of this clinical course, Asfotase alfa has been considered as a possible treatment due to the persistence of extended skull deficits.

Clinical outcome in primary hyperparathyroidism: A 10-year tertiary care centre experience in Pakistan

Shehla Tabassum[1], Ehsun Naeem[1], Javed Iqbal[2] & Najmul Islam[1]
[1]Aga Khan University, Karachi, Pakistan; [2]Health Department, Lahore, Pakistan.

Background
Primary hyperparathyroidism (PHPT) is characterized by abnormal regulation of PTH secretion by calcium. The most common clinical presentation of PHPT is asymptomatic (80% cases), followed less likely by the classical symptoms of bones, stones, abdominal moans, and psychic groans. The diagnosis of PHPT is usually first suspected because of the finding of an elevated serum calcium concentration along with a rise in Parathyroid hormone (PTH) level. Serum phosphorus levels are usually normal to high in patients with PHPT. These investigations are then followed by the localization studies such as Ultrasound Neck, Sestamibi scan or CT/MRI scan. Parathyroid adenoma resection is the only definitive treatment to cure the disease.
Objectives
This study was designed primarily for the evaluation of diagnostic characteristics and management outcomes of PHPT over a span of 10 years at a tertiary care hospital in Pakistan.
Methods
It was a Descriptive cohort study. Total 55 patients with biochemical and radiological diagnosis of PHPT were included in study between January, 2007 to December, 2016. Patients' medical record files were reviewed & data recorded.
Results
Of the 55 subjects, with mean age of 39.68 ± 14.35 years, 44 (80%) were females while 11 (20%) were males. The patients presented at a mean duration of 1.20 ± 3.12 years after onset of symptoms. The most frequent complaint was joint & bone pains noted by 49 (89.1%) pts. SestaMIBI scan proved the culprit lesion to be on the right side of neck in 24 (43.6%) pts, left side in 22 (40%) pts and bilateral in 7 (12.8%) pts. Overall, 40 (72.7%) patients underwent surgical resection of parathyroid adenoma, out of which 33 (82.5%) achieved remission while the rest had to undergo repeat surgery to achieve remission. Fifteen (27.3%) patients refused to opt surgical option, thus not achieving remission. Alendronate was the most commonly adopted medical treatment.
Conclusion
To the best of our knowledge, this important endocrinal entity of PHPT had never been studied in Pakistan in terms of estimating the prevalence of its clinical profile, understanding the diagnostic characteristics in our set-up and observing the management outcome. PHPT most commonly presents with skeletal manifestations (80.1%) in our area. Surgical adenoma resection is followed by the documentation of remission in 82.5% pts. With the continuously improving surgical skills, we expect that the figures attaining remission after primary surgical resection will rise in the decades to come.

Primary hyperparathyroidism-localisation studies' sensitivity

Sabina Elena Oros[1,2], Robert Andrei Gongu[1], Laura Alina Diaconescu[2], Mirela Ivan[2], Daniel Grigorie[1,2], Emilia Gudovan[2], Anda Dumitrascu[2], Dan Hortopan[2] & Andrei Goldstein[2]
[1]Carol Davila University of Medicine and Pharmacy, Bucharest, Romania; [2]C.I. Parhon National Institute of Endocrinology, Bucharest, Romania.

Primary hyperparathyroidism can be caused by adenoma, adenocarcinoma, parathyroid hyperplasia or ectopic parathyroid glands. The American Association of Endocrine Surgeons Guidelines for Definitive Management of Primary Hyperparathyroidism recommends imaging as a helping tool in locating the causative lesion rather than a must for diagnosis. Experienced surgeons rely on the intraoperative localisation of the lesion. Pre surgery localisation helps for a minimally invasive approach. Technetium sestamibi scintigraphy, cervical-mediastinal CT and cervical region ultrasound are the most frequent used techniques but their sensitivity and specificity differs. In our center surgeons appreciate a pre-surgery localisation. We present the results of a retrospective pre surgery localisation study, conducted in C.I Parhon National Institute of Endocrinology, Bucharest, which enrolled 466 subjects with primary hyperparathyroidism, hospitalized between 01.08.2015 and 31.07.2017. Anterior cervical region ultrasound was performed to all subjects, 33% underwent scintigraphy, and 60% were CT scanned. In our hospital, sensitivity for cervical ultrasound was 59%, 50% for technetium scintigraphy and 76% for CT. In conclusion, we use at least two pre surgery localisation imaging technique. The most frequently used one is ultrasound doubled either by cervical CT or scintigraphy. Choosing the second imaging technique depends of the expertize of the center.

Characterization of the parathyroid hormone requests and hyperparathyroidism etiologies in a tertiary hospital

Vânia Gomes, Sampaio Matias, Florbela Ferreira & Helena Proença
Hospital de Santa Maria, Centro Hospitalar Lisboa Norte EPE, Lisboa, Portugal.

Introduction
Hyperparathyroidism is a disease characterized by excessive secretion of parathyroid hormone (PTH). There are three main etiologies: primary (PHPT), secondary (SHPT) and tertiary hyperparathyroidism (THPT). PHPT is characterized by abnormal regulation of PTH secretion by calcium, resulting in hypersecretion of PTH relative to the serum calcium concentration. SHPT is the overproduction of PTH in context of hypocalcemia, most frequently because of vitamin D deficiency and/or chronic kidney disease (CKD). THPT is a state of excessive secretion of PTH after longstanding SHPT and resulting in hypercalcemia.
Objectives
To evaluate the PTH requests and the causes of hyperparathyroidism in a central hospital.
Methods
Retrospective study of PTH measurements and corresponding patients' records performed between May 2016 and June 2017. Hyperparathyroidism was defined as PTH >72 pg/ml, determined by electrochemiluminescence immunoassay. CKD was established according to the Kidney Disease Outcomes Quality Initiative guidelines. Statistical analysis was performed with SPSS software, version 20.
Results
A total of 1085 PTH measurements were recorded, corresponding to 955 patients. Of these, 349 had hyperparathyroidism. Excluding patients with insufficient clinical information ($n=22$), there were 327 patients (62.1% female; 68.7 ± 0.9 years), with the following diagnosis: PHPT, $n=28$ (78.6% female, 64 ± 2.6 years); SHPT $n=296$ (60.5% female, 69.4 ± 1 years), THPT $n=2$ (100% female, 42.5 ± 17.5 years) and 1 case of familial hypocalciuric hypercalcemia (male, 49-year-old). The causes of SHPT were: chronic kidney disease (CKD, 122); vitamin D deficiency (107); combined CKD and vitamin D deficiency (64); Paget's disease (2) and pseudohypoparathyroidism (1). Patients with CKD (186) presented the following distribution: stage 3, $n=69$; stage 4, $n=63$ and stage 5, $n=54$. In the patients with hyperparathyroidism, the PTH measurement was requested by different departments: Internal medicine (127), Nephrology (69), Rheumatology (38), Endocrinology (38), Haematology (13), Infectious diseases (10), Pneumology (9), Gastroenterology (4), Neurology (4), Cardiology (4), Gynaecology (3), Oncology (3), Surgery (3) and Urology (2).
Conclusions
SHPT was the most prevalent etiology of hyperparathyroidism, particularly the one secondary to CKD, as expected because of the high prevalence of CKD in general population. Different medical specialties requested the measurement of PTH. Probably, in our institution, this is a laboratory test excessively requested, increasing medical costs without benefits for the patients.

Tertiary hyperparathyroidism associated with prolactinoma – case report

Cristina Corina Pop-Radu[1,2]
[1]University of Medicine and Pharmacy, Targu Mures, Romania; [2]Mures County Hospital, Targu Mures, Romania.

Introduction
Tertiary hyperparathyroidism (HPT) occurs most commonly in the setting of renal transplant where patients with secondary HPT continue to have elevated PTH levels after receiving a renal allograft. This disease is observed in up to 30%

of kidney transplant recipients. This paper will include a case report and a review of epidemiology and pathophysiology, complications and clinical findings, indications for treatment, and the drugs currently available to treat this condition.
Case report
The 35-years-old woman with a kidney transplant history (2006), subsequently with kidney graft rejection (2014), hemodialysis for 3 years, has addressed to our department in March 2017 for amenorrhea – galactorrhea syndrome (last menstrual cycle 10 years ago). The serum levels of TSH was slightly elevated (8.8 UI/l) with normal FT4, prolactin was 263 ng/ml and FSH, LH, Estradiol, IGF1, basal Cortisol at 8 a.m. were normal. The evaluation of phospho-calcic metabolism emphasized normocalcemia, hyperphosphatemia with elevated intact PTH levels (1050 pg/ml), normal serum levels of 25-hydroxy vitamin D (30 ng/ml) and increased levels of alkaline phosphatase (772 U/L). An ultrasound scan of the neck showed the hyperplasia of three parathyroid glands. 99mTc sestamibi scintigraphy was negative. Bone densitometry (DEXA L1-L4) revealed osteopenia. Pituitary MRI has described a microadenoma. Medical treatment was initiated with Cabergoline and subtotal parathyroidectomy was recommended. Long term follow-up is required for monitoring related complications.
Keywords: tertiary hyperparathyroidism, prolactinoma, subtotal parathyroidectomy.

Effect of bariatric surgery on free vitamin D3 levels

Montserrat Marques-Pamies[1], Silvia Pellitero[1], Marisa Granada[1], Cecilia Soledad Santillan[1,2], María López[1] & Manel Puig-Domingo[1]
[1]Endocrinology Department, Germans Trias i Pujol University Hospital, Badalona, Spain; [2]Endocrinology Department, Oñativia Hospital, Salta, Argentina.

Total vitamin D levels are decreased in obese patients probably due to an increased volume of distribution mechanism. Recently introduced direct assays allow the measurement of free-vitaminD3 levels (fvitD3). Few data are available regarding fvitD3 levels in obese people and the effect of bariatric surgery upon its circulating concentration. We aimed to evaluate fvitD3 in a cohort of obese patients before and after bariatric surgery treatment and its relationship to phosphocalcic parameters.
Methods
Retrospective study including 24 patients (48 y, 20 women, initial weight of 124.66 ± 30.76 kg, waist 131.65 ± 14.19 cm and BMI 48.16 ± 10.73 kg/m^2) treated with sleeve gastrectomy. All patients received standard supplementation with daily 800IU of colecalciferol p.o. after surgical procedure. Evaluation was done before and one year after the intervention and samples for measurement were collected during summertime period. Data regarding body weight, BMI, waist, lipid profile, albumin-corrected calcium, phosphate, PTH, 25-OH-vitaminD and fVitD3 was recorded before and after surgery.
Results
Before surgery, 25-OH-vitaminD in obese patients was 22.08 ± 11.54 ng/ml and fvitD3 was 5.28 ± 2.29 pg/ml; 25-OH-vitaminD and fvitD3 levels showed a positive correlation between them ($r_s = 0.7$, $P < 0.0001$). 25-OH-vitaminD showed an inverse correlation with PTH levels ($r_s = -0.46$, $P < 0.04$) but there was no correlation with fvitD3. Neither 25-OH-vitaminD, nor fvitD3 correlated with weight or BMI before surgery. One year after bariatric surgery (waist 102.64 ± 15.41 cm, BMI 34.82 ± 9.0 kg/m^2), mean 25-OH-vitaminD was 27.31 ± 11.83 ng/ml (p = n.s vs pre-surgery) and fvitD3 increased to 6.64 ± 2.25 pg/ml ($P = 0.03$ vs pre-surgery). There was no statistical correlation between the percent change of fvitD3 and the magnitude of weight loss although absolute concentrations of fvitD3 and 25-OH-vitaminD were inversely correlated with final weight ($r_s = -0.60$, $P = 0.002$ and $r_s = -0.46$, $P = 0.02$ respectively).
Conclusion
fvitD3 is correlated with 25-OH-vitaminD either, pre and post bariatric surgery in morbidly obese patients and it increases 1 year after surgical procedure. Weight and both 25-OH-vitaminD and fvitD3, reestablished a negative correlation after surgery, being the last one of higher magnitude in coincidence with its increased circulating concentrations in the follow up period. This finding may be related with a postsurgical reduction of the kidnaping effect of adipose tissue and affects preferentially the free form rather the total vitD.

Utility of contrast-enhanced ultrasound in preoperative evaluation of primary hyperparathyroidism

Paola Parra Ramirez, Patricia Martin Rojas Marcos, Antonio Santiago Hernando, Arturo Lisbona Catalan, Alejandro Casto Calvo & Cristina Alvarez Escolá
La Paz University Hospital, Madrid, Spain.

Purpose
The aim of this study was to evaluate the sensitivy of contrast-enhanced ultrasound (CEUS) in the detection of pathological parathyroid gland in patients with primary hyperparathyroidism in comparison to the 99m-MIBI-SPECT scintigraphy.
Methods
29 patients consecutive (22 female, 7 male) with biochemically confirmed primary hyperparathyroidism, who underwent preoperative imaging with Technetium 99m-MIBI-SPECT scintigraphy and CEUS and subsequent successful parathyroidectomy over a 4 year period were reviewed. All patients were investigated by the same radiologist who was blinded to the result of the scintigraphy.
Results
On pathologic examination, 31 abnormal glands were confirmed. All the glands were adenomatous. CEUS revealed a sensitivity of 62.1% (95% CI 42.3–79.3) for detection of single-gland disease in comparison to 72.4% (95% CI 52.7–87.3) for 99m-MIBI-SPECT scintigraphy. Moreover using CEUS, double adenomas could be detectect in 1 of 2 cases. Alll patients showed normal serum levels of calcium and parathyroid hormone serum levels 3 months after parathyroidectomy.
Conclusion
In our study, CEUS does not replace scintigraphy in localization of pathological parathyroid glands in patients with primary hyperparathyroidism.

In situ preservation of parathyroid glands in thyroid surgery for prevention of hypoparathyroidism

Nada Santrac[1] & Radan Dzodic[1,2]
[1]Surgical Oncology Clinic, Institute for Oncology and Radiology of Serbia, Belgrade, Serbia; [2]Medical Faculty, University of Belgrade, Belgrade, Serbia.

Introduction
Hypoparathyroidism (HPT) is one of the most frequent and severe complications of thyroid surgery. It is caused by intraoperative damage, devascularization or accidental removal of the parathyroid glands (PTG). The incidence of postoperative HPT is directly proportional to surgery extent and surgeon's experience. However, it can be significantly reduced by excellent surgical technique. The authors present original technique of *in situ* preservation of PTGs during thyroid surgery and 40-years-experience results in postoperative HPT.
Methods
Dzodic's original surgical technique (personal *PhD thesis*, 1993; published in *J BUON*, 2017) focuses on meticulous capsular dissection and ligation of blood vessels close to thyroid capsule. The key step is preservation of the middle thyroid, Kocher's, vein trunk, as well as vein branches that accompany posterior branch of superior thyroid artery and inferior thyroid artery trunk. The use of methylene blue dye for sentinel lymph nodes biopsy facilitates identification of PTGs during removal of thyroid gland, as well as central neck dissection (in case of thyroid carcinomas), since PTGs are not colored in blue, unlike central lymph nodes.
Results
After 40 years of experience in thyroid surgery, and several thousands of preserved PTGs using *Dzodic's original surgical technique*, a total prevalence of permanent HPT in the personal series is less than 0.5%.
Conclusions
Dzodic's original surgical technique of venous trunk's preservation, along with so far known surgical steps for *in situ* preservation of PTGs on arterial pedicles, provides good outcome for patients after total thyroidectomy, with or without central neck dissection, regarding HPT as one of the most severe complications of thyroid surgery. We find methylene blue dye of great importance, not only for sentinel lymph nodes biopsy, but also for avoiding accidental removal of unrecognized PTGs.

P257

Primary hyperparathyroidism after thyroid surgery and autotransplantion of parathyroid gland

Bernardo Marques, Raquel Martins, Joana Couto, Jacinta Santos, Teresa Martins & Fernando Rodrigues
Endocrinology Department, Portuguese Institute of Oncology of Coimbra FG, EPE, Coimbra, Portugal.

Introduction
Multiple endocrine neoplasia type 2A syndrome (MEN 2A) is caused by a germline mutation in the RET proto-oncogene and its phenotype includes medullary thyroid cancer, pheochromocytoma and primary hyperparathyroidism (PHPT). Parathyroid reimplantation in the sternocleidomastoid muscle or in the brachioradial muscle can be performed in case of intraoperative lesion of the parathyroid glands. In some cases, PHPT may occur due to the proliferation of autotransplanted parathyroid tissue, which may hinder its diagnosis.
Case report
Female patient, 55 years old, with personal and family history of MEN2A, with medullary thyroid carcinoma, but no evidence of pheochromocytoma or PHPT. She underwent total thyroidectomy for medullary thyroid carcinoma and remained under surveillance and in remission for 20 years (levels of calcitonin, PTH, serum calcium and plasma metanephrines within the normal range). Afterwards, she developed PTH-dependent hypercalcemia, with serum calcium of 11.1 mg/dl (8.6–10.5 mg/dl), PTH 194.3 pg/ml (12–67 pg/ml) and 24 h urine calcium of 430 mg (80–300 mg). A cervical ultrasound was performed, which showed a 20 mm nodule, anterior to the right sternocleidomastoid muscle and a parathyroid scintigraphy, which described a moderate uptake in the right lateral cervical region, raising questions regarding its etiology. We reviewed the patients' medical charts and found out that the surgical team performed an autotransplantation of the right lower parathyroid in the sternocleidomastoid muscle at the same time of the thyroidectomy, due to likely intraoperative lesion of the parathyroid glands. We decided to perform a fine needle aspiration biopsy of the nodule, which was compatible with parathyroid tissue and PTH measurement in needle washout, which was 33 363 pg/mL. She underwent parathyroidectomy and the histological report was compatible with parathyroid adenoma. The patient is currently in remission, with serum calcium of 8.8 mg/dl and PTH 63.6 pg/ml.
Discussion
Patients with MEN2A who develop PHPT after thyroidectomy and parathyroid gland autotransplantation might be a diagnostic challenge. At reoperation, only enlarged parathyroid glands should be excised. This is a rare case that highlights the importance of clinical evaluation and preoperative localization imaging tests as well as long-term surveillaince of serum calcium and PTH levels.

Metabolic encephalopathy following intravenous zolendronate for hypercalcaemia of malignancy: a perfect storm

Mohit Kumar
WWL Foundation Trust, Wigan, Greater Manchester, UK.

A 56 year old lady was diagnosed with cancer of unknown primary after the discovery of liver metastases. Prior to the commencement of EOX chemotherapy (epirubicin, oxaliplatin and capecitabine) she was given a dose of 4 mg zolendronic acid for hypercalcaemia of malignancy. Three weeks later she presented to our hospital with a history of rapid decline and reduced oral intake, with associated diarrhoea. She had reduced GCS and hypotension. Initial investigations revealed an acute kidney injury (Ur 74.4 mmol/l, Cr 461 umol/l) with normal potassium, severe hypocalcaemia at 1.10 mmol/l (adjusted) and magnesium 0.41 mmol/l (0.5–0.8). Electrocardiogram showed severe QTc prolongation at 587ms. She was managed on intensive care with intravenous antibiotics, fluids and electrolyte replacement. PTH was appropriately elevated at 32.8 pmol/l (1.5–7.6) with Vitamin D 27 nmol/l. Despite improving metabolic status her GCS remained persistently low; subsequent investigations revealed a normal MRI brain scan, lumbar puncture and paraneoplastic antibiotics. She was diagnosed with metabolic encephalopathy secondary to hypocalcaemia; over a period of four weeks she gradually improved with continued electrolyte correction. Hypercalcaemia of malignancy is found in up to 44% of patients with malignancy, with a number of potential mechanisms involved. Intravenous fluids and bisphosphonates remain amongst the mainstays of treatment. Hypocalcaemia is a recognised complication of zolendronate therapy, with trials suggesting up to 1% of patients may develop a significantly low calcium. The development of renal failure is both a potential complication of this treatment as well as a potentiator of it. Our case illustrates the rare occurrence of metabolic encephalopathy as a consequence of zolendronic acid treatment, risk factors of hypocalcaemia as well as highlighting the importance of giving appropriate education and arranging robust follow-up when patients treated with intravenous bisphosphonates are discharged.

Primary hyperparathyroidism: a rare cause of hypertension?

Ana Lopes, Isabel Palma, Sofia Teixeira & Helena Cardoso
Serviço de Endocrinologia, Centro Hospitalar do Porto, Porto, Portugal.

Backgroud
Primary hyperparathyroidism is the most common cause of hypercalcemia, which is associated with an increased frequency of hypertension. However, there are no data on the prevalence of primary hyperparathyroidism in patients who present with hypertension.
Clinical case
We present the case of a 40-year-old woman with a history of hypertension for ten years. In 2017 she was referred for evaluation of hypercalcemia. The patient denied any symptoms related to hypercalcemia. Laboratory testing revealed calcium 2.77 mmol/l (Ref. 2.09–2.42), phosphate 0.64 mmol/l (Ref. 0.87–1.45), parathormone *(*PTH) 121.5 pg/ml (Ref. 15–65), creatinine 0.78 mg/dl (Ref. 0.5–0.9) and vitamin D 72 nmol/l. The patient had no evidence of renal lithiasis on renal ultrasound. Bone densitometry was normal. Although cervical ultrasound was normal, sestamibi scan revealed a left retrosternal lesion, suggestive of a parathyroid adenoma. A CT scan of the neck confirmed a suprasternal oval expansive lesion, in the anterior and superior mediastinum, with 21×11 mm, suggestive of an ectopic parathyroid adenoma. The patient denied family history of hypercalcemia. She is waiting for parathyroid surgery.
Conclusion
Most patients with primary hyperparathyroidism are asymptomatic, but others may present with symptoms related to chronic hypercalcemia, such as hypertension. Hypertension may or may not remit after successful parathyroidectomy. We will follow this patient to evaluate hypertension remission.

Atypical Parathyroid adenoma in a young individual, presented with nephrocalcinosis

Marjeta Kermaj, Vilma Cadri, Ruden Cakoni, Dorina Ylli, Thanas Fureraj, Edlira Hoxha, Ermira Muco, Anisa Zeqja & Agron Yll
UHC 'Mother Tereza', Tirana, Albania.

Introduction
Primary hyperparathyroidism (PHPT) is a rare disorder among young adults. Classic manifestations of PHPT, such as nephrocalcinosis, nephrolithiasis, are rarely seen today.
Case report
We refer the case of a young male, 25 years old, presented in emergency unit with: headaches, lumbago, epigastric pain, weight loss (5 kg during six last months), polydipsia-polyuria. Medical history: He has been diagnosed with nephrolithiasis and gastritis a year ago. Negative family history. Blood biochemistry: Ca^{2+} level 2 mmol/l (N1.13–1.32 mmol/l), total calcemia 17.6 mg/dl (N 8.5–10), Phosphorus 2 mg/dl, Mg^{2+}1.5 mg/dl, Hct 35,3%, Hgb11.3 g/dl, WBC: 5900/mm^3, urea: 69 mg/dl, creatinine 1.6 mg/dl, sodium 144 mmol/l, potassium 3.7 mmmol/l, glucose 83 mg/dl, ALT 11U/l, AST 14U/l, GGT15U/l, LDH 140 U/l, Bilirubin Total 0.4 mg/dl, Chol 118, Tg 98, ferritinemia 89 mg/dl,TSH 1.49 ui/ml, Protein total 6.8 mg/dl. HGA resulted normal. Kidney ultrasonography: kidneys with calcifications of the pyramids, decreased cortico-medullary differentiation. Fundus oculi normal. Firstly we thought for chronic renal disease third stage in a subject with nephrocalcinosis. We performed PTH 745 ng/l (N15-65), 25 OH Vitamin D3 (16.3 ng/dl). We suspected a parathyroid gland disease, so we performed, Thyroid ultasonography: Right thyroid lobe normal, Left thyroid lobe with a well-restricted heterogeneous nodus, with internal cystic degenerations of 19×23 mm in the lower medial part. Isthmus normal. Thyroid shintiscan: with a hypofixant zone at the lower part of left thyroid lobe. Parathyroid scintigraphy resulted with parathyroid adenoma located at lower part of left thyroid lobe. Bone densitometry(DXA) showed in the forearm bones, high-risk osteoporosis with Tscore-5.4,osteopenia in femoral head and L4 lumbar vertebrae expressed osteoporosis,genetic testing was not done. He was treated with fluids i/v, diuretics, antihypertensives drugs. After diagnostic work-up,we concluded to PHPTcaused by parathyroid adenoma and the patient underwent surgical intervention with left hemithyroidectomy and left lower parathyroidectomy. Pathological examination: atypical parathyroid adenoma. After surgery he was treated with calcium orally and he was follow-up with PTH

level, calcium level and DXA.We think that his problem was resolved by surgery. He continues to be stable, under nephrologist and endocrinologist follow up.
Conclusion
PHPT is a rare situation in a young person. A nephrocalcinosis can be related to PHPT. Given the low frequency of atypical parathyroid adenoma,especially in young individuals, physician should always raise awareness of possible PHPT as cause of nephrocalcinosis and kidney injury, for early diagnosis and treatment. Nephrocalcinosis may be the presenting feature of atypical parathyroid adenoma,our case confirmes that.

Is there a relationship between mean platelet volume as a cardiac marker and serum calcium levels in patients with parathyroid disease

Murat Dogan[1], Merve Lehimcioglu[1], Senay Durmaz[2], Askin Gungunes[2], Ayse Carlioglu[3] & Kubra Oklu[1]
[1]Department of Internal Medicine, Kirikkale, Turkey; [2]Department of Endocrinology and Metabolism, Kirikkale, Turkey; [3]Department of Endocrinolog, Erzurum, Turkey.

Introduction and aims
Mean platelet volume (MPV) is a newly indicator of platelet activation which was associated with atherosclerosis. There are limited studies in the literature about MPV levels in patients with both hypoparathyroidism and hyperparathyroidism. This preliminary study, we aimed to investigate a relationship with MPV and serum PTH and calcium levels in patients with disorder of calcium metabolism.
Materials and methods
Fourty-nine hyperparathyroid patient (56.8±13.0 year), 13 hypoparathyroid patients (48.5±14.2 year) and 18 healthy subjects (45.2±14.2 year) were included in our study. All data associated with calcium metabolism including serum total calcium, phosphor, 25-OH vitamin D, parathyroid hormone levels were compared to study groups. All complete blood count, biochemical and hormonal analysis were performed by automatic analyzer.
Results
Serum total calcium levels were different between study groups (10.3±0.8 mg/dl in hyperparathyroid patient, 8.3±1.1 mg/dl in hypoparathyroid patients, and 9.3±0.4 mg/dl in control group, $P=0{,}0001$, respectively). There was no significant difference in MPV value (9.7±0.8 fl in hyperparathyroidism, 9.8±0.9 fl in hypoparathyroidism, 9.5±0.5 fl in control group, $P>0.05$, respectively]. In addition, there was not any correlation between MPV and all studied parameters of associate of calcium metabolism. Preliminary results was presented in this article, but we continue to the study.
Conclusions
Our findings do not support the existence of a relationship between MPV and calcium metabolism. However, preliminary results was presented in this article, we continue to the study.

Hypercalcemia, hypercortisolism and multiple vertebral fractures in a 49-year-old man

Paula Fernandez-Trujillo-Comenge[1], Agnieszka Kuzior[1], Manuel Esteban Nivelo-Rivadeneira[1], Ana Delia Santana-Suarez[1], Carmen Acosta-Calero[1], Claudia Arnas-Leon[2], Sara Quintana-Arroyo[2] & Francisco Javier Martinez-Martin[3]
[1]Endocrinology and Nutrition Department, University Hospital of Gran Canaria Doctor Negrin, Las Palmas de Gran Canaria, Spain; [2]Endocrinology and Nutrition Department, Hospitales San Roque, Las Palmas de Gran Canaria, Spain; [3]Outpatient Hypertension Clinic, University Hospital of Gran Canaria Doctor Negrin, Las Palmas de Gran Canaria, Spain.

Introduction
The most frequent causes of hypercalcemia in the general population are primary hyperparathyroidism and malignancies. However, we must sometimes consider other causes, such as Cushing's syndrome.
Clinical case
A 49-year-old man who was being assessed for hypertrophic cardiomyopathy was referred to our Endocrinology Clinic in order to investigate the incidental finding of hypercalcemia (11.08 mg/dl) with high PTH (84.6 pg/ml), hypophosphatemia (1.84 mg/dl) and low 25-hydroxy vitamin D (11.9 ng/ml). He was a former smoker with history of hypertension, type 2 diabetes mellitus, dyslipidaemia and sensorimotor axonal polyneuropathy. He was unable to stand upraight and walked with a cane because of limb weakness and intense lumbar pain. He had lost 10 kg in the previous month, and complained of asthenia and constipation with haematochezia. Examination revealed BMI 29.07 kg/m^2, BP 173/99 mmHg, aortic systolic murmur, skin bruising, neck hump and proximal limb muscle atrophy. Amyloidosis and multiple myeloma were ruled out. Bone densitometry and lumbar CT showed severe osteopenia and multiple vertebral fractures. Neck ultrasound showed a lesion suggestive of parathyroid adenoma, but the parathyroid scan showed no evidence of hyperparathyroidism. Fasting plasma cortisol was 38.6 µg/dl, and 51 µg/dl after 1 mg overnight dexamethasone suppression test. The 24 h urinary free cortisol level was 718 µg/dl. He was admitted in our Endocrinology Department for Cushing's syndrome workup. The lab tests: ACTH 98.30 pg/ml, FSH 1.28 mUI/ml, LH 0.85 mUI/ml, free testosterone 0.76 mg/dl, FT4 0.62 ng/ml, TSH 0.58 ng/ml prolactine 12.1 ng/dl. A cranial MRI showed a pituitary tumor measuring 1.6×1.6×0.8 cm. The final diagnosis was Cushing's disease and hypogonadism due to a pituitary adenoma. An abdominal scan was performed to evaluate haematochezia and weight loss, and a mass of 1.5×6 cm was found in the rectum along with multiple lesions in the liver suggestive of haemangioma but needing further confirmation.
Conclusion
In this clinical case hypercalcemia was the key symptom which guided us to the final diagnosis of Cushing's disease. This is an unusual presentation, but the typical comorbidities (diabetes, central obesity, dyslipidaemia and hypertension) and complications (bone fractures) were present. With the presence of hyperparathyroidism, pituitary adenoma and a gastrointestinal mass, a MEN-1 syndrome must be considered. This case emphasizes the need for a comprehensive workup of the hypercalcemic patient.

Severe hypercalcemia due to atypical parathyroid adenoma

Bengur Taskiran, Guven Baris Cansu, Orhan Kalayci, Kismet Civi Cetin & Ruya Mutluay
Yunus Emre State Hospital, Eskisehir, Turkey.

Introduction
Primary hyperparathyrodism is due to benign parathyroid adenomas in more than 90% and parathyroid cancer (PC) in less than 1% of cases. There are no definite clinical criteria differentiating PCs and adenomas. Another subtype, parathyroid neoplasm of uncertain potential is also referred as atypical parathyroid adenoma (APA) and share a few histopathologic features common to cancers.
Case
A 47 year old female patient was consulted due to hypercalcemia (total calcium 23.3 mg/dl) and admitted to endocrinology clinic. She was complaining of nausea, vomiting, vague abdominal and skeletal pain, fatigue, and muscle weaknees for 1 month. Her past medical history was nonsignificant. She denied urolithiasis and fracture due to osteoporosis. On physical examination oral mucosa was dry, and thyroid palpable on left side. We suspected PC or another malignancy related hypercalcemia due to severe hypercalcemia. Saline, furosemide, and zoledronate were infused along with subcutaneous calcitonin. Laboratory studies revealed high parathyroid hormone (PTH) (3134 pg/ml), hypercalciuria (381 mg/day), and vitamin D deficiency (8.2 ng/ml). *T* score and *Z* score of femur neck and lumbar spine were −3.5 on DEXA study. 4 days after admission calcium level was normalized. Impaired phosphorus, creatinine, and potassium levels improved with therapy. Neck ultrasound revealed a hypoechoic nodule 32.7×24.0 mm in size without suspicious lymph nodes. Tc-MIBI scan revealed increased uptake. A lobulated heterogenous mass 32×28 mm in size in close proximity to oesophagus was observed on contrast enhanced thorax-neck CT series. Invasion to neighbouring tissues and pathologic lymphadenopathies were absent. Histopathologic evaluation yielded an encapsulated parathyroid adenoma measuring 40×30×20 mm in size and equivocal areas of capsular invasion. Stains for PTH, Cyclin D1, and p53 were positive and negative for TTF-1 (−). Kİ67 was %15. Neither HRPT2 gene mutation analysis nor immunostain for parafibromin were available. After successful operation, PTH dropped to 82.6 pg/ml and a nadir of 19.4 pg/ml. While minimum calcium level was 7.8 mg/dl on 5th day of the operation, ALP reached 555 U/l at maximum. She was eucalcemic at the last time she was seen.
Conclusion
There is no single histologic feature pathognomonic of PC and APAs. APAs may present with severe hypercalcemia and very high levels of PTH similar to parathyroid cancers. The definition vascular invasion is also important. APAs must be kept in mind in differential diagnosis of primary hyperparathyroidism.

Functional hypoparathyroidism secondary to magnesium deficiency in long-term users of proton pump inhibitor: case report

Lilit Egshatyan[1] & Svetlana Mirnaya[2]
[1]Endocrinology Research Centre, A.I. Evdokimov Moscow State University of Medicine and Dentistry, Moscow, Russian Federation; [2]Endocrinology Research Centre, Moscow, Russian Federation.

Introduction
Gastroesophageal reflux disease (GERD) is now widely prevalent around the world, with clear evidence of increasing prevalence in many developing countries. Treatment for most people with GERD includes lifestyle changes and medication. Proton pump inhibitors (PPIs) are a mainstay therapy for all gastric acid-related diseases. Long-term use of PPIs is associated with hypomagnesaemia, hypokalemia, hypocalcaemia, osteoporosis and bone fractures, renal disease, and other. Clinical concerns arise from a small but growing number of case reports presenting PPI-induced hypomagnesaemia as a consequence of long-term PPIs use.
Case report
We present the case of a 56-year-old patient with muscle cramps, violation of cardiac rhythm, lethargy and other caused by hypomagnesaemia (magnesium, 0.31 mmol/l), hypocalcaemia (calcium, 1.82 mmol/l), hypokalemia (kalium, 3.2 mmol/l) and hyperglycemia (6.7 mmol/l) with a low parathyroid hormone level (parathyroid hormone, 0.7 pg/ml). He had GERD and had been using a PPI (omeprazole 20-60 mg/day) since 2005. Physical examination revealed clinical signs of hypocalcaemia, hypomagnesaemia (Chvostek's and Trousseau's signs), hypokalemia. He had electrocardiogram abnormalities (prolonged QT interval, paroxysmal supraventricular tachycardia). After exclusion of possible causes, hypomagnesaemia secondary to PPI was diagnosed and omeprazole was stopping. Hypomagnesemia is often associated with hypokalemia (due to urinary potassium wasting) and hypocalcemia (due both to lower parathyroid hormone secretion and end-organ resistance to its effect). After only magnesium repletion all abnormalities resolved, his symptoms improved. It was shown association between hypomagnesemia and hypocalcemia, hypokalemia, hyperglycemia. A causal relation with PPI use was supported by the recurrence of hypomagnesaemia after re-challenge.
Conclusion
GERD patients using PPI should have their magnesium, kalium and calcium serum levels measured periodically, and non-specific symptoms such as asthenia, paresthesia or life-threatening manifestations (seizures, arrhythmias) should not be neglected.

Utility of ^{11}C-methionine PET/CT in preoperative localization of a parathyroid adenoma in a patient with primary hyperparathyroidism: a case report

Violetta Rosiek & Beata Kos-Kudła
Department of Endocrinology and Neuroendocrine Tumors, Department of Pathophysiology and Endocrinology, Medical University of Silesia, Katowice, Poland.

Introduction
Parathyroid adenoma is the most common cause of primary hyperparathyroidism. Effective preoperative imaging and localizing the parathyroid adenoma is a prerequisite for the surgical treatment. 99mTc-MIBI scintigraphy in combination with ultrasound of the neck are the imaging modalities of choice before parathyroidectomy. However, both have limitations in terms of their efficacy in localizing the adenomas; ^{11}C-Methionine or 18F-Fluorocholine PET/CT has been reported to have utility in such cases.
Case report
We present a case of a 55-year-old woman with a long-lasting history of recurrent nephrolithiasis, and osteopenia, who was diagnosed with primary hyperparathyroidism. Two 99mTc-MIBI SPECT/CT scans were performed (2/2015 and 09/2015), and neither identified the parathyroid adenoma. ^{11}C-Methionine PET/CT was then performed (04/2016), and revealed the parathyroid adenoma as a focal (7×9 mm in size) uptake of the tracer behind the lower part of the right thyroid lobe.
Conclusions
^{11}C-MET PET/CT has utility in preoperative localization of a parathyroid adenoma negative on 99mTc-MIBI scintigraphy in patients with primary hyperparathyroidism, and should be considered as a second-line imaging in such cases.

Ulnar osteoclastoma as first manifestation in primary hyperparathyroidism: case report

Irina Bojoga[1,2], Oana Enache[2], Sorina Martin[1,2] & Simona Fica[1,2]

Background
Nowadays, primary hyperparathyroidism is usually diagnosed incidentally, in asymptomatic patients, while only around 15% of patients present the classical manifestations. Osteoclastoma, a benign bone lesion, is usually the late manifestation of hyperparathyroidism.
Objective
We present the case of a 52 years old female (non-menopausal) recently diagnosed with ulnar osteoclastoma, primary hyperparathyroidism and secondary osteoporosis.
Material and methods
The patient had a history of pathological fracture of right ulna secondary to osteoclastoma; she had undergone surgery removal of the tumor followed by bone grafting and screw fixation one year before being admitted to our hospital. At admission to our hospital, the patient had walking difficulties caused by the harvesting of fibular graft. Except for this, the physical exam was unremarkable. Laboratory findings revealed hypercalcemia (11.8 mg/dl), hypophosphatemia (2.2 mg/dl), low 25(OH)vitamin D level (6.45 ng/ml), high level of PTH (811.7 pg/ml) and elevated level of 24-h urinary calcium excretion (374 mg/24 h). Screening for multiple endocrine neoplasia type 1 and type 2A was negative. Neck ultrasonography revealed a hypoechoic mass (2.5/1 cm) suggestive for a lower right parathyroid adenoma. DXA of the lumbar spine, left hip and left radius showed low mineral bone density: L1–L3 T score = −3.8 S.D., Z score = −3.2 S.D., left hip (neck) T score = −3 S.D., Z score = −2.3 SD, distal left radius T score = −2.1 S.D. Z score = −1.9 S.D.. Abdominal ultrasonography showed bilateral renal microlithiasis.
Results
Clinical and paraclinical findings led to the diagnosis of primary hyperparathyroidism that eventually caused ulnar osteoclastoma and secondary osteoporosis. We recommended sestamibi parathyroid scintigraphy for adequate localization of the adenoma, followed by surgical removal. Based on the DXA score, we decided to initiate antiosteoporotic treatment with denosumab 60 mg 1 injection/6 months and supplementation with 1000 IU vitamin D3.
Conclusions
Although the classical hyperparathyroidism is not frequent nowadays, this diagnosis should be taken into consideration when dealing with osteolytic bone lesions such as osteoclastomas, so that proper treatment could be initiated. In the case we presented above, the late diagnosis of primary hyperparathyroidism led to multiple complications such as ulnar osteoclastoma with pathological fracture and secondary osteoporosis.

Lithium-associated Hyperparathyroidism in a Filipino woman presenting as recurrent ischemic stroke: a case report

Danica Francisco[1,2], Karen Lazaro[1] & Patricia Puno-Ramos[1]
[1]The Medical City, Pasig, Philippines; [2]De La Salle University Medical Center, Dasmarinas, Philippines.

Background
Lithium salts have been widely known to induce thyroid dysfunction, however, parathyroid dysfunction due to lithium use is uncommonly encountered. Hypercalcemia is a relatively common consequence of lithium therapy presenting with nonspecific symptoms that may be overlooked. Although cerebral infarction may be an independent event from psychiatric disorders, it can also be a rare complication that must be recognized particularly in patients on lithium therapy.
Case
A 64-year old female diagnosed with bipolar disorder and maintained on Lithium for 25 years, noted to have multiple recurrent cerebral infarctions presenting as dizziness, headache and vomiting. She had a multinodular nontoxic goiter and osteoporosis. Work-up showed elevated ionized calcium and intact PTH, with evidence of bilateral renal parenchymal calcifications and the parathyroid scintigraphy revealed two Sestamibi-avid nodules.

Discussion
Hypercalcemia and hyperparathyroidism are common but often unrecognized consequences of lithium therapy. Lithium causes a shift in the inhibitory set point for PTH secretion to a higher serum calcium concentration and, although rare, complications include cerebral infarction due to hypercalcemia and should be watched out for in these patients. Single as well as multigland involvement may be seen in patients with LAH and preoperative localization studies should be done in patients with surgical indications. The low incidence of lithium-associated hyperparathyroidism limits acquisition of enough information for formulation of clinical guidelines for diagnosis and management, hence documentation and reporting of cases are important contribution for a larger pool of data.

Looked like a goiter, proved to be a giant parathyroid adenoma

Niculina Racolta[1], Clothilde Wagner[2], Rita Caro Lopez[3], Laure Droy Dupré[4], Martine Patey[5] & Agnès Smagala[1]
[1]Endocrinology and Diabetes Department, Civil Hospital 'Louis Pasteur', Colmar, France; [2]Medicine Faculty of Strasbourg, Strasbourg, France; [3]O.R.L. Department, Civil Hospital 'Louis Pasteur', Colmar, France; [4]Pathology Department Civil Hospital 'Louis Pateur', Colmar, France; [5]Pathology Department, University Hospital of Reims, Reims, France.

Primary hyperparathyroidism is the third most common endocrine disorder, caused, in the majority of cases, by a single parathyroid adenoma and rarely by multigland adenoma or parathyroid carcinoma. Giant parathyroid adenomas, defined as larger than 3 g, represent an uncommon cause of primary hyperparathyroidism, with only a few cases described in the literature. We present the case of a 47 years old female who presented with a significant, unpainful, left cervical mass associated to light symptoms of fatigue, minor polyuria and hypercalcemia >3 mmol/l. Hormonal testing revealed very important elevation of parathyroid hormone, low phosphatemia and hypercalciuria, with preserved renal function. Ultrasound of the cervical region found a nodular, solid lesion, hyperechoic with hypoechoic areas and multiple microcysts measuring 7.6 cm of greatest diameter, in contact with the inferior pole of the left thyroid lobe. 99Tc sestamibi scan was positive for a voluminous inferior left-sided, hyperfunctioning parathyroid adenoma. CT scan confirmed the mass and described a right deviation of the trachea. Fine needle aspiration found cellularity compatible with parathyroid tissue. After controlling calcium levels, surgery was performed, consisting of removal of the mass as well as the left thyroid lobe attached to it. The parathyroid lesion measured 9×6, 3×3, 5 cm and weighted 80 g. Histological diagnosis was challenging because of relative capsule invasion and demanded second opinion to finally conclude in favor of a benign adenoma. Early postoperative calcium and active vitamin D supplementation was necessary to keep normal calcium levels. Parathyroid adenomas weighing more than 70 g are extremely rare. Our patient presented the second biggest giant parathyroid adenoma described to date. Surpisingly, despite its dimensions, this giant parathyroid adenoma did not cause severe hypercalcemic or local pressure symptoms. Differential diagnosis with a parathyroid carcinoma represented the greatest difficulty prior to surgery, as well as histologically due to several overlapping characteristics.
