This is a retrospective and prospective cross-sectional study with descriptive and analytical aims conducted over a period of 4 years between January 2018 and October 2022 in the department of endocrinology and metabolic diseases of the Ibn Sina University Hospital in Rabat as well as the consultation center. Patients with type 1 diabetes with less than 5 years of evolution, secondary diabetes, and patients with gestational diabetes were excluded. Sociodemographic, clinical and biological parameters as well as degenerative complications were collected using a predefined questionnaire. Univariate and multivariate statistical analysis were performed using JAMOVI 2.3.18 software. The significance threshold was set at the conventional value of 0.05.
Results
We included 250 diabetic patients, from which 207 were found to have type 2 diabetes mellitus. The mean age of our patients was 55.2 years ±14.8 years. The overall prevalence of diabetic peripheral neuropathy was found to be 26.8% of. 71 patients (28.4%) were found to have painful diabetic neuropathy. The multivariate logistic regression analysis revealed that the factors significantly associated with diabetic peripheral neuropathy were: diabetes duration ≥10 years (OR= 7.42; IC95%: 1.49-36.83, $P=0.01$), and sedentary lifestyle (OR= 10.64; IC95%: 2.28-49.57; $P=0.003$). On the other hand, the factor significantly associated with neuropathic pain was: sedentary lifestyle (OR= 6.43; IC95%: 1.55-26.65, $P=0.01$).
Conclusion
Our study underlines that the duration of diabetes and sedentary lifestyle are risk factors for the occurrence of diabetic peripheral neuropathy and neuropathic pain. Particular attention should be paid to the interest of regular screening as well as physical activity in order to relieve diabetic patients and improve their quality of life.

EP367

The reliability of ankle brachial index measurement in screening for peripheral arterial disease

Malak Iggar, Nassim Essabah Haraj, Siham El Aziz & Asma Chadli
UHC Ibn Rochd, Endocrinology and Metabolic Disorders, Casablanca, Morocco

Introduction
The peripheral arterial disease is a serious complication of diabetes. Although frequent, it is often underestimated in our diabetic patients.
Goal of the Study
The aim of our study is to verify the validity of ABI measurement in the screening of PAD in diabetic patients.
Patients and Methods
Retrospective, descriptive and analytical study taking place over a period of 3 years, including 120 diabetics, where doppler ultrasound was performed in the face of suggestive symptoms or as part of an arterial assessment. The measurement of the ABI was carried out in all our patients. Data entry and statistical analysis was done using IBM SPSS software.
Results
The average age of our patients was 57.3 years, where type 2 diabetes predominated in 83.4% of cases with an average duration of evolution of 17 years, the average HbA1c was 9.8%. The major risk factors for atherosclerosis found in

our patients were dyslipidemia in 43.3%, hypertension in 28.3%, obesity in 26.6% and smoking in 16.6%. The trophic disorders were objectified in 31.6% of our patients and the pulses were weakly perceived in 35.8% of the patients, 40% of the patients reported intermittent claudication. The ankle brachial index was measured in both limbs with an average ABI of 0.94, it was pathological in 66.6%. An ABI < 0.9 was found in 51.6% of patients and an ABI > 1.3 in 15%. The PAD objectified corresponding to a pathological arterial Doppler ultrasound was 84.1%. Atheromatous overload was objectified in 39.1%, 9.1% had arterial stenosis and 15.8% had arterial mediacalcosis. A significant relationship was found between the ABI and the doppler ultrasound of the lower limbs with a $P=0.003$. For the validity of the IPS, the sensitivity was 72.3% and the specificity was 63.2%, the PPV was 91% and the NPV was 30%.

Conclusion

Given its silent nature, peripheral arterial disease is often underdiagnosed in diabetics, resulting in a delay in diagnosis and management. The ankle brachial index remains a reliable way to detect and assess the severity of PAD.

Impact of glycemic and blood pressure control on diabetes management during the covid-19 pandemic and social isolation

Liana Jashi[1], Tamar Peshkova[2], Ketevan Dundua[1], Rusudan Kvanchakhadze[1] & Eter Margalitadze[2]
[1]David Aghmashenebeli University Of Georgia, Medicine, T'bilisi, Georgia; [2]Batumi Shota Rustaveli State University, Medicine, Batumi, Georgia

For the first time in Georgia (Ajara) has been started in parallel two research populations in with the management of diabetes and its complications during social isolation under the conditions of the Covid 19 pandemic. The research (PHDF-22-2943) is carried out with the financial support of Shota Rustaveli National Science Foundation.

Aim

The aim of the study is to compare ,How adequately used blood glucose and blood pressure control at home, the opinion of diabetic patients and doctors regarding the management of the disease during the covid-19 pandemic in the conditions of social isolation.

Material and Methods

a cross-sectional study design with a special questionnaire was used. Two survey forms were developed for Doctors and for Patients with diabetes. Both questionnaires were converted to the Microsoft form format. The study began in October 2022. So far, 220 Patients with diabetes and 72 doctors have participated in the survey.

Results and Discussion

According to preliminary data, it was found that, although 97% of patients have a personal glucometer and tonometer. During the isolation 11% of patients did not monitor blood glucose level, 33% tested once a week, 11% once a day, 44% several times a day; According to doctors opinion, 3% of patients did not test for blood glucose, 42% tested once a week, 21% once a day, 34% several times a day. Glycemic ranged between 140-250 mg% was 72% in the group of patients and 84.5% cases in the group of doctors. In the group of patients, 19.5% did not test their blood pressure. High BP up to 150 mm/hg was 39% of patients were observed in the group of doctors 69%. According to the doctors, medical intervention was needed 13% for angina pectoris attack, myocardial infarction 8%, heart failure 8%, arterial hypertension 43%, hyperglycemia 7% hypoglycemia 2%; among the patients in 13% cases heart attack, high blood pressure 22%, hyperglycemia 8%, kidney stones 2%. In both groups, there was insomnia in the group of patient 56% and in the group of doctor 62%, as well as anxiety in the group of doctors 82%, in the group of patients 58% and Feeling of loneliness 28%.

Conclusion

Inadequate glycemic and blood pressure control in diabetic patients increases the risk of developing cardiovascular disease and subsequent death, especially during emotional instability and isolation. It is necessary to increase the patient's awareness about blood pressure and glycemic control in order to prevent complications.

Prevalence and determinants of hypophosphatemia during the treatment of diabetic ketoacidosis

Omar Gargouri[1], Rim Marrakchi[1], Sana Chbili[1], Mariem Boudaya[1], Kamel Jamoussi[1], Mouna Turki[1], Faten Haj Kacem Akid[2] & Mohamed Abid[2]
[1]Hedi-Chaker University Hospital of Sfax, Biochemistry Departement, Sfax, Tunisia; [2]Hedi-Chaker University Hospital of Sfax, Endocrinology Departement, Sfax, Tunisia

Introduction

Diabetic ketoacidosis (DKA) is an extreme metabolic state caused by insulin deficiency. Hypophosphatemia in DKA often occurs during hospitalization. The aim of this study was to determine the prevalence and determinants of hypophosphatemia during the treatment of diabetic ketoacidosis.

Methods

This is a retrospective cross-sectional descriptive study concerning all patients hospitalized in the Endocrinology Department for DKA between October 2021 and January 2022. Glycemia at presentation and phosphatemia levels during treatment were determinated on AU 680® Beckman Coulter. Glycosylated haemoglobin (HbA1c) levels were determined on ADAMS ® ARKRAY at presentation. Hypophosphatemia was defined as measured serum phosphate less than 0.8 mmol/l. The treatment phase was defined as 1.5 hours from admission to the end of the treatment.

Results

A total of 30 patients were hospitalized for DKA. The mean age of the group was 26.73 $\pm$10.41years, 60% (18/30) of the cases was female. Type 1 diabetes was observed in 63.3% of patients. There were 33.4% newly diagnosed diabetes. Phosphore levels were measured during the treatment phase in 21 cases. The mean phosphate levels was 0.877 mmol/l (range 0.2 to 1.59; SD $\pm$0.37). Hypophosphatemia ($<$0.8 mmol/l) was present in 33% (7/21) and severe hypophosphatemia ($<$0.32 mmol/l) in 14% (3/21). None of the patients suffered from symptoms related to hypophosphatemia. Means glycemia and HbA1c in the group who presented hypophosphatemia and for the group with normal phosphate during the treatment were similarly high 23.52 $\pm$ 18.44 mmol/l; 13.45 $\pm$ 1.92% and 18.26 $\pm$ 7.46 mmol/l; 12.86 $\pm$ 3.08% ($P=0.29$; $P=0.334$) respectively. Means of duration of insulin therapy were 40.42 $\pm$ 20.44 hours and 31.12 $\pm$ 20.36 hours ($P=0.85$) respectively for the group who presented hypophosphatemia and for the group with normal phosphate during the treatment. The group who presented hypophosphatemia during the treatment received statistically similar total insulin dose infusion 80.85 $\pm$40.88 units vs 62.25 $\pm$40.72 units; ($P=0.85$).

Conclusion

Hypophosphatemia was present in 33% of patients with DKA during treatment The systematic and repeated measurements of phosphate levels are necessary in monitoring patients during treatment.

The dietary survey, an unreliable tool for assessing the authentic nutritional status in elderly patients with diabetes mellitus

Siddiqa Soomauroo, Nadia Charfi, Abdel Mouhaymen Missaoui, Wafa Belabed, Halima Ghalia, Houda Drira, Nabila Rekik Majdoub & Mohamed Abid
Hedi Chaker University Hospital, Department of Endocrinology, Sfax, Tunisia

Objective

To test the reliability of the classic diabetic survey (DS) in the diagnosis of malnutrition in elderly patients with diabetes mellitus (DM).

Patients and Methods

Analytical study of 55 patients aged over 65 years who were hospitalized in the Endocrinology Department. A DS was performed for all patients. The diagnosis of malnutrition was established according to the criteria proposed by the HAS 2021. Two subgroups were compared: G1 ($n=18$) undernourished seniors. G2 ($n=30$) non undernourished senior.

Results

The mean age of the included seniors was 71.4 $\pm$ 6.6 years with a female prevalence (53.7%). Very old patient with DM ($>$ 70 years) represented 46.3% of our population. The mean HbA1C level was 11.2 $\pm$ 3.2%. Significant glycaemic imbalance (HbA1C $>$ 10%) was reported in 77.8% of cases. The majority of patients were treated with insulin (84.9%). The mean BMI was 26.7 $\pm$ 5.5 kg/m^2. The mean daily energy intake was slightly lower in G1 without statistical significance. The ROC curve study of the DS variable shows an area under the curve of 0.62 with CI95% = [0.44-0.81]. The DS is thus an unreliable tool for determining the nutritional status of elderly patients with DM with a very poor sensitivity (57.7%) and specificity (40%).

Discussion

Malnutrition is a pathology that accompanies and aggravates the various geriatric syndromes. The daily caloric intake estimated by a classic DS does not indicate the nutritional status of elderly patients with DM. To better detect malnourishment in the geriatric population, we recommend the use of more reliable clinical tools such as the Mini-nutritional Assessment (MNA) score.

Assessment of nutritional status in in-patients with diabetic mellitus using Nutritional Risk index

Houcem Elomma Mrabet, Boubaker Fadia, Yesmine Elloumi, Yosra Abderrahim, Najoua Lassoued, Alaya Wafa, Zantour Baha & Sfar Mohamed Habib
University Hospital Tahar Sfar, Department of Endocrinology, Mahdia, Tunisia

Background
Patients with Diabetes Mellitus (DM) are exposed to malnutrition, due to dietary restrictions and associated conditions. However, in daily practice, malnutrition is often under-diagnosed among these patients.
Aim
To assess the risk of malnutrition in patients with DM admitted to an Endocrinology Department using the Nutritional Risk Index (NRI).
Methods
We conducted a cross-sectional study to calculate the NRI in patients with DM admitted to the Endocrinology department between March and September 2020. We used the formula NRI= (1.489×serum albumin) +41.7×(actual weight/usual weight). Patients were considered in no risk of malnutrition if NRI >100. Patients with NRI between 97.5-100 and 83.5-97.5 were considered in mild and moderate risk of malnutrition respectively. Patients with NRI less than 83.5 are in risk of severe malnutrition.
Results
In total, 106 patients with DM were admitted. Among them, 67 patients (63.2%) reported loss of weight, but in only 28 patients (26.4%), the maximal weight could be determined. The Mean weight upon admission was 70 +- 14.95 kg, the mean loss of weight was 12.07+-6.35 kg. The mean usual body weight was 82.09 +- 14.8 kg. The median NRI was 88.45 [80.2-89.14]. According to the NRI, 16 patients (57.1%) were considered in moderate risk while 11 patients (39.3%) were considered in the high risk group. Only one patient was considered in no risk of malnutrition.
Discussion and conclusion
Our results show the frequency of malnutrition among patients with DM. in fact, approximately two thirds (63.2%) of admitted patients with DM report loss of weight. Those with loss of weight were mostly in moderate or high risk of malnutrition. These results emphasize the need to incorporate assessment of nutritional status in diabetic patients in daily practice to prevent and manage malnutrition in a timely manner.

EP372

This study compared the impact of TGC beginning during surgery versus after surgery on postoperative adverse events in individuals undergoing heart surgery

B B Bharti[1] & Ajay Kumar Sinha[2]
[1]Ford Hospital, Medicine, Patna, India; [2]Nalanda Medical College Hospital, Medicine, Patna, India

Introduction
During the perioperative period, surgical operations put patients under a great deal of physical stress. The immune system produces cytokines and other immune mediators in response to this threat. Recent studies have shown that using insulin to regulate blood glucose can reduce systemic inflammation.
Objective
The objective of this research was examined how postoperative intensive insulin treatment (IIT) affects the inflammatory response in a synthetic pancreas during heart surgery with cardiopulmonary bypass.
Method
Two groups of patients undergoing cardiopulmonary bypass surgery were formed: the IIT group ($n=15$) and the conventional treatment (CT) group ($n=15$). At the start of surgery, an artificial pancreas was used to manage blood glucose in the IIT group. The blood sugar level was kept at 110 mg/dl for 20 hours after surgery. To track changes in serum cytokine levels over time, blood samples were taken. The mean±standard deviation was used to express all data. The nonparametric test (Mann-Whitney U-test) was used to assess the data for single comparisons. It was deemed statistically significant when $P<0.04$ was used.
Results
The characteristics of the patients were similar between groups. After surgery, blood glucose levels were much higher in the CT group. Interleukin-6, high-mobility group box 1, and tumor necrosis factor- serum levels were all greater in the CT group than in the IIT group.
Conclusion
During the postoperative period, IIT was safely performed during cardiac surgery with cardiopulmonary bypass utilizing an artificial pancreas. IIT also showed anti-inflammatory properties. An artificial pancreas used in conjunction with intensive insulin therapy has the potential to be a useful way to manage blood sugar during surgery, which would reduce the risk of both perioperative and postoperative problems. The inflammatory response was significantly reduced during the perioperative period when IIT was used in the artificial pancreas. Additionally, no signs of hypoglycemia was found in individuals receiving IIT. This shows that patients who are severely unwell may benefit from the safe and efficient use of IIT in a synthetic pancreas.

Lipid profile of postmenopausal women

Dunja Šojat[1,2], Klara Ormanac[1], Romana Marušić[1,3] & Tatjana Bačun[1,4]
[1]Faculty of Medicine Osijek, Osijek, Croatia; [2]Osijek Health Center, Osijek, Croatia; [3]National Memorial Hospital Vukovar, Department of Internal Medicine, Vukovar, Croatia; [4]Clinical Medical Center Osijek, Department of Internal Medicine, Division of Endocrinology, Osijek, Croatia

Aim of the Study
The main objectives were to examine the incidence of hyperlipoproteinemia in postmenopausal women and to determine the differences in lipid profile considering age, duration of menopause and body mass index in postmenopausal women.
Material and Methods
The research was structured as a cross-sectional research with historical data. The research used data collected during regular check-ups in primary health care clinics in the Osijek Health Center, Croatia, from November 2021 to March 2022. Collected data were: demographic data, information on the duration of menopause, body mass, body height, body mass index, values of total cholesterol, LDL cholesterol, HDL cholesterol and triglycerides and data on associated diseases.
Results
The study included 98 postmenopausal women, median age of 68. The median duration of postmenopause was 17 years. Statin therapy was used in 40.8% of respondents. Over 50% of respondents had elevated total cholesterol values (median: 5.60 mmol/l) and LDL cholesterol values (median: 3.25 mmol/l). 39.8% of respondents had elevated triglyceride values (median: 1.50 mmol/l). The values of total cholesterol (Kruskal Wallis test, P0.001) and LDL cholesterol (Kruskal Wallis test, P0.01) were significantly higher in the group of respondents aged 45 to 64 years, compared to older respondents. No significant differences were found in lipid profile in relation to the duration of postmenopause and the body mass index. Using the SCORE2 table, it was estimated that 65% of the respondents had a very high cardiovascular risk and 24% of them had a high cardiovascular risk. Only 6% of the respondents achieved the target values of LDL cholesterol. Respondents who did not reach the target values were significantly older (Mann Whitney U test, P0.01) and for a longer period of time in menopause (Mann Whitney U test, P0.009) compared to the respondents who achieved the lipid profile target values. No association of body mass index with the achievement of lipid profile target values was found.
Conclusion
Incidence of hyperlipoproteinemia in postmenopausal women is very high. Age and duration of menopause have an impact on the poorer achievement of the target values of the lipid profile. Given the high prevalence of respondents with a very high cardiovascular risk intensive interventions are needed at all levels of health care which include non-pharmacological and pharmacological methods of treating hyperlipoproteinemia.

Atherogenic Index of Plasma Associated Cardiovascular Risk in 10,241 Paediatric Patients

Tomader Ali, Radwa Helal, Rayan Khaled, Hani Sabbour & Nader Lessan

Imperial College London Diabetes Centre, Abu Dhabi, United Arab Emirates

Background
Cardiovascular disease (CVD) is a leading cause of mortality. Childhood obesity is a major contributor to CVD. Atherogenic index of plasma (AIP) is an indicator of risk of atherosclerotic CVD. Associations between childhood obesity and CVD risk in the region remains under-explored. We aim to investigate this association as a predictor of CVD in this young population.
Methods
Patients who attended our Centre (2009-2019), age $\leq$19 years and with complete lipid profiles were assessed. Extracted data was grouped per sex, age and BMI percentile: normal-weight (NrWt) 5th – 85th percentile, overweight (OvWt) 85th – 95th percentile and obese (Ob) 95th percentile. AIP was calculated using the logarithmic formula, log(Triglyceride(TG)/high-density lipoprotein cholesterol (HDL-C)) [1]; patients were divided into three risk groups (Gps): Gp1 = low, Gp2 = intermediate and Gp3 = increased CVD risk.
Results
In our study population (n = 10,241), 52.9% of total patients were females. Female percentage is different in each AIP risk group: Gp1 = 59.6%, Gp2 = 46.5% and Gp3 = 35.4% in low, intermediate and high risk groups respectively. In the different BMI percentiles, CVD risk varied; 88.00%, 8.75% and 3.25% in Gp1 (low), Gp2 (intermediate) and Gp3 (high) respectively. In the overweight/obese (OvWt/Ob) group specifically, 41.3% of patients were in Gp1 (low risk), 72.7% of patients were in Gp2 (intermediate risk) and 81.4% were in Gp3 (high risk).
Conclusion
Even at a young age, all patients displayed some level of AIP associated CVD risk. There is a significant group of children and adolescents with increased risk of cardiovascular disease who do not belong to familial hypercholesterolemia group. This is further exacerbated by obesity. The data highlights the importance of early identification of these patients at a younger age, potentially earlier than previously acknowledged to prevent long-term detrimental complications.

Statin Treatment in Children and Adolescents with Elevated LDL-c in Patient with Normoglycaemia and Dysglycaemia

Radwa Helal, Tomader Ali, Rayan Khaled & Nader Lessan
Imperial College London Diabetes Centre, Abu Dhabi, United Arab Emirates

Background
The obesity prevalence surge in children and adolescents is associated with dysglycaemia, dyslipidaemia and long-term cardiovascular complications. Use of lipid-lowering medications[1] has been recommended following lifestyle modifications. We aim to investigate the demographic, and changes in LDL-c, in these young patients, in the presence and absence of dysglycaemia.
Methods
Complete lipid profiles of patients ($\leq$19 years old) with hyperlipidaemia who are prescribed statin therapy was extracted based on International Classification of Diseases (ICD) Codes (n = 150). Patients with familial hypercholesterolemia (n = 20), or prescribed Omega-3 supplements (n = 61), were excluded. The remaining patients (n = 69) were further sub-grouped per sex and diabetes status. Median (IQR) LDL-c levels were calculated with Wilcoxon matched-pairs signed rank test for Pre- and Post-statin therapy (6 months) initiation was analysed using GraphPad PRISM 9 with statistical significance set at the $\leq$0.05 level.
Results
Within the study population (n = 69 patients) receiving statin therapy (females = 51.43%), mean age was 15.97 $\pm$ 3.02 years (minimum = 6 years; maximum = 19 years). Sub-grouped per diabetes status; normoglycaemic (NGT; n = 15 [21.7%]), Pre-Diabetes (Pre-Dia; n = 10 [14.5%]), type 1 diabetes (T1DM; n = 33 [47.8%]), type 2 diabetes (T2DM; n = 8 [11.6%]), MODY (n = 2, 3.0%) and secondary diabetes (n = 1; 1.4%). Median (IQR) LDL-c levels for all patient groups significantly decreased compared to baseline; *P*-value 0.01 - $<$0.0001.
Conclusion
All patients receiving statin therapy, independent of their diabetes status, showed a significant decrease in LDL-c levels post-statin therapy. Data further highlights the importance of identifying young patients where lifestyle modifications alone is not effective particularly in the presence of obesity and/or diabetes. This indicates that early detection, diagnosis, and timely intervention in management of dyslipidemia, is cornerstone in avoiding long-term cardiovascular disease in young patients. Patients (n = 61) were assessed Pre- and Post-lipid lowering (statin) therapy. Median (IQR) LDL-c levels were calculated with statistical significance ($\leq$0.05 level).

Berberine vs Pioglitazone: Management of NAFLD and its Impaired Glucose Metabolism

Khawaja Ahtesham Ahmad[1] & Manish Kumar[2]
[1]Zak Multispeciality Hospital, Diabetes, Siwan, India; [2]Chikitsa Clinic, Medicine, Patna, India

This study aimed to determine if berberine (BBR) or pioglitazone (PGZ) is more effective and safer for treating people with type 2 diabetes or non-alcoholic fatty liver disease (NAFLD). 184 people with NAFLD and impaired glucose metabolism were randomly allocated 16 weeks of lifestyle intervention (LI), LI plus PGZ (15mg daily) or LI plus BBR (1.5 g daily) as their course of treatment. We measured the levels of blood insulin, osteocalcin, C reactive protein (CRP), liver enzymes, glucose and lipid metabolism, and hepatic fat content (HFC) by 1 H-MRS both before and after treatment. In comparison to LI alone, BBR plus LI treatment was linked to significantly greater decreases in HFC (51.30% vs 27.98%), triglycerides, total cholesterol, waist circumference, body weight, alanine aminotransferase (ALT), as well as significant elevation in early phase insulin and serum osteocalcin levels. In terms of 2-hour glucose and ALT, PGZ plus LI considerably outperformed LI group, while the difference in HFC between PGZ and control was not statistically significant (41.02% vs 27.98%). Fasting glucose, LDL-c, HDL-c, HbA1c, glutamyl transferase, serum CRP levels, and aspartate aminotransferase, improved more in the LI + BBR or PGZ group than in the LI group, but the differences between the groups were not statistically significant. There were substantial differences in the incidence of drug-related adverse events between groups. LI, LI + BBR, or LI + PGZ are all successful treatments for NAFLD patients with aberrant glucose metabolism in terms of improving glucose metabolism, lowering HFC, and lowering liver enzymes. The lipid profile, early phase insulin secretion, weight loss, reduction in waist circumference, and serum osteocalcin levels were all improved by BBR more than the other two therapies. All of BBR and PGZ were accepted.

Familial chylomicronemia syndrome: A case report

Angham Seghir, Numydia Nebti, Safia Achir & Zakia Arbouche
CHU Benimessous, Department of Endocrinology, Algiers, Algeria

Background
Familial chylomicronemia syndrome is a rare disorder of lipoprotein metabolism with an incidence of one per million in the general population. It is characterized by marked elevation of triglyceride and chylomicron levels, resulting in lipemic plasma and recurrent attacks of acute pancreatitis, eruptive xanthoma, hepatosplenomegaly, and lipemia retinalis.
Case Presentation
We report the case of an 18 years old patient, an only son ,from a cansanguineous marriage of 2nd degree with a personal history of 4 episodes of acute pancreatitis since the age of 4 months, who presents a lipemic fasting blood and a lipid profile with triglyceride levels over 15000 mg/dl, a normal cholesterol and a low high-density lipoprotein (HDL) levels .Physical examination was insignifcant for any findings. There were no eruptive xanthomas or abdominal pain. Abdominal ultrasound was normal. The lipid profile of his father shows a moderate hypertriglyceridemia at 2860 mg/dl, the mother assessement was normal.Familial chylomicronemia syndrome was diagnosed. Our patient was given a special diet devoid of triglyceride and containing medium chain fatty acid diet and was also started with fenofibrate and omega 3. After a month, repeated blood test revealed a reduction in triglyceride level to 3100 mg/dl.
Discussion and Conclusion
Familial chylomicronemia syndrome is an autosomal recessive disorder resulting from lipoprotein lipase (LPL) or apolipoprotein C-II deficiency or due to the presence of an inhibitor of LPL. The diagnosis of familial LPL deficiency is based on the demonstration of lipemic plasma with elevated chylomicron and triglyceride levels and a reduced to normal VLDL level, and is confirmed by assessment of LPL activity in plasma. Familial apolipoprotein-CII deficiency shows a raised VLDL level in addition to the derangements as seen in LPL deficiency. Acute relapsing pancreatitis is the most significant and often life-threatening complication. Dietary modification plays a key role in the management of this disease. Dietary fat should be restricted to <20 g/day and $<15\%$ of the total caloric intake so that triglyceride levels are maintained below 1500 mg/dl. Fibric acid derivatives and omega 3 are recommended. Fenofibrate may reduce hepatic triglyceride synthesis and increase LPL activity. Adverse effects of fibrates include elevated creatinine kinase and liver enzymes. Volanesorsen are new therapeutics that reduce triglyceride levels to less than 750 mg/dl in 77% of patients with familial chylomunclonemic syndrome. thrombocytemia and injection site reactions were common adverse effects.
Keywords: Chylomicronemia, Lipoprotein lipase ,acute pancreatitis .

Efficacy and durability of a very low calorie ketogenic diet protocol on metabolic parameters

Elisabetta Camajani[1], Stefania Proietti[2], Agnese Persichetti[3], Alessandra Feraco[1], Andrea Armani[1], Mauro Lombardo[1], Sabrina Basciani[4] & Massimiliano Caprio[1]
[1]San Raffaele Roma Open University, Department of Human Sciences and Promotion of the Quality of Life, Rome, Italy; [2]Unit of Clinical and Molecular Epidemiology, Istituto di Ricovero e Cura a Carattere Scientifico (IRCCS) San Raffaele, Rome, Italy; [3]Service of Pharmacovigilance, IRCCS-Regina Elena National Cancer Institute, 00144 Rome, Italy; [4]La Sapienza University of Rome, Experimental Medicine, Rome, Italy

Metabolic Syndrome (MetS) is characterized by the association of insulin resistance, hypertension, dyslipidemia, non-alcoholic fatty liver disease, and is strictly related to increased cardiovascular risk. Recent scientific evidence confirms that very low calorie ketogenic diet (VLCKD) is a valuable treatment for patients with insulin resistance and visceral obesity. After the VLCKD phase it is essential to gradually reintroduce carbohydrates and increase calories in order to switch towards a Mediterranean nutritional approach. The aim of this study was to evaluate the efficacy and durability of a VLCKD protocol on cardiometabolic parameters related to MetS. Twentynine patients with MetS, obesity and insulin resistance [12 males and 17 females, homeostatic model assessment index (HOMA) ≥ 2.5, age 56.7 ± 6.4 years, body mass index (BMI) 35.3 ± 3.9 kg/m^2)] followed a VLCKD for 45 days (≤ 800 kcal/day). After the VLCKD phase (45 days), they followed a low calorie diet (LCD, 1100-1200 Kcal) with a low carbohydrate content (60-80 g/day) for 45 days. Subsequently, patients were switched to a hypocaloric Mediterranean diet (HMD-1500 Kcal) with 120-130 g/day carbohydrate content and monitored for additional 60 days (150 days). Anthropometric indexes, blood and urine chemistry, and body composition were assessed. Body weight [-8.7 ± 3.3, $P<0.001$], BMI [-3.2 ± 1.0 kg/m^2, $P<0.001$], blood pressure (-9.1 ± 14.2 mmHg, $P=0.002$], waist circumference [-6.4 ± 3.0 cm, $P<0.001$], HOMA index [-4.3 ± 5.8, $P<0.001$], insulin [-13.6 ± 14.4 µIU, $P<0.001$], total and low-density lipoprotein cholesterol (LDL) [-49.5 ± 31.2 mg, $P<0.001$; -36.7 ± 20.6 mg, $P<0.001$ respectively] and triglycerides [-65.9 ± 93.6 mg, $P<0.001$] markedly decreased in all participants during VLCKD phase (day 45). Importantly, body weight [-3.5 ± 1.7 kg, $P<0.001$], BMI [-1.3 ± 0.6 kg/m^2, $P<0.001$], total and LDL cholesterol [-21.4 ± 20.8 mg, $P<0.001$; -19.2 ± 17.2 mg, $P<0.001$, respectively] showed a further significance decrease during LCD phase (day 90), as compared to the end of VLCKD phase. Noteworthy, a significant reduction of visceral adipose tissue (VAT) was observed at the end of VLCKD phase [-103.5 ± 128.7 cm^3, $P<0.001$], as well as the end of LCD phase [-80.5 ± 120.3 cm^3, $P=0.002$]. Importantly, a trend in body weight reduction [-0.6 ± 1.5 kg, $P=0.125$] was observed at the end of HMD phase (day 150), compared with the end of LCD phase (day 90). Our study confirms that VLCKD protocol is an effective strategy in the management of obesity and its metabolic comorbidities, due to its pleiotropic effects, particularly on the reduction of visceral adipose tissue. Indeed, favourable effects on body weight and metabolic risk factors persist also after the reintroduction of carbohydrates and the switch to a HMD.

Does prebiotics consumption improve glycemic parameters in obese adults?

Rym Ben Othman, Zeineb Zemni, Chaima El Ghali, Awatef Kacem, Wafa Douiri, Berriche Olfa, Ramla Mizouri, Nadia Ben Amor, Faten Mahjoub & Jamoussi Henda
National Institute of Nutrition of Tunis, Obesity Research Unit, Bab Saadoun, Tunis, Tunisia

Background
Alteration of gut microbiota leads to increased intestinal permeability, inflammation, and metabolic disorders. The aim of our study was to determine the effect of prebiotic supplementation on glycemic parameters in addition to a weight loss program.
Methods
This is an interventional study including 30 obese patients consulting the obesity unit of the Institute of Nutrition in Tunis. The patients were divided into 2 groups matched for age, sex and BMI: diet alone and prebiotics (30g of carob/day). Glycemic parameters (fasting blood glucose, HbA1c, fasting insulin levels and HOMA index= insulin resistance score) were assessed at T0 and at one month after the intervention (T1).
Results
The mean age was 40.3 $\pm$6.7years with sex ratio Male/Female $=0.25$. Diabetes was found in 6.7% of patients in the diet alone group and 26.7% of patients in the prebiotic group (the difference between the two groups was not significant $P=0.3$). There was no significant difference between the two groups for glycemic parameters at T0 (fasting blood glucose, HbA1c, fasting insulin levels and HOMA index). For the diet alone group, there was a significant decrease in HbA1c between T0 and T1 ($P=0.03$). For the prebiotic group, we found a significant decrease in insulin levels ($P=0.002$) and insulin resistance score ($P=0.009$). A statistically significant difference between the diet alone group and the prebiotic group was found for the decrease in fasting blood glucose (0.01), insulin levels ($P=0.03$) and insulin resistance score ($P=0.01$).
Conclusion
Prebiotics are superior to diet alone in improving the glycemic profile. Thus, they therefore have their place in the therapeutic arsenal of pre-diabetes and diabetes in obese patients.

Relationship between nutritional screening CIPA and sarcopenia in hospitalized patients

Elena Márquez Mesa[1], Cristina Lorenzo González[1] , Carla Rodríguez Rodríguez[2], José Pablo Suárez Llanos[2] & Ignacio Llorente Gómez de Segura2 1Our Lady of Candelaria University Hospital, Endocrinology and Nutrition, Santa Cruz de Tenerife, Spain; [2]Our Lady of Candelaria University Hospital, Santa Cruz de Tenerife, Spain

Introduction
Malnutrition and sarcopenia are interrelated and frequent in hospital settings, being related to a higher morbimortality. CIPA nutritional screening (performed at the Hospital Universitario Nuestra Señora de Candelaria) is positive when one or more of the following criteria is met: a) decreased oral intake in 72 h (<50%), b) albumin <3 g/dl, and c) BMI <18.5 g/m^2 or mid-upper arm circumference (MUAC) ≤ 22.5 cm.
Aim
To determine the relationship between the results of CIPA screening and the diagnosis of sarcopenia in hospitalized patients.
Method
Single-center, cross-sectional study. Hospitalized subjects >18 years old who underwent CIPA malnutrition screening were included. Loss of muscle mass was measured by bioimpedanciometry (appendicular skeletal muscle mass, ASMI), and strength by handgrip measure. Sarcopenia was established according to the EWGSOP2 diagnostic criteria.
Results
332 patients were analyzed. The mean age was 66.04 ±14.41 years (52.1% men). Distribution by specialties is shown in table 1. CIPA was positive in 36.1% (criteria why CIPA was positive are shown in Table 2), while 19.9% of the whole sample had sarcopenia. 33.3% of positive CIPA patients had sarcopenia vs 12.3% of negative CIPA ($P<0.0005$). The positivity of the CIPA variables BMI/MUAC (31.8% vs 16.5%; $P<0.0005$) and oral intake control (35.8% vs 16.8%; $P=0.001$) correlated with the presence of sarcopenia. The trend to significance was observed with the positivity of albumin (27.8% vs 17.7%; $P=0.058$).
Conclusions
in this cohort of patients a positive CIPA nutritional screening test is related to a higher prevalence of sarcopenia, so it represents a valid tool to identify patients with the highest risk of morbimortality.

Table 1 Distribution by specialties

Admissions by specialty	*n*	%
Internal medicine	46	13.9
General surgery	28	8.4
Vascular surgery	12	3.6
Gastroenterology	54	16.3

Metabolic effects of caffeine consumption in obese patients

Sana Khamassi, Berriche Olfa, Rahma Khalaf, Nesrine Dhieb, Amel Gamoudi, Awatef Kacem, Nadia Ben Amor, Rym Ben Othman, Ramla Mizouri & Jamoussi Henda
National Institute of Nutrition, Department A, Tunis, Tunisia

Background and Aim
Coffee is consumed worldwide and have been an important aspect of societal norms and cultural traditions for centuries.The health effects of routine caffeine consumption and their potential function as modifiable risk factors for cardiovascular disease have recently been the suggested by many studies. The aim of this study is to evaluate the daily caffeine consumption in obese patients and its clinical and metabolic effects.
Methods
This is a cross-sectional study conducted in 70 obese patients. Patients' demographic and anthropometric characteristics, obesity related complications and biological parameters were collected. Insulin resistance was estimated by HOMA-IR index. Metabolic syndrome was defined according to the International Diabetes Federation criteria (2009). Caffein daily consumption was evaluated depending on the average quantity of coffee and the type of coffee consumed according to the international caffein organization[1]. Low caffeine consumption was defined by an average consumption of less than 200 mg per day,a consumption of caffeine between 200 and 400 mg per day defined a moderate consumption and high caffeine consumption was defined as a daily intake of more than 400 mg. In this study we combined moderate and high caffeine consumption to improve precision of estimates.
Results
Mean age was 50.91±11.5years with female predominance(90%).Mean Body mass index (BMI)was 39.42±6.47 kg/m^2, mean waist circumference was 118.95±11.04 cm. Of the study population, 22.9% of patients had class 1 obesity,38.6% of patients had class 2 obesity and 37.1% had morbid obesity. Insulin resistance was noted in 87.5% of cases and more than half of patients had metabolic syndrome (65.7%). Coffee was consumed on a daily average of 193±73.42 ml, which was equivalent to an average of 133.96±85.95 mg of caffeine per day. Caffeine intake was minimal, moderate, and high in 81.2%, 17.1% and 1.4% of cases, respectively. Patients with minimal caffeine intake had a significantly higher prevalence of metabolic syndrome compared to patients with moderate to high caffeine intake (61.4% vs 4.3%; $P=0.001$). Prevalence of nonalcoholic fatty liver disease and insulin resistance did not statistically differ between the two groups. Systolic and diastolic blood pressure values, total cholesterol,triglyceride,HDL-c and LDL-c levels did not statistically differ between the two groups.
Conclusion
Moderate to high habitual consumption of caffeinated beverages is safe across a broad range of cardiovascular conditions.Our findings support the hypothesis on the possible health benefits of caffein consumption particularly on metabolic syndrome, yet further research on large-scale studies is needed.

Evaluation of the results of weight loss at 5 years after bariatric surgery at the Regional Hospital of Málaga

Viyey Kishore Doulatram Gamgaram[1] , Jose Abuin[2], Nadia Koury Chicheportiche[3] , Francisco Hevilla Sánchez[1] & Sergio Valdes[1]
[1]Hospital Regional Universitario de Málaga, Endocrinology and Nutrition, Málaga, Spain; [2]Hospital Quirón Salud Málaga, Endocrinology and Nutrition, Málaga, Spain; [3]Universidad de Málaga, Málaga, Spain

Introduction
Morbid obesity is a highly prevalent disease, with bariatric surgery being a fundamental pillar in its treatment.
Objectives
To analyze the results of weight loss at 5 years in patients operated by gastric bypass and sleeve at the Regional University Hospital of Malaga.
Methods
This is a retrospective observational study, where 104 patients with morbid obesity who underwent bariatric surgery at the Regional University Hospital of Malaga between 2011 and March 2017 were analyzed.
Results
The mean age at the intervention was 46.6 years (19-67), 77 women and 27 men, 41 were operated by bypass and 63 by sleeve. The mean baseline weight was 131.1±26.4 kg with a mean BMI of 48.9±7.7 kg/m^2. 56.8% had a BMI between 40-50 kg/m^2, 7.8% between 35-40 kg/m^2, 24.5% between 50-60 kg/m^2 and 9.8% had a BMI above 60 kg/m^2. The average weight at one year of the intervention was 86.6 kg, at 2 years 84.8 kg, at 3 years 88.7 kg, at 4 years 91.1 kg, and at the fifth year, the mean weight was 95 kg. The percentages of excess weight lost were also calculated, at one year it was 71.8%, at 2 years it was 73.6%, at 3 years it was 66.4%, at 4 years it was 63.6% and at 5 years it was 59.0%. Likewise, the percentage of patients who had lost more than 50% of the excess weight they had prior to surgery was obtained: at one year it was 88.3%, at 2 years it was 90.0%, at 3 years it was 77.3%, at 4 years it was 78.9% and at 5 years it was 66.3%.
Conclusions
Satisfactory weight results are observed 5 years after bariatric surgery, achieving a loss above 50% of excess weight in 66.3% of patients.

Association between sleep duration and sociodemographic characteristics, mental health and chronic diseases in obese adults

Zeineb Zemni[1], Nadia Ben Amor[1], Faten Mahjoub[1], Nesserine Dhieb[1], Chaima Sdiri[2], Maryam Cheikhrouhou[2], Rym Ben Othman[1], Ramla Mizouri[1], Berriche Olfa[1] & Jamoussi Henda[1]
[1]National Institute of Nutrition, Obesity Research Unit, Bab Saadoun, Tunis, Tunisia; [2]National Institute of Nutrition, Outpatient Departement and functional exlorations, Bab Saadoun, Tunis, Tunisia

Background
Sleep is crucial for brain function, productivity, physical and mental well-being. The objective of our work was to examine the relationship between short sleep duration and its associated factors (sociodemographic characteristics, mental health and chronic diseases) in adult individuals with obesity.
Methods
Cross sectional study, including 100 obese adult patients consulting the Obesity Unit of the National Institute of Nutrition in Tunis in 2022. Exclusion criteria: patients with shift work or night work, psychiatric illness, neuroleptic medication or any medication that may interfere with sleep. Data were collected during one-to-one interviews. Sleep duration was self-reported. Sleep duration <7 hours/day was considered as short. Sociodemographic characteristics and medical history were also collected. Screening for anxiety and depression was performed using the HAD questionnaire.
Results
Mean age was 46.7 ± 12.3 years with a sex ratio M/F 0.3. Almost half of the women (52.6%) were menopausal. Our patients were professionally active in 47% of the cases but only 22% of the participants had a higher education level. The majority of our study population (70%) belonged to the middle socioeconomic class and 73% were married. Half of the patients (54%) had a low level of physical activity. The mean BMI was 40.3 ± 6.6 kg/m^2 with class III obesity in 46% of cases. Complications of obesity in descending order were: sleep apnea syndrome (83%), hypercholesterolemia (64%), hypertension (48%), prediabetes (41%), gastroesophageal reflux disease (31%), diabetes (30%), hyperuricemia (29%), hypertriglyceridemia (28%), osteoarthritis (15%), and cardiovascular disease (7%). we found a high prevalence of anxiety (41% of patients had doubtful to certain symptomatology) and depression (42% of patients had doubtful to certain symptomatology). Mean sleep duration was 7 h:16 ± 1 h38 and 46.7% of patients had short sleep duration (<7 h/day). Analytical study showed that Short sleep duration was significantly associated with low socioeconomic level ($P=0.014$), diabetes ($P=0.014$), anxiety ($P=0.005$) and depression ($P=0.031$).
Conclusion
Poor socio-economic conditions represent a source of stress that affects sleep duration. Besides, obese population is at high risk of psychological complications that in return affect sleep.

What is the impact of prebiotic supplementation on anxiety symptoms and stress levels in obese patients?

Rym Ben Othman, Zeineb Zemni, Chaima El Ghali, Wafa Douiri, Berriche Olfa, Ramla Mizouri, Nadia Ben Amor, Faten Mahjoub & Jamoussi Henda
National Institute of Nutrition in Tunis, Obesity Research Unit, Bab Saadoun, Tunis, Tunisia

Background
Obese population is at risk of psychological complications such as anxiety and depression. We carried out this study to assess the effect of a weight loss program and prebiotic supplementation on anxiety symptoms and stress levels in an obese adult population.
Methods
Interventional study involving 30 obese patients consulting the obesity unit of the National Institute of Nutrition in Tunis between June and August 2022. Patients were divided into 2 groups matched for age, sex and BMI: diet alone and prebiotics (30 g carob/day). All patients were screened for anxiety symptoms using the HAD score (anxiety dimension). The Cungi stress scale was used to evaluate stress level. The two questionnaires were administered at T0 and one month after the start of the diet (T1).
Results
The mean age was 40.3 ± 6.7 years with a female predominance (80% of women). There was a significant weight loss in each group (diet only group: -2.5 kg $P=0.001$ and prebiotic group: -2.2 kg, $P=0.003$). However, there was no significant difference between the two groups ($P=0.7$). For the diet alone group, at T0, anxiety related symptoms were present in 100% of the patients (13.3% doubtful symptoms and 86.7% certain symptoms). For the prebiotic group, anxiety related symptoms were present in 80% of patients (13.3% doubtful and 66.7% certain) but no statistically significant difference between groups was found ($P=0.4$). More than half of the study population (73.3%) had a high to very high level of stress (80% of diet alone group vs 66.6% of prebiotic group) but no statistically significant difference between groups was found ($P=0.7$). At T1, there was a significant improvement in the HAD-anxiety scores for both groups: diet alone group (mean difference (T0-T1) $=2.1$, $P=0.02$) and prebiotic group (mean difference (T1-T0) $=1.9$, $P=0.01$). Likewise, we have noticed a significant improvement in the Cungi stress scale scores for both groups: diet alone group (mean difference (T0-T1) $=6.7$, $P=0.01$) and prebiotic group (mean difference (T0-T1) $=4.8$ $P=0.001$). There was no significant difference between the two groups for the improvement of anxiety symptoms or stress level between T0 and T1 ($P=0.8$ and $P=0.5$ respectively).
Conclusion
Our study showed a high prevalence of psychological distress among obese patients. The improvement in anxiety symptoms and stress levels was not related to prebiotic consumption. This improvement is more related to the weight loss.

A secular trend in childhood obesity: Post-COVID statistical analysis

Ketevani Obolashvili, Teona Nutsubidze & Shota Janjgava
The National Institute of Endocrinology, Endocrinology, Tbilisi, Georgia

Introduction
Childhood obesity has reached epidemic levels in developed as well as in developing countries. According to WHO data, an increasing number of low- and middle-income countries are now facing the "double burden" of obesity and overweightness. This problem is increasing aggressively in urban settings. This rise has occurred similarly among boys and girls. In 2016, 18% of girls and 19% of boys were overweight. In comparison, two data illustrate the pandemic scale of childhood obesity growth: just under 1% of children and adolescents aged 5–19 were obese in 1975, while more than 124 million children and adolescents (6% of girls and 8% of boys) were obese in 2016. A study conducted by The National Institute of Endocrinology Tbilisi, Georgia has identified additional childhood epidemic outbreak linked with post-COVID lifestyle.
Methods and Materials
The target group was 828 children aged 5–8 years who underwent medical and physical examinations during ambulatory visits to The National Institute of Endocrinology clinics in 2021 and 2022. Children with congenital disease and/or birth weights lower than 2500 g were excluded. Only the information collected during the first visit was used to evaluate the post-COVID effect on childhood obesity statistics. The collected data included age, gender, and anthropometric characteristics. Statistical analyses were performed using the electronic health system Doctra Enterprise, version 8.3.19.1150. BMI-for-age percentile was calculated based on CDC growth charts for children and teens aged 2 through 19 years (3).
Results
The medical records for 730 patients aged 5–8 years, of which: 426 were girls and 304 were boys, were analyzed. During 2021, from 326 evaluated patients, 50.92% ($n=166$) had healthy weights, 13.49% ($n=44$) were overweight, 30.06% ($n=98$) were obese, and 2.45% ($n=8$) were underweight. During 2022, from 404 evaluated patients, 42.07% ($n=170$) had healthy weights, 15.34% ($n=62$) were overweight, 37.62% ($n=152$) were obese, and 4.95% ($n=20$) were underweight.
Conclusions
There has been a significant increase in the incidence of obesity among children. A limitation of this study was the small number of participants and scope of the inquiry. However, the spike in overweight and obesity cases indicates as yet unknown changes caused by the COVID-19 pandemic. Several studies are currently being conducted by The National Institute of Endocrinology in Tbilisi, Georgia to determine the root cause of the current spike.

EP386

Evaluation of the ratio of C-reactive protein to prealbumin (CP ratio) as a diagnostic tool for malnutrition. transversal study

Laura Mola Reyes, Ines Lobo, Rosa María García Moreno, Alexa Pamela Benítez Valderrama, Ines Lobo & Irene Aguilera García, Bricia López Plaza, Samara Palma Milla La Paz University Hospital, Madrid, Spain

Introduction
Disease-related malnutrition (DRM) is characterized by the presence of an acute or chronic inflammatory response. The traditional parameters for diagnosis, such as albumin, have failed in their application, forcing a reconsideration of the criteria used for the diagnosis of DRM. The ratio of C-Reactive Protein to prealbumin (CP ratio) allows to assess nutritional changes in relation to the inflammatory environment. The objective of this study is to assess the diagnostic capacity for malnutrition of CP ratio, correlating it with GLIM criteria.
Material and Method
Cross-sectional pilot study in hospitalized patients, under follow-up by the Nutrition Unit of Hospital La Paz. Patients with inflammation, diagnosed by C-Reactive Protein (CRP) > 0.5 mg/dl, were included. CP ratio was measured in the initial evaluation and compared with isolated prealbumin for the clinical assessment of malnutrition. ROC curves were used in the statistical analysis.
Results
91 patients were included, 65 with DRM (28 with severe DRM) based on GLIM criteria. The CP ratio presented an area under the curve (AUC) = 0.556 (95% CI: 0.420-0.691) for the diagnosis of malnutrition versus normally nourished; and AUC = 0.552 (95% CI: 0.408-0.696) for the diagnosis of severe versus moderate DRM. Prealbumin presented an AUC = 0.536 (95%CI: 0.402-0.671) for the diagnosis of malnutrition versus normally nourished and AUC = 0.551 (95%CI:0.407-0.694) for severe versus moderate DRM. When comparing CP ratio with prealbumin alone, there were no significant differences in the ability to detect DRM($P = 0.880$) or severe DRM ($P = 0.992$).
Conclusions
The CP ratio has poor diagnostic accuracy for DRM and the degree of malnutrition. It does not show superiority with respect to prealbumin in patients with inflammation.

EP387

Effect of the integration of the weight loss protocol of the endocrinology service in the follow-up of patients with severe osahs and obesity at the Juan Ramón Jiménez hospital

Jose Alvaro Romero Porcel[1], Eyvee Arturo Cuellar Llocl la[1] & Jessica Ivana Hilares Vera[2]
[1]Hospital Virgen de Valme, Endocrinology, Sevilla, Spain; [2]Hospital Juan Ramon Jimenez, Pneumology, Huelva, Spain

Introduction
Obstructive sleep apnea-hypopnea syndrome (OSAHS) and obesity are two pathologies increasingly prevalent in population related to each other. Obesity is present in between 60-90% of patients diagnosed with OSAHS being the most important modifiable risk factor. Obesity influences the risk factor for OSAHS degree of severity, increasing its severity by up to 30%. The degree of relation between both pathologies, we created a protocol Endocrinology and Pneumology services, searching the effect on weight loss in our patients.
Material and Methods
Descriptive, retrospective, cross-sectional study. We incluided 70 patients diagnosed with severe OSAHS (apnea-hypopnea index -AHI- greater than 30) and with obesity (BMI greater than 25 kg/m^2). 35 patients received a basic intervention in nutrition and dietetics and another 35 received the recommendations included in the weight loss protocol created by the Endocrinology service. We compared weight loss one year after the nutritional intervention.
Results
Between the patients who received a basic intervention in nutrition and diet, 79.4% were men and 20.6% were women. 44.1% (p 0.033) of these patients had been diagnosed with Type 2 Diabetes Mellitus; 17.6% of the patients had previously presented an ischemic cardiovascular event and had an average BMI of 34 kg/m^2. 11.8% of the patients (P: 0.045) had lost weight one year later with an average of 34 kg. The patients who received the protocol guideline created by the Endocrinology Service, 90.3% were men and 9.7% women. 19.4% (P 0.033) had been diagnosed with Type 2 Diabetes Mellitus and they had an average BMI of 35 kg/m^2. 32.3% of the patients (P 0.045) had lost weight one year later with an average of 31 kg.
Conclusions
The weight loss applying the Endocrinology service protocol was statistically significant (P 0.045) in our study, observed in 32.3% of the patients to whom said protocol was applied, compared to the application of a basic intervention, where a weight loss of 11.8% (P: 0.045) is observed.

Neck circumference and metabolic syndrome: A cross-sectional study

Rahma Khalaf, Berriche Olfa, Sana Khamassi, Nesrine Dhieb, Ramla Mizouri, Nadia Ben Amor, Rym Ben Othman, Awatef Kacem, Amel Gamoudi & Jamoussi Henda
National Institute of Nutrition, Department A, Tunis, Tunisia

Background and Aim
Metabolic syndrome (MetS) is a complex disorder that increases the risk of cardiovascular diseases. Neck Circumference (NC) can estimate the subcutaneous upper body fat distribution which has been recognized as associated with MetS. The aim of our study is to investigate the possible association of NC with cardiometabolic risk factors and MetS and to determine the possible cutoff points of NC for the diagnosis of MetS.
Methods
This is a cross sectional study including 60 obese patients. Diagnosis of MetS was based on the International Diabetes Federation 2009 criteria. Clinical characteristics, anthropometric measures (BMI, waist circumference and NC) were collected. Fasting plasma glucose, HDL-cholesterol (HDL-C), triglyceride (TG) levels, systolic and diastolic blood pressure were assessed. We used ROC curve analysis to estimate the optimal sex-specific NC cut-off point in the diagnosis of MetS.
Results
Mean age was 48.1 ± 15.46 years with female predominance (68.4%).Type2 diabetes mellitus and hypertension were noted in 77.1% and 41.3% of cases. Mean BMI was 32.1 ± 8.1 kg/m^2, mean waist circumference was 106.4 cm ± 14.63 for men and 110.4 cm ± 19.62 for women. Mean NC was 40.3 cm ± 3.7 for men and 38 cm ± 4.5 for women. MetS was diagnosed in 33 (55%) of patients.NC was shown to be significantly associated with waist circumference ($P < 10^{-3}$), systolic and diastolic blood pressure ($P = 0.03$;$P = 0.02$,respectively), triglyceride levels ($P = 0.04$), fasting plasma glucose ($P = 0.001$), and HDL-C level($P < 10^{-3}$) as well as MetS ($P = 0.03$). After multivariate analysis, NC was an independent factor associated MetS (OR 3.5, 95% CI 1.27- 21.16, $P = 0.02$). The optimal cutoff points of neck circumference in the diagnosis of MetS for women is 34 cm (sensitivity of 70% and specificity 30%) and 38 cm for men (sensitivity of 65% and specificity 35%).
Conclusion
This study supports that NC is an effective anthropometric indicator associated with MetS. It has been suggested that more studies should be conducted to analyze the predictive effect of the combined application of anthropometric indicators currently in use and NC.

Sleep quality in patients with obesity: what is the association?

Mehrez Achwak, Fatma Boukhayatia, Chaima Sdiri, Rahma Khalaf, Salma Mohsen, Sana Khamassi, Asma Ben Brahim, Rym Yahiaoui, Haifa Abdessalem, Kamilia Ounaissa & Chiraz Amrouche
The National Institute of Nutrition of Tunis, Outpatient Department, Tunis, Tunisia

Introduction
Obesity and unhealthy eating pattern have been associated with altered sleep quality. We aimed to assess the sleep quality in a population of obese patients.
Methods
This cross-sectional study included 45 patients who consulted the obesity unit of the National Institute of Nutrition in Tunis. The sleep quality was assessed *using the Pittsburgh Sleep Quality Index (PSQI*, which defines a poor sleeper profile for a score ≥5 points. *Sociodemographic data and anthropometric measures were collected.*
Results
The average age was 46 years (14-79) with a female predominance (80%). The average weight was 99 ± 20 kg with an average Body mass index (BMI) of 37 ± 6 kg/m^2 and an average waist circumference of 116 cm (89-170). Overall, 51% of the subjects were good sleepers (PSQI < 5) while 49% were poor sleepers (PSQI ≥5). Better sleep quality was positively associated with physical activity ($P = 0.003$). Poor sleepers, when compared to good sleepers, had significantly higher weight (108 ± 16 kg vs 88 ± 19 kg, $P < 0.001$), BMI (39.5 ± 5.5 kg/m^2 vs 36 ± 6 kg/m^2, $P = 0.04$), and waist circumference (123 ± 16 cm vs 109 ± 12 cm, $P = 0.003$). Good sleepers had lower systolic arterial tension (117 ± 14 mmHg vs 133 ± 16 mmHg, $P = 0.002$), and better glycaemic profiles (fasting blood glucose measure = 7 mmol/l vs 8 mmol/l with $P = 0.07$ and HbA1C = 6% vs 7% with $P = 0.1$).
Conclusion
In conclusion, poor sleepers had higher BMI and waist circumference and lower systolic arterial tension. Physical activity was correlated to better sleep quality.

These results highlight that sleep assessment should be an integral part of the management of obesity in order to improve the quality of medical care.

Obesity and obesity-related diseases as a new clinical features in 3q27.3 microdeletion syndrome involving adipoq gene: A case study

Davide De Brasi, Roberto Novizio, Elisabetta Scarano, Livia Barba, Domenico Serino, Vincenzo Novizio & Francesco Scavuzzo
Azienda Ospedaliera di Rilievo Nazionale "Antonio Cardarelli", Endocrinology and Metabolism, Naples, Italy

Introduction
Adipose tissue is recognized as an important endocrine organ, secreting many endocrine factors. Adiponectin is the most abundant peptide released into circulation, encoded by ADIPOQ gene localized in chromosome 3q27.3. Adiponectin decreases intracellular ceramide, implicated in insulin resistance, inflammation and atherosclerosis. It stimulates fatty acid oxidation in skeletal muscle and inhibits glucose production in the liver. Hypo-adiponectinemia plays a central role in obesity and obesity-related disease. Since the advent of Comparative Genomic Hybridization Array (CGH-Array), numerous new microdeletional syndromes have been described. Few cases of autosomal dominant 3q27.3 microdeletion syndrome have been described, mostly characterized by intrauterine growth retardation, marfanoid habitus, cranio-facial dysmorphism, intellectual disability, psychosis and mood disorder. We describe a family affected by 3q27.3 microdeletion involving ADIPOQ gene, adding obesity and obesity-related disease to constellation of major clinical findings reported in 3q27.3 microdeletion syndrome.
Case Study
A 21-year-old Caucasian male underwent genetic investigation by CGH-Array during a diagnostic study for familiar schizoid-type personality disorder, cognitive delay, macrocephaly and thickening of skull cap. Array analysis revealed a 1.43-Mb deletion in the long arm of chromosome 3 (3q27.3), including ADIPOQ gene and other two OMIM disease genes (KNG1 and BCL6). The analysis was then extended to parental couple, demonstrating the paternal origin of the rearrangement. Afterwards, same microdeletion was demonstrated in his 26-year-old sister. Deletions were confirmed by fluorescent *in situ* hybridization. All family members shared a complex syndromic clinical spectrum consisting of severe neuropsychiatric impairment, schizoid-type personality disorder, cognitive delay and thickening of skull cap, signs compatible with other clinical findings reported in literature for 3q27.3 microdeletion. No marfanoid habitus was reported, even though all had history of ligament laxity-related disorders. All three members of the family shared moderate-severe hyperphagia, early central obesity, marked hyperinsulinemia, obstructive sleep apnea syndrome, arterial hypertension, dyslipidemia and hepatosplenomegaly with hepatic steatosis, composing a new syndromic frame in the context of 3q27.3 microdeletion syndrome.
Discussion
This new clinical spectrum associated with 3q27.3 microdeletion involving ADIPOQ gene reinforce a suggested role of adiponectin haploinsufficiency in central obesity, atherogenic metabolic status, fat accumulation in the liver and dyslipidemia. A possible role of adiponectin on food intake at hypothalamic level is also suggested. The involvement of adjacent loci and genes, such as OMIM genes, may contribute to these novel features in 3q27.3 microdeletion syndrome. The fewer number of bases involved, 1.43-Mb vs >5-Mb described in literature, could explain the absence of some syndromic features.

Metabolic syndrome in postmenopausal women with type 2 Diabetes

Hana Ben Jemâa , Chaima Jemai, Dorra Ben Salem, Olfa Lajili, Hedfi Imene, Zohra Hadj Ali, Yosra Htira & Feika Ben Mami
National institute of Nutrition, Tunis, Tunisia

Introduction
The metabolic syndrome is associated with an increased cardiovascular risk. The objective of our study was to describe the metabolic profile of postmenopausal diabetic women and to investigate a link between menopause and metabolic syndrome.
Methods
A retrospective study of 30 postmenopausal women with type 2 diabetes was performed in the Nutrition C department of the national institute of Nutrition Tunisia between January and March 2022.
Results
The average age of the patients was 63.69±8.06 years with extremes ranging from 47 years to 80 years. The average duration of diabetes was 12.3±9.23 years. Seventy-seven percent of patients were treated exclusively with insulin, 6% with oral antidiabetics and 50% with dual therapy. Degenerative complications were represented by nephropathy (42%), neuropathy (21.3%), retinopathy (26%), lower limb arteriopathy (11%) and only 2% had a history of stroke. No coronary artery disease was noted. We noted unbalanced diabetes in 75% of cases with an average glycated hemoglobin of 11.8% ±2.12. Arterial hypertension and dyslipidemia were noted in 62% and 51% respectively. The lipid profile showed the following averages: Total cholesterol 4.91±2.5 mmol/l, HDL-cholesterol 1.3±0.5 mmol/l, LDL-cholesterol 1.5 ±0.62 and triglycerides 1.9±0.96 mmol/l. Obesity was found in 53.6% of women with an average body mass index (BMI) of 34.2±1.2 kg/m^2. The waist circumference varied between 89 and 117 cm with the presence of android type obesity in 89.7%. No statistically significant correlation was found between age at menopause and weight, BMI and waist circumference with respectively (P=0.635; r=-0.05), (P=0.487; r =-0.123) and (P=0.716; r=-0.68).
Conclusion
Hormonal changes are associated with an increased cardiovascular risk which is amplified with the coexistence of a metabolic syndrome ,therefore the need for screening and regular monitoring.

Exercise is one of the major determinants of a healthy lifestyle, being crucial in childhood as a powerful preventive tool. On the other hand, obesity and arterial hypertension rate has been increasing in children, thus increasing the risk of developing cardiovascular and metabolic diseases in adult life. Of vital importance is the modality and volume of exercise required to get benefits. In this feasibility study 35 obese children were enrolled. Autonomic and metabolic control alongside auxological and lifestyle parameters were assessed before and after a 12-week online exercise training. Participants were subdivided into two groups according to the volume of exercise performed (above or below 1200 MET•minutes/week). This threshold level was obtained in two different ways: in subdivision A the total weekly physical activity volume was considered (i.e., time spent both walking for at least 10 min consecutively and performing structured exercise), while in subdivision B only the weekly volume of structured exercise was taken into account. Only in subdivision B a reduction in arterial pressure percentile as well as an improvement of vagal and metabolic control markers were found. Moreover, this 12-week online exercise training, defined on individual fitness level and progressively adapted as per individual reached goal, proved to be sustainable from both an economical and organizational perspective.

Prevalence of obesity and metabolic profile in a group of diabetic patients: About 623 cases

Amine Gueddari, Nassim Essabah Haraj, Siham El Aziz & Asma Chadli
UHC Ibn Rochd, Endocrinology and Metabolic Disorders, Casablanca, Morocco

Introduction
Obesity is the result of an imbalance in the energy balance. It is associated with many metabolic pathologies, in particular type 2 diabetes, which presents a medical and economic challenge throughout the world.
Objective of the Study
The objective of our study was to determine the prevalence of obesity and the metabolic profile in a group of diabetic patients.

Materials and Methods
This is a descriptive cross-sectional observational study including 623 patients followed in the endocrinology and metabolic diseases department of the Ibn Rochd University Hospital in Casablanca in a day hospital or in conventional hospitalization between January 2021 and July 2022. The painful diabetic neuropathy was assessed by the DN4 score. Statistical analysis of the data was performed using SPSS version 25.
Results
We included 623 patients, 63.4% of whom were women. The average age of the patients was 51.4±16.1 years. Diabetes was type 2 for 79.9% of patients. The mean HbA1c was 10.22±2.53%. Among our patients, 30.2% were overweight and 30.4% obese including 19.4% grade 1 obesity, 7.1% grade 2 obesity and 3.9% grade 3 obesity. In our study, 28.9% of patients were dyslipidemic. In bivariate analysis, obesity was higher in patients over 69 years old ($P<0.001$), in men ($P<0.001$), in patients with a university education ($P<0.001$), hypertensive patients ($P<0.001$), dyslipidemics ($P<0.001$), smokers ($P<0.001$) and in patients on insulin. In multivariate analysis, it was associated with gender ($P<0.001$) and arterial hypertension ($P<0.001$).
Conclusion
The frequency of obesity in diabetic patients potentiates cardiovascular risk. This recalls the interest of hygienic-dietary rules, in particular the Mediterranean diet and regular physical activity in these patients.

Nutritional follow-up after bariatric surgery

Amine Gueddari, Nassim Essabah Haraj, Siham El Aziz & Asma Chadli
UHC Ibn Rochd, Endocrinology and Metabolic Disorders, Casablanca, Morocco

Introduction
Obesity is known to be a risk factor for chronic conditions such as cardiovascular disease, diabetes, chronic kidney disease, non-alcoholic fatty liver disease and many cancers. The use of surgeries for the treatment of it is increasingly common.
Material and Methods
Retro and prospective study including 09 patients followed for obesity in the department of endocrinology and metabolic diseases of the UHC Ibn Rochd and who benefited from bariatric surgery with metabolic and nutritional management in the perioperative period.
Results
We reported the observations of nine patients. The average age was 39.3 years (32-47). The 9 patients were morbidly obese with an average BMI of 53.9 kg/m^2 (46-78) and a waist circumference of 120 cm. The mean duration of obesity was 17 years. Among the triggering factors: pregnancy, divorce and the peripubertal period. All patients underwent sleeve gastrectomy except one "gastric bypass". The 9 patients were placed on a high-protein diet one week before surgery with postoperative nutritional support and vitamin, iron, calcium and magnesium supplementation. The average weight loss was 33.6% of the initial weight in 1 year. Nutritional complications have been noted such as: anemia, hair loss and dry skin, zinc, vitamin B12, calcium and vitamin D deficiency.
Conclusion
The success of bariatric surgery is conditioned by multidisciplinary care with quality nutritional support before and after surgery, in order to optimize long-term weight loss while avoiding the risk of nutritional deficiencies.

Impact of Glucagon-like peptide-1 (GLP-1) receptor agonists on insulin resistance and weight as prevention of type 2 diabetes at overweight and obesity patients

Merita Emini[1], Nadije Morina Kuçi[2] & Ardiana Perjuci Begolli[1]
[1]University Clinical Center of Kosova, Clinic of Endocrinology, Pristina, Kosovo; [2]University Clinical Center of Kosova, Kosovo

Introduction
Obesity today is a growing epidemic throughout the world. With weight gain, the risk of type 2 diabetes and hypertension increases. With the approval of GLP-1 RA (semaglutide) by the FDA in June 2021 for weight reduction, a big push was given regarding the possibilities of obesity and especially for people at high risk of developing type 2 diabetes.
Aim
To analyze the impact of semaglutide on insulin resistance and weight loss in patients with prediabetes.
Methods and Material
The study prospective with 24 overweight and obese patients without diabetes and other chronic diseases but with high risk for tipe 2 diabetes because of high insulin resistance. In the study, the treatment period varied from 6-12 weeks. HOMA index and body weight reduction was monitjored. Treatment with semaglutide was done with dozes of 0.25 mg, 0.50 mg and 1 mg s.c. once a week. Each patient is instructed to change the lifestyle such as healthy food and physical activity.
Results
The weight loss of the studied population varied and the longer they took the treatment the weight loos was greater. On average, the weight loss for patients who continued the treatment for more than 3 months was from 3-18% (1-14 kg) as well as a significant decrease in the HOMA index.The side effects that were identified were nausea, vomiting and rarely diarrhea. Such weight loss has also been seen in trial studies such as SUSTASIN (Semaglutide Unabated Sustainability in Treatment of Type 2 Diabetes, 1-10 trials), STEP (Semaglutide Treatment Effect in Persons) with Obesity, 1-5 trials) and PIONEER (Peptide Innovation for Early Diabetes Treatment 1-10 trials) after witch FDA approved semaglutide for obesity treatment.
Conclusion
The patients in this study had a decrease weight and an improvement in cardiometabolic factors. The number of such risk factors for cardiovascular and metabolic diseases such as type 2 diabetes makes these medications a priority in clinical practice and the only factor that hinders access is the easy prescription of high-priced drugs on the market. Another benefit of semaglutide in weight management is its long-term use.

DOI: 10.1530/endoabs.90.EP395

Cerebellar ataxia and new onset diabetes, clinical case report

Tamar Kvaratskhelia
New Vision University Hospital, Outpatient Department, T'bilisi, Georgia

Introduction
High levels of autoantibodies to glutamic acid decarboxylase (GAD-Ab) have been described in multiple conditions such as: stiff-man syndrome, type 1 diabetes mellitus, latent autoimmune diabetes in adults (LADA), patients with auto-immune polyglandular failure and etc. In addition, some of the patients with progressive cerebellar ataxia show high titer of GAD-Ab, it may play a critical role in its development, as these antibodies are involved in the pathogenesis suggesting its auto-immune origin. This is a case report of a patient presenting with cerebellar ataxia with new onset latent autoimmune diabetes in adults.
Case Report
A 32-year-old Georgian woman presented with polyuria, polydipsia and 8 kg weight loss for past 2 months. One year before presentation the patient was diagnosed with cerebellar ataxia and was currently disabled, using cane to walk. For two years before the diagnosis she had complained of progressive gait instability and at the diagnosis brain magnetic resonance imaging showed mild cerebellar atrophy. The patient examination revealed dysarthria, horizontal nystagmus, right side head deviation, motor deficiency in right upper and lower limbs, positive Romberg sign. Routine biochemical studies as well as an immunological screening were performed. The laboratory examination showed marked hyperglycemia, glucosuria, ketonuria and impaired insulin secretion. Farther examination showed high Anti-glutamic acid decarboxylase (GAD) antibodies in patient's serum.
Conclusion
In this case cerebellar ataxia and latent autoimmune diabetes in adults can be related autoimmune conditions.

DOI: 10.1530/endoabs.90.EP396

EP397

A case report: Empagliflozin-Induced Rhabdomyolysis

Kenan Sakar[1], Melek Avci[2], Gulhan Akbaba[1] & Nese Cinar[1]
[1]Mugla Sitki Kocman University Faculty of Medicine, Department of Endocrinology and Metabolism, Muğla, Turkey; [2]Mugla Sitki Kocman University Faculty of Medicine, Department of Internal Medicine, Muğla, Turkey

Introduction
Sodium/glucose co-transporter 2 (SGLT2) inhibitors are novel oral hypoglycemic agents that are increasingly used in the management of type 2 diabetes mellitus

(T2DM). They are now recommended as second-line pharmacotherapy (in conjunction with metformin) in patients with type 2 diabetes and established atherosclerotic heart disease, heart failure or chronic kidney disease due to their favourable effects on cardiovascular and renal outcomes. We report a case of a 47-year-old woman who developed rhabdomyolysis after commencing the SGLT2 inhibitor empagliflozin. Case presentation: A 47-year-old female case was followed in the endocrinology clinic for T2DM, hyperlipidemia and chronic renal failure (Cre:1.73 mg/dl, GFR:35 ml/min and spot urine albumin/creatinine ratio:243 mg/g). She had been using linagliptin, insulin detemir, fenofibrate, rosuvastatin, candesartan and acetylsalicylic acid for two years. Empaglifozin was added because of her high HbA1c level (7.8%) and renal dysfunction. The patient presented to the emergency department with the complaint of muscle pain two weeks after starting empaglifozin. Laboratory results showed elevated creatinine kinase (CK) level of 3014 U/l (reference range 0-150 U/l) and increased creatinine level (2.84 mg/dl). Her CK levels were in normal range before empagliflozin treatment. No elevation in troponin levels was observed during follow-up. The patient was hospitalized with a diagnosis of rhabdomyolysis. Intravenous saline infusion therapy was started. Rosuvastatin, fenofibrate and empaglifozin were stopped. During the follow-up, creatinine kinase levels decreased to normal levels and creatinine level regressed to its basal level within a week.
Conclusion
Drug-induced myopathies may present with varying severity, ranging from asymptomatic CK elevation, myalgia to rhabdomyolysis with acute kidney injury. Commonly implicated agents are statins and glucocorticoids. There are few case reports in the literature reporting development of myopathy after empaglifozin treatment with/without statins. On the otherhand, a retrospective study including 2202 cases of myopathy by Alkabbani et al., found that reports of myopathy were not disproportionally higher among those using SGLT-2 inhibitors with statins compared to SGLT-2 inhibitors or statins alone at the class level. Although our patient was using rosuvastatin and fenofibrate which are well-described causes of drug-induced rhabdomyolysis, we thought that empaglifozin might induce rhabdomyolysis because of long-term use of anti-hyperlipidemic drugs and the development of rhabdomyolysis 2 weeks after starting empaglifozin. Since the pathogenesis is not known, further studies are needed to determine the relationship between SGLT2 inhibitors and drug-induced myopathy and clinicians should keep in mind the risk of rhabdomyolysis with increased utilization of these drugs.

Watch out! Starvation ketoacidosis mimicking diabetic ketoacidosis

Anara Karaca[1], Gopika Sreejith[2], Bashir Mahamud[1], Casimiro Cruz Maningas III[2], Juthi Roy[2] & Gideon Mlawa[1]
Barking, Havering and Redbridge University Hospitals NHS Trust, Endocrinology and Acute Medicine, London, United Kingdom; [2]Barking, Havering and Redbridge University Hospitals NHS Trust, Acute Medicine, London, United Kingdom

Background
Starvation ketoacidosis (SKA) represents one of three metabolic acidosis caused by the accumulation of ketone bodies in blood. While easily treated, it is a diagnosis that can be easily mimic diabetic ketoacidosis, particularly in the presence of hyperglycemia[1].
Case
We report a 54-year old female, who had been feeling unwell with ongoing nausea and vomiting, and not eating nor drinking for 5 days. She had a history of alcohol excess but had abstained for some time prior admission, and had an anxiety and depression. Regular medication included mirtazapine and propranolol. Her BM was found 21.8 mmol with positive ketones in urine. Venous blood gas revealed metabolic acidosis. Diagnosis of diabetic ketoacidosis with new onset of diabetes and possible SKA were made. She was managed using the local DKA protocol and saw prompt resolution of her acidosis. This patient also received IV thiamine due to concerns regarding overlap of alcoholic ketoacidosis (AKA). As a result, her HbA1c was 34 mmol and anti GAD antibodies were negative. Thus, DKA was ruled out, and diagnosis of starvation ketoacidosis was finally made.
Conclusion
SKA represents raised anion gap metabolic acidosis caused by the accumulation of ketone bodies in the blood and normal or low glucose levels. The other two causes of a ketoacidosis are alcoholic ketoacidosis and the much more common diabetic ketoacidosis as it was previously thought in this case. As, our patient had severe hyperglycemia, which misdirected us to DKA. Thus importantly consider checking HbA1c to confirm DKA.

Localisation of the steroid 5β-reductase in hepatoma cells

Tom Potter[1,2], Jeremy Tomlinson[2] & Laura Gathercole[1,2]
[1]Oxford Brookes University Headington Campus, Department of Biological and Medical Sciences, United Kingdom; [2]Oxford Centre for Diabetes, Endocrinology and Metabolism, University of Oxford, Radcliffe Department of Medicine, Headington, United Kingdom

The hepatic enzyme 5β-reductase (AKR1D1) sits at the interface between two metabolic pathways, converting steroid hormones to their inactive 5β-reduced metabolites during steroid clearance, and as a step in the synthesis of bile acids from cholesterol. Both the steroid substrates and the bile acid products of AKR1D1 are potent hormones that regulate hepatic energy metabolism and inflammation. It is not known how these two functions are spatially organised within hepatocytes. The subcellular localisation of steroid metabolising enzymes is thought to have a role in determining their activity and substrate preference. Key bile acid synthesis enzymes upstream of AKR1D1 are localised to the endoplasmic reticulum (ER) membrane and we hypothesised that a fraction of AKR1D1 would localise at the ER to facilitate its role in bile acid synthesis. To test this hypothesis, AKR1D1 tagged with green fluorescent protein (AKR1D1-GFP), or GFP alone, were overexpressed in HepG2 hepatoma cells. The ER was labelled using a targeted red fluorescent protein (ER-RFP). Serial optical sections of cells expressing both AKR1D1-GFP (or GFP) and ER-RFP were imaged using Airyscan laser scanning confocal microscopy, and the 3D colocalisation of the fluorescent probes was quantified using ImageJ. There was no difference in the degree of colocalisation with ER-RFP between AKR1D1-GFP or GFP. These data suggest that AKR1D1 does not localise to the ER more than GFP alone. However, the overexpression of AKR1D1-GFP appeared to disrupt the normal localisation of AKR1D1 and so these results need to be confirmed in cells with endogenously tagged AKR1D1. AKR1D1-GFP was observed in both the cytoplasm and nucleus of HepG2 cells. To confirm whether native AKR1D1 localises to the nucleus, nuclear and cytoplasmic fractions were isolated from HepG2 cells and fraction purity confirmed by Western blot using Lamin A/C and β-Tubulin as controls. AKR1D1 was detected in the cytoplasmic but not the nuclear extract, suggesting that the nuclear staining may be an artefact of overexpression.

Circadian profiles of amino acids and biogenic amines in serum and dried blood spot assessed by LC-MS/MS in healthy subjects

Ilaria Improta[1,2], Valentina Bissi[2], Greta Galante[2], Lorenzo Tucci[1,2], Valentina Vicennati[1,2], Uberto Pagotto[1,2], Flaminia Fanelli[2] & Guido Di Dalmazi[1,2]
[1]S. Orsola-Malpighi Polyclinic, Endocrinology and Diabetes Care and Prevention Unit, Bologna, Italy; [2]Alma Mater Studiorum - Bologna University, Dept. Of Medical and Surgical Sciences, Center for Applied Biomedical Research, Bologna, Italy

Introduction
Recent studies demonstrated that circulating concentration of many metabolites fluctuates with circadian rhythmicity. However, detailed information on amino acid and biogenic amine daily variations is still lacking. Dried blood spot (DBS) sampling appears to be a convenient tool for studies requiring multiple daily sampling.
Aim
To verify the validity of DBS as a suitable device, we compared serum and DBS levels and changes along the day of a large panel of amino acids and biogenic amines.
Methods
Six healthy normal weight (BMI = 18.5-25.0 kg/m^2) subjects (3/3 men/women) aged 26-50y were enrolled. All had a standard Mediterranean normocaloric diet during the observation and the 6 preceding days. Six paired serum, from venous, and DBS, from capillary, blood sampling were collected 30 min before and two hours after breakfast (07:30), lunch (13:30) and dinner (19:30). Twenty amino acids and 21 biogenic amines were measured by liquid chromatography-tandem mass spectrometry.
Results
All amino acids were measurable in both serum and DBS. Of 21 biogenic amines, 14 could be measured in both serum and DBS. One was only detected in serum. Concentrations of amino acids and biogenic amines were 16.4-796.2 and 0.049–96.2 μM in serum and 18.9–550.9 and 0.17–157.6 μM in DBS, respectively. Among amino acids, 15 were higher and 3 were lower in serum vs DBS (P: <0.001–0.018). Among biogenic amines, 6 were higher and 5 were lower in serum vs DBS (P: <0.001–0.010). Direct correlations between serum and DBS levels were observed for 14 amino acids (P: <0.0001–0.022) and 11 biogenic amines (P: <0.0001–0.047). Strongest correlations were observed for amino acids in leucine (r=0.794), isoleucine (r=0.760), valine (r=0.740) and proline (r=0.739), and for biogenic amines in acetylornithine (r=0.941), creatinine (r=0.655), putrescine (r=0.590) and serotonin (r=0.582). Parallel significant daily variations were observed both in serum and in

DBS for isoleucine, leucine, methionine, phenylalanine, proline, tryptophan, tyrosine, valine and methionine sulfoxide (*P*: 0.001–0.068). The positive quadratic trend indicated higher levels in the morning and evening, and lower levels at midday. Additional significant reduction along the time points was observed in DBS for creatinine ($P < 0.001$) and kynurenine (*P*0.007).

Conclusions

Information conveyed by DBS parallels those by serum for most of the analytes. Furthermore, DBS provided additional evidences on creatinine and kynurenine daily variations. DBS represents a valid opportunity to study amino acid and biogenic amine circadian variations in physiologic and clinical conditions related to the HPA axis.

Role of selective arterial calcium stimulation test in the evaluation of hypoglycaemia post Roux-en-Y gastric bypass

Rabih Hijazi[1], Maguy Chiha[1], Maria Matar[1], Cynthia Salloum[1], Ola Jarad[1] & Mahra AlMheiri[2]

[1]Cleveland Clinic Abu Dhabi, Endocrinology, Diabetes, and Metabolism, Abu Dhabi, United Arab Emirates; [2]Cleveland Clinic Abu Dhabi, Graduate Medical Education, Internal Medicine Residency, Abu Dhabi, United Arab Emirates

We present the case of a 50-year-old male who developed severe hypoglycaemia after Roux-en-Y gastric bypass (RYGB), illustrating the role of selective arterial calcium stimulation test (SACST) in the diagnosis and management of hypoglycemia. Our patient presented with recurrent hypoglycaemia one to two hours after meals, which started 15 years post RYGB performed for morbid obesity with hypertension, impaired glucose tolerance, NAFLD and ischemic heart disease. The hypoglycaemia events were severe and frequent, with glucose levels reaching 39 mg/dl (2.2 mmol/l) associated with altered level of consciousness. During these events, patient had high insulin (1086 pmol/l), proinsulin (26.2 pmol/l), and C-peptide (6.08 nmol/l) levels, normal levels of beta-hydroxybutyric acid, with negative sulfonylurea screen, negative insulin antibodies and normal IGF2 levels, all suggestive of endogenous hyperinsulinemia. The patient failed to have hypoglycaemia during a mixed meal test and a 72- hour fast. He had normal thyroid, kidney and adrenal function tests. Imaging and functional studies of the pancreas and abdomen were negative; these included abdominal computed tomography, abdominal magnetic resonance imaging and Gallium Dotatate PET CT. In addition, endoscopic ultrasound (EUS) was performed and did not show any pancreatic masses. Acarbose was initiated with dietary modification which included a low carbohydrate and high protein diet, however, hypoglycaemia episodes persisted. He was then started on daily octreotide injections and nifedipine. The hypoglycaemia episodes became less severe and less frequent subsequently. To further investigate the source of endogenous hyperinsulinemia in our patient, a selective arterial calcium stimulation test (SACST) was performed in order to differentiate between insulinoma (uni or multifocal) and non-insulinoma pancreatogenous hyperinsulinemia. This showed two to threefold increase in insulin levels post arterial calcium stimulation in all pancreatic regions and no tumor blush was observed. Therefore, the test did not localize a focal region of the pancreas that is responsible for excess insulin secretion and that would be amenable to surgery. Lastly, he was not a candidate for gastrojejunostomy stoma reduction/plication as there was evidence of Roux-en-Y anatomy with a micro pouch on upper endoscopy. Reversal of the bypass was also discussed but not pursued given patient's morbid obesity and overall poor health condition. The decision was to continue with medical and dietary therapies for non-insulinoma pancreategenous hyperinsulinemia. Our case illustrates the importance of SACST in the evaluation of endogenous hyperinsulinemic hypoglycaemia with negative localization studies. In this case, it spared the patient from undergoing an additional highly morbid surgery (pancreatectomy).

Estimation of reproductive state in women with DM1

Mushtariy Mahkamova[1], Mukima Karimova[1] & Zulaykho Shamansurova[1,2,3]

[1]Ferghana Medical Institute of Public Health, Endocrinology, Ferghana, Uzbekistan; [2]Tashkent Pediatric Medical Institute, Endocrinology, Tashkent, Uzbekistan; [3]Institute of Biophysics and Biochemistry, Metabolomics, Tashkent, Uzbekistan

Introduction

Past years with increasing of duration of life, improving of treatment and increasing of life longevity and new knowledges about Diabetes Mellitus pathogenesis and treatment rise interest to reproduction in these women, especially with type 1 DM. Well known, that late puberty, abnormal menstrual cycle, pregnancy and childbirth pathology, infertility. The aim of our study was investigate the functional state of reproductive system in woman with DM1.

Material and Methods

72 control female patients with type 1 diabetes and 40 healthy women were examined. The age of the examined patients ranged from 11 to 28. In all female patients blood plasma FSG, LG, Estrogen, Progesterone, Testosterone level were determined by the enzyme immunoassay method, uterine and ovarian Ultrasound were performed.

Results

In patients with DM1 blood plasma level of Estrogen were decreased in 60% of them, Progesterone - in 24%, Testosterone - in 45%, whereas FSG and LG levels were increased and suggested about hypergonadal hypogonadism in women with DM1. Anamnesis data shown among women with DM1 about 44% had amenorrhea, 16% had infertility, 11% had stillbirth, and 9% had premature birth. On ultrasound examination of the uterus and ovaries in women with DM1 shown that 20% had uterine hypoplasia and was in line with blood hormones level.

Conclusion

In observed woman with DM1 according to anamnestic data shown abnormalities in functional state of reproductive system such as amenorrhea (44%), infertility (16%), stillbirth (11%), premature birth (9%), which accompanied with decreasing of peripheral sex hormones level and increasing of pituitary hormones and uterine hypoplasia (20%) on ultrasound suggested about hypergonadal hypogonadism.

The association between vitamin D3 deficiency and acute kidney injury in COVID-19 patients

Mitra Kazemijahromi[1], Mohsen Arabi[2], Hamidreza Samimagham[3], Azadeh Moradkhani[3], Fatemeh Khajavi Mayvan[4], Sara Binaei[4] & Ali Salimi Asl[4]

[1]Endocrinology and Metabolism Research Center, Hormozgan University of Medical Sciences, Bandar Abbas, Iran; [2]Preventive Medicine and Public Health Research Center, Family Medicine Department, Iran University of Medical Sciences,Tehran, Iran; [3]Clinical Research Development Center, Shahid Mohammadi Hospital, Hormozgan University of Medical Sciences, Bandar Abbas, Iran; [4]Student Research Committe,Faculty of Medicine, Hormozgan University of Medical Sciences, Bandar Abbas, Iran

Introduction

Vitamin D deficiency is a common clinical finding in the general population and hospitalized patients, including patients in the intensive care unit(ICU). Acute kidney injury (AKI) occurs in more than 50% in ICU admitted patients.

Objectives

Due to the fact that there are few studies about AKI in COVID-19 patients, we investigated the relationship between vitamin D3 deficiency and the occurrence of AKI in COVID-19 patients.

Patients and Methods

This cross-sectional study was conducted on 69 COVID-19 patients who were hospitalized in the ward for 12 months. Their serum vitamin D3 levels were measured in the first 24 hours of hospitalization in the ward. Patients were divided into three groups based on the serum level of vitamin D3: >50 ng/ml: normal, 20-50 ng/ml: insufficient, <20 ng/ml: deficiency. The patients were studied until the occurrence of acute renal injury or the occurrence of death.

Results

Out of 69 hospitalized patients in the ward with COVID-19, there were 39 patients in group vitamin D3 <20 ng/ml, 21 patients in group vitamin D3 20-50 ng/ml and 9 patients in group vitamin D3 >50 ng/ml. The frequencies of AKI in group vitamin D3 <20 ng/ml, 20-50 n/ml, and >50 ng/ml were 46%, 28%, and 23%, respectively. Significant relationship was observed between AKI and our study groups (*P*-value $=$ 0.011). Furthermore, there was a significant association between our study groups and mortality (*P*-value $=0.014$), ICU admission (*P*-value $=0.041$) and hospital length of stay (*P*-value $=0.017$). In another division in patients with different levels of vitamin D3 in the presence or absence of AKI, there was a significant association between group of patients with vitamin D3 <20 ng/ml in presence of AKI and mortality ($P=0.042$), ICU admission (*P*-value $=0.024$) and hospital length of stay (*P*-value $=$ 0.027).

Conclusion

Our study showed significant association between vitamin D deficiency and AKI in ICU-admitted COVID-19 patients. Moreover, there was relationship between vitamin D deficiency and mortality, ICU admission and hospital length of stay. These results suggest the correction of vitamin D deficiency may be beneficial to reduce AKI in patient with COVID-19.

Effects of Metabolic Syndrome on Cardiovascular Outcomes of Psoriatic Patients With Coronary Artery Disease

Lin Zhao[1], Lin Sun[1], Yan Zeng[1] & Xianliang Zhou[1]
[1]Fuwai Hospital, National Center for Cardiovascular Disease, Chinese Academy of Medical Sciences and Peking Union Medical College, Cardiology, Beijng, China

Background
Psoriasis is associated with a heightened prevalence of cardiovascular risk factors, including metabolic syndrome (MetS). As so far, it is not clear whether MetS will cause differences on clinical outcomes of psoriatic patients who have already suffered from coronary artery disease.
Methods
We conducted a retrospective cohort study to determine the effects of MetS in psoriatic patients with coronary artery disease. Comparisons were made between patients with and without MetS. The Cox regression analysis and Kaplan-Meier survival analysis were used to evaluate the association between variables.
Results
Of the 307 participants, 94 met criteria (30.6%) for MetS. Individuals with MetS were more common in females ($P<0.001$). The levels of platelet counts and hsCRP were higher in the MetS group ($P=0.038$ and 0.005, respectively). After the mean follow-up of 35.32 ± 18.61 months, major adverse cardiovascular events (MACEs) and non-fatal myocardial infarction were more prone to occur in MetS group than Non-MetS group (33.3% vs 20.6%, $P=0.02$; 26.4% vs 15.7%, $P=0.032$, respectively). Kaplan-Meier estimates showed the same trend. The COX regression analysis showed that MetS [hazard ratio (HR) = 1.738, 95% confidence interval (95%CI): 1.045–2.891, $P=0.033$] and left ventricular ejection fraction (HR = 0.968, 95%CI: 0.945–0.991, $P=0.006$) were associated with an increased risk of MACEs.
Conclusion
In psoriatic patients with coronary artery disease, MetS was more common in females and it independently predicted MACEs. In addition, left ventricular ejection fraction was associated with an increased risk of MACEs. To reduce the cardiovascular disease risk associated with MetS, it is necessary to increase awareness of the condition.

Adherence to lipid lowering treatment in type 2 diabetics with dyslipidemia

Dorra Ben Salem, Olfa Lajili, Selma Mohsen, Hana Ben Jemâa, Chaima Jemai, Yosra Htira, Zohra Hadj Ali, Hedfi Imene & Feika Ben Mami
National Institute of Nutrition, Tunis, Tunisia

Introduction
Dyslipidemia is highly prevalent in patients with type 2 diabetes, which increases the risk of cardiovascular disease in these patients. Lipid-lowering treatment has demonstrated beneficial effects in the primary and secondary prevention of cardiovascular events.
Objective
Evaluate the therapeutic compliance of dyslipidemia treatment in type 2 diabetic patients and identify the factors limiting the follow-up of the therapeutic prescription in them.
Materials and Methods
It was a cross-sectional study, including 60 patients with type 2 diabetes hospitalized in the department C of the National Institute of Nutrition of Tunis for 3 months (October-December 2022).
Results
The mean age was 51.67 ± 12.5 years. The sex ratio was 0.3. The mean duration of diabetes was 11.1 ± 6.1 years. One third of patients were treated with insulin (30.4%). Cardiovascular risk was moderate, high, and very high in 17.9%, 50% and 32.1% of patients, respectively. Among all participants, mixed- dyslipidemia was the most prevalent (52.2%), followed by hypercholesterolemia (27.6%) while hypertriglyceridemia was identified in 20.2% of patients. Dyslipidemia was treated with atorvastatin in 82.1% of cases. In primary prevention, no patient reached the therapeutic goals, whereas in secondary prevention, the objectives were reached in only 13.2% of cases. Only 46.4% of patients reported following the clinical and biological monitoring rhythm after starting a statin treatment. More than half of the patients (56.5%) reported stopping treatment on their own. The main reasons for non-adherence to statin therapy were high cost, unavailability of treatment, side effects, and poly-medication reported in 46.2%, 23.1%, 7.7%, and 23.1% of cases, respectively. However, two thirds of patients receiving statins were not informed about their effectiveness in cardiovascular protection.
Conclusion
Non-adherence to lipid-lowering treatment in type 2 diabetic patients is a limiting factor in therapeutic efficacy. Strengthening therapeutic education for these patients would be essential to improve adherence to medical prescriptions and prevent cardiovascular events in this at-risk population.

Combination of mutations in the HNF1A and ABCC8 genes: Clinical polymorphism in members of the same family

Irina Eremina, Elizaveta Raykina, Elena Titovich, Valentina Peterkova & Dmitry Laptev
Endocrinology Research Center, Children Department, Moscow, Russia

Mutations in HNF1A gene underlie the development of maturity onset diabetes of the young type 3 (MODY3). Mutations in ABCC8 gene are the cause of neonatal DM and the rare MODY12, which is clinically similar to MODY3. In these forms of MODY, there is a high sensitivity to sulfonylurea, but over time, patients may need insulin therapy.
Patient A, 17 y.o. He was born to woman with gestational DM. At the age of 12.5, fasting hyperglycemia of 13 mmol/l was detected. Insulin therapy was not prescribed due to the parents refusal. At the 14.5 y.o, since his mother was diagnosed with MODY3, a pathogenic variant p.R54X in HNF1A was detected, a MODY3 was diagnosed. At the age of 15, he was hospitalized with hyperglycemia 13.8 mmol/l. HbA1c - 9.8%. Long-acting insulin was assigned. Subsequently, the patient used insulin irregularly and consumed large amounts of fast carbohydrates. His maximum HbAc1 was 20.5%. At 17 y.o, he was admitted to hospital: glycemia was 18.6 mmol/l, HbAc1 - 12.6%, islet antibodies were negative. Intensified insulin therapy (0.9 units/kg/day) led to the normalization of glycemia. Specific diabetic complications were not detected. In addition to the variant in the HNF1A, a p.R521X variant was found in the ABCC8. After 3 months, the boy was successfully transferred to glibenclamide 7.5 mg/day.
Patient L, 37 y.o, proband's mother. At the age of 20, gestational DM was diagnosed: fasting glycemia was 6-9 mmol/l, she refused insulin therapy. At the 32 y.o, an examination for cholelithiasis revealed hyperglycemia, the variant p.R54 X in the HNF1A was detected. To date, she has not received hypoglycemic therapy, followed a carbohydrate-restricted diet. At the last examination at the age of 37, HbAc1 was 6.7%, a variant of p.R521X was found in the ABCC8 as in the son.
Patient S, 8 y.o, proband's sister. HbAc1 – 5.4%, fasting glycemia – 4.7 mmol/l. There are variants of p.R54X in the HNF1A and p.R521X in the ABCC8.
Conclusion
MODY associated with variants in the HNF1A and ABCC8 is characterized by a different degree of carbohydrate metabolism disorders, depending on the location of mutation in gene and its severity. We have presented a description of clinical polymorphism in members of family with a combination of identical mutations in the two MODY genes. The more severe disease in proband, apparently, is due to the low compliance. Normoglycemia in sister may be due to age, which requires further dynamic observation.

The influence of the metabolic profile on the manifestations of diabetic neurogenic bladder

Abdel Mouhaymen Missaoui, Faten Haj Kacem Akid , Siddiqa Soomauroo, Wafa Belabed, Nabila Rekik Majdoub, Mouna Elleuch & Mohamed Abid
Hedi Chaker University Hospital, Department of Endocrinology, Sfax, Tunisia

Objective
To determine the influence of metabolic disturbances associated with diabetes mellitus (DM) on the clinical manifestations of the diabetic neurogenic bladder (DNB).
Patients and Methods
Analytical cross-sectional study comparing two groups of patients suffering from DM: G1 ($n=159$) with manifestations of DNB versus G2 ($n=41$) without signs of DNB.

Results
G2 patients were younger than G1 patients (58±12 years vs 59.7±10.3; $P=0.36$) with a female predominance (63.4% vs 52%; $P=0.16$). The duration of diabetes was significantly longer in G1 (11.9 vs 7.7 years; $P=0.03$). A glycemic imbalance was statistically more pronounced in G1 (88% vs 61%; $P=0.000$). Patients in G1 were more likely to have high blood pressure (53.8% vs 30%) and dyslipidemia (59.7% vs 47.5%) without statistical significance. The mean BMI was significantly higher in G1 (29.2±5.5 vs 26.4±4.2 kg/m^2; $P=0.03$). The mean waist circumference was also greater in G1 (103.5 vs 95.7 cm; $P=0.01$). The prevalence of obesity was higher among G1 patients (34% vs 14.6%; $P=0.016$). Although more prominent in G1, the metabolic syndrome did not appear to significantly influence the clinical manifestations of DNB (65.8% vs 34.2%; $P=0.07$).
Discussion
Certain metabolic disturbances, notably android obesity, seem to be a factor aggravating the manifestations of DNB. Through chronic inflammation and alteration of para-sympathetic neurons, obesity-induced insulin resistance disturbs bladder muscle function. Thus, several studies highlight the interest in weight loss as a therapeutic target to improve the symptoms of DNB in obese patients with DM.

« Echocardiography indicators after endovascular revascularization in patients with type 2 diabetes mellitus and chronic heart failure»
Feruza Khaydarova & Diera Inogamova
Republican Specialized Scientific Practical Medical Center of Endocrinology of Public Health Ministry named by acad. Ya.Kh. Turakulov,, Tashkent, Uzbekistan

Aim
To study the parameters of heart Doppler before endovascular revascularization in patients with type 2 diabetes mellitus and without it in patients with coronary artery disease.
Research Material
60 patients (prospectively) with CHF were examinedafter endovascular revascularizationin the period of 2021 at the Center of Surgery named after acad. V.V. Vakhidov.All observed patients were divided into 2 groups: 1 gr. – 35 patients with DM2 with CHF and undergoing CABG. 2 gr. – 25 patients with CHF without DM2 who underwent CABG. The control group consisted of 20 patients with type 2 diabetes without CHF. To characterize the examined patients were used: general clinical, biochemical and instrumental examinations.
Material and Methods
general clinical, biochemical (bilirubin, direct, indirect, lipid spectrum, ALT, AST, coagulogram, blood sugar, glycated hemoglobin, urea, creatinine, GFR, galectin-3, insulin, renin, aldosterone in the blood) and instrumental: ECG, Echo-ECG, cardiac angiography, Dopplerography of the main vessels of the heart and legs, ultrasound of internal organs, fundus.
Results
We analyzed 60 patients with type 2 diabetes mellitus complicated by coronary artery disease and chronic heart failure. Of these, 19 women, 41 men. Biochemical blood tests showed that the average values of the lipid spectrum were significantly increased in all patients of groups 1 and 2, compared with the control group ($P<0.05$).The next stage of our research was to study the relationship between various parameters and LV ejection fraction on Echo-ECG by groups. In patients of group 1, Echo-ECG showedrevealed left ventricular dysfunction and cardiomyopathy in 100% of cases, while in patients of group 2 thesechanges were detected in 17% of cases ($P<0.05$). In patients of group 1, hemodynamic parameters of the heart were significantly lower than in patients of group 2.
Conclusions
It was found that in patients of groups 1 and 2, no significant differences in mean age, BMI, glycemia, renin values, insulin, HOMA index were found depending on the EF values. At the same time, the significance of differences was revealed only for aldosterone and galectin-3; these values significantly increased as EF decreased in patients of group 1. ($P<0.05$).

"Features of Doppler ultrasound of the heart and kidneys in patients with type 2 diabetes mellitus with cardio-renal syndrome"
Kamola Alimova & Feruza Khaydarova
[1]Republican Specialized Scientific Practical Medical Center of Endocrinology of Public Health Ministry named by acad. Ya.Kh. Turakulov, Department of Diabetic Nephropathy, Tashkent, Uzbekistan

Purpose of the Study
To study the relationship between the renal perfusion index and systolic heart function in type 4 cardiorenal syndrome in patients with type 2 diabetes mellitus"
Material and Research Methods
The study, which was performed from January to May 2022, included 48 patients with type 2 diabetes mellitus and stage 1-3 CKD. (16 F, 32 M, age 50±17 years, BMI 27.02±3.44 kg/m^2) according to the study protocol. Hypertensive nephropathy (HT-CKD) addressed 12 patients. None of the patients included in the study had heart failure. The control group consisted of 20 patients with DM2 without CHF and without CKD. The study used clinical and biochemical research methods (glycemia, glycated hemoglobin, IRI, C-peptide, ALT, AST, bilirubin, urea, creatinine, PTI, hormonal studies (renin, angiotensin, aldosterone) as well as instrumental methods of examination - ultrasound internal organs,ultrasonography with an assessment of the overall intensity of cortical perfusion of the kidneys and the renal perfusion index (RPI),ECG, Echo-ECG, indicators of the quality of life of patients (questionnaire), as well as statistical methods.
Research Results
Analyzing the data of dopplerography of the heart and kidneys, we present for the first time the effect of systolic heart function on RI in patients with type 2 diabetes with CKD. This allows with the probability of early non-invasive detection of cardiac systolic pathology during ultrasound of the kidneys, when high-quality ultrasound examination of the structures of the heart is impossible (lack of technique, emphysema, obesity). Finally, it is likely that RI assessment may be useful for early detection of CRS associated with reduced cardiac output [14]. However, the applicability of RI for diagnosing early anomalies of the cardio-renal axis requires further study.
Conclusions
1) In the group of patients with DM 2 and CKD stages 1-3 without CHF, we detected Echo-ECG changes according to the type of LV diastolic dysfunction of 1-2 degrees with a tendency to increase the mean pressure in the pulmonary artery. 2) RI can be used as an independent marker for predicting the outcomes of CKD in type 2 DM.

Etiological profile and outcomes of acute pancreatitis in patients with type 1 diabetes
Abdel Mouhaymen Missaoui, Fatma Mnif, Wafa Belabed, Mouna Elleuch, Mouna Mnif, Nabila Rekik Majdoub, Dhoha Ben Salah & Mohamed Abid Hedi Chaker University Hospital, Department of Endocrinology, Sfax, Tunisia

Objective
To describe the etiological profile the outcomes of acute pancreatitis (AP) in patients with type 1 diabetes (T1DM).
Patients and Methods
A retrospective descriptive study of 10 T1DM patients who presented at least one episode of AP during their follow-up.
Results
The mean age at diagnosis of T1DM was 19.7±9.3 years, with a female predominance (60%). T1DM was frequently inaugurated by a cardinal syndrome (50%) or spontaneous diabetic ketoacidosis (DKA) (20%). In 10% of patients, T1DM was diagnosed at the time of AP. The episode of AP occurred at a mean age of 26.9±14.9 years. In 57.1% of the cases, the AP wasclassified as stage E. Stages A, B, or C were less commonly reported with a frequency of 14.3%, each. The identified etiologies of AP were autoimmune (20%) or major hypertriglyceridemia (10%). In 70% of the cases, the mechanism of AP remained undetermined. Despite a favorable outcome after the first episode, recurrence of AP is still frequent in T1DM with a rate of 16.7%. Discussion: The pathophysiological mechanism of AP in patients with T1DM remains poorly understood. The consequences of AP on pancreatic tissue previously weakened by autoimmune destruction related to T1DM would be more prominent compared to control subjects. Thus, our work highlights an increased incidence of stage E with more frequent recurrence in this population. Further studies with a large number of subjects are needed to find more precise explanations.

Glycosylated haemoglobin levels in new and known diabetes patients with hyperglycaemic ketoacidosis

Safouane Charfi[1], Rim Marrakchi[1], Ksentini Mohamed[1], Mariem Boudaya[1], Kamel Jamoussi[1], Mouna Turki[1], Faten Haj Kacem Akid[2] & Mohamed Abid[2]
[1]Hedi-Chaker University Hospital of Sfax, Biochemistry Departement, Sfax, Tunisia; [2]Hedi-Chaker University Hospital of Sfax, Endocrinology Departement, Sfax, Tunisia

Background/Aims
Ketosis in patients with known Type 2 diabetes mellitus is overlooked due to atypical symptoms. Type 2 diabetes (DT2) is characterized by a longer period of asymptomatic hyperglycaemia than Type 1 diabetes(DT1). The objective of this study was to compare glycosylated haemoglobin (HbA1c) levels in ketoacidosis (DKA) occurring in known and newly diagnosed diabetes.
Methods
This is a retrospective cross-sectional descriptive study concerning all patients hospitalized in the Endocrinology Department for DKA between November 2021 and January 2022. HbA1c levels were determined on ADAMS ® Arkray at presentation. The data were analyzed using SPSS 26.
Results
There were 14 known DT1 or DT2 patients and 6 newly diagnosed diabetes. The mean age was 24±8.30 years The mean HbA1c of all admissions was 12.03±2.96% ($n=20$) . The mean HbA1c in known DT1 or DT2 and newly diagnosed diabetes patients were similarly high 11.6±3.2% and 13.6±1.6% (P0.15) respectively. The averages of HbA1c above 8% were statistically similar in the both groups of patients (93.3% in known DT1 or DT2 vs 100% in newly diagnosed diabetes patients.
Conclusions
DKA is associated with markedly elevated HbA1c levels in known DT1 or DT2 and new onset diabetes.

An inaugural diabetic ketoacidosis revealed by odontogenic facial cellulitis

Ahmed Boukhalfa, Sana Rafi, Ghizlane El Mghari & Nawal El Ansari
Mohammed VI University Hospital Center Marrakech, Endocrinology, Diabetology and Metabolic Diseases Department, Marrakech, Morocco

Introduction
Odontogenic facial cellulitis (OFC) is a soft cellulo fatty tissue infection of lesser resistance in different spaces, delimited by the musculoaponeurotic insertions on the maxillary and mandibular bone cortices. when patients have underlying diseases such as diabetes mellitus (DM) or cancer, compromised immune systems may lead to the opportunistic progression of seemingly minor infections. We report the case of a patient who presented an inaugural diabetic ketoacidosis (DKA) revealed by OFC.
Case Report
A 40- year-old female patient with a passive smoking history, presented to the emergency department for consciousness disorders, interview with the family reveals the notion of a toothache 2 weeks before complicated by jugal pain and fever. The physical assessment had revealed a tchycardia of 122 bpm, 100/63 mmhg blood pressure, high respiratory rate 29 cpm and 39.2 °C of temperature. The face was swollen and erythematous with trismus. A facial CTscan was performed which showed collection of the left masseter muscle, hypodense, peripherally enhanced with air bubbles measuring $16^{\times}35.5^{\times}33.5$ mm with thickening of the left jugal subcutaneous soft tissue. In the side the biological assessment was in favor of an elevated plasma glucose level of 4.2 g/l, metabolic acidosis and urine ketones. C-reactive protein level was at 291 mg/l with white blood cell count 25910 per mm^3. The diagnosis of OFC with an inaugural diabetic ketoacidosis was retained. After stabilization, the management consisted of surgical drainage of the abscess with antibiotic therapy guided by the result of the antibiogram of the pus sample, in addition to insulin therapy and rehydration.
Discussion and Conclusion
OFC is a rare but serious infection which can engage the vital prognosis by its encephalic complication like the thrombophlebitis of the cavernous sinus and cervical like the collections or even mediastinitis especially when it occurs in an immunocompromised state such as diabetes. The diagnosis must be suspected in front of any inflammatory facial pain or swelling on a precarious dental ground. The corner-stone of treatment is based on broad-spectrum antibiotics with surgical draining in suppurative phase in parallel with the management of diabetic decompensation.
Keywords: inaugural DKA-facial-odontogenic cellulitis.

Risk factors for lower limb amputation in patients with diabetes

Ines Bani, Nadia Ben Amor, Faten Mahjoub, Abir El Amri, Berriche Olfa, Ramla Mizouri, Rym Ben Othman, Gammoudi Amel, Lahmar Ines & Jamoussi Henda
National Institute of Nutrition and Technology, A, Tunis, Tunisia

Introduction
The diabetic foot is a frequent complication that can be life-threatening for the diabetic patient. The risk of amputation is multiplied by 40 in the diabetic patient compared to the non-diabetic population. Our aims were to determine the prevalence of foot amputation in patients hospitalized for poorly controlled diabetes, and to determine the risk factors associated with amputation.
Method
This is a cross-sectional analytical study, including type 2 diabetic patients hospitalized at the National Institute of Nutrition in Tunis during the year 2021.
Results
Our study included 209 patients with type 2 diabetes, of which 121 are female and 88 are male. The mean age was 51±18 years. The average duration of diabetes was 11.6±8.8 years, and more than half (55.5%) of the patients had diabetes older than 10 years. Among the study population, 42 patients were active smokers. Alcohol consumption was noted in 6.2%. Hypertension, dyslipidemia, and hypothroidism were present in 50.2%, 59.8%, 8.6% of the patients respectively. Moreover, obesity was noted in 28.7% of patients. The average glycated hemoglobin was 10.6±2%. Nine patients had a history of lower limb amputation due to diabetic foot complications. The antecedent of amputation was significantly higher in men ($P=0.005$), and increases significantly with the duration of diabetes ($P=0.01$). However, there was no association with smoking, alcohol consumption and amputation. Lower limb amputation for diabetic foot was significantly associated with diabetic nephropathy ($P=0.012$) cerebral vascular accident ($P=0.029$), and autonomic neuropathy ($P=0.019$). Nevertheless, it was not associated with coronary artery disease and diabetic retinopathy.
Conclusion
In our study we found that the risk of amputation increases with the presence of other degenerative complications of diabetes. This emphasizes the importance of regular follow-up to detect and prevent the development of these complications.

Diabetes and cardiovascular risks (about 557 cases)

Sara Charkaoui, Nassim Essabah Haraj, Siham El Aziz & Asma Chadli
CHU Ibn Rochd, Department of Endocrinology, Diabetology and Metabolic Diseases, Ibn Rochd University Hospital, Casablanca, Morocco

Introduction
Alone or associated with other vascular risk factors, diabetes is responsible for heavy morbidity and mortality all over the world.
Objective of the Study
To stratify diabetic patients according to cardiovascular risk anddetermine the elements that increase this risk.
Materials and Methods
Retrospective, cross-sectional and descriptive study of patients followed in the endocrinology, diabetology and metabolic disease department of CHU IBN Rochd in Casablanca, The cardiovascular risk was assessed according to the

recommendations of theEuropean Society of Cardiology (ESC), European Association for the Study of Diabetes (EASD) on diabetes and prediabete.
Results
Our study involved 557 diabetic patients, with an average age of 51.19 years, with a female predominance in 64% of cases. Among our patients; 79% had type 2 diabetes and 21% had type 1 diabetes. Mean HbA1c was 10.3%. For associated cardiovascular risk factors; 42% were hypertensive, 29% dyslipidemic, 16% were smokers and 30% had obesity. Regarding the degenerative complications of diabetes, 16% of cases already presented a cardiovascular event and 34% of patients had microangiopathy (10% nephropathy and 24% diabetic retinopathy). In our series, 40% were at very high risk, 39% at high risk and 21% had a moderate cardiovascular risk. In patients who were at very high cardiovascular risk, this was mainly linked to organ damage and the age of diabetes or the fact that diabetes was associated with another cardiovascular risk factor.
Conclusion
Our study has shown that the cardiovascular risk in diabetic patients is strongly linked to degenerative complications, hence the interest of their early detection and the use of the choice of anti-diabetics which have demonstrated better cardiovascular and renal prevention. .

EP415

Low-density lipoprotein cholesterol target achievement in patients with diabetes: A Tunisian study

Rahma Khalaf, Sana Khamassi, Fatma Boukhayatia, Mehrez Achwak, Nesrine Dhieb, Haifa Abdesselem, Kamilia Ounaissa & Chiraz Amrouche
National Institute of Nutrition, Outpatient Department and Functional Exploration, Tunis, Tunisia

Background and Aim
Diabetes is often associated with other cardiovascular (CV) risk factors wich elevates morbi-mortality in these patients. Primary and secondary CV prevention depends on the control of CV risk factor including low- density lipoprotein cholesterol (LDL-C) level. The aim of this study was to assess the CV risk level of diabetic patients and to determine the rate of lipid targets achievement.
Methods
It was a descriptive cross-sectional study including 122 type 2 diabetes patients. All patients had mixed dyslipidemia treated by statins.CV risk level and LDL-c goal achievement were assessed according to European Society of Cardiology updated guidelines in 2021. New is the introduction of a stepwise approach to intensify preventive treatments.
Results
The mean age was 58.56 ± 9.05 years with a female predominance (56.5%). Mean diabetes duration was 13 ± 7.44 years, mean glycated hemoglobin was 9.9% $\pm$ 1.74, 20.4% of patients used oral glucose-lowering drugs (OGLDs) only,and 79.6% used OGLDs plus insulin .Only 12.5% used insulin analogs. Microvscular complications were present in 52.1% of patients. Meam Body Mass Index was 29.53 ± 8.07 kg/m^2 ,59% of patients had high blood pressure and 22.66% were tabacco users. Mean dose of Atorvastatine was 40 mg, prescribed as secondary prevention in 13.7% of cases. According to new guidelines, 23.3% and 76.7% were considered at very high and high CV risk, respectively. Step1 LDL-c goals were achieved in 65.1% of cases while step 2 LDL-c goals were achieved in 32.1% of patients according to their CV risk level. Patients at high and very high CV risk achieved LDL-c goal level in 27.5% and 4.6% of cases respectively. Non-achievement of LDL-c goals was due to non-availibility of treatment in 40% of cases and poorly adapted dosage in 36.6% of cases.
Conclusions
Most of patients didn't achieve recommended goals likely due to non avaibility of treatment and therapeutic inertia.The cost of treatment could explain these results as this later is a fundamental criterion in countries with low financial resources as Ezetimibe and PCSK-9 inhibitors are not available or available at high cost.

EP416

Smoking during pregnancy is not a risk factor for gestational diabetes mellitus: A systematic review and meta-analysis

Kleoniki I. Athanasiadou[1], Stavroula A. Paschou[1], Evgenia Papakonstantinou[2], Fotini Kanouta[3], Paraskevi Kazakou[1], Aikaterini Stefanaki[1], Georgia N. Kassi[3], Christothea A. Tsiridis[4], Theodora Psaltopoulou[1], Dimitrios Goulis[5] & Eleni Anastasiou[3]
[1]Alexandra General Hospital, Athens, Greece, Endocrine Unit and Diabetes Centre, Department of Clinical Therapeutics, Athina, Greece; [2]Ippokratio General Hospital, Thessaloniki, Greece, Department of Pediatric Oncology, Thessaloniki, Greece; [3]Alexandra Hospital, Athens, Greece, Department of Endocrinology, Athens, Greece; [4]St. George's, University of London, Medical School, London, United Kingdom; [5]Papageorgiou General Hospital, Medical School, Aristotle University of Thessaloniki, Thessaloniki, Greece, Unit of Reproductive Endocrinology, 1st Department of Obstetrics and Gynaecology, Thessaloniki, Greece

Background
While the association between cigarette smoking and type 2 diabetes is established, the impact of smoking on developing gestational diabetes mellitus (GDM) remains controversial.
Aim
To investigate whether maternal cigarette smoking during pregnancy is a risk factor for developing GDM.
Methods
MEDLINE, Scopus, CENTRAL and Google Scholar databases were searched from inception to December 2022 to identify eligible original articles. A systematic review and meta-analysis (weighted data, random-effects model) were performed. The primary outcome was the development of GDM in pregnant women. The results were expressed as odds ratios (OR) with 95% confidence interval (CI) (Inverse Variance method). Subgroup analysis was planned according to the maternal smoking status and GDM diagnostic criteria. Statistical heterogeneity was checked with the Chi-squared (Chi^2) test and the I^2 index was used to quantify it. The studies were evaluated for publication bias. A sensitivity analysis was performed to assess the effect of each study.
Results
Thirty-five studies, including 23,849,696 pregnant women, met the inclusion criteria. The pooled OR of cigarette smoking during pregnancy compared with non-smoking (never smokers and former smokers) was 1.06 (95% CI 0.95-1.19), $P=0.30$; $I^2=90\%$; $Chi^2=344$; $df=34$; $P<0.001$. Subgroup analysis was performed according to the Carpenter-Coustan GDM diagnostic criteria, due to the high heterogeneity among the other applied methods. The pooled OR for GDM for the studies that applied the Carpenter-Coustan criteria was 1.19 (95% CI 0.95-1.49), $P=0.12$; $I^2=63\%$; $Chi^2=27$; $df=10$; $P<0.002$. Further subgroup analysis according to maternal smoking status was not performed due to missing data.
Conclusions
There is no evidence to support an association between maternal cigarette smoking during pregnancy and the risk for GDM. Universally accepted diagnostic criteria for GDM must be adopted to reduce heterogeneity and clarify the association between smoking and GDM.

EP417

Main risk factors for Hyperglycemia in Pregnant Bulgarian Women

Anna-Maria Borissova[1,2], Boyana Trifonova[1,2] & Lilia Dakovska[1]
[1]University Hospital Sofiamed, Sofia, Bulgaria, Clinic of Endocrinology, Sofia, Bulgaria; [2]Sofia University Saint Kliment Ohridski, Sofia, Bulgaria, Faculty of Medicine, Sofia, Bulgaria

The conducted national screening of Bulgarian pregnant women showed a frequency of Hyperglycemia among them of 14.4%. It is known that a number of factors have a significant impact on this disorder. The aim: to assess risk factors for the development of Hyperglycemia in pregnant women in Bulgaria.
Material
We screened 547 pregnant women, mean age 30.49 ± 5.12 years, divided into two groups: up to 24 gestational week –g.w. (n-386, 70.6%) and after 24 g.w. (n-161, 29.4%).
Methods
BMI before pregnancy and the current one at the time of the study were calculated. A two-hour, 75 g oral glucose tolerance test (OGTT) was performed. Plasma glucose was quantitatively determined using enzymatic reference method with hexokinase (Roche reagent) in the Central laboratory on the day of the blood sampling. The results were in mmol/l. The statistical analysis was performed using SPSS 13.0 for Windows.

Results
The screened pregnant women had Hyperglycemia in fasting state or during OGTT in 7.5% in group up to 24 g.w. vs 31% in group after 24 g.w, $P<0.01$. The age of the group of pregnant women with Hyperglycemia (n-79) vs the others with Normoglycemia (n-468) was significantly higher - 32.18 ± 5.26 years v.s. 30.21 ± 5.05 years, $P<0.005$. The women with a higher BMI before and during pregnancy are significantly at risk of developing glucose disorders during pregnancy, $P<0.0001$. Family history of diabetes occurred in 29.1% (n-23/79) of the pregnant women with Hyperglycemia, vs 13.5% (n-63/468) of those with Normoglycemia, $P<0.001$. There was a significant difference between the incidence of Hyperglycemia in pregnant women with previous GDM compared with those without - 3/79 (3.8%) vs 3/468 (0.6%), $P<0.04$.
Conclusion
Considering the main risk factors for Hyperglycemia during pregnancy, identified in the screening - advanced maternal age, obesity, family history of diabetes, and previous GDM, a verbal screening would be very helpful and would direct us to screen each pregnant woman with any of these risk factors.

Evaluation of diabetes-associated antibodies in patients With newly diagnosed type 1 diabetes mellitus

Tatsiana Mokhort[1], Alena Mokhort[1], Volha Shyshko[2], Volha Lazovtseva[2] & Alena Dashkevich[3]
[1]Belarusian State Medical University, Endocrinology, Minsk, Belarus; [2]Minsk City Clinical Endocrinological Center, Minsk, Belarus, 310th City Clinical Hospital, Minsk, Belarus

Introduction
The presence of diabetes-associated antibodies is an indicator of β-cell destruction. Our goal was to find out the prevalence of autoantibodies associated with the new onset of type 1 diabetes mellitus (DM1) without family history.
Subjects and Methods
22 patients (10 women and 12 men) with newly diagnosed DM1 no family history were examined. Average age of patients was 31.7 ± 7.3 y.o., experience of DM1 was 2.3 ± 0.8 months. All the patients underwent the determination of autoAbs, such as glutamic acid decarboxylase (GAD-Ab), islet antigen-2 (IA2-Ab), and islet cell cytoplasmic (ICA-Ab), zinc transporter 8 (ZnT8-Ab). The determination of the level of antibodies was carried out by the method of quantitative enzyme immunoassay using the analyzer Freedom Evo (Tecan).
Results
GAD-Ab were found in 90% of the examinees. IA2-Ab were observed in 36%. ZnT8-Ab were detected in 14 patients (63.6%). Auto-Antibodies were more frequently observed in combination than alone. 13 patients (59%) had ZnT8-Ab and GAD-Ab. IA2-Ab, GAD-Ab and ZnT8-Ab were detected in 5 patients (22.7%). ICA-Ab were not detected.
Conclusion
The antibodies that are most frequently observed in newly diagnosed DM1 are GAD-Ab, IA2-Ab and ZnT8-Ab. Along with GAD-Ab antibodies, it is possible to determine ZnT8-Ab and IA2-Ab antibodies, since ZnT8-Ab and IA2-Ab are detected in 63.6% and 36% of patients, respectively. We have not identified ICA-Ab, which confirm the usefulness of this investigation.

Degenerative profile in diabetic patients and their glycemic control: Epidemiology in morrocan diabetics

Ali Halouache, Hajar Srifi & Guerboub Ahmed Anas
Hopital Militaire d'Instruction Mohamed V, Endocrinology, Rabat, Morocco

Background and Aims
The objective of our study is to evaluate the degenerative profile in diabetic patients and their glycemic control
Materials and Methods
This analytical cross-sectional study for analytical purposes was conducted during the period from January 2022 to January 2023, within the department of endocrinology and metabolic diseases of the Military Hospital of Instruction Mohamed V of Rabat.
Results
215 patients were included, all with type 2 diabetes, whose mean age was 59.3 +/- 8.59 years. 54.9% (118) were male with a sex ratio (M/W) of 1.21. HbA1c was less than 7.5% in 41.4% (89) of the patients, and the median age of diabetes was 10 [6,14.5] years. Regarding the antidiabetic treatment; 33% (71) of our patients were under oral treatment containing a hypoglycemic sulfonamide, 26% (56) were under oral treatment without sulfonamide, 30.7% (66) were under basal-bolus insulin therapy, and 10.2% (22) were under bed-time. The degenerative complications of diabetes were present in 47% of cases, distributed as follows: 34% (75) of the patients had diabetic retinopathy, 18.6% (40) had diabetic nephropathy, 6.5% (14) had ischemic heart disease, 1% (2) had ischemic stroke and 2.3% (5) had diabetic neuropathy. In multivariate analysis, and adjusting for age, sex, duration of diabetes and glycemic control, the duration of diabetes (OR: 1.26 IC95% [1.09-1.45]) is a risk factor for microangiopathy while intensification of treatment with insulin therapy is a protective factor (OR:0.056 IC95%[0.2-0.8]), for macroangiopathy: male sex (OR:1.3 IC95%[1.2-0.0025]) glycemic imbalance and insulin therapy are risk factors ($P<0.001$ OR > 1).
Discussion
The degenerative complications are the gravity of diabetes mellitus, Their frequency increases with that of diabetes; according to the IDF (International Diabetes Federation): DR is present in 35% of diabetic patients, and remains among the first causes of blindness, the same result has been reported in our study 34%. The IDF also reports a rate of 36% of diabetic patients suffering from ND, a rate that is much higher than that found in our study. Regarding macroangiopathic complications; coronary artery disease was present in 6.5% of our patients, the IDF reported a much higher figure between 12 and 31%, while only 1% of our patients reported a history of stroke.
Conclusion
In spite of the efforts made by the learned societies, diabetes remains a frequent and serious disease by its evolution towards complications difficult to avoid, and involving a major social and personal handicap.

Auditing inpatient diabetes care in Our Lady of Lourdes Hospital, Drogheda, Ireland

Deirdre Green, Jenny Thompson & Tomás Ahern
Our Lady of Lourdes Hospital, Drogheda, Medicine, Drogheda, Ireland

Optimal in-patient glycaemic control improves morbidity and mortality in in-patients with diabetes[1]. The National Inpatient Diabetes Audit (NaDIA) is an annual snapshot audit of diabetes inpatient care in England and in Wales. We performed a similar audit in Our Lady of Lourdes Hospital, Drogheda (OLOLHD, 363 in-patient beds) on 26/01/2022 and 08/10/2020. Data from all adult in-patients with diabetes were gathered using a standard proforma. Data from the OLOLHD 2022 cohort were compared to those from either the OLOLHD 2020 cohort or the 2019 NaDIA annual report using Fisher's exact test or the independent-samples *t*-test. The prevalence of in-patient diabetes in OLOLHD was similar in both years (12.9% ($n=47$) vs 13.2% ($n=48$), $p>0.99$). Neither age (71.1 ± 16.4 vs 75.4 ± 12.8 years, $P=0.159$) nor length of stay (15.7 ± 28.4 vs 13.6 ± 16.0 days, $P=0.664$) differed between the two time-points audited. Feet were examined in 4.2% of the 2022 cohort ($n=2$), 6.4% of the 2020 cohort ($n=3$, $P=0.677$) and 33.6% of the NaDIA 2019 cohort ($n=5.201$, $P<0.001$). A glycaemia management error occurred in 18.8% of the 2022 sample ($n=9$), 8.5% of the 2020 sample ($n=4$, $P=0.232$) and 30% of the NaDIA 2019 sample ($n=4.643$, $P=0.113$). A member of the diabetes team reviewed 31.3% of OLOLHD diabetes in-patients in 2022 ($n=15$) and 74.7% of UK diabetes in-patients in 2019 ($n=11.563$, $P<0.001$). Despite less in-patient diabetes resource being available in OLOLHD, there was a trend towards less glycaemia management errors here. More effort needs to be put into making foot examination routine.

The impact smoking on the course of type 2 diabetes mellitus. Case study

Rajmonda Tare[1] & Ema Lumi[2]
[1]Spitali Elbasan, Endocrinology, Elbasan, Albania; [2]Spitali Rajonal Korce, Endocrinology, Korce, Albania

Introduction
We already know that smoking is one of the causes of type 2 diabetes. Cigarette smoking increases the risk for type 2 diabetes incidence and is an independent risk factor for type 2 diabetes. Nicotine in tobacco is responsible for the association between cigarette smoking and development of diabete.
Aim
The purpose of this study was to evaluate the impact of smoking on the course of type 2 diabete.
Material and Methods
A total of 191 patients were included in the study, divided into four groups based on whether they smoked or not and on medication. Group 1: smoking ($n=39$), Group 2: non-smoking ($n=153$), Group 3: treatment of diabetes drugs ($n=77$), group 4: treatment of insulin ($n=114$).
Results
The mean age of 62.23 ± 10.85 years (43-82 years) with a sex ratio (M/F) of 0.94. The majority were 114 patient (59.6%) type 2 diabetics treatment of insulin and 77 patient (40.3%) treatment of diabetes drugs. The mean age of diabetes was 9.74 ± 4.23 year (0:30). The mean HbA1C was $8.35\pm6.59\%$ (4.8-13.3%). Obesity was present in 56.4% of patients. The incidence of hyperuricemia was 21.8%. In ours study were noted smoking in 39 patient (20.4%) of cases of wich 28 patient (71.7%) were men and 11 patient (28.2%) were women. 27 patient (69.2%) in treatment of diabetes insulin and 12 patient (30.7%) patient in treatment of diabetes drugs. The mean HbA1C of smoking patients was $8.55\pm4.04\%$ (4.6-12.2%). Diabetes was found to be balanced in 18 patient (46.1%) smoking of wich 12 patient (66.6%) in treatment of diabetes insulin with HbA1C $6.86\pm3.70\%$ (4.6-7.5%) and 6 patient (33.3%) smoking in treatment of diabetes drugs with HbA1C $6.94\pm3.72\%$ (5.7-7.5%). The mean HbA1C it was not comparable between the two smoking groups.
Conclusion
Smoking increases not only the risk for type 2 diabetes mellitus but there is also has an impact on its progress. Our study showed that individuals with type 2 diabetes mellitus and smokers had a poor course of diabetes compared to non-smoking individuals with type 2 diabetes mellitus and smoking individuals treated with insulin had better progress than those treated with drugs.

CoMICs (Concise Medical Information Cines) videos on diabetes mellitus and polycystic ovary syndrome have better quality, content, and reliability compared to videos from other sources

Dania Shabbir[1] , Shams Ali Baig[2], Fazna Rahman[2], Syeda Sabbah Batool[2], Mukunth Kowsik[2], Josh Banerjee[2], Kushi Kumar[2], Mohammed Faraaz Saiyed[2], Vardhan Venkatesh[2], Pranav Viswanath Iyer[2] & Punith Kempegowda[3]
[1]Jinnah Medical and Dental College, Karachi, Pakistan; [2]College of Medical and Dental Sciences, University of Birmingham, Birmingham, United Kingdom; [3]Queen Elizabeth Hospital, University Hospitals Birmingham NHS Foundation Trust, Birmingham, United Kingdom

Introduction
It is important to ensure the information shared on social media is up to date to current clinical practice, reliable and appropriate to the target audience. YouTube is the most popular social media platform for video-based medical information worldwide. You and Your Hormones is a UK-based website endorsed by Society for Endocrinology hosting videos on various medical conditions aimed at the public. CoMICs (Concise Medical Information Cines) are short videos providing bite-sized information on a variety of topics using illustrations and infographics. We compared the quality of diabetes and PCOS videos between CoMICs, YouTube and You and Your Hormones.
Method
A search using the terms "Diabetes" or "PCOS" was conducted on YouTube on 26th October 2022. The search was limited to those videos with content in English and a duration of less than 10 minutes. After excluding videos with no audio, in non-English language or duration longer than 10 minutes, the top 50 most popular videos in the category of diabetes and in PCOS were included in this study. All videos related to diabetes or PCOS on the CoMICs website were also included in the study. All 124 included videos were evaluated for content, quality, and reliability using three video analysis tools: Quality Criteria for Consumer Health Information (DISCERN), Global Quantitative Strategies (GQS), and Journal of the American Medical Association (JAMA) benchmark criteria. The average score from two independent reviewers was obtained for all videos. Grouped scores in the three scoring systems were compared between YouTube videos and CoMICs.
Results
CoMICs videos had overall higher mean DISCERN scores compared to YouTube videos across both diabetes (CoMICs vs YouTube vs Your and Your Hormones: 2.4 ± 0.6 vs 1.6 ± 0.4 vs 1.5 ± 0) and PCOS (2.9 ± 0.64 vs 1.9 ± 0.5 vs 1.5 ± 0). CoMICs videos had the highest DISCERN score for reliability (25.4 ± 2.6 vs 19.1 ± 3.9 vs 19 ± 0). The median (IQR) GQS scores between the three groups were similar at 3 (2-4), 3 (2-4) and 3.5 (2.75-4). No video met all the JAMA criteria. JAMA scores for authorship across the three groups were 100% vs 32.3% vs 50%. Overall, CoMICs were of higher quality compared to YouTube and You and Your Hormones.
Conclusion
CoMICs videos have a higher level of accuracy and reliability compared to YouTube and You and Your Hormones on diabetes and PCOS, making them a reliable source of medical information for both patients and healthcare professionals.

Plasma Renin activity in patients with Diabetes Mellitus

Anna Alieva[1], Shohista Karimjonova[2] & Zulaykho Shamansurova[2,3]
[1]Republican Specialised Scientific Practical Medical Center of Endocrinology, Endocrinology, Tashkent, Uzbekistan; [2]Tashkent Pediatric Medical Institute, Endocrinology with Pediatric Endocrinology, Tashkent, Uzbekistan; [3]Institute of Biophysics and Biochemistry, Metabolomics, Tashkent, Uzbekistan

Introduction
Renin angiotensin system play a crucial role in the development of Diabetes Mellitus and its complications. According many studies, plasma renin level increased at the DM. However, mechanisms of its elevation is not clear yet. The aim of our study was compare plasma renin level in DM1 and DM2 patients and its relationship with glycemic control.
Material and Methods
In 44 people with DM1 and 85 with DM2 whose admitted into Hospital of the Republican Specialised Scientific Practical Medical Centre Endocrinology were collected clinical and anamnestic data, hemodynamic status, blood glycemia, HbA1c, and blood plasma renin activity were measured using immunoassay.
Results
Patients average age were significantly differ by type 19.0 ± 2.33 and 58.17 ± 1.17 y.o. DM duration were 2.51 ± 0.94 and 8.74 ± 0.93 years in DM1 and DM2 groups respectively. HbA1c level were $10.7\pm0.38\%$ in DM1 and $8.86\pm0.27\%$ in DM2 patients. Plasma renin activity were significantly higher than in healthy people in both group and was in 1.2 times higher in DM2 group. Interestingly, Plasma renin activity shown correlation with age, urine protein, also with FIB4 score in patients with DM1 but no any correlation found in DM2 group. Thus, results suggested about different mechanisms of elevation of plasma renin activity in DM1 and DM2.
Conclusion
Plasma renin activity significantly increased in both DM1 and DM2 groups, and suggested about high activity of RAAS. Plasma renin activity shown correlation with age, urine protein level in DM1 group, but not in DM2 and proposed about different mechanisms of its elevation depending of type.

EP424

The dynamics of growth in the frequency of Charcot foot in the Republic of Uzbekistan for the period 2012 - 2021 years

Telman Kamalov & Salim Tojiboev
Republican Specialized Scientific Practical Medical Center of Endocrinology of Public Health Ministry named by acad. Ya.Kh. Turakulov,Tashkent, Uzbekistan

Aim
To study the frequency of Charcot foot in the Republic Uzbeistan during 2012-2021 years.
Material and Methods
Reports of regional endocrinological dispensaries of 13 regions of the country and the Republic of Karakalpakstan for the studied period were used. In total, in 2012, 2648 patients with a foot Charcot were registered. All patients during the observation period were subjected to general clinical, biochemical (control of glycemia, HbA1C ,et al), instrumental (ECG, X -ray of the foot, examination of the oculist other) research method.
Results
During the period 2012-2021, the frequency of Charcot foot in country increased by 4.3 times. So, if in 2012 2648 patients with a foot of Charcot consisted in the country, then in 2021 their number reached 11560.Among the leading regions was the Ferghana region: in 2012, 1430 patients were registered there, and in 2021 already 2145. It should be noted that in 2012 year, 116,517 patients with DM 2 were registered in the Republic Uzbekistan, and in 2021 year-291 567 patients. Such an increase in the number of patients with a foot of Charcot foot can be explained both by an increase in the splash of DM 2 and an improvement in the detection of its complications.
Conlusion
During the period 2012-2021, the frequency of Charcot foot in the Republic of Uzbeistan increased by 4.3 times. Such an increase in the number of patients with a foot of Charcot foot can be explained both by an increase in the splash of DM 2 and an improvement in the detection of its complications

Association of Latent Autoimmune Diabetes of the Adults with other systemic and organ-specific autoimmune diseases

Georgios Boutzios, Sofia Chatzi, Vasileios Pezoulas, Maria Fanouraki, Ilias Giovannopoulos, Theodoros Androutsakos, Eleni Koukoulioti & Andreas Goules
National and Kapodistrian University of Athens, Department of Pathophysiology, Medical School, Athens, Greece

Introduction
Latent autoimmune diabetes of the adults (LADA) is a heterogeneous type of diabetes sharing clinical characteristics of type 2 DM and serum markers of pancreatic autoimmunity detected in type 1 DM. It accounts for 2-12% of all patients with diabetes. The aim of our study is to identify the association between LADA and other systemic or organ-specific autoimmune diseases.
Materials and Methods
We conducted an observational study in the outpatient clinic of autoimmune endocrinopathies of the Department of Pathophysiology at Laikon University Hospital. All patients were positive for GAD antibodies. They were also evaluated for TPOAbs, TGAbs, APCA, ANA and clinical information for other systemic autoimmune diseases were obtained from their medical record. Demographic data and clinical characteristics regarding the age of LADA onset, duration of LADA, time span not requiring insulin treatment, BMI, metabolic syndrome and chronic related diabetic complications were also collected. Laboratory tests for FPG, basal c-peptide and insulin, HbA1c were performed.
Results
A total of 24 patients were analyzed. Mean age was 55.5 ± 13.4 years, 91.7% of them were females and 33.3% were smokers. Mean BMI was 22.9 ± 3.8 kg/m^2, HbA1c at diagnosis was 8.65 ± 1.7%, mean c-peptide $= 0.49 \pm 0.59$ ng/ml and mean anti-GAD titer $= 80.3 \pm 7.8$ IU/ml. 22.7% had metabolic syndrome and 17.39% presented with chronic LADA related complications. Autoimmune gastritis with positive APCA antibodies was present in 31.25% of the patients and thyroid autoimmunity with positive TgAbs and/or TPOAbs in 50%. Moreover, ANA were positive in 41.6% of our patients. There is a statistical significance among LADA and thyroid autoimmunity, autoimmune gastritis and other autoimmunities ($P = 0.0000073$, $P = 0.0000074$ and $P = 0.00049$, respectively).
Conclusion
In our study we demonstrated a statistical significant association between LADA and thyroid autoimmunities, autoimmune gastritis and other systemic or organ specific autoimmune diseases.

Maternal weight status and gestational diabetes

Bachir Moctar Rakia, Bensbaa Salma, Nassim Essabah Haraj, Siham El Aziz & Asma Chadli
CHU Ibn Rochd, Endocrinologie- Diabétologie et Maladies Métaboliques, Casablanca, Morocco

Introduction
Maternal overweight is a major risk of gestational diabetes that can impair glycemic control. The objective of our study was to assess the impact of maternal weight status on glycemic control and pregnancy outcomes in patients followed for gestational diabetes.
Methods
Our work is a retrospective study, including 182 patients with gestational diabetes followed in the Endocrinology-Diabetology department between January 2016 and January 2022.
Results
The study included 182 patients with an average age of 32 years. The mean term at first visit was 21 weeks of amenorrhea (AS). The mean pregestational BMI was 29 kg/m^2. The average intake of weight was $+6$, 7 kg. all patients ($n = 7$) with a BMI < 18.5 kg/m^2), were on a hygiene-dietetery diet, with a weight gain of $+0.37$ kg/SA. Those with a BMI between 18.5-24.9 kg/m^2, 85.71% ($n = 60$) were on a hygiene-dietetery diet, with a weight gain of $+0.39$ kg/SA, 14.29% ($n = 10$) on insulin. BMI between 25-29.9 kg/m^2 with a weight gain of $+$ 0.4 kg/SA, 94.51% ($n = 86$) observed insulin therapy, 5.49%($n = 5$) on a hygiene-dietetery diet. Patients with a BMI > 30 kg/m2 with a weight gain of $+$ 0.42 kg/SA were all on insulin. However, weight gain was significantly greater in patients treated with insulin than in those treated with a hygiene-dietetery diet ($P = 0.06$).
Discussion
Maternal hyperglycemia during GDM was related to pregestational weight status and weight gain appeared to be a factor associated with insulin therapy. Hence the interest of raising awareness among patients from the prenatal consultation.

Autoantibody-negative insulin-dependent diabetes mellitus after COVID 19: Case report

Zahra Ismail[1,2], Ahmed Boukhalfa[1], Sana Rafi[1], Ghizlane El Mghari[1] & Nawal El Ansari[1]
[1]CHU Mohamed VI, Departement of Endocrinology, Diabetes and Metabolic Disease, Marrakech, Morocco; [2]Mohammed VI University Hospital Center, Department of Endocrinology, Diabetes, Metabolic Diseases and Nutrition, Marrakech, Morocco

Introduction
The COVID pandemic was a challenge in terms of physiopathology and therapeutics. Diabetics represent more than 40% of patients hospitalized for COVID. There was many new cases of diabetes declared during or after a COVID. The purpose of this report is to raise the link between Sars-Cov-2 infection and the appearance of glycemic disorders and new cases of diabetes.
Case Presentation 1
A 28-years-old man who had a serious COVID-19 a month ago, treated in intensive care with corticosteroid therapy. He had no diabetic family history. His BMI was in the normal range. He presented classic type 1 diabetes symptoms with ketoacidosis. His glycated hemoglobin was at 8.8%. His serum anti-GAD and anti IA2 antibodies were negative. He received insulin therapy.
Case Presentation 2
A 34-year-old overweight woman who had a mild Sars-cov-2 infection treated at home; she has an obvious autoimmunity history. No diabetic family history. She presented few months later severe symptoms of hyperglycemia and ketosis, her glycated hemoglobin was at 12.9%. She had negative antibodies. She was on insulin.
Discussion
The relationship between diabetes and COVID-19 is bidirectional. Diabetes exposes to a higher risk of severe COVID and more mortality. Furthermore, COVID exposes to more metabolic complications and possible diabetes new cases. This issue have been raised after an increase in new cases of diabetes after the pandemic stated in multiple studies. Several cases of post COVID diabetes with negative antibodies have been reported in the literature. Most of them were patients between 26 and 50 years-old, who all had a type 1 diabetes clinical presentation with a post-COVID delay ranging from one week to 3 months. They all had negative antibodies. Some of the cases reported were no longer on insulin, which the authors attributed to a possible transient

pancreatic dysfunction. The mechanisms of the pancreatic dysfunction suggested were: A direct effect of the virus on the pancreatic beta-cell; the triggering of the immune reaction leading to type 1 diabetes; the systemic inflammatory response or the cytokine storm; the effect of prescribed corticosteroid therapy and the effect of the lock-down independently of the viral infection itself. A study confirmed the presence of Sars-cov-2 in beta cells of patients who died of COVID.
Conclusion
Current data have confirmed the hyperglycemic power of Sars-cov-2 virus, through a complex and multifactorial mechanism, but do not confirm its direct role in the appearance of a new diabetes type.

Evaluation of physical activity and sleep patterns in patients with type 2 diabetes during the month of Ramadan

Nana Aichatou Harouna, Nassim Essabah Haraj, Siham El Aziz & Asma Chadli
CHU Ibn Rochd, Endocrinologie- Diabétologie et Maladies Métaboliques, Casablanca, Morocco

Introduction
Fasting during Ramadan very often requires a change in lifestyle for patients and adaptation is not easy in individuals with type 2 diabetes (T2D). Physical activity, sleep duration and sleep time are subject to change during Ramadan, due to changes in the number and times of meals.
Study Objectives
This study aims to assess the physical activity and sleep patterns of T2DM patients during Ramadan.
Material and Methods
We assessed physical activity using the IPAQ questionnaire and the impact on sleep patterns (quality and quantity) during the month of Ramadan using the PSQI form and a sleep quality rating scale ranging from 1 to 10. Data analysis was done with SPSS software version 25.
Results
Fifty patients were enrolled in our study, all T2DM, 80% of whom were on ODA during the month of Ramadan over a period of 29 days. The average age was 60.4 years, our study included 34 women for 16 men with a sex ratio M/F of 0.47. By making an average distribution over 24 hours, the average duration of sports activity is 47 minutes ($\pm$7 minutes), that of night prayers is 1 h20 mn ($\pm$ 10 minutes), the average duration of household chores is 3 hours ($\pm$23 minutes), daily shopping takes an average of 1 hour. There is a significant reduction in the total number of hours of sleep and The average total sleep duration is 4 hours 35 min ($\pm$28 min). Only 15 patients (30%) took an average nap of 52 minutes. Nighttime sleep quality was observed to be low in this period, with 38 patients or 76% reporting early morning awakening and 22 patients (44%) reporting sleep-onset insomnia. hours of nighttime sleep during the period of Ramadan with a shift in the sleep slice. The overall assessment of sleep quality (night and nap) remains fairly good at 20% ($n=10$); Somewhat poor in 70% ($n=35$); very bad in either 10% of patients or $n=5$.
Conclusions
Our study shows a high prevalence of low physical activity among people with T2DM during Ramadan, and short sleep durations during Ramadan compared to the period outside Ramadan. A larger study is needed in the future covering before, during and after Ramadan to assess the impact of lifestyle changes related to fasting during Ramadan in type 2 diabetics.

Dimensions of sexuality among women with type 2 diabetes mellitus: A comparative study

Meriem Marrakchi[1], Kamilia Ounaissa[2], Nesrine Dhieb[2], Fatma Boukhayatia[2], Asma Ben Brahim[2], Rim Yahyaoui[2], Haifa Abdelsellem[2] & Chiraz Amrouche[2]
[1]Basic Health Center, Carthage, Tunisia; [2]National Institute of Nutrition, Tunis, Tunisia

Introduction
Sexuality can include several dimensions such as thoughts, fantasies, desires, beliefs... But these can be influenced by biological, psychological, socio-economic factors or somatic pathologies, such as diabetes. The aim of our study was to evaluate the sexuality of women with type 2 diabetes mellitus and its different dimensions, as well as the predictive factors of female sexual dysfunction (FSD) among this population.
Methods
This is a comparative study of 30 women with type 2 diabetes mellitus (G1) compared to a control group of 30 women (G2) collected from the department of the National Institute of Nutrition. Sexual function was assessed using the "Female Sexual Function Index (FSFI)" survey. A score of less than 26.55 characterizes FSD. We compared the dimensions of sexuality according to the FSFI survey for the 2 groups.
Results
The mean age of the patients was 42.97$\pm$6.6 years. A high level of education was noted in 30% of women with diabetes and 45% of controls. The mean total FSFI score was 25.53$\pm$6.11 for G1 and 29.75$\pm$4.19 for G2. FSD was diagnosed in 53% of G1 vs 17% of G2. All dimensions of sexuality were affected according to the scores of desire, arousal, lubrication, orgasm as well as satisfaction. The mean score of all dimensions was lower for the G1 compared to G2. Sexual desire is strongly affected by the duration of diabetes ($P=0.016$) as well as parity ($P=0.02$). The advanced age of the patients is correlated with a low level of sexual arousal ($P=0.04$). 40% of women who had FSD wanted to consult a sexologist. Higher level of education was strongly correlated with this request ($P=0.03$).
Conclusion
These results justify the imperative of systematic screening and appropriate management of FSD in order to improve quality of life. The evaluation of sexuality is therefore necessary for an early treatment of these disorders in order to avoid conflicts and marital disagreements, sources of stress and therapeutic resistance.

YouTube Videos adressing diabetes: is popularity correlated with quality?

Hadami Ben Yamna, Radhouen Gharbi, Marwa Chiboub, Sahar Abidi, Manel Jemel, Hajer Kandara & Ines Kammoun
Institut De Nutrition, Tunis, Tunisia

Introduction
Nowadays, social media has become a valuable source of health-related information which can have an important impact on people's behaviors and decisions regarding their diseases. To improve management of diabetes, patients often seek health information in social media platforms, including Youtube. We aim in this review to analyse factors associated with the popularity of videos found on YouTube that adress diabetes management.
Methods
A YouTube query using the search terms "diabetes treatment" in arab language was performed at the date of January 17th 2023.The most viewed 50 videos which first appeared in the search results were included in the analysis. The reliability of the videos was determined using the modified DISCERN criteria, and the quality with the Global Quality Score. Visual quality was also assessed. Popularity was determined by views number, likes and comments.
Results
The video quality was assessed by the Global Quality Standard and the mean score was 1.78 $\pm$0.61. The reliability of the videos was determined using the modified DISCERN criteria was at 0.86$\pm$0.64. Popularity didn't correlate neither with quality nor reliability. Graphic and audio quality didn't correlate with popularity. Average likes numbers was 48153 for videos sharing incorrect and misleading informations, and 14560 for those with only correct content ($P=$ 0.0001). Average commentes number was 1597 for videos sharing incorrect content, and 843 for those containing correct informations ($P=0.04$). The percentage of videos containing false and misleading informations was 63% of the total.
Conclusion
The most popular videos often content unreliable, incorrect, even dangerous content. This may have harmful consequences for the diabetes community. More studies are needed to analyse the reasons explaining this paradoxical phenomenon.

Relationship between Blood Glucose and Urine Glucose Levels in Type 2 Diabetes Mellitus Patients on sodium-glucose co-transporter-2 inhibitor Therapy

Soichi Takeishi & Tatsuo Inoue
Inuyama Chuo General Hospital, Diabetes, Inuyama-City, Japan

We evaluated the relationship between blood glucose and urine glucose levels in type 2 diabetes (T2D) patients who had reached steady state upon taking a sodium-glucose co-transporter-2 inhibitor (SGLT-2 inhibitor). Ten patients with T2D taking Luseogliflozin 2.5 mg for more than 2 weeks were hospitalized for diabetes treatment. During hospitalization, the patients used a continuous glucose monitor (CGM) [iPro2] for 6 days (CGM attachment: day 1) while continuing Luseogliflozin 2.5 mg intake. All other antidiabetic treatments were adjusted to improve glycemic variability. From day 2 to day 5, starting from 9 AM, we obtained four consecutive 24-hour mean blood glucose levels (24-h MGL) and 24-hour urine glucose levels (24-h UGL), respectively. "24-h MGL and 24 h-UGL during the same period" (paired MUGL) were compared. We arranged paired MUGL in descending order of 24-h MGL. Then, consecutive 20 paired MUGLs were selected while shifting selection start one by one. Estimated glomerular filtration rate (eGFR) was measured once during hospitalization. For each selected group, we used multivariate linear regression analysis to predict the 24-h UGL from the 24-h MGL and eGFR, where we commonly applied eGFR as a pair for the four paired MUGLs per each patient. One paired MUGL was excluded from the analysis due to inaccurate urine glucose measurement. The arranged paired MUGL were numbered from 1 to 39 and consecutive 20 paired MUGLs were selected 20 times (from "1–20" to "20–39": 20 groups). 24-h MGL positively correlated with 24-h UGL ($r=0.81$; $n=39$). For the results analyzed using multivariate linear regression analysis in each group, standard partial regression coefficient (β) for eGFR, β for 24-h MGL, p for eGFR, p for 24-h MGL, adjusted-R2 for a regression formula (RF), and p for RF correlated with mean of 24-h MGL in each group ($r=$–0.61, –0.76, 0.72, 0.62, –0.62, and 0.62, respectively; $n=20$). Under steady state for SGLT-2 inhibitor in T2D, decreased 24-h MGL may be associated with decreased 24-h UGL. Increased 24-h MGL could lead to a reduced ability of predicting 24-h UGL using both 24-h MGL and eGFR.

Whey Protein in Type 2 Diabetes Mellitus: A Systematic Review and Meta-Analysis

Zyrah Lou Samar & Genecarlo Liwanag
Ospital ng Makati, Internal Medicine, Makati, Philippines

Background
Type 2 Diabetes Mellitus is the more prevalent type, caused by a combination of insulin resistance and inadequate insulin response to hyperglycemia1. Aside from pharmacologic interventions, medical nutrition therapy is an integral part of the management of patients with Type 2 Diabetes Mellitus. Whey protein, which is one of the best protein sources, has been investigated for its applicability in improving glycemic control in patients with Type 2 Diabetes Mellitus. This systematic review and meta-analysis was conducted to measure the magnitude of the effect of whey protein on glycemic control in type 2 diabetes mellitus. The aim of this review is to evaluate the efficacy and safety of whey protein in patients with type 2 diabetes mellitus.
Methods
A systematic electronic search for studies in the PubMed and Cochrane Collaboration database was done. Included in this review were randomized controlled trials of whey protein enrolling patients with type 2 diabetes mellitus. Three reviewers independently searched, assessed and extracted data from the individual studies.
Results
A systematic literature search on online databases such as Cochrane Central Registry, PubMed and Herdin Plus was conducted in April to September 2021 to identify eligible studies. The search yielded 21 randomized controlled trials after removing duplicates. Only 5 articles were included after reviewing the full text which met the criteria for selection.
Conclusion
Whey protein supplementation significantly reduced fasting blood glucose. However, it did not reduce post-prandial blood glucose, HbA1c level and weight when compared with placebo. There has been a considerate heterogeneity across all studies for which may have contributed/confounded with its effects. A larger sample size and better inclusion and a more specific study may be included in the future reviews.

Can exenatide, an antidiabetic drug, cause chronic pancreatitis? A case presentation

Kader Ugur[1], Umur Özbay[2], Mithat Mızrak[1] & Süleyman Aydın[3]
[1]Faculty of Medicine, Firat University, Department of Internal Medicine (Endocrinology and Metabolism Diseases), Elazığ, Turkey; [2]Faculty of Medicine, Firat University, Department of Internal Medicine, Elazığ, Turkey; [3]Faculty of Medicine, Firat University, Department of Medical Biochemistry and Clinical Biochemistry (Firat Hormones Research Group), Elazığ, Turkey

Introduction
Pancreatitis is one of the serious side effects of glucagon-like peptide-1 receptor analog exenatide, which is an incretin hormone with anti-glycemic effects secreted from the intestine and is used for treating type 2 diabetes.
Case
A 60-year-old female patient with type 2 diabetes mellitus for 11 years had been using exenatide for 6 years (no history of acute pancreatitis) along with insulin glargine and metformin. She was admitted to the emergency department with complaints of nausea, vomiting, and abdominal pain radiating to the back for the last 3 days. The patient's laboratory results are shown in Table 1. Possible factors, other than the ones associated with exenatide, (alcohol, hypertriglyceridemia, infections, and other drugs) were excluded. Contrast-enhanced computed tomography revealed multiple calcifications in the pancreatic parenchyma and irregular dilatation of the main pancreatic duct that was 17 mm in width at its widest point. Additionally, 7 mm calculus was found in the main pancreatic duct at the level of the papillary opening. These findings were indicative of chronic pancreatitis. In addition to these data, endoscopic retrograde cholangiopancreatography (ERCP) was performed. ERCP showed dilatations and stenosis along the entire pancreatic duct and fibrotic bands in the parenchyma, which indicated toward chronic pancreatitis. Therefore, exenatide was removed from the patient's treatment regimen, and she was discharged and prescribed metformin, dapagliflozin, gliclazide MR, and glargine.
Discussion
It has been reported that the risk of pancreatitis in patients with diabetes is 3–4 times higher than in the non-diabetic population. The risk of pancreatitis in general patient population using exenatide is 0.34–0.44 times higher than other patients. This risk is 2.83 times higher in people with diabetes. As the risk of pancreatitis is increased in patients with diabetes mellitus using exenatide, it might be beneficial to prescribe alternative drugs to these patients.

Table 1 Demographic and laboratory data in the diabetic patient

Age (year)	60
BMI (kg/m^2)	29.4
Amylase (U/l)	46 (28-100)
Lipase (U/l)	26 (7-60)
T.Cholesterol (mg/dl)	150 (120-200)
LDL (mg/dl)	112 (0-130)
Triglyceride (mg/dl)	87 (40-180)
HbA1c (%)	9.6 (4.6-6)
Creatinine (mg/dl)	0.5 (0.6-1.2)
AST (UL)	17 (5-40)
ALT (UL)	8 (5-40)
ALP (U/l)	113 (30-120)
GGT (U/l)	14 (0-55)
T. Bilirubin (mg/dl)	0.3 (0-1.1)
D. Bilirubin (mg/dl)	0.1 (0-0.35)
Hb (g/dl)	12.9 (11.1-17.1)
Plt (×109/l)	438 (140-360)
WBC (×109/l)	11.74 (3.8-8.6)
Albumin (g/dl)	4.07 (3.5-5.3)
Ca (mg/dl)	8.62 (8.5-10.8)

Effect of semaglutide on weight, hba1c and liver enzymes in type 2 diabetes patients

Sara El Ghandour[1,1] , Nisrine Al Ghazal[2] & Shreya Pilai[3]
[1]Mediclinic Parkview Hospital, Dubai, United Arab Emirates; [2]Mediclinic Dubai Mall, Dubai, United Arab Emirates; [3]Mediclinic Corporate Office Dubai, Abu Dhabi, United Arab Emirates

Introduction
Type 2 diabetes, obesity and fatty liver disase are the most common comorbidities at the orgin of metabolic syndrome. Treatment of these conditions overlaps significantly. The most recent innovation in the armamentarium of pharmacotherapy of type 2 diabetes is Glp 1 agonist, More recent research on the effect of GLP-1 receptor agonist on weight loss, metabolic parameters and fatty liver disease are promising. The weight reduction offered by GLP-1 agonist treatment has significant impact on the progression of fatty liver. Semaglutide, a weekly GLP 1 agonist, is used to treat type 2 diabetes patient and more recently approved for the treatment of obesity in patient without type 2 diabetes.Newsome et al, have shown that ALT normalized in 25-48% subjects treated with semaglutide (1).
Rational
The rational of this study is to assess the improvement of hba1c, weight reduction and improvement in AST and ALT in type 2 diabetes patients treated with semaglutide.
Methods
50 patients attending Endocrinology Clinic in Mediclinic Parkview Hospital and Mediclini Dubai mall and started on Semaglutide were followed. Hba1c, weight and AST ALT levels were recorded before and 6months and 12 months after starting semaglutide.
Results
Our sample included 50 treated subjects (43 male (86%), 7 female). While the medication did not show a significant reduction in ALT and AST levels in 6 months, semaglutide showed a significant reduction in weight in 6 months. 82% of the sample had an average of 5% percentage change reduction in weight from baseline to 12 months, with all 7 women having reduced on 11% average and men with 4% percentage reduction in weight. Semaglutide also had a significant relation with HbA1c, showing reduction at 6 months (-0.15 percentage points, $P<0.001$) as well as in 12 months (-0.14 percentage points, $P<0.001$).
Discussion
Our study have shown two established benefits of semaglutide, a reduction of hba1c and reduction of body weight. However it did not show a signficiant improvement in AST and ALT, one possible explanation is that the sample of patients did not have established fatty liver disease at baseline, they were also not followed for a long enough period of time to establish a significant relationship.

A case of euglycemic ketoacidosis under iSGLT2 and a review of literature about predictive factors

Boubaker Fadia, Mariem Souissi, Houcem Elomma Mrabet, Younes Ayadi, Zantour Baha, Najoua Lassoued, Alaya Wafa & Sfar Mohamed Habib
Taher Sfar University Hospital, The Endocrinology Department of the Taher Sfar University Hospital of Mahdia, Mahdia, Tunisia

Introduction
SGLT2 (sodium-glucose cotransporter 2) inhibitors are a molecule more and more used in type 2 diabetes. However, it can cause a metabolic decompensation in some cases. Euglycemic ketoacidosis may be atypical, misplacing and delaying the diagnosis. We investigated the precipitating factors of this metabolic complication in our case study and in the literature.
Presentation of the Case
We report the case of a normal BMI (19 kg/m^2) ,66-year-old woman with incidentally discovered diabetes for 3 years, switched from dual oral antidiabetics to insulin analogues (basal-plus regimen (0.48 IU/kg/24 h)) a year before her hospitalization. Since the patient did not accept the multiple insulin injections, she was put on hypocaloric diet and changed to an insulin bedtime regimen with the addition of Dapagliflozin (10 mg/d). A few days later, she went to the emergency room with asthenia, epigastralgia, vomiting and dyspnea. At the workup, venous glucose was 10 mmol/l. On urine dipstick, glucosuria was two crosses and acetonuria was four crosses. On arterial blood gas, the patient presented a severe metabolic acidosis (PH=7.08, bicarbonates at 8) with hypocapnia (PCO2 at 27). The diagnosis of severe euglycemic ketoacidosis was retained and the patient was transferred to the intensive care unit where she received hydration, insulin therapy with an electric syringe pump with adapted potassium supplementation and discontinuation of oral antidiabetics. The ketoacidosis was resolved after three days. The insulin regimen was re intensified.
Discussion
Euglycemic ketoacidosis under iSGLT2 can be explained by several mechanisms, mainly the alteration of the insulin/ glucagon ratio. iSGLT2 increases glucagon production by directly stimulating pancreatic alpha cells but also in response to the decrease in blood glucose. Glucagon increases the activity of CPT-I (carnitine palmitoyl transferase-I) inducing the overproduction of ketone bodies[1]. Conditions such as relative insulin deficiency, low body mass index with reduced glycogen stores and a low carbohydrate diet are then predictive factors of ketoacidosis under iSGLT2[1]. Other precipitating factors may include pancreatic damage and alcoholism. In our case, the reduction of insulin doses, the hypocaloric diet and the low BMI could be the incriminating factors.
Conclusion
Euglycemic ketoacidosis under iSGLT2 is a rare and serious entity which can be overlooked in the face of normal blood glucose. A clinical attention should be carried to predictive factors.

EP436

Audit on the effect of oral Semaglutide on HbA1c and Weight reduction in type 2 diabetes

Waqar Ahmad, Alex Maliekal, Leena Malik, Denisa Telalagic, Paul Peter & Praveen Partha
Darlington Memorial Hospital, Endocrinology and Diabetes, Darlington, United Kingdom

Background
Semaglutide is a glucagon-like peptide-1 receptor agonist (GLP-1 RA) which is widely used for the management of type 2 diabetes as well as for the obesity treatment. Evidence suggest that the level of HbA1c reduction and weight loss with oral semaglutide were similar to those of the subcutaneous formulation[1]. However, oral formulation not only improves the patient's compliance to treatment but also makes it a favourable option for those who are reluctant to use an injectable agent. The aim of this audit is to evaluate the effect of oral Semaglutide on mean reduction of HbA1c and weight following mean duration of treatment of 6 months.
Materials and Methods
A comprehensive retrospective review of patient's clinical and laboratory database was conducted for 36 patients (22 males / 14 females, mean age 58±20 years, duration of diabetes 20 years or less) in our region in County Durham Darlington, United Kingdom during the period between September 2020 - March 2022. The starting dose of oral Semaglutide was 3mg for the first month, 7 mg during the second month and then increased to 14 mg from third month onwards. The effect of this drug on mean reduction in HbA1c and weight was measured following mean duration of 6 months of treatment.
Results
At baseline, mean HbA1c was 75.3±19 mmol/mol and mean weight was 97.4±27 kg among the audited 36 patients. The mean duration of treatment was 6.2 months (95% CI=3, 14 months). Following 6.2 months of treatment, mean HbA1c was 67.7±17 mmol/mol and mean weight was 94.9±26 kg. Hence, mean HbA1c reduction was 7.5 mmol/mol (95% CI=-44, 41 mmol/mol) and mean weight reduction was 2.53 kg (95% CI=-9.2, 3.14 kg). The p-value was 0.01.
Conclusion
To conclude, we can say that, oral Semaglutide is an effective pharmacological agent in reducing both HbA1c and weight. However, our observations need to be confirmed in larger cohorts and for extended period of treatment.

Real-world effectiveness analysis of oral versus subcutaneous semaglutide in patients with type 2 diabetes mellitus

Juan Carlos Ferrer Garcia[1], Raquel Albalat-Galera[1], Victor Atienza Moya[2], Jessica Sanchez Hernandez[3], Luis Arribas Palomar[1], Ignacio Ramos Casamayor[1], Ana Artero Fullana[1], Cintia Gonzalez Blanco[1], Ana Jiménez Portilla[1] & Carlos Sánchez Juan[1]
[1]University General Hospital of Valencia, Endocrinology, Diabetes and Nutrition, Valencia, Spain; [2]General Hospital of Requena, Endocrinology, Diabetes and Nutrition, Requena, Spain; [3]Medical Center of Picassent, Primary Care, Picassent, Spain

Background and Objective
Semaglutide, a glucagon-like peptide 1 (GLP1a) receptor agonist, reduces the risk of major adverse cardiovascular events in patients with type 2 diabetes mellitus (DM2). An oral version of semaglutide is now available, and patients may prefer it to the subcutaneous form. Our objective was to compare the effectiveness and safety of both formulations in real life.
Methods
Retrospective real-world efficacy analysis including aGLP1-naïve adults with T2DM who were started on oral or subcutaneous semaglutide add-on to T2DM treatment during the year 2022. The primary outcome was change in HbA1c. Secondary outcomes were changes in weight and lipid profile, occurrence of gastrointestinal side effects (GSEs), and discontinuations. Linear mixed models were used to estimate changes in HbA1c, weight, and BMI, and logistic regression was used to analyze GSEs and discontinuations.
Results
136 patients were included, 82 in the subcutaneous semaglutide group and 54 in the oral semaglutide group. Mean age was 60 years (SD 1.5) and HbA1c 8.2% (SD 0.2). At 24 weeks, the mean reductions in HbA1c were: -1.2% (SD 0.2) with subcutaneous semaglutide and -1.3% (SD 0.2) for oral semaglutide (p n.s). The mean changes in body weight from baseline to week 24 were: -5.5 kg (SE 2.3) for subcutaneous semaglutide and -6.9 kg (SD 2.4) for oral semaglutide, (p n.s). There were no differences in the lipid profile. Some type of adverse event occurred in 41 patients in the subcutaneous semaglutide group (50%) and in 21 patients in the oral semaglutide group (39%), mostly mild gastrointestinal effects. There were 11 withdrawals from treatment in the subcutaneous semaglutide group (13.4%) and 5 in the oral semaglutide group (9.2%).
Conclusion
Semaglutide, in its two presentations (subcutaneous and oral) are effective in the treatment of patients with DM2. There were no differences in HbA1c, weight, or lipid profile, or in the appearance of adverse effects or dropouts.

The influence of the endocrinologist in the management of type 2 diabetes

Silvia González Martínez [1,2], Raúl Rodríguez Escobedo[1,2], Agnieszka Kuzior[1], Paula Aristegui Montero[1], Aida Saavedra Ojeda[1] & Daniel Martín Roque[3]
[1]Hospitales Universitarios San Roque, Endocrinology and Nutrition, Maspalomas, Spain; [2]Instituto de Investigación del Principado de Asturias (ISPA), Endocrinology, Nutrition, Diabetes and Obesity Research Group (ENDO), Oviedo, Spain; [3]Hospitales Universitarios San Roque, Endocrinology and Nutrition, Las Palmas de Gran Canaria, Spain

Introduction
In Spain, the specialist in endocrinology and nutrition is the reference in the care of patients with diabetes mellitus. In the year 2022, access to these specialists has been facilitated in the south of Gran Canaria. The aim of the study is to determine how this has influenced the management of type 2 diabetes (T2D).
Methods
We included those patients with T2D assessed by the Endocrinology service in 2022 in which two analyses were performed 6 months apart. Patients diagnosed with T2D in 2022 or who had been assessed by an endocrinologist after July 2021 were excluded. The change in glycosylated haemoglobin (HbA1c) and LDLc was assessed in all patients and by subgroups. The change in anti-diabetic and lipid-lowering treatment was studied. In addition, we analysed the influence on metabolic control of the introduction of basal insulin, iSGLT2, aGLP1 and assessment by the hospital dietician team.
Results
A total of 77 patients were included, 58.41% were male. The mean duration of diabetes was 12.28 years. 76.62% were in primary prevention. The change in HbA1c, expressed in%, with basal insulin initiation (4 patients), iSGLT2 (16 patients), aGLP1 (16 patients) and assessment by dietician (13 patients) was 10.45 ± 1.67 vs 7.33 ± 1.12 ($P = 0.125$), 7.981 ± 1.44 vs 6.694 ± 0.73 ($P = 0.0004$), 8.33 ± 1.71 vs 6.687 ± 0.80 ($P = 0.0002$) and 7.523 ± 1.84 vs 6.646 ± 0.83 ($P = 0.415$), respectively.
Conclusion
Patients with T2D managed by endocrinologists have improved metabolic and lipid profile control. There has been a marked increase in the use of iSGLT2, aGLP1 and statins, as recommended in disease management guidelines. The introduction of iSGLT2 and aGLP1 achieved a statistically significant decrease in HbA1c.

Table 1 Change in HbA1c, expressed as%, and in LDL-C, expressed as mg/dl

	Patients	Initial	6 months	*P*
HbA1c		7.36±1.37	6.67±0.73	<0.001
HbA1c >7	34	8.52±1.28	7.04±0.75	<0.0001
HbA1c > 8	18	9.45±1.11	7.30±0.80	<0.0001
LDLc		95.7±42.60	75.5±33.00	<0.001
LDLc > 70	51	117.6±31.90	85.5±33.45	<0.0001
LDLc > 100	34	135.2±23.57	90.8±38.02	<0.0001

Table 2 Use of drugs, expressed as a percentage of patients

Drug	Initial	6 months	Change
Basal insulin	18.2	23.4	+5.2
Bolus Insulin	7.8	6.5	-1.3
Metformin	76.6	77.9	+1.3
iDPP4	32.5	24.7	-7.8
aGLP1	13.0	32.5	+19.5
iSGLT2	42.9	62.3	+19.5
Sulfonylurea	10.4	7.8	-2.6
Glinides	2.6	3.9	+1.3
Pioglitazone	1.3	3.9	+2.6

Effect of Liraglutide on glycemic control in type 2 diabetic patients

Zouaoui Chadia, Bel Hadj Sliman Chayma, Baltagi Myriam, Bchir Najla, Annam Benchhida & Haroun Ouertani
Military Hospital of Tunis, Endocrinology, Tunis, Tunisia

Introduction
Liraglutide is a glucagon-like peptide-1 receptor agonist (GLP-1 RA), approved for management of type 2 diabetes (T2D).
Aim
The aim of our study is to evaluate the effectiveness of Liraglutide in controlling blood glucose levels over a period of 6 to 12 months in Tunisian type 2 diabetic patients.
Methods
We conducted a prospective descriptive study at the endocrinology-nutrition department of the military hospital of Tunis, including 22 patients with T2D who were not treated with GLP-1 RAs. Liraglutide 1.2 mg was administered subcutaneously once daily. Fasting glycemia and glycated hemoglobin were checked before and 6 to 12 months after starting treatment. Clinical and paraclinical data were collected from medical records.
Results
Our population included 8 men and 14 women. The mean age was 53.8 ± 9 years old. The mean duration of diabetes was 11.2 ± 6.9 years. Our patients had a mean weight of 109 ± 19.2 kg and a mean BMI of 39.4 ± 7 kg/m^2. Hypertension, dyslipidemia and coronary artery disease were found in respectively 15, 16 and seven patients. Nineteen patients were treated with metformin, 15 patients with dipeptidyl peptidase inhibitors, 16 patients with sulphonylureas and five patients with insulin. The mean HbA1c was 10 ± 11.3% before starting Liraglutide and 8.4 ± 1.8% after 6 to 12 months of treatment ($P = 0.004$). The mean fasting blood glucose was 2.1 ± 0.5 g/l before starting Liraglutide and 1.7 ± 0.5 g/l after 6 to 12 months of treatment ($P = 0.049$). Glycemic control remained stable in three patients, worsened in four patients, and improved in 15 patients. Ten patients achieved therapeutic targets of HbA1c. Among those treated with sulphonylureas, the dose was reduced in 10 patients. Among those treated with insulin, the dose was reduced in four patients.
Conclusion
Our study shows the effectiveness of Liraglutide, used in combination with other hypoglycemic agents, in reducing HbA1c and glycemia in patients with T2D.

Glycaemic control parameters in patients with diabetes mellitus secondary to exocrine pancreas diseases using flash glucose monitoring

Ana Ortolá Buigues[1] , Carla Valles Valverde[2], Emilia Gómez Hoyos[1], Rebeca Jiménez Sahagún[1], Juan José López Gómez[1], Beatriz Torres Torres[1], Esther Delgado García[1], Gonzalo Díaz Soto[1], María de la O Nieto de la Marca[1] & Daniel de Luis Román[1]
[1]Hospital Clínico Universitario Valladolid, Endocrinology and Nutrition, Valladolid, Spain; [2]Facultad de Medicina. Universidad de Valladolid, Valladolid, Spain

Introduction
Diabetes mellitus secondary to exocrine pancreas diseases (pancreatogenic DM) has an unknown incidence and is considered underdiagnosed. Our objective was to evaluate the glycemic control parameters in patients with pancreatogenic DM who started Flash glucose monitoring (FGM).
Methods
Prospective, observational study in a Spanish hospital. Patients with pancreatogenic DM who started FGM from January 2021 to August 2022 were recruited. Patient data collected included demographic, clinical, anthropometric variables, and the etiology, years of evolution, and treatment of DM. Additionally, following blood glucose control variables from the Abbott FreeStyle Libre were recorded for the first 14-days: glucose management indicator (GMI), coefficient of variation (CV), percentage of time in range (TIR) (70-180 mg/dl), in hypoglycemia (<70 mg/dl), in hyperglycemia (>180 mg/dl) and hypoglycemic events.
Results
20 patients were included. 60% were men. Median age was 63 [IQR 57-76] years and evolution of DM was 6.5 [IQR 3.0-11.7] years. 55% were secondary to pancreatectomy (30% total, 25% partial), 25% chronic pancreatitis, 15% cystic fibrosis, and 5% hemochromatosis. Regarding of chronic complications, 15% had cardiovascular disease, and 35% microvascular complications (25% nephropathy, 15% retinopathy, 5% nephropathy). Median weight was 66.1 [IQR 61.1-71.7] kg and BMI 25.4 [IQR 22.8-27.5] kg/m2. Patients required 19.0 [IQR 14.0-27.0] IU/day of basal insulin and 6.0 [IQR 4.1-12.8] IU/day of rapid-acting insulin (total: 0.40 [IQR 0.28-0.49] IU/kg/day). In the first 14-days of FGM, a TIR of 64.0 [IQR 55.5-76.5]% (40%>70%), a time in hyperglycemia of 34.5 [IQR 21.0-44.5] % (35% <25%), and a time in hypoglycemia of 0.0% [IQR 0.0-1.7] (85% <4%, with 0% of the time in glucose < 54 mg/dl) were recorded. The CV was 32.4 [IQR 26.6-36.3]%, the GMI was 7.1% [IQR 6.9-7.7]%, and hypoglycemic events were 1.0 [IQR 0.0-3.5]. A significant higher percentage of time in hypoglycemia was obtained when comparing patients with total pancreatectomy vs other causes (1.5 [IQR 0.7-5.0]% vs 0.0 [IQR 0.0-0.2]%, $P=0.026$), as well as hypoglycemic events (3.5 [IQR 1.5-10.5]% vs 0.5 [IQR 0.0-2.0]%, $P=0.041$). However, there were no differences in TIR (63.5 [IQR 58.7-72.0]% vs 64.0 [IQR 48.5-82.2]%, $P=0.968$), in GMI (7.0 [IQR 6.9-7.4]% vs 7.3 [IQR 6.8-8.0]%, $P=0.437$) or in CV (34.8 [IQR 31.5-42.3]% vs 29.8 [IQR 26.2-35.7]%, $P=0.109$).
Conclusion
Despite the heterogeneous etiology of pancreatogenic DM that influences the pancreas beta cell reserve, we did not find differences in most of the glycemic control parameters. Only the time in hypoglycemia was significantly higher in patients with total pancreatectomy.

The closed-loop system in type 1 diabetes management of a pregnant patient: A case report

Mehrez Achwak, Geraldine Levy, Maelle Torres, Manon Guillot, Frederic Carrié & Jean Michelle Andrieu
Béziers Hospital, Endocrinology Department, Beziers, France

Introduction
Managing type 1 diabetes during pregnancy can be challenging. Stricter glycaemic targets are recommended due to maternal and fetal risks. The closed-loop system is an advanced technology more and more commonly used in type 1 diabetes control but rarely reported during pregnancy. We report the case of a patient with type 1 diabetes, treated with the Medtronic 780 G system during pregnancy.
Case Report
A G3P3A0 pregnant patient with type 1 diabetes since the age of 9 years. High glycaemic variability was reported in previous pregnancies when treated with insulin injections. The closed-loop system was activated before the third pregnancy. Pregnancy was reported at 7 weeks. At the beginning of pregnancy, her weight was 45 Kg and glycated hemoglobin (HbA1c) was 6.7%. At week 22, maternal weight was 50 kg, continuous glucose measure (CGM) indicated 70% of the time in range (TIR; 70–180 mg/dl), 5% of time <70 mg/dl, and 25% of time >180 mg/Dl, estimated HbA1C of 7.1% and coefficient of variation of 25%. At week 32, maternal weight was 54 kg, Improved glycaemic control with time spent in different ranges achieved as follows: <70 mg/dl: 1%, 70–180 mg/dl: 94%, and above the target in 5%, estimated HbA1C of 6.3% and a coefficient of variation of 24.3%. During the last month of pregnancy, her overall mean sensor glucose was 134 +/- 32 mg/dl with a coefficient of variation (CV) of 24.2%, and mean HbA1C of 6.5% indicating healthy glycaemic control. Her CGM metrics indicated 92% of the time in range (TIR; 70–180 mg/dl), 1% of time <70 mg/dl, and 7% of time >180 mg/dl. The end of pregnancy took place at week 38 via cesarean section, during which the closed loop was maintained with an 81% TIR, 19% TAR, and no hypoglycemia. In the immediate postpartum period, the automatic mode was not suspended and good glycaemic control was maintained. There were no obstetric complications. The newborn required temporary monitoring in the Neonatal Intensive Care Unit for hypoglycaemia that rapidly resolved within 24 hours. Otherwise, the newborn was healthy, weighting 3840 g. Both mother and baby were discharged on the third day after delivery.
Conclusion
The use of a closed-loop system during pregnancy was associated with decreased episodes of severe hypoglycaemia and better glycaemic control. Further clinical studies on the use of closed-loop systems in pregnancy, delivery, and immediate postpartum should be encouraged.

How do people's emotions affect their Diabetes Mellitus?

Selda Celik[1] & Merve Murat[2]
[1]University of Health Sciences, Hamidiye Faculty of Nursing, Internal Medicine Nursing Department, Istanbul, Turkey; [2]University of Health Sciences, Hamidiye Faculty of Nursing, Psychiatric Nursing Department, Istanbul, Turkey

Diabetes Mellitus (DM) is, characterized by high blood glucose levels, one of the most common chronic diseases worldwide. In 2021, according to International Diabetes Federation, 537 million adults aged between 20 and 79 are diagnosed with DM. Environmental and genetic factors affect its etiopathogenesis. Disturbances in emotions or emotion regulation are regarded as a major contributor to the pathophysiology and etiology of the disease. People with DM who experience diabetes distress have detrimental emotional effects on self-care and glycemic control. Numerous research has emphasized the impact of people's emotions on DM. In patients with DM, we discovered indications of abnormalities in the emotional identification process, particularly diminished emotional clarity and management, and self-efficacy. People who are capable of managing their DM alone get better health results. It is essential to pay close attention to emotions when tackling a variety of issues in order to improve self-management. The Emotional Freedom Technique (EFT) is one of the interventions used to alleviate psychological distress. It is a brief exposure therapy that combines cognitive and physical components. In this review, we focus on how emotions influence people with DM in their daily lives and the effectiveness of EFT on people with DM.

Are our diabetic patients satisfied with their treatment?

Wissal Ghamgui, Hadj Ali Zohra, Zemni Zayneb, Htira Yosra & Ben Mami Feyka
Zouhair Kallel National Institute of Nutrition, Department C, Tunis, Tunisia

Introduction
The aim of diabetes treatment is to keep blood glucose levels as near to normal as possible. Training in self management of diabetes forms an essential part of diabetes management. Treatment should be agreed on an individual basiss and

adress medical psychosocial and lifestyle issues. But how much diabetes patients are satisfaied about their treatment?
Materials and Methods
Diabetes Treatment Satisfaction questionnaire (**DTSQs**) was used to measure satisfaction and adherence of patients to their treatment. The questionnaires were filled out anounymously. The first factor assesses treatment satisfaction and consists of six questions (Q1, 4, 5, 6, 7 and 8). These six questions ask about « satisfaction with current treatment », « flexibility », « convenience »,«understanding of diabetes », « recommend treatment for others », and « willingness to continue », respectively. The second factor consists of two questions (Q 2 and 3) wich assess the burden from hyper- and hypoglycemia, respectively.
Results
We submitted 48 patients with type 2 diabetes to the DTSQs questionnaire. The average age of our patients was 56 years. The sex ratio was 0.82.the mean total score of DTSQs (the sum of six questions = 0-36) was 23.85, with the mean score of each question being 3.97. The mean scores of Q2(hyperglycemia) and Q3 (hypoglicemia) were 3.70 and 1.97 respectively.
Conclusion
A number of factors are associated with treatment satisfaction like macrovascular complications actual hypergycemia and specially diabetes education. Self-management education programmes should incorporate this factors to improove the well-bebing of diabetes patients.

Dietary habits' assessment in a population of pregnant women with gestational diabetes mellitus

Dorra Ben Yedder[1], Chaima Jemai[1], Hana Ben Jemaa[1], Yosra Htira[1], Skander Msolly[1], Dorra Ben Selem[1], Imen Hedfi[2], Zohra Hadj Ali[1] & Feika Ben Mami[1]
[1]National Institute of Nutrition of Tunis, C, Tunisia; [2]National Institute of Nutrition of Tunis, Tunis, Tunisia

Introduction
Gestational Diabetes Mellitus (GDM) in a common endocrinopathy during pregnancy. Anectodal evidence suggests that nutritional management of patients with gestational diabetes may reduce the risk of complications. Therefore, the aim of our study were, to assess eating habits in a population of pregnant women with GDM.
Methods
It was a prospective study about 120 pregnant women with gestational diabetes recruited at the Diabetes and Pregnancy Research Unit (UR17SPO2) of Department C In the National Institute of Nutrition of Tunis. We performed an assessment of eating habits followed by a personalized nutritional education.
Results
The mean age was 30 ± 5.17 years with extremes of 20 and 42 years. 48.8% were multiparous. 47.3% had a family history of type 2 diabetes (T2D) and 29.5% a personal history of GDM. Among patients with a history of GDM, only 12% had achieved postpartum glycemic control. The preconception body mass index (BMI) was 29.36 ± 5.1 kg/m^2. Eating habits' evaluation had shown that 91.7% took at least 3 meals a day. The average duration of food intake was more than 15 min in 55% of patients. The most common cooking methods were steam (97%), oven (96%) and grill (96%). Skipping meals was frequent by 43.3% (skipping breakfast: 39.2%; skipping dinner: 29.2%). Skipping meals was linked to a lack of appetite (65.42%) or a time constraint (34.8%). Snacking was found in 72.4% of cases. The consumption of food supplements was noted in 91.6% of cases. They were based on iron (85.7%), vitamin B9 (20.2%) or calcium (17.6%). 47.9% consumed caffeinated drinks, with at least one drink per day for 45.3% of cases.
Conclusion
Eating habits' assessment is essential. Proscribing bad habits such as snacking, caffeinated drinks and systematic consumption contribute to improving the prognosis of these at high-risk pregnancies.

Polyglandular autoimmune syndrome type IV with latent autoimmune diabetes of the adult (LADA) and Alopecia Areata - A case report

Daniel Cosma[1] , Cristina Alina Silaghi[2] & Horatiu Silaghi[3]
[1]Horezu City Hospital, Diabetes, Nutrition and Metabolic Diseases Outpatient Clinic, Horezu, Romania; [2]"Iuliu Hatieganu" University of Medicine and Pharmacy, Endocrinology Department, Cluj-Napoca, Romania; [3]"Iuliu Hatieganu" University of Medicine and Pharmacy, 5th Department of Surgery, Cluj-Napoca, Romania

Polyglandular autoimmune syndromes (PAS) are a heterogeneous group of rare diseases characterized by autoimmune activity against more than one endocrine organ, although non-endocrine organs can be affected. PAS type IV is a rare syndrome characterized by the association of autoimmune endocrine gland disorder which doesn't fulfill the criteria of PAS type I-III. A 35-years old female diagnosed with alopecia areata and latent autoimmune diabetes of the adult (LADA) one year and respectively two months before her transfer to our outpatient clinic, presented with multiple symtomatic hypoglycemic episodes after initiation of the basal-bolus regim with Glargin U-300 and Aspart insulin in an university diabetes center. The patient stated that the current insulin regim and the recommended carbs intake doesn't fit her work schedule causing huge distress and affecting her daily quality of life. The LADA diagnosis was established based on positive GAD-65, anti-insulin, anti-tyrosine phosphatase-related IA2 antibodies and a normal C-peptide value of 1.36 ng/ml (NV: 0.78-1.89). The labs exams also revealed: Gl = 136 mg/dl, ketonuria (15 mg/dl),mild hypercholesterolemia and A1c = 5.8% (under treatment with Metformin 500 mg/day). The screening for celiac and thyroid autoimmune diseases was negative alongside with the tests for microvascular specific diabetes complications. Based on A1c value and the patient profile, she was switched from basal-bolus regimen to Metformin with progressive dose titration up to 1.5 g/day (maximum tolerated dose) leading to pre-prandial values of 74-101 and post-prandial of 99-200 mg/dl. Also, vitamin D 2000IU/day was recommended from September until May. After 3 months due to a slightly increase in A1c (6.1%) and post-prandial glycemic values (93-236 mg/dl), Sitagliptin 50 mg/day was added leading to a very good glycemic control without hypo events which persists to this day (6 months from initiation). The constalation of one endocrine and one non-endocrine abdnormalities led to the diagnosis of PAS type IV. The good glycemic control obtained by adding a DPP-4 inhibitor to Metformin is in line with the previous reported cases suggesting the benefits of this class in the LADA management.

Clinical and genetic profile in a cohort of adults with morbid obesity

Esteban Sánchez Toscano[1], Cristian Jesús Lucena Morales[1], Jesús Domínguez Riscart[2], Laura Larrán Escandón[1] & Isabel Mateo Gavira[1]
[1]Hospital Universitario Puerta del Mar, Endocrinology and Nutrition Department, Cádiz, Spain; [2]Hospital Universitario Puerta del Mar, Pediatrics and Specific Areas Department, Cádiz, Spain

Introduction
There have been more than 130 genes described in relation with the development of obesity, which condition hyperphagia and early obesity. The aim of this study is to determine the prevalence of genetic alterations in a cohort of patients with morbid obesity.
Materials and Methods
We designed a descriptive cross-sectional study for a cohort of subjects with obesity grade III or higher (BMI $\geq$40 kg/m^2), treated at endocrinologist consultations of Hospital Puerta del Mar. In order to determine cases of genetic obesity, an obesity panel has been designed based on exome sequencing of 80 genes.
Results
Preliminarily, we recruited 80 patients, 54 (67.5%) female with a median age of 50 (42-56) years. The maximum weight recorded was 137 (118-158.7) kg. and the maximum BMI was 50.8 (46-56) kg/m^2. Regarding metabolic comorbidities, 39 patients (48.8%) had arterial hypertension, 49 (61.3%) hepatic steatosis, 22 (27.5%) obstructive sleep apnea syndrome, 24 (30%) type 2 diabetes mellitus and 7 (8.8%) impaired fasting blood glucose. A total of 11 (13.6%) patients were diagnosed of hypothyroidism and 6 (7.5%) had history of cardiovascular events. Genetic variants were detected in 48 patients (60%), 33 of them (68.8%) were considered uncertain significance variants, 4 (8.3%) were probably pathogenic variants and 11 (22.9%) were considered pathogenic variants. Regarding the probably pathogenic variants, only a POMC variant [NM_001035256.2:c.638C > T p.(Ala213Val)] with autosomal dominant inheritance could justify the patient's symptoms. The other three

probably pathogenic variants (one in ALSM1, another one in BBS10 and another one in IFT4), all of them with autosomal recessive inheritance, should be considered as carrier patients. Regarding pathogenic variants, a variant in MCR4 [NM_005912.3(MC4R):c.27G>A p.(Met9Ile)] with autosomal dominant inheritance could justify the patient's symptoms, whereas the other variants (one in BBS1, one in CEP290, one in IFT74 and seven in PSCK1) with autosomal recessive inheritance should be considered as carrier patients.
Conclusions
In our cohort, we detected a high incidence of variants, although most of them are uncertain significance variables whereas those that are pathogenic or probably pathogenic should be considered as a carrier status in many cases. Only 2 variants could be considered as a definitive diagnosis of non-syndromic genetic obesity: a variant in POMC [NM_001035256.2:c.638C>T p.(Ala213Val)] and another in MCR4 [NM_005912.3:c.380C>T p.(Ser127Leu)].

Menopausal symptoms in postmenopausal women and its association with sarcopenia

Nikitha Sriramaneni[1], Chitra Selvan[1] & Nanda Kumar S[2]
[1]Ramaiah Medical College, Endocrinology, Bangalore, India; [2]Ramaiah Medical College, Physiotherapy, Bangalore, India

Background and Objectives
With menopausal transition, there is decline in estrogen concentration with potential vasomotor, physical, psychosocial, and sexual health consequences. The loss of muscle mass, strength, and function, known as sarcopenia is common in postmenopausal women. The primary objective of this study is to assess the menopausal symptoms in postmenopausal women and its association with sarcopenia.
Methods
This study was conducted from January to December 2022 in Endocrinology OPD, Ramaiah Hospital, Bengaluru. A total of 106 postmenopausal women with the onset of menopause at >45 years of age were included in the study. Menopausal symptoms, and risk of sarcopenia were assessed with Menopause Rating Scale (MRS) and SARC-F questionnaires respectively. Sarcopenia was defined and assessed according to the Asian Working Group for Sarcopenia guidelines 2019. Data analysis is done with the statistical software SPSS 22.0.
Results
The mean age of the participants was 59.34±7.21 years and the mean age at menopause was 49.50±2.67 years. Majority (80.2%) of the women had high MRS score (moderate-58.5%; severe-21.7%). Among the MRS domains, majority of women had mild somatic symptoms (37.7%), moderate psychologic symptoms (44.3%) and severe urogenital symptoms (60.4%). Urogenital symptoms were significantly high($P=0.002$) in older women. SARC-F score was low in 85.8% and high in 14.2% of women. In our study, 45.3% of women had sarcopenia, 31.1% had possible sarcopenia and 23.6% had no sarcopenia. Women with sarcopenia were significantly older in age($P=0.002$), shorter ($P=0.005$) and their mean weight, BMI were significantly low($P<0.001$). Among women with sarcopenia, majority had mild somatic (41.7%), moderate psychologic (41.7%) and severe urogenital (66.7%) symptoms respectively. Somatic symptoms were significantly severe in women with sarcopenia($P=0.044$). Women with low appendicular skeletal muscle mass index were significantly older and had significantly low hand grip strength and physical performance.
Conclusions
Most of the women (80.2%) had moderate to severe MRS score suggestive of a poor quality of life. Majority of the women (76.4%) had sarcopenia or possible sarcopenia. Most of the women (81.3%) felt they were strong (according to SARC-F score) despite having sarcopenia. There was significant association between somatic symptoms and sarcopenia. There was no significant difference in MRS score or SARC-F score with age. It is essential to assess for sarcopenia in all women ideally during perimenopause and thereby advise for improvement of muscle mass and muscle strength. The limitations of this study are its cross-sectional nature and relatively small sample size.

Trends in the prevalence and mortality rate of protein-energy malnutrition in Tunisia

Selma Mohsen[1] , Dorra Ben Salem[2], Mziou Emna[1], Khiari Hyem[1], Mehrez Achwak[2] & Berriche Olfa[3]
[1]Institut Salah Azaiez, Tunisia; [2]Institut de Nutrition, Service C, Tunisia; [3]Institut de Nutrition, Service A, Tunisia

Introduction
Protein-energy malnutrition (PEM) results from an imbalance between the intake and the needs of the body, which is still noted in developing countries. The aim of this work was to describe the trend of prevalence and mortality rate during the period 2010- 2019 in people aged over 55 years in Tunisia.
Methods
This was a retrospective descriptive study. The data source was the Washington Institute of Health Metrics for Tunisia. We performed a direct standardization of prevalence and mortality rates and analyzed their Trend over 9 years using JointPoint software.
Results
During 2010-2019, the prevalence of malnutrition increased by 9%; the annual average percentage of change (AAPC) was of +1% (95% CI [0.8%-1.2%] for both genders; ($P<10^3$). In the masculine gender the APC was only significant during the period 2017-2019 with a percentage of 4.3% (95% CI [3.1%-5.4%]); $P<0.001$. In contrast, for the female sex we noted a significant APC during the 2 periods 2010-2017 and 2017-2019 respectively of 0.4% (95% CI [0.3%-0.5%] and 3.1% (95% CI [2.3%-4%]) ($P=0.001$). The mortality rate showed a clear decrease of -18% with a AAPC of -1.8 (95% CI [2.3%-1.4%] significant for both genders ($P<0.001$).
Conclusion
Even if the ECD mortality rate in Tunisia has decreased during the last decade owing to early diagnosis, the prevalence still notes a significant increase. This underlines the importance of an adequate nutritional management.

Sulfite oxydase deficiency encephalopathy: Description of a new pathogenic mutation in SUOX gene

Fatima Zahra Outtaleb[1], Tazzite Amal[2], Gazzaz Bouchaïb[3] & Dehbi Hind[1,2]
[1]Ibn Rochd University Hospital, Laboratory of Medical Genetics, Casablanca, Morocco; [2]Faculty of Medicine and Pharmacy. Hassan II University, Cellular and Molecular Pathology Laboratory, Casablanca, Morocco; [3]Royal Gendarmerie, Genetics Analysis Institute, Casablanca, Morocco

Sulfite oxidase deficiency encephalopathy is a rare genetic disease, secondary to the mutation of the SUOX gene, which codes for the enzyme sulfite oxidase that catalyzes the oxidation of sulfite to sulfate, an essential process for the catabolism of sulfur amino acids. This rare disease is characterized clinically by seizures, progressive encephalopathy and lens dislocation. The objectives of this report are to describe the clinical, paraclinical and evolutionary characteristics of this pathology, as well as the interest of prenatal and pre-implantation diagnosis in its management. This case involved a first-degree relative referred to the medical genetics department because of a personal history of 3 neonatal deaths in their offspring, at d6, d5 and d21 of life respectively, in a picture of epileptic encephalopathy appearing 12 hours after birth. The 3 pregnancies were well followed, carried to term, without any notion of acute fetal suffering, infectious syndrome or toxic intake. The newborns had normal birth weight and Apgar score, and no malformative or dysmorphic signs. A brain MRI could be performed in the last child and showed a T2 hypersignal of the supratentorial white matter, an arachnoid cyst of the posterior cerebral fossa, and hypoplasia of the cerebellum. Since no genetic analysis could be performed in the 3 newborns, and in view of the clinical and paraclinical picture suggesting an inborn metabolic disorder and the notion of 1st degree consanguinity, a high-speed sequencing of the exome of both parents was requested. A missense mutation NM_000456.2:c.1187A>G p.(Gln396Arg) of unknown significance (class 3) in the SUOX gene was found in the heterozygous state in both parents. In addition, a pathogenic missense mutation (class 1) of the TTC21B gene was found incidentally in the heterozygous state in the father. This mutation is responsible for hereditary nephronophthisis in the homozygous state. Given the family history

and the results of genetic tests, the diagnosis of encephalopathy by sulfite oxidase deficiency by homozygous mutation of the SUOX gene was retained. This rare genetic disease, of unknown prevalence, is transmitted by autosomal recessive mode. Thus, the risk of recurrence for this couple is 25%. This explains the interest of genetic counselling, in order to propose a prenatal or pre-implantation diagnosis to the couple, and a search for the mutation in relatives at risk.

Keywords: encephalopathy by sulfite oxidase deficiency, SUOX gene, prenatal diagnosis, pre-implantation diagnosis.

Combination of mutations in the HNF1A and ABCC8 genes: clinical polymorphism in members of the same family

Irina Eremina, Elizaveta Raykina, Elena Titovich, Valentina Peterkova & Dmitry Laptev

Endocrinology Research Center, Children Department, Moscow, Russia

Mutations in HNF1A gene underlie the development of maturity onset diabetes of the young type 3 (MODY3). Mutations in ABCC8 gene are the cause of neonatal DM and the rare MODY12, which is clinically similar to MODY3. In these forms of MODY, there is a high sensitivity to sulfonylurea, but over time, patients may need insulin therapy.

Patient A, 17 y.o. He was born to woman with gestational DM. At the age of 12.5, fasting hyperglycemia of 13 mmol/l was detected. Insulin therapy was not prescribed due to the parents refusal. At the 14.5 y.o, since his mother was diagnosed with MODY3, a pathogenic variant p.R54X in HNF1A was detected, a MODY3 was diagnosed. At the age of 15, he was hospitalized with hyperglycemia 13.8 mmol/l. HbA1c - 9.8%. Long-acting insulin was assigned. Subsequently, the patient used insulin irregularly and consumed large amounts of fast carbohydrates. His maximum HbAc1 was 20.5%. At 17 y.o, he was admitted to hospital: glycemia was 18.6 mmol/l, HbAc1 - 12.6%, islet antibodies were negative. Intensified insulin therapy (0.9 units/kg/day) led to the normalization of glycemia. Specific diabetic complications were not detected. In addition to the variant in the HNF1A, a p.R521X variant was found in the ABCC8. After 3 months, the boy was successfully transferred to glibenclamide 7.5 mg/day.

Patient L, 37 y.o, proband's mother. At the age of 20, gestational DM was diagnosed: fasting glycemia was 6-9 mmol/l, she refused insulin therapy. At the 32 y.o, an examination for cholelithiasis revealed hyperglycemia, the variant p.R54 X in the HNF1A was detected. To date, she has not received hypoglycemic therapy, followed a carbohydrate-restricted diet. At the last examination at the age of 37, HbAc1 was 6.7%, a variant of p.R521X was found in the ABCC8 as in the son.

Patient S, 8 y.o, proband's sister. HbAc1 – 5.4%, fasting glycemia – 4.7 mmol/l. There are variants of p.R54X in the HNF1A and p.R521X in the ABCC8.

Conclusion

MODY associated with variants in the HNF1A and ABCC8 is characterized by a different degree of carbohydrate metabolism disorders, depending on the location of mutation in gene and its severity. We have presented a description of clinical polymorphism in members of family with a combination of identical mutations in the two MODY genes. The more severe disease in proband, apparently, is due to the low compliance. Normoglycemia in sister may be due to age, which requires further dynamic observation.

Severe hypoglycemia in non-diabetic patients

Amine Gueddari[1] , Nassim Essabah Haraj[1], Siham El Aziz[1] & Asma Chadli[1]

[1]UHC Ibn Rochd, Endocrinology and Metabolic Disorders, Casablanca, Morocco

Introduction

Non-diabetic hypoglycemia (NDH) is defined by a glycemia <0.50 g/l with the presence of neuroglycopenic signs and their disappearance after glucose administration.

Objective of the Study

Describe the diagnostic and therapeutic aspects of severe NDH cases in our department.

Material and Methods

Over a period of 12 years (2010 – 2022), 32 patients met the definition criteria.

Results

The average age of our patients was 48.4 years, with a female predominance (76.3%). Hypoglycemia was recurrent in 81% of cases with an average capillary blood sugar of 0.32 g/l occurring in a fasting state in 67% of patients and in post-prandial in 33% of cases. The fasting test carried out in 24 patients, with an average duration of 15.2 hours, pointed to an organic cause in 65% of cases with complementary imaging: pancreatic CT (34.1%), abdominal MRI (25%), CT angiography (6.7%), echo-endoscopy (28%), chest CT (3.1%) and pituitary MRI (3.1%). The different etiologies found were: an insulinoma (14, malignant in 2 cases), factitious hypoglycemia (6), an extrapancreatic tumor secreting IGF2 (4), functional hypoglycemia (6), nesidioblastosis (1) and corticotropic insufficiency (1).

Discussion

These results summarise the severity of NDH with female predominance.

Non-islet cell tumour hypoglycaemia (NICTH)

Yin Yin, Lanitha Sikugan, Cynthia Mohandas, Arthur Ogunko & Itopa Abedo

Darent Valley Hospital, Endocrine and DM, Dartford, United Kingdom

An 87-year-old lady was admitted to hospital with severe unexplained hypoglycaemia with capillary glucose of 1.8 mmol/l and went on develop recurrent episodes of symptomatic hypoglycaemia during this admission. She had a background history of diabetes mellitus, well under controlled with diet and a previous diagnosis of solitary fibrous pleural tumour of left lung, which was resected completely in 2013 but reoccurred in 2022 with left sided pleural effusion. Her liver and renal function tests were within normal reference range. She has a normal cortisol response to synacthen test as follows: 335nmol/l at zero minutes,955 nmol/l at 30 minutes and 1066nmol/l at 60 minutes. CT chest showed a 22 cm solid lesion in the left hemithorax, which had enlarged, considerably in comparison with previous scans and represented a recurrence. Laboratory assessment during one of the hypoglycaemic episodes (venous glucose 1.3 mmol/l (3.6-5.4)) revealed a C-peptide of 25 pmol/l(normal range 370- 1470) and insulin level of $<$ 12 pmol/l (normal level 18-173). Paraneoplastic hypoglycaemia likely due to NICTH was suspected, however insulin like growth factor 2(IGF-2) level could not be processed due to unavailability of radiolabelled assay. She was deemed an unsuitable candidate for further operation and chemotherapy by the lung multi-disciplinary team .An initial attempt to treat hypoglycaemia with a tapered dose of prednisolone failed, so she was continued on oral prednisolone 15 mg once a day. Unfortunately, hypoglycaemia (capillary blood glucose 1.7 mmol/l) re-occurred and she was re-admitted to hospital and Prednisolone dose was increased to 30 mg once day. If this fails Growth hormone injection will be next available treatment option for her although her prognosis is poor in view of the advanced neoplastic disease.

Discussion

- NICTH is a rare cause of paraneoplastic hypoglycaemia and is mostly seen in mesenchymal and epithelial tumours.
- It is due to an underlying tumour producing excessive IGF-2 or pro IGF-2.
- It can cause profound and persistent hypoglycaemia and may not respond to medical treatment and the main stay of treatment is surgical excision of underlying tumour.

High blood pressure in obese patients: body composition and dietary patterns

Rahma Khalaf, Berriche Olfa, Sana Khamassi, Ramla Mizouri, Nadia Ben Amor, Rym Ben Othman & Jamoussi Henda
National Institute of Nutrition, Department A, Tunis, Tunisia

Background and Aim
Obesity is a major risk for the development of hypertension.These cardiovascular risk factors are associated with nutritional targets. The aim of our study was to determine clinical characteristics,body composition and hypertension-related dietary patterns of obese patients with high blood pressure.
Methods
This was a cross sectional study including 70 patiens. Clinical characteristics, anthropometric measures were collected. Body composition was determined by Bioelectrical impedance analysis. Adjusted body weight (ABW) was calculated for all patients. Dietary intake data were collected by trained nutritionists using a 24-hour recall method.Patients were divided into 2 groups: Group1 (G1) consists of 43 obese patients without hypertension and groupe2 (G2) consists of 27 obese patients with hypertension. Clinical caracteristics,anthropometric measures,body composition and dietary intake were compared between the two groups.
Results
Mean age was significantly higher in G2 patients (55.33 $\pm$ 13.4 vs 38.81 $\pm$ 15.4; $P<10^{-3}$). Prevalence of diabetes, dyslipidemia and obstructive sleep apnea syndrome was signifiantly higher in G2 patients($P=$ 0.03; $P=0.002$;$P<10^{-3}$, respectively). Mean Body Mass Index and waist circumference did not statistically differ among the two groups($P=$ 0.3 and $P=$ 0.5, respectively). Body water percentage was significantly higher in G1 patients (42.73% $\pm$ 6.1 vs 39.54% $\pm$ 4.25; $P=$ 0.04) while lean mass, skeletal muscle mass and fat mass percentage did not statistically differ among the two groups (76.95 kg $\pm$ 11.11 vs 55.92 kg $\pm$ 7.39; $P=0.39$, 53.04 kg $\pm$ 9.1 vs 56.44 kg $\pm$ 11.34; $P=0.2$ and 43.31% $\pm$ 11.24 vs 42.51% $\pm$ 8.43; $P=$ 0.78, respectively). Mean saturated fatty acid intake and total fat intake were significantly higher in G2 patients (9.68% Total energy intake (TEI) $\pm$ 2.99 vs 8.1% TEI $\pm$ 2.92; $P=$ 0.015 and 1.58 g/kg ABW $\pm$ 0.68 vs 1.18 $\pm$ 0.5 g/kg ABW; $P=0.02$, respectively). Fiber intake and simple sugar intake and protein intake did not statistically differ among the two groups ($P=$ 0.4, $P=$ 0.2 and $P=$ 0.1, respectively). G1 patients had significantly higher magnesium intake (395.55 mg/d $\pm$ 278 vs 291.71 mg/d $\pm$ 101.07; $P=0.04$) , iron intake (12.92 mg/d $\pm$ 9.16 vs 8.9 mg/d $\pm$ 2.64; $P=0.01$) and calcium intake (792.12 mg/d $\pm$ 305.79 vs 549.64 mg/d $\pm$ 195.25; $P=$ 0.005) compared to G2 patients. Sodium, potassium and sodium/potassium ratio did not statistically differ among the two groups ($P=0.07$; $P=0.09$ and $P=0.1$, respectively).
Conclusion
This study shows inappropriate nutritional habits in patients with hypertension, related to the coexistence of obesity.Our results are in line with other studies. Patients should be guided to choose more low-fat dairy products and other low-fat calcium sources and to increase intakes of magnesium.

Does the prebiotic and probiotic supplementation influence the lipid profile of obese patients?

Rym Ben Othman, Zeineb Zemni, Amel Gamoudi, Berriche Olfa, Chaima El Ghali, Ramla Mizouri, Nadia Ben Amor, Faten Mahjoub & Jamoussi Henda
National Institute of Nutrition of Tunis, Obesity Research Unit, Tunis, Tunisia

Background
The role of gut microbiota on our health is increasingly well known. It plays a role in digestive, metabolic, immune and neurological functions. The objective of our work was to evaluate the effect of prebiotic and probiotic supplementation on the lipid profile in addition of a weight loss program.
Methods
This is an interventional study involving 45 obese patients consulting the obesity unit of the Institute of Nutrition of Tunis during the period from May to August 2022. Patients were divided into 3 groups matched for age, sex and BMI: diet alone, prebiotics (30g of carob/d) and probiotics (1 tablet of Lactibiane*/d). The lipid profile (total cholesterol (TC), triglycerides (TG), HDL-c and LDL-c) was performed at T0 and at one month after the intervention (T1).
Results
The mean age was 48.73 $\pm$ 7.7 years with a female predominance (93.3% of women). There was a significant decrease in total cholesterol (-0.4 mmol/l) and LDL-cholesterol (-0.3 mmol/l) for the diet alone group between T0 and T1 ($P=0.03$ and 0.05 respectively). For the prebiotic group we noted a significant decrease in total cholesterol (-0.4 mmol/l), LDL-cholesterol (-0.4 mmol/l) and TG (-0.5 mmol/l) ($P=0.005$, $P=0.003$ and $P=$ 0.001 respectively). For the probiotic group, there was a significant decrease in plasma levels of total cholesterol (-0.7 mmol/l) and triglyceride (-0.3 mmol/l) ($P<0.001$ and $P=0.006$ respectively). There was no significant improvement in HDL-c levels in the three groups. For the comparison between groups: The three groups were comparable for improvement in total cholesterol. The prebiotic and diet alone groups were comparable for improvement in LDL-c ($P=0.4$) and the prebiotic and probiotic groups were similar for improvement in TG ($P=0.2$).
Conclusion
The improvement of total cholesterol and LDL-c was not related to the use of symbiotics. On the other hand, the use of symbiotics seems to improve triglyceride levels with a comparable effect for prebiotics and probiotics.

Features of psycho-emotional status and quality of life in patients with metabolic syndrome

Olga Moskalenko & Edward Kasparov
Federal Research Center «Krasnoyarsk Science Center» of the Siberian Branch of the Russian Academy of Sciences, Krasnoyarsk, Russia

Metabolic syndrome (MS) is characterized by obesity, hypertension, dyslipidemia, and insulin resistance. The severity of the clinical manifestations of MS affects the quality of life (QoL) of patients, while indicators of physical and mental health decrease. In patients, anxiety and depressive disorders in 80-90% of cases are latent, which can aggravate the course of the underlying disease. The purpose of our work is to study the psycho-emotional status and quality of life in patients with metabolic syndrome.
Research Methods
The study was conducted on the basis of the clinic of the Scientific Research Institute of Medical Problems of the North FRC KSC SB RAS. All patients were divided into groups: group 1 - 76 patients with MS, group 2 - 42 practically healthy volunteers without concomitant diseases and not obese. Patients were examined with determination of anthropometric parameters: waist circumference (cm), body weight (kg), BMI (kg/m^2). The assessment of the quality of life was determined using the SF-36 questionnaire. The level of anxiety and depression was assessed in points according to the hospital anxiety and depression scale HADS (1983).
Results
According to the obtained results, the majority of QoL indicators differed statistically significantly in the group of patients with MS relative to the control group (Group 2). Thus, the indicators of the level of QoL are significantly higher in healthy individuals than in patients with obesity. Differences in all groups are significant ($p \leq 0.05$). It was also found that a decrease in the average level of parameters on the scale "physical functioning" by 19.7% ($P<0.05$), "role functioning" by 35.2% ($P<0.05$), "general health" by 15, 1% ($P<0.05$), "vitality" by 18% ($P<0.05$), "emotional functioning" by 53.1% ($P<0.05$). The assessment of the level of anxiety and depression in patients with MS corresponded to a subclinically expressed level, and the level of depression exceeded the indicator of the control group (Group 2) by 19.3%. The level of QoL in patients with obesity is significantly lower than in healthy individuals.
Conclusion
The obtained results show that in patients with MS, quality of life indicators decrease, most patients have significant changes in the state of the psycho-emotional sphere, subclinical anxiety-depression is determined. Also, patients require correction of psychological disorders, which will reduce the level of anxiety and depressive disorders, which will further improve the quality of life.

Comparison of symptoms and clinical complaints in people with various manifestations of metabolic syndrome

Gulhayo Khasanova[1], Gulzor Rakhmanova[2], Aziza Khalilova[2], Nigora Maksutova[3], Mokhira Aykhodjaeva[3], Ilkhom Abdiev[4] & Zulaykho Shamansurova[2,5]
[1]Gulistan State University, Biochemistry, Sirdarya, Uzbekistan; [2]Tashkent Pediatric Medical Institute, Endocrinology with Pediatric Endocrinology, Tashkent, Uzbekistan; [3]Republican Specialised Scientific Practical Medical Centre of Endocrinology, Endocrinology, Tashkent, Uzbekistan; [4]Termez branch of Tashkent Medical Academy, Endocrinology, Termez, Uzbekistan;

[5]Institute Biophysics and Biochemistry at the National University of Uzbekistan, Endocrinology with Pediatric Endocrinology, Tashkent, Uzbekistan

Introduction
Metabolic syndrome (MetS) is combined groups of diseases with common pathogenesis and clinical signs and symptoms. Usually MS starts with obesity and last step appeared as a Diabetes Mellitus. We aimed to compare clinical signs and patients complaints according to type of manifestation of MetS.
Material and Methods
Patients data, clinical complaints, anthropometric, biochemical parameters in 248 patients with various manifestations of the MetS, such as obesity, impaired glucose tolerance (IGT), polycystic ovary syndrome (PCOS), type 2 diabetes mellitus (DM2).
Results
The age of patients was important as a risk factor for the development of various manifestations of MetS. In particular, patients with PCOS were the youngest, and in the direction of obesity, IGT and DM2 the age were getting older. The BMI was higher in all patients with MetS, which indicated higher body weight in all groups. In particular, BMI was highest in obesity group (42.83 kg/m^2), followed by IGT (36 kg/m^2), PCOS (34.6 kg/m^2), DM2 (32.34 kg/m^2). Analysis of patients' complaints made it possible to identify those that specific for manifestation forms of MetS. In particular, for DM2 the presence of dry mouse, thirst, frequent urination, weakness, dry skin were specific, whereas excessive food intake, weight gain, dyspnea were shown in IGT and obesity, excessive skin hairiness, infertility, menstrual cycle irregularities are more pronounced in PCOS, that could facilitate the identification and differential diagnosis of type of MetS manifestation in overweight or obese individuals in medical practice.
Conclusion
People age was main risk factors in the development of MetS where patients with PCOS were younger and getting older in direction to Obesity, then IGT and DM2. Comparing of BMI showed that it was higher in Obesity group and lowered into direction of IGT, PCOS then DM2. Comparison of people complaints revealed specific for various manifestation of MetS that will help in identification of type of MetS in people with obesity.

Assessment of physical activity levels in a population of obese patients

Mehrez Achwak, Fatma Boukhayatia, Chaima Sdiri, Rahma Khalaf, Sana Khamassi, Salma Mohsen, Asma Ben Brahim, Rym Yahiaoui, Haifa Abdessalam, Kamilia Ounaissa & Chiraz Amrouche
The National Institut of Nutrition of Tunis, Outpatient Department, Tunis, Tunisia

Introduction
The health benefits of physical activity have been demonstrated in many diseases, including obesity. The aim of our study was to assess the physical activity level of obese patients.
Methods
A prospective cross-sectional study was conducted on 55 obese patients who consulted the obesity unit of the National Institute of Nutrition in Tunis between March and July 2022. The level of physical activity was assessed by the Ricci and Gagnon questionnaire, which defines an active profile for a score $\geq$18 points.
Results
The average age was 47 years (14-79) with a female predominance (82%). The average weight was 99 $\pm$ 19 kg with an average BMI of 38 $\pm$ 6 kg/m^2. The average waist circumference was 116 $\pm$ 15 cm. Of the patients included, 10 were active (18%) and 45 were inactive (82%). The average Ricci and Gagnon score reported by the patients is 13.5 $\pm$ 6.9, which is considered inactive. Men were more active than women (P = 0.04). Physical activity was associated with fewer articular complications (P = 0.02). Physically inactive patients had higher BMI (37 kg/m^2 vs 36 kg/m^2, P = 0.04) and higher waist circumstance (117 cm vs 113 cm, P = 0.1). *Physical activity* was associated with better sleep quality assessed by *the Pittsburgh Sleep Quality Index* (P = 0.03). Physically active patients had higher HDL cholesterol (1.3 g/l vs 1.1 g/l, P = 0.04) and lower fasting blood glucose measure (7.6 mmol/l vs 8.6 mmol/l, P = 0.5).
Conclusion
The majority of patients were inactive. Physical activity was associated with a better anthropometric and glycaemic profile, higher HDL cholesterol, and better sleeping quality. These results underline the importance of physical activity in the treatment of obesity. The prescription should be based on an analysis of daily physical activity, medical situation, motivation, barriers, and risks in order to develop an individualized and adapted program for each patient.

A simple score for predicting non-alcoholic fatty liver disease in obese patients

Meriam Dalhoum[1], Berriche Olfa[1], Riahi Sameh[2], Hamza Sahar[2], Tlili Raja[2], Amel Gamoudi[1], Rym Ben Othman[1], Nadia Ben Amor[1], Ramla Mizouri[1], Awatef Kacem[1], Kallel Lamia[2] & Jamoussi Henda[1]
[1]National Institute of Nutrition in Tunis, Human Obesity Research Unit, Tunis, Tunisia; [2]Mahmoud El Matri Hospital, Ariana, Gastroenterology Department, Tunis, Tunisia

Introduction
Non-alcoholic fatty liver disease (NAFLD) represents the most common and fastest growing liver disease. Its incidence is associated with the global obesity epidemic.
Objective
To develop a simple score to predict the risk of NAFLD in the obese patient.
Methods and Materials
This is a descriptive cross-sectional study including 95 patients who consulted at the Human Obesity Research Unit of the National Institute of Nutrition in Tunis. Patients were interviewed, anthropometric measurements (weight, height, body mass index (BMI), waist circumference) were taken, biological assessment (fasting blood glucose, triglyceride, total cholesterol, HDL-cholesterol) and abdominal ultrasound were conducted to look for hepatic steatosis.
Results
The mean age of our patients was 48.7 $\pm$ 7 years with a female predominance (91.6%). The mean BMI was 41 $\pm$ 13 kg/m^2. The mean waist circumference was 114 $\pm$ 8 cm. The frequency of hepatic steatosis was 70.5%. In univariate analysis, the following NAFLD risk factors: BMI, waist circumference, waist-to-height ratio $\geq$0.7 and triglyceride/HDL cholesterol ratio $\geq$2.5 were all correlated with hepatic steatosis with a statistically positive P (P < 0.05). In multivariate analysis, only waist-to-height ratio $\geq$0.7 was independently associated with NAFLD with an adjusted Odds Ratio of 4.1 (P = 0.03).
Conclusion
Waist-to-height ratio $\geq$0.7 is an independent risk factor for NAFLD in obese patients. It is a simple parameter that can be used in routine practice as a screening tool for non-alcoholic fatty liver disease.

Evaluation of cardiovascular risk and use of arterial age in an obese Tunisian population

Ben Ali Khaoula, Eya Safi, Berriche Olfa, Zeineb Zemni, Imen Ouderni, Hajer Moalla, Rim Rachdi, Faten Mahjoub, Rym Ben Othman & Jamoussi Henda
National Institute of Nutrition, Service A of Diabetology and Nutrition, Tunisia

Introduction
The objective of our study was to calculate the risk of cardiovascular event and arterial age in an obese Tunisian population.
Methods
This is a cross-sectional study conducted in service A of the National Institute of Nutrition in Tunis. 25 patients were included. The score from The Framingham Heart Study(1) was used to calculate cardiovascular risk and arterial age.
Results
The mean age was 44.28 + 13.2 years, the average duration of obesity was 20.8 + 10.4 years, the mean BMI was 47.9 + 9.2 kg/m^2, average waist circumference was 134.01 + 18.48 cm, the mean arterial age was 53.12 + 18.59 years. High blood pressure, Type 2 Diabetes, smoking, hypercholesterolemia and Low HDL cholesterol were noted in 40%, 34%, 20%, 46%, 23% of patients respectively. A cardiovascular risk higher than 10 was noted in 32% of population (n = 8). The analytical study showed a significant difference between chronological age and arterial age (P = 0.001). Arterial age and cardiovascular risk were not correlated with BMI or waist circumference or duration of obesity progression.
Conclusion
Our study has shown that cardiovascular risk stratification is possible on simple clinical-biological data. Obesity increases the cardiovascular risk mainly through its complications, hence the interest of repeating the cardiovascular evaluation at each consultation in order to improve the vital prognosis in this population.

Complications of obesity: a retrospective study of a Tunisian population

Eya Safi, Ramla Mizouri, Zeineb Zemni, Imen Ouderni, Ben Ali Khaoula, Olfa Lajili, Nadia Ben Amor, Rym Ben Othman, Faten Mahjoub, Berriche Olfa & Jamoussi Henda
National Institute of Nutrition, A, Tunis, Tunisia

Objective
To study the characteristics of obesity in a Tunisian population and determine the associated complications.
Methodology
Retrospective study including 60 obese patients followed at the obesity unit of the National Nutrition Institute of Tunis.
Results
The mean age was 44 ± 11.08 years with a female predominance of 87%. The average body mass index (BMI) was 35.7 ± 4.8 kg/m^2. Obesity class I, class II and morbid obesity were observed in 51.7%, 30% and 18.3% of cases respectively. Sleep apnea syndrome was noted in 26.7% of patients. It was significantly more frequent in cases of morbid obesity than in the other classes ($P=0.001$). High blood pressure was present in 22.4% of the population without significant difference according to the severity of obesity ($P=0.21$). Metabolic complications were dominated by hypoHDLemia (56.9%), glucose intolerance (31%), hyperuricemia (27.6%) and hypertriglyceridemia (22.4%). Only the association of hyperuricemia with class III obesity was statistically significant ($P=0.006$). Digestive complications were dominated by hepatic steatosis in 25% of obese patients. It was significantly more present in cases of morbid obesity ($P=0.003$). Osteoarticular complications were present in 51.7% of cases with no statistically significant difference according to BMI.
Conclusion
Complications of obesity, especially morbid, were frequent in our population. This imposes the implementation of preventive measures as well as an adequate management of this pathology.

About 2 rare cases of morbid obesity with syndromic character

Imane Boubagura, Sana Rafi, Ghizlane El Mghari & Nawal El Ansari
Department of Endocrinology, Diabetology and Metabolic Diseases, University Hospital of Marrakech, Marrakech, Morocco

Introduction
Bardet-Biedl syndrome (BBS) is a rare disorder. It is an autosomal recessive hereditary ciliopathy, including: Multivisceral impairment, associated with obesity, learning disabilities, with or without intellectual deficit. We report the observation of 2 patients followed in our training for morbid obesity.
Case Report
Case 1: O. Y. 17 years old, from a non-consanguineous marriage. Admitted for management of morbid obesity, BMI = 70 kg/m^2, Malformative syndrome: [Postaxial hexadactyly of the 4 limbs, Club feet, Ogival palate]. Ophthalmologic anomalies: [Nystagmus, Strabismus]. Neurological examination: [Coordination disorders]. Paraclinical check-up: Eye fundus: retinitis pigmentosa, Standard radiography: Hexadactyly of the 4 limbs with club feet. Abdominal ultrasound: a left upper polar renal cyst. The biological workup was unremarkable, apart from a vitamin D deficiency that was being corrected.
Case 2: A.F. 15 years old, from a non-consanguineous marriage. Admitted for management of morbid obesity.BMI = 40 kg/m^2, Malformative syndrome: [brachydactyly of both hands, club feet]. Ophthalmologic anomalies: [Strabismus]. Paraclinical check-up: Fundus: retinitis pigmentosa, standard X-ray: brachydactyly of both hands with club feet, abdominal-pelvic ultrasound: no genitourinary malformation. The biological workup was unremarkable.
Discussion and Conclusion
BBS is an inherited ciliopathy resulting in multivisceral involvement and intellectual deficit. The diagnosis of BBS is clinical and defined by the association of four major criteria or three major and two minor criteria according to Beales et al. The diagnosis of BBS was made in the first patient because of the first four major criteria, which were also associated with three other minor criteria: strabismus, coordination disorder and ogival palate. In the second patient, the diagnosis was based on 3 major and 2 minor criteria. The medical management of BBS is multidisciplinary because of the multivisceral involvement

Eating Habits of Obese Patients: One obesity center Experience

Emre Çapar, Elif Kazel Öztürk, Tuncay Tığcı, Ömer Yanartaş & Dilek Gogas Yavuz Marmara
University Pendik Research And Education Hospital, İstanbul, Turkey

Introduction
Obesity is a component of eating disorders grouped under several eating disturbances due to emotional problems. Eating habits are directly influenced by eating disorders. Eating disorder rates in obese patients are reported to be 15-50% in various populations. This study aimed to evaluate obesity related eating habits (OREH) in obese patients who followed in an obesity center.
Methods
A total of 752 (F/M: 636/116, 42.6 ± 11.6 yrs) obese patients (BMI > 30) who applied to the Obesity Center of Marmara University Pendik Education and Research Hospital (ERH) were included in this cross-sectional study. Obesity is classified as Stage 1 (BMI 30-34.9), Stage 2 (BMI 35-39.9), and Stage 3 (BMI > 40). We evaluated graze eating, night eating, eating addiction, and binge eating in the context of OREH in accordance with the literature. Self-report tests including The Short Inventory of Grazing (SIG), Modified Yale Food Addiction Scale (mYFAS), Night Eating Questionnaire (NEQ), Emotional Eating Scale (EES), and Binge Eating Scale (BES) were given to the patients. OREH results were determined based on these test's cut-off points.
Results
Mean BMI was found to be 42.1 ± 6.6 kg/m^2. There were no statistically significant difference between both genders in respect of age and BMI ($P > 0.05$). Mild grazing habits was observed in 136 (18%) cases, moderate grazing in 309 (41%) cases, and severe grazing in 229 (30%) cases. Modarete stage grazing was more common in women (265, 41.6%) and men (44, 47.6%). Binge eating was recorded in 337 of the total (44.8%) patients, in 287 of women (45.1%) and 50 men (43.1%). Emotional eating was present in 113 of the total patients (15%), in 103 of women (16.1%) and 10 men (8.6%). Food addiction were seen in 402 of all cases (53.4%). High stage food addiction was more common in women (169, 51.1%) and men (30, 42.2%). Night eating was found in 225 patients among all (29.9%) with 185 (29%) to be in women and 40 (34.4%) in men. Emotional eating ($P=0.032$) and night eating ($P=0.025$) were found to be statistically significant in regard of BMI.
Conclusion
In this cross-sectional study, many of obese patients had obesity related eating habits whereas 65% of all cases had more than one component of obesity related eating habits. Determining the eating disorders prior to obesity treatment are necessary for planning and treatment compliance.

Analysis of covid inpatients lethality in adults with metabolic disoders such as diabetes and/or obesity

Olena Antonyuk
Bogomolets National Medical University, Social Medicine and Public Health, Kyiv, Ukraine

COVID-19 significantly influenced global mortality; it caused 6.6 million cases of death. Mortality or crude death rate (CDR) is a typical statistical value for analyzing the demographic processes among the population. In Ukraine, we observed an increase in CDR in 2020-2021. It could be caused directly by the COVID-19 pandemic and indirectly; due to social distancing. Some people avoid visiting a doctor and neglect their treatment of chronic diseases. Comorbidities such as obesity could lead to the rapid progression of COVID-19, especially in the presence of a 'deadly triad' (Lim S. et al., 2020) as age, male gender, and access to adiposity in the body). We decided to check the influence of obesity on the outcome of COVID-19 hospitalization. The research aimed to find the correlation between BMI and laboratory findings such as C-reactive protein and interleukin-6. We researched inpatients with COVID-19 and metabolic disorders to determine whether obesity influenced the inflammatory process and caused poor outcomes with a high probability of acute respiratory distress syndrome; the obtained data from the performed research approved that hypothesis. We analyzed 130 cases of hospitalization due to COVID-19 in the Medical Centre Universal Clinic "Oberig" in 2020-2021. We compared the group of inpatient survivors ($n=90$) and non-survivals ($n=42$). The mean age was 81 years (CI 78-84) and 79 years (CI 70-81), correspondingly ($P<0.001$). In previous studies, we found that the frequency of obesity raised to. We compared several parameters, such as the minimal absolute lymphocytes count that was observed during hospitalization (0.56 (0.4-0.9) and 0.19 (0.1-0.28), $P<0.001$); the highest C-reactive protein (CRP) (37.57(17.06-72.97) and 120.98 (75.21-179.6), $P<0.001$); baseline IL-6

(23.5 (9.1-43.4) and 33.4 (17.7-74.9), $P=0.008$); baseline ferritin (328 (154-558) 735 (415.5-1175), $P<0.001$). Mean Hb1Ac was 5.26% (4.78-5.87) and 5.5 (4.98-6.52), $P=0.089$). According to the received data, we calculated the correlation between BMI and the highest CRP (Ro = 0.512), $P=0.01$.); between BMI and baseline IL-6 (Ro = 0.686, $P<0.01$); between severity of respiratory insufficiency and minimal lymphocyte count (Ro = -0.598, $P<0.01$).
Conclusion
the paper is devoted to solving a significant scientific and practical problem of individual assessment of COVID-inpatients on the presence in them of high inflammatory rates, especially in the case of diabetes and obesity comorbidity as it could influence mortality and could be associated with poor prognosis.

Overweight and Obese Indians' Attitudes Toward Obesity, Willingness to Lose Weight, and Treatment Preferences
Bharat Saboo
Prayas Diabetes Center, Diabetology, Indore, India

Obesity has become a major health concern around the world, and it is linked to a variety of diseases and complications. Losing weight is an effective strategy for lowering BMI and avoiding the complications of obesity. However, weight loss is determined by an individual's attitude toward obesity as well as their willingness to lose weight.
Aim
To investigate attitudes toward obesity, willingness to lose weight, and treatment preferences among Indians who are overweight or obese. An analytical cross-sectional study was carried out among overweight and obese Indians. The study was carried out using a self-administered questionnaire from December 2021 to November 2022. Inclusion Criteria: 1. Obese by WHO guidelines 2. willing to be a part of the study. The results showed that 78.5% of the 327 participants were unhappy with their current body weight. Controlling chronic disease was a major motivation for losing weight (57.2%), and exercise and diet were the most preferred methods of losing weight. Age is an important factor in deciding attitude towards obesity. ($P=0.0001$).
Conclusion
Participants in the current study reported high levels of dissatisfaction with their current weight and a willingness to lose weight. Health workers should focus on talking and informing more about obesity as they will encounter an large number of these patients in opd.

Barriers of adaptations with psycho-social problems in type 2 diabetes
Maarja Randväli
Tallinn Health Care College, Tallinn, Estonia

Type 2 diabetes is a progressive chronic disease that is on a global upward trend and involves high healthcare costs. Obstacles to adaptation to this disease include knowledge of the disease, fear of treatment, inability to adapt to changes in lifestyle, lack of physical activity and exhaustion. Type 2 diabetes significantly affects brain function, including cognitive function, and increases the risk of depression. The studies reveal that there has been no comparison of neurological changes in healthy people over the lifespan experienced by diabetics of the same age. Cognitive dysfunction mechanisms are multifactorial. It is affected by age, disease duration, HbA1c, comorbidities and medications. Depression is a very common problem in type 2 diabetes and has a multi-directional effect. Depression can trigger type 2 diabetes and develop depression in type 2 diabetes. The mental health problem worsens coping, and quality of life and increases mortality rates. Depression is often undiagnosed or inadequately treated for this disease. Psychosocial problems include a person's attitudes towards diabetes, expectations of treatment and outcomes, mood changes, available resources, and psychiatric background. To detect early symptoms of depression, we can use non-invasive methods, one of which is brain ultrasound. For an objective assessment of sleep disorders, it is possible to use melatonin determination in urine, which is simple and easily available. The purpose of the study is to examine the changes in the raphe nuclei in the brain, melatonin levels in urine, along with mental health and sleep quality questions and comprehensive background data in people with type 2 diabetes. A double-blind controlled study of barriers to adjustment to illness in people with type 2 diabetes. The sample consists of ($n=600$) people with type 2 diabetes and their relatives in the control group. Data are collected during one year from the regional hospital and private health center included in the study. As a result of the study, we get evidence of the changes in the Raphe nuclei of the brain for comparison with the results of the Moca test, and the change in the melatonin level in cognitive disorders in people with type 2 diabetes.

"Knowledge, Beliefs, and Practices of People with Type 2 Diabetes toward Self Management and Diabetic Foot"
Hani Naguib
Ghala, Endocrinology, Muscat, Oman

Introduction
Diabetic foot is a physio pathological state with an etiopathogenic neuropathic basis, induced by sustained hyperglycaemia in which, with or without the co-existence of Peripheral Arterial Disease, and with a prior triggering trauma, ulcers and/or deep tissue destruction occur on the feet of diabetics.
Objectives
To evaluate the knowledge, beliefs, and practices regarding diabetes and its complications among Omani type 2 diabetes patients.
Patients and Methods
A cross-sectional study enrolled 150 participants from the Diabetes Clinic at Bausher polyclinic, Muscat. Data was collected using questionnaires.
Results
Only 38% checked their feet regularly and only 5.6% were having diabetic foot. The practices regarding physical activity and blood glucose monitoring were found to be poor. results were as follows 84% don't know the cause of diabetes also 37.3% don't know the complications of the same while 55.3% don't know cause of diabetic foot and 50% don't know the symptoms of diabetic foot.
Conclusions
Educational interventions that approach the adoption of essential behaviour with regard to foot care are considered the ideal practices for this public, which should include daily foot examination and preventive care for skin, nails and callosity. Professionals should incorporate the practice of health-related education in their daily routines to better assist their patients. Furthermore, as those responsible for promoting, protecting and recovering health, they are expected to obtain desirable results with diabetics in preventing and delaying the onset of foot complications and help diabetics to improve their quality of life.

Lipid metabolism in patients type 1 and type 2 diabetes mellitus combined with Ischemic heart disease
Gulnora Artykbaeva & Talat Saatov
Institute of Biophysics and Biochemistry under MirzoUlugbek National University of Uzbekistan, Lab of Metabolomics, Tashkent, Uzbekistan

Diabetes mellitus with characteristic high blood serum glucose may cause various disorders, including damages to blood vessels. Both type 1 and type 2 DM increase the IHD risk by 4-6 times. The work was initiated to study parameters of lipid metabolism in patients with the IHD-combined type 1 and type 2 DM.
Materials and Methods
We examined concentrations of total lipids, triglycerides (TG), total cholesterol (TC) and high density lipoprotein cholesterol (HDL C) in 58 patients with

diabetes mellitus. 20 patients had diabetes mellitus without IHD, 8 and 12 persons with type 1 and type 2 DM, respectively, among them. In 38 patients DM was combined with IHD.
Results and Discussion:
Total lipids, TC and TG were found increased in all patients, but the ratios varied by the DM type. TC concentrations were approximately identical in all groups of patients, while those of TG, TC and HDL C were found to change by the DM type and presence of IHD. The most significant changes in the TG concentrations were observed in the blood serum of the patients with type 2 DM in combination with IHD (286.0±27.5 mg%); the concentrations in patients with type 2 DM without IHD were similar to those in the controls (139.3±0.3 mg%). The highest mean level of total lipids was measured in patients with the IHD-combined type 1 DM (11.42±0.61 g/l).The HDL C concentrations were found reduced in most patients, being more significant in those with the IHD-combined type 1 DM. In patients with the IHD-combined type 2 DM, concentrations of TC, TG and HDL C were higher than those in the patients with the IHD-combined type1 DM. In patients with the IHD-combined type 2 DM, concentrations of total lipids, TC and TG were higher than those in the diabetic patients without IHD, while concentrations of HDL C were found lower. Concentrations of total lipids, TC and TG were higher in patients with the IHD-combined type 1 DM than those in the diabetics without IHD. Thus, IHD exacerbated the DM course. Regardless of the DM type, the HDL C percentage of the total cholesterol was lower in the diabetics with the IHD. The parameter is more instrumental than the absolute TC percentage in the fraction. Calculation of TC/TG coefficients demonstrated changes in the concentrations of TC and TG in the transport forms with the predominance of the latter in patients with the IHD-combined DM of both types.

Unmet needs in diabetic neuropathy: A cross sectional analysis from a tertiary care diabetes centre in Sri Lanka

Kavinga Kalhari Kobawaka Gamage[1,2], T G Athukorala[3], Harsha Anuruddhika Dissanayake[3,4], Sivatharshya Pathmanathan[3], Manilka Sumanatilleke[3] & Noel Somasundaram[3]
[1]Royal Alexandra Hospital, Diabetes and Endocrinology, Paisley, United Kingdom; [2]NHSL, Dibetes and Endocrinology, Colombo, Sri Lanka; [3]NHSL, Diabetes and Endocrinology, Colombo, Sri Lanka; [4]John Radcliffe Hospital, United Kingdom

Background
Diabetic neuropathy, especially distal symmetric polyneuropathy (DSPN), is a common but under-recognized problem among people living with diabetes, particularly in developing countries. Aims: We aimed to describe the clinical characteristics, associated factors, treatment practices, outcomes and impact of DSPN among Sri Lankan adults living with diabetes.
Methods
A cross sectional study was conducted at the Diabetes Clinic of National Hospital of Sri Lanka over 4 consecutive months. Clinic attendees were screened for presence of symptoms and/or signs of DSPN and were invited to participate. Data was collected using an interviewer administered questionnaire which included a SF-36 questionnaire, and through findings from routine end-organ screening.
Results
A total of 201 patients (mean age 60.7 +9.5 years, men 38.8%, mean duration of diabetes 14.4 +8.5 years) were interviewed. Mean HbA1c was 9.3 +2.2% and 87.5% were on metformin. Overall, 92.0% had symptoms of DSPN (numbness 83.6%, pain 64.2%, hyperesthesia 32. 2%), whereas 99.0% had loss of protective sensation (73.9% on 3-point monofilament, 88.6% on increased vibration threshold). 11.9% had foot deformities (hammertoe 10.0%, bunion 2.0%, overlapping toes 1.0%, Charcot 0.5%). While 57.7% had pre-ulcer lesions (toe web infections 50.2%, callosities 13.9%, in-grown toenails 1.5%), 4.5% had active ulcers, and 4.5% had evidence of lower limb amputations. Evidence of diabetic retinopathy was noted only in 41.0% and 19.9% had at least one macrovascular complication. No clinical or demographic factors were associated with DSPN on multivariate logistic regression. Among 129 patients with neuropathic pain, only 35 (27.1%) were given treatment and among them only 8 (24.2%) reported symptom improvement. Painful neuropathy was associated with poor scores in physical functioning, energy level and general health. Despite the presence of diabetic neuropathy, 57.0% were barefoot most of the time.
Conclusions
Feet pain is common among people with DSPN. It remains undertreated and affects QoL. Deformities and toe-web infections are common, placing the feet at high risk of ulceration. There is room to improve foot-care provision and self-management among adults with DSPN.

Achilles tendon rupture in an uncontrolled diabetes patient

Şerife Ezgi Doğan, Serife Mehlika Kuskonmaz, Gönül Koç, Tülay Omma, Sevde Nur Fırat & Cavit Çulha
Ankara Training and Research Hospital, Endocrinology, Endocrinology, Ankara, Turkey

Diabetes is one of the risk factors for Achilles tendon rupture. Tendon thickening and impaired collagen organization have been reported in diabetic patients in small studies. In this report, we present the rupture of the Achilles tendon in a female patient with poorly controlled diabetes mellitus and diabetic neuropathy. A 52-years-old woman with a medical history of diabetes treated by intensive insulin therapy, developed pain in the right heel without previous trauma. The patient applied to the hospital because of the inability to walk for the last 5 days. Spontaneous rupture of the right Achilles tendon was diagnosed with MRI. Primary repair of achilles tendon planned. Diabetic ketosis treatment was performed due to preoperative blood sugar being 550 mg/dl and urine ketone positive. Afterwards, the tendon was treated by suture. Chronic hyperglycemia affects the Achilles tendon as well as many organs. Degenerative changes were more common in men and those with peripheral neuropathy. Although the risk of Achilles tendon rupture was more common in those with uncontrolled diabetes and female gender. Systemic approach is important in the follow-up of diabetic patients and heel pain should be evaluated in terms of Achilles tendon rupture, apart from diabetic neuropathy and diabetic foot.

Myocardial infarction in young adults with type 1 diabetes mellitus: A case report

Ben Salem Maram , Manel Jemel, Ons Maaoui, Marwa Chiboub, Hajer Kandara & Ines Kammoun
National Institute of Nutrition, Department of Endocrinology, Tunis, Tunisia

Background
The risk of myocardial infarction among patients with type 1 diabetes is, in addition to traditional cardiovascular disease risk factors, associated with duration of diabetes, reduced glycemic control and renal complications. However, the specific cardiovascular risk predictor models for type 1 diabetes mellitus are subject to many limitations and aggressive macrovascular disease can rarely happen at an early age.
Case Presentation
We report a case of a 22-year-old woman, non-smoker, with a medical history of type 1 diabetes since the age of 4 years old. The glycemic control was not optimal during five years and screening for microvascular complications was negative. Her blood pressure was normal and the lipid profile was within the target with an LDL cholesterol level at 0.6 g/l. She presented an acute chest pain and the electrocardiogram showed a negative T wave in the anterior territory. Echocardiography showed an altered left ventricular ejection fraction of 46% and coronarography revealed an occlusion of the anterior interventricular artery. Angioplasty was successfully performed.
Discussion
The rapidly progressive macrovascular disease observed in this case demonstrates the different degrees of aggressiveness and unpredictable clinical evolution observed in some cases. It also confirms the need for a multi-factorial, early and optimized clinical management regime of type 1 diabetes mellitus.

DOI: 10.1530/endoabs.90.EP471

Characteristics of type 2 diabetes in insulin-requiring elderly subjects

Fatma Zaouali[1], Najoua Lassoued[2], Zantour Baha[2], Alaya Wafa[2] & Sfar Mohamed Habib[2]
[1]University of Monastir, Family Medicine Department, Monastir, Tunisia; [2]Tahar Sfar University Hospital, Endocrinology Department, Mahdia, Tunisia

Introduction
Type 2 diabetes, which accounts for more than 90% of all diabetes in the elderly, is a major public health problem. It is associated with high morbidity and mortality, mainly due to complications such as cardiovascular events and renal failure. The objective of our study was to determine the characteristics of type 2 diabetes in insulin-requiring elderly subjects.

Methods
A cross-sectional study on type 2 diabetic insulin dependent elderly recruited from the outpatient endocrinology consultation over a period of 7 months from April 2021 to October 2021.
Results
A total of 282 patients were included in our study with a mean age of 72.33 ± 6.35 years and a sex ratio of 0.9. In association with diabetes, hypertension was the most common chronic disease (71.3%) followed by dyslipidemia (58.9%). The mean duration of diabetes and insulin therapy was 15.89 ± 7 and 7.85 ± 5.5 years, respectively. Only one third of patients were on insulin analogue. The basal double injection regimen was the most prescribed in our population (22.7%). Regular follow-up and self-monitoring of blood glucose were noted in 68.1% and 55% of patients, respectively. Nocturia, hypoglycaemic malaise, unrecognized hypoglycaemia, and severe hypoglycaemia were reported by 59.2%, 69.1%, 23.8%, and 30.5% of patients, respectively. The mean HbA1C level was 9.72% ± 1.81%. Only 17% of our patients had controlled diabetes. Less than a third of the patients (29.8%) had a history of hospitalization for diabetes decompensation, mainly for chronic diabetes imbalance (70.2%). Degenerative complications of diabetes were dominated by microangiopathic complications (83.7%). Diabetic neuropathy accounted for 72% followed by diabetic retinopathy in 57.4% of cases and diabetic nephropathy (17%). Macroangiopathic complications were noted in 45% of cases: the most frequent was arteriopathy obliterating of the lower extremities (27%) followed by myocardial infarction in 23.8% and stroke (12.8%). The diabetic foot was found in 8.5% of patients.
Conclusion
Despite unprecedented advances in insulin therapy and injection means, controlling diabetes in the elderly remains a challenge. Indeed, initiation of insulin therapy in older diabetic patients requires a complete geriatric assessment to identify factors that may complicate diabetes control.

Relationship between lipid profile and serum uric acid concentration in patients with type 2 diabetes

Zeineb Zemni[1], Nesserine Dhieb[1], Ramla Mizouri[1], Chaima Sdiri[2], Maryam Cheikhrouhou[2], Rym Ben Othman[1], Nadia Ben Amor[1], Faten Mahjoub[1], Berriche Olfa[1] & Jamoussi Henda[1]
[1]National Institute of Nutrition of Tunis, Department A, Bab Saadoun, Tunis, Tunisia; [2]National Institute of Nutrition of Tunis, Outpatient Department and Functional Explorations, Bab Saadoun, Tunis, Tunisia

Introduction
hyperuricemia is a marker of cardiovascular risk. The aim of this study was to examine the relationship between lipid profile and serum uric acid concentration in patients with type 2 diabetes (T2D).
Method
A retrospective study including 100 patients followed in the A department of the National Institute of Nutrition in Tunis. Data were collected from patients' medical records. The lipid profile includes low density lipoprotein (LDL), high density lipoprotein (HDL), non high density lipoprotein (non-HDL), triglyceride (TG) and total cholesterol (TC). Hyperuricemia was defined as serum uric acid greater than 6 mg/dl (360 µmol/l).
Results
The mean age of patients was 56.75 ± 12 years ,48% were men and 52% were women. The average duration of diabetes was 8.27 ± 6 years. The mean body mass index (BMI) was 29.55 ± 4.33 kg/m^2. Almost one third of the patients (29%) had hyperuricemia (with no clinical manifestations of gout) and 64.5% had dyslipidemia. We found a positive and statistically significant correlation between TG and uric acid level (r = 0.45, P0.002). Non-HDL cholesterol was positively correlated with uric acid levels and trend to significance (r = 0.28, P0.052). There was no correlation between LDL, HDL and uric acid concentration.
Conclusion
The results of our study illustrate the strong association between uric acid increase and lipid disorder in patients with T2D suggesting a crucial role of uric acid in the regulation of dyslipidemia.

Assessment of diabetic patients' knowledge of the diabetic foot

Meriam Dalhoum, Berriche Olfa, Rym Ben Othman, Nadia Ben Amor, Ramla Mizouri & Jamoussi Henda
National Institute of Nutrition in Tunis, Department A, Tunis, Tunisia

Introduction
Trophic disorders of the diabetic foot and their complications represent a major public health problem. Treatment must be accompanied by quality therapeutic education to allow patients to self-manage their disease. The objective of this work is to evaluate, with the help of a questionnaire, the knowledge of diabetic patients on the diabetic foot.
Materials and Methods
We conducted a descriptive, cross-sectional study among 50 diabetic patients hospitalized in ward A, at the National Institute of Nutrition in Tunis.
Results
The average age of our patients was 52 ± 12 years with a M/F sex ratio of 0.22. The majority of patients were type 2 diabetics (n = 34). The average age of diabetes was 12.5 ± 7 years. During the clinical examination of the foot, plantar hyperkeratosis was the most noted manifestation with a frequency of 72%. It was noted that 86% of the patients had never attended a therapeutic education session for diabetic foot and 48% of the patients had no idea about its mechanisms and favoring factors. Regular foot inspection was present in only 28% of patients, while 26% were unaware of the clinical manifestations and 30% did not cite any means of prevention. On the other hand, 92% of our patients knew that amputation was the main risk of the diabetic foot.
Conclusion
Therapeutic education of patients regarding the diabetic foot is crucial. Nevertheless, educational deficiencies persist, highlighting the need for a structured program involving the entire health care team.

Hospital investigation of hypoglycemia in type 1 diabetics: About 28 cases

Mariem Souissi, Amal Zaafrane, Boubaker Fadia, Houcem Elomma Mrabet, Malek Belkhiri, Zantour Baha, Najoua Lassoued, Alaya Wafa & Sfar Mohamed Habib
The Endocrinology Department, Taher Sfar University Hospital of Mahdia, Mahdia, Tunisia

Introduction
Hypoglycemia is a major obstacle to glycemic control in type 1 diabetics. Approximately two episodes of symptomatic hypoglycemia occur weekly in type 1 diabetic and this risk increases with the duration of diabetes and the strict control[1]. The aim of this study was to identify the most frequent etiologies of hypoglycemia in hospitalized type 1 diabetic patients.
Patients and Methods
This is a retrospective descriptive study that involved 28 type 1 diabetic patients hospitalized for hypoglycemia in the endocrinology department of the Taher Sfar University Hospital of Mahdia between 2011 and 2022.
Results
The average age of our patients was of 34.44 ± 13.88 years. The patients were divided into 6 men and 22 women. The average duration of diabetes was of 11.7 ± 7.45 years. The mean glycated hemoglobin in our patients was of 9.46% ± 2.68. The average frequency of hypoglycemia was 3 episodes per week. Severe hypoglycemia was present in ten cases. Several interrelated factors were often incriminated in the same patient. Hypoglycemia was attributed to poor education in 13 patients: 6 cases of insulin dose error, 6 cases of dietary error, 6 cases of injection in lipodystrophic areas. Two cases of hypoglycemia were attributed to severe renal failure. Hypoglycemia secondary to Addison's disease was diagnosed in 15 patients. A context of a malabsorption syndrome due to celiac disease has been demonstrated in three patients. Fake hypoglycemia was the cause of hypoglycemia in one patient.
Discussion and Conclusion
Hypoglycemia is a dread for any caregiver because of its neurocognitive impact on the quality of life and carbohydrate balance of type 1 diabetics. Rigorous etiological research is needed, requiring sometimes hospitalization and treatment reevaluation. In the literature, the occurrence of Addison's disease in type 1 diabetics is rare with a prevalence of 1.2%[2]. The explanation of the higher prevalence of Addison's disease in our population need to be explored.

Bezold abscess in diabetics: A case report

Rania Dassoufi, Hind Ouakrim, Sana Rafi, Ghizlane El Mghari & Nawal El Ansari
Mohammed VI University Hospital of Marrakesh, Department of Endocrinology, Diabetes, Metabolic Diseases and Nutrition, Marrakech, Morocco

Introduction
Benzold abscess remains rare, and its occurrence implies immunosuppression, particularly within unbalanced diabetes.
Methods and Results
Observation of a 76-year-old patient, diabetic for 29 years, on metformin, admitted for CMO of the right ear, complicated by Bezold's abscess. The interrogation revealed purulent otorrhea hypoacusis. The clinical examination revealed hyperglycemia,a swelling of the sternocleidomastoid, responsible for a torticollis. MRI of the rocks: abscessed and fistulated right cholesteatomatous otitis in the sternocleido-mastoid muscle. The biological tests showed an inflammatoire profil. Management: Insulin therapy and oral antidiabetics, drainage.
Discussion
Bezold's abscess is a rare extra-cranial complication of CMT occurring in immunosuppressive conditions such as chronic hyperglycemia in diabetes. It requires a CT scan or better an MRI for diagnosis. While the management is essentially based on an adapted antibiotics associated most often with surgical drainage.
Conclusion
Diabetes is an immunosuppressive factor exposing patients to an increased risk of infections such as abscess. Early, efficient and multidisciplinary management is required management to improve the prognosis.

Digital necrosis in a diabetic patient with probable Leo berger's arteritis

Widad Douali, Fatima Zahra El Jaafari, Sana Rafi, Ghizlane El Mghari & Nawal El Ansari
CHU Mohamed VI, Marrakech, Department of Endocrinology, Diabetology, Metabolic Diseases and Nutrition, Marrakech, Morocco

Introduction
Digital necrosis of the upper limbs is the final and often the only clinical manifestation of a of a distal arterial or microcirculatory pathology of the MS. The approach to The approach to this condition is very different, hence the particularity of our observation which highlights the severity of vascular lesions found in diabetic patients.
Observation
This is a 58 year old diabetic patient on mixtard 30: 16-00-08 ui; schizophrenia; on classic neuroleptic drugs; alcoholic and chronic smoker at Interrogation: Poorly monitored diabetes; Incoherent proposalsincoherent;an exacerbation of SPUPD;clinical examination: Patient conscious, cachectic, BMI 15 kg/m^2; Radial pulse weakly perceived bilaterally; Neuropathic feet; Thyroid not paLpable;On workup: Nfs: normal; CRP: negative;Ionogram: normal; Liver workup: normal;-AFP:8.19; CA19-9=1.1; total PSA =2; free PSA=0.338; serology: negative,echodopler of the MS: requested, the therapeutic management was based on:Optimization of his insulin regimen +local treatment of digital lesion.
Discussion and Conclusion
Digital necrosis and ulceration of the upper limb have various causes (vascular and metabolic, mechanical, toxic, etc.) and are often of polyfactorial origin. The positive diagnosis of a digital necrosis of the upper limbs is easy and represents only the visible face of a microcirculatory arterial pathology of the upper limb dominated by leo-burger type arteritis as in the case of our patient.

Diabetic Nephropathy

Hana Ben Jemâa, Chaima Jemai, Abir El Amri, Ines Bani, Hedfi Imene, Zohra Hadj Ali, Yosra Htira & Feika Ben Mami
National Institute of Nutrition, C, Tunis, Tunisia

Introduction
Nowadays, Diabetic nephropathy (DN) has become one of the leading causes of end-stage kidney disease.
Aim
The aim of our study was to determine the prevalence of diabetic nephropathy and to investigate its association with other comorbidities associated with diabetes.
Methods
A retrospective descriptive study was performed on 369 diabetic patients hospitalized in the c nutrition and metabolic diseases department. The definition as well as the different stages of diabetic nephropathy have been retained referring to the recommendations of the American Diabetes Association (ADA) of 2022.
Results
The median age of patients was 56.43 $\pm$15.7 years old. The majority of patients in our study has type 2 diabetes (65.6%).The average duration of development of diabetes is 11 years. The prevalence of DN was 42.8% (29.1% stage 1; 8.2% stage 3; 2.1% stage 2; 2.5% stage 4 and 0.9% stage 5). Among them 31.3% has microalbuminuria and 11.5% has macroalbuminuria. High blood pressure is noted in 58.3% of patients with DN. High fasting blood glucose values as well as glycated hemoglobin outside the targets were noted in 78% of patients with DN. In our study a significant correlation was found between DN and diabetic retinopathy ($P<10$-3) , dyslipidemia ($P=0.004$) and the duration of diabetes ($P<10$-3). Nevertheless, there were no significant differences in age($P=0.283$) sex ($P=0.277$) and type of diabetes ($P=0.725$) between those with and without DN.
Conclusion
The prevention of the Diabetes kidney disease is a global challenge based on early detection to limit the progression to terminal kidney disease.

A Rare Complication of Diabetes: Hemiballism Syndrome Associated with Non-ketotic Hyperglycemia

Ozlem Kanburoglu Meletli, Cigdem Birinci, M. Cuneyt Bilginer, Hulya Coskun, Irfan Nuhoglu, Ozge Ucuncu & Mustafa Kocak
Karadeniz Technical University Faculty of Medicine, Department of Endocrinology and Metabolism, Trabzon, Turkey

Introduction
Hemiballism is a rare hyperkinetic movement disorder characterized by involuntary, violent, coarse and wide-amplitude movements involving the ipsilateral arm and leg. Here, we aimed to present a case diagnosed as hemiballism due to non-ketotic hyperglycemia.
Case Report
A 60-year-old female patient presented to the emergency department with involuntary movements in the right half of the trunk for 10 days. It was a large amplitude proximal extremity movement in the right arm and also occurred in the right lower extremity. Movements did not continue during the night's sleep. On physical examination, she was conscious and well oriented to time and place. Hemodynamics and vital signs were stable. There was no sign of facial paralysis. Osteotendinous reflexes were symmetrical. Cranial nerves were intact. There were no other accompanying physical examination findings. She had type 2 diabetes for 10 years. She was using gliclazide 30 mg and linagliptin 5 mg, but she did not have regular doctor checks and did not measure blood glucose. She had no history of alcohol or substance abuse. Laboratory results showed a high plasma glucose of 540 mg/dl and a serum osmolarity of 302 mOsm/kg. The patient's kidney and liver functions were normal and there was no accompanying serious electrolyte imbalance. There was no finding compatible with metabolic acidosis in venous blood gas, there was no ketone positivity in urinalysis, and glucosuria was present. No signs of intracranial hemorrhage or ischemia were detected in the brain computerized tomography (CT) imaging, and there was an increase in asymmetric density at the right putamen compared to the left. Similarly, there was hyperintensity on T1-weighted sequences at the right putamen in brain

magnetic resonance imaging (MRI). As a result of clinical, laboratory and radiological evaluations, the patient was accepted as non-ketotic hyperglycemia-associated hemibalism syndrome. The patient was first hydrated, crystallized insulin infusion was started with close blood glucose monitoring, and then intensive insulin therapy was started. When plasma glucose began to improve, involuntary extremity movements also decreased. At 3-month follow-up, both normoglycemia and hemiballism were almost completely resolved.
Conclusion
Non-ketotic hyperglycemia-associated hemiballism syndrome is a rare initial manifestation of diabetes and is usually seen in elderly diabetic patients with poor glycemic control. It should be kept in mind that hemiballism may be the first sign of undiagnosed diabetes, and this rare neurological complication should be recognized as it is easily resolved with hyperglycemia treatment.

Clinical aspect and diagnosis of osteomyelitis in diabetic foot

Sara Ragbi, Mjabber Amal, Nassim Essabah Haraj, Siham El Aziz & Asma Chadli
UHC Ibn Rochd, Endocrinology and Metabolic Disorders, Casablanca, Morocco

Introduction
Diabetic foot osteomyelitis is a frequent complication of a preexisting infected foot wound. It is mostly the consequence of a soft tissue infection that spreads into the bone thus increasing the risk of amputation and the burden of foot care. The aim of this work is to describe the clinical and therapeutic aspect of diabetic foot osteomyelitis in our department.
Patients and Methods
It's a retrospective and descriptive study conducted in our department, between January 2008 and January 2021, including all diabetic patients with foot osteomyelitis. Statistical analysis was performed using SPSS software.
Results
A total of 127 patients with a mean age of 57 years old were included. Male patients represented 61.3% of patients. Most of them were type 2 diabetics (84%) with a mean duration of 11.5 years and an average HbA1c of 11.3%. The diagnosis was essentially clinical, based on the chronic evolution of the ulcer, the presence of positive probe-to-bone test and the sausage-like toes. X-ray imaging often found erosion of cortical bone, osteolysis and in some cases bone sequestrations. Serum inflammatory markers as white blood cells (WBC), C-reactive protein and procalcitonin (PCT) were usually high when associated with soft-tissue or systemic infection. The treatment consisted of antibiotic therapy with an average duration of 9 weeks. Off-loading, perfect glycemic control and thromboembolic prevention were indicated in all patients. Among the cases, 9% were referred to surgical department for surgical management of necrosis and collections.
Conclusion
Osteiteomyelitis is an infection that can complicate diabetic foot ulcers. Early and optimal diagnosis and management limit the risk of unfavorable evolution, thus minimizing the risk of surgery and amputation.

Perception of the risk of becoming type 2 diabetic in patients with gestational diabetes

Yousra Settai, Nassim Essabah Haraj, Siham El Aziz & Asma Chadli
UHC Ibn Rochd, Endocrinology, Diabetology, Nutrition and Metabolic, Casablanca, Morocco

Introduction
Gestational diabetes is a state of glucose intolerance, regardless of its severity, discovered during pregnancy in a woman not known to have diabetes before pregnancy. It is associated with a risk of recurrence in subsequent pregnancies and progression to type 2 diabetes.The objective of this work was to evaluate the perception by parturients of the risk of recurrence and type 2 diabetes, to evaluate their knowledge of preventive measures and their adherence to these measures, and thus, to light on the value of monitoring these patients even after delivery.
Materials and Methods
Prospective descriptive study conducted at the Department of Endocrinology-Diabetology of the UHC Ibn Rochd – Casablanca, in patients followed for gestational diabetes, and having answered a questionnaire that we established in order to evaluate their knowledge in particular concerning the risk of progression to T2D and the benefit of follow-up.
Result
The average age of our parturients was 31 years (22-45), with an average gestational age of 28SA, the average body mass index (BMI) before pregnancy was 29.3 kg/m^2, with an average weight of 11.3 kg (9-15) during pregnancy. Treatment by lifestyle and dietary rules was sufficient in 68.7% of our parturients and 40.8% had a family history of type 2 diabetes. The majority considered themselves at high risk of becoming diabetic (65.4%), but 38.2% had no not changed their diet, and 85.5% had not changed their physical activity. Among our patients, 15% were postpartum, and all were aware of the value of follow-up, but none had maintained the lifestyle and dietary rules after childbirth. The perception of the risk of developing type 2 diabetes was not significantly influenced by gestational age at the discovery of diabetes, nor by previous BMI or weight gain during pregnancy. However, patients treated with insulin, as well as those with a family history of type 2 diabetes, considered themselves at greater risk of becoming diabetic ($P<0.01$).
Conclusion
Gestational diabetes is a risk factor for the onset of type 2 diabetes. Parturients are often unaware of this risk, and lost sight after the delivery. Hence the interest of highlighting these data when educating parturients with gestational diabetes, in order to make them aware of this risk, and thus, encourage them to pursue a healthy lifestyle with regular follow-up, even after childbirth.

Factors affecting the severity of diabetic foot ulcer

Sara Ragbi, Nassim Essabah Haraj, Siham El Aziz & Asma Chadli
UHC Ibn Rochd, Endocrinology and Metabolic Disorders, Casablanca, Morocco

Introduction
Diabetic foot is a public health problem that affects the quality of life of diabetic patients. The severity of diabetic foot ulcer causes complications that are not only costly but can lead to amputation. The objective of this work is to study the factors related to the severity of diabetic foot ulcers.
Material and Methods
It's a retrospective study from January 2020 to May 2022 involving patients treated in the endocrinology department for diabetic feet. The severity of the lesions was evaluated by the Wagner classification. The analysis was performed using SPSS 21 software.
Results
The total of patients was 175, with an average age of 56 years, of which 64% were male and 36% female. Type 2 diabetic patients represented 87.4% of patients. The average duration of diabetes was 14.7 years. Most of patients were unbalanced with an average HbA1c of 14.7%. About degenerative complications, 70.3% had diabetic microangiopathy and peripheral arterial disease was present in 53.1% of cases. Among these patients, 9.7% had a history of amputation. Concerning ulcers, 44% had grade 1 ulcers of the Wagner classification, 48.6% grade 2 ulcers and only 7.4% grade 3 ulcers. The factors associated with the severity of the lesions were the duration of the diabetes ($P=0.009$), glycemic imbalance ($P=0.001$) association with arteriopathy ($P=0.001$), history of amputation ($P=0.003$) and the existence of Charcot's foot ($P=0.001$.
Conclusion
The study of factors involved in the severity of diabetic foot lesions will allow the implementation of preventive measures and greater vigilance in patients at risk carrying these factors.

Diabetic foot and vascular damage: About 102 cases

Malak Iggar, Nassim Essabah Haraj, Siham El Aziz & Asma Chadli
UHC Ibn Rochd, Endocrinology and Metabolic Disorders, Casablanca, Morocco

Introduction
Diabetes promotes the development of arterial damage. Peripheral arterial disease is a classic localization of macroangiopathy, serious in its evolution; it constitutes a major risk factor for the occurrence of foot lesions in diabetics.

Goal of the Study
The aim of our study is to analyze the vascular profile of diabetic patients hospitalized for diabetic foot.
Patients and Methods
Descriptive retrospective study taking place over a period of 3 years, including 102 diabetics hospitalized in the endocrinology-diabetology department of the CHU Ibn Rochd for foot lesions.
Results
The average age of our patients was 57.5 years, with a clear male predominance of 62.7%, type 2 diabetes predominated in 85.2% of cases with a duration of evolution greater than 10 years in 74.5% and an average of HbA1c of 10%. The major risk factors for atherosclerosis found in our patients were dyslipidemia in 48% of cases, hypertension in 46%, obesity in 36.2%, smoking in 16.6% and physical inactivity in 60.7% of cases. Target organ damage was found in 56.8% of our patients, of whom 49% had diabetic retinopathy, 27.4% had diabetic nephropathy and 45% had peripheral neuropathy. 12.7% of our patients had a history of amputation. 68.6% of our patients were classified at very high cardiovascular risk. The foot lesions found were: MPP in 35% of cases, arteritic ulcer in 29.4% of cases, dermohypodermitis in 24.5% and osteitis in 23.5%. The ankle brachial index was pathological in 68.8% of patients, where 50% had an ABI <0.9 and 18.6% had an ABI >3. Doppler ultrasound objectified PAD in 88.2% of patients, arterial stenosis was found in 24.5% of cases where it was bilateral in 6.9%, atheromatous overload was present in 48.5% of patients and mediacalcosis in 15.9%. Doppler returned normal in 11.7% of patients. The evolution was marked by infection in 32.5% of patients and necrosis in 1.9% of patients. The mean healing time was 77 days.
Conclusion
The peripheral arterial disease is a serious complication of diabetes and the main factor of amputation. Prevention through the fight against cardiovascular risk factors is the basis of treatment.

DOI: 10.1530/endoabs.90.EP483

Prevalence of autoimmune diseases in patients with type 1 diabetes

Imane Hasbi, Nassim Essabah Haraj, Siham El Aziz & Asma Chadli
University Hospital Center Ibn Rochd, Endocrinology, Diabetology and Metabolic Diseases, Casablanca, Morocco

Introduction
Type 1 diabetes (T1D) is frequently associated with other autoimmune diseases The Aim of the study is to determine the prevalence of autoimmune diseases (AID) that may be associated with type 1 diabetes and to study the particularities of this association.
Patients and Methods
this was a retrospective study including 251 patients with type 1 diabetes followed in the diabetology, endocrinology department of the IBN Rochd hospital center in Casablanca. Clinical and paraclinical data were recorded for all patients.
Results
The study population was composed of 116 women (46.2%) and 135 men (53.8%). The average age was 25.2 years and the average duration of diabetes was 10.82 years. Autoimmune diseases were found in 32 patients or 12.74%: 21 women and 11 men. Autoimmune dysthyroidism topped the list with 8 cases of Graves' disease and 6 cases of Hashimoto's thyroiditis, followed by 6 cases of Addison's disease, 5 cases of psoriasis, 4 cases of celiac disease and 3 cases of vitiligo. Patients with associated AID were older (29.4 vs 24.6 years; $P=0.005$) and had longer diabetes duration (12.55 years vs 9.57 years, $P= 0.001$) and a higher prevalence of microangiopathy (41.9% vs 22.27%) ($P=0.005$). The prevalence of macroangiopathic complications was comparable between patients with and without AID ($P=0.2$). On the other hand, the cardiovascular risk was significantly higher in patients with other autoimmune diseases ($P=0.001$).
Conclusion
The coexistence of autoimmune diseases in patients with type 1 diabetes is not uncommon. According to our results, this association is characterized by an increase in microangiopathic complications and cardiovascular risk, which further encourages them to be detected and treated at the discovery of diabetes.

Diagnosis and management of acute Charcot foot

Malak Iggar, Nassim Essabah Haraj, Siham El Aziz & Asma Chadli
UHC Ibn Rochd, Endocrinology and Metabolic Disorders, Casablanca, Morocco

Introduction
Diabetic osteoarthropathy or Charcot's foot is a serious complication of diabetes whose early diagnosis is complex and often delayed. It manifests itself in the acute phase by localized inflammation of the foot or ankle, and in the absence of discharge, it leads to severe bone damage. Hence the need for better knowledge and early and adequate treatment.
Goal of the Study
The aim of our study is to describe a cohort of diabetic patients followed for acute Charcot foot.
Patients and Methods
Retrospective study over 3 years taking place from May 2019 to May 2022 at the CHU Ibn rochd. 28 records of patients followed for Charcot's foot were collected, including 6 received in the acute phase. We describe the 6 patients followed for acute Charcot's foot secondarily confirmed by imaging. Stabilization of Charcot's foot was defined by the clinical disappearance of inflammatory signs.
Results
The average age of our patients was 51 years old, with a clear male predominance of 5/1 and an average BMI of 25.6 kg/m^2. Type 2 diabetes predominated in 66.6% with an average duration of evolution of 14 years, the mean HbA1c was 9.7%. The injury was in the right foot in 83.3% of cases. The clinical elements reported were swelling in 100% of cases, warmth in 83.3% of cases, redness in 66.6% of cases, deformities were described in 33.3% of cases. The main triggering factors were unsuitable footwear in 50% of cases and trauma in 33.3% of cases. The mean time to diagnosis was 50 days. All the patients benefited during the initial phase from a strict discharge by circular fenestrated cast in 83.3% and by thermoformable splint in 16.6% of the cases then of a relay by orthopedic shoe in 100% of the cases. One patient received medical treatment with bisphosphonates. Stabilization was obtained in 83.3% of patients with an average delay of 274 days.
Conclusion
Acute Charcot's foot is a rare but severe complication, difficult to identify, it is often underdiagnosed, causing delays in management and compromising the functional prognosis of the diabetic patient.

DOI: 10.1530/endoabs.90.EP485

EP486

The prevalence and risk factors of peripheral arterial disease in diabetics

Malak Iggar, Nassim Essabah Haraj, Siham El Aziz & Asma Chadli
UHC Ibn Rochd, Endocrinology and Metabolic Disorders, Casablanca, Morocco

Introduction
Peripheral arterial disease (PAD) is a classic localization of macroangiopathy in diabetics. It is a major risk factor for amputation.
Goal of the Study
know the prevalence and analyze the risk factors associated with peripheral arterial disease.
Patients and Method
Descriptive and analytical retrospective study conducted in the department of endocrinology and metabolic diseases of the CHU Ibn Rochd, where 544 asymptomatic diabetic patients were screened for peripheral arterial disease. PAD was defined by an ABI measurement less than 0.9 or greater than 1.3.
Results
A total of 544 patients were included in our study, 65.6% of whom were women. The average age of our patients was 51.2 years (15-89). Type 2 diabetes predominated in 80.5% of cases with an average duration of evolution of 10.6 years and an average HbA1c of 10.1%. The prevalence of PAD was 21.7%. The risk factors significantly associated with PAD were: advanced age ($P=0.001$), hypertension ($P=0.002$), dyslipidemia ($P=0.002$), physical inactivity ($P=0.002$), coronary artery disease ($P=0.001$), a history of stroke ($P=0.027$), the presence of micro albuminuria ($P=0.001$), retinopathy ($P=0.001$) and diabetic neuropathy ($P=0.000$). On the other hand, neither tobacco nor obesity was linked to PAD.
Conclusion
The prevalence of PAD is high in diabetics. These results encourage systematic screening and rigorous follow-up of high-risk patients and to include control of cardiovascular risk factors and glycemic control in management strategies.

Clinical and paraclinical profile of patients followed for idiopathic hirsutism: About 30 cases

Oumaima Magouri[1], Nisrine Bouichrat[1], Dounia Zerrouki[1], Siham Rouf[2] & Hanane Latrech[2]
[1]Endocrinology-Diabetology and Nutrition Department Hospital University Center Mohammed VI, Oujda, Morocco; [2]Endocrinology-Diabetology and Nutrition Department Hospital University Center Mohammed VI, Laboratory of Epidemiology, Clinical Research and Public Health, Faculty of Medicine and Pharmacy, Mohammed First University Oujda, Oujda, Morocco

Introduction
Hirsutism is a frequent reason for consultation, it is defined by the presence of terminal hair with male distribution in women, it is however essential to determine the cause, since it can reveal a serious underlying pathology and as it may be due to a benign cause see idiopathic in some cases. Idiopathic hirsutism is second in line to polycystic ovary syndrome in the etiological search for hirsutism. The objective of this study is to describe the clinical and paraclinical aspects of idiopathic hirsutism in patients.
Patients and Methods
This is a retrospective and descriptive study of 30 patients followed for idiopathic hirsutism at the Endocrinology-Diabetology-Nutrition Department of the Mohammed VI University Hospital center in Oujda. The collected data were analyzed by SPSS-version-21 software. All patients benefited from a biological exploration of the adrenal gland (synacthene test, 24-hour urinary cortisol level), and a pelvic ultrasound.
Results
Idiopathic hirsutism represents only 20% of the causes of hirsutism in our series, the average age of our patients was 24.9 ± 5.1 years [16-35 years]. Hirsutism appeared during puberty in 33.3% of cases and after puberty in 50% of cases, it was mild in 33.3%, moderate in 43.3% and severe in 23.3% of cases, with an average Ferriman and Gallwey score of 17.9 ± 5.2. However, all the patients in our series did not have menstrual cycle disorders. Concerning the other minor signs of hyperandrogenism, acne and seborrhea were found in 56.7% and 20% of cases respectively. Overweight was reported in 33.3% and obesity in 13.4% of patients with 3 cases of metabolic syndrome (10%). Biological exploration showed a mean testosteronemia level of 0.47 ± 0.24 ng/ml. Dyslipidemia was observed in 13.3% of cases, of which hypoHDLemia was the most frequent lipid anomaly (40%) and 27% of carbohydrate tolerance disorders.
Discussion and Conclusion
The etiologic investigation of hirsutism requires careful exploration for an accurate diagnosis and to rule out any adrenal or ovarian causes before retaining the diagnosis of idiopathic hirsutism and thus to guide the therapeutic management. This study shows that metabolic disturbances have been demonstrated in these patients, but their prevalence remains low, which is consistent with the data reported in the literature. Other studies on a larger number of patients should be carried out to study insulin resistance in women followed for idiopathic hirsutism in order to establish new and more effective therapeutic strategies.

DOI: 10.1530/endoabs.90.EP487

EP488

Nutrition and body changes during the menstrual cycle in women of childbearing age

Yonca Sevim[1], Ahsen Isıl Karabacak[1], Tugce Ozlu[1] & Hikmet Karabacak[2]
[1]Bahcesehir University, Nutrition and Dietetics, İstanbul, Turkey; [2]Medicana Hospital in Konya, Gynecology and Obstetrics, Konya, Turkey

Objective
Changes in mood, appetite, dietary intakes and physic during a menstrual cycle has been controversial in studies. The aim of this study is to determine the nutritional behavior and body changes during the menstrual cycle in women of childbearing age by comparing dietary records and anthropometric measurements in three phases of menstrual cycle.
Method
This prospective study included 34 healthy regularly menstruating women aged 20-39 years in April-May 2022. Women were followed during one menstrual cycle, three face to face interviews were conducted at three phases during a cycle. The phases of menstrual cycle of women was determined as secretory, menstruation and proliferative by a obstetrician. The data form consists of questions on sociodemographic characteristics such as age, marital status, income, education level and the second part consist of questions about nutritional behaviors at the three phases of menstrual cycle. All anthropometric measurements were taken at the three phases of menstrual cycle via bioelectrical impedance analysis. Three day food records were taken in three phases of menstrual cycle.
Result
There were not any changes of anthropometric measurements during the menstrual cycle. Women had significant changes between phases on experiencing anxiety, tiredness, irritability, depressive thinking, pain, swelling and edema, sweet craving and appetite increase ($P < 0.05$). These mood and appetite changes reduced especially in proliferative phase. In menstruation phase, an increase in fiber, vitamin B1, vitamin B9, vitamin C, potassium, magnesium, phosphorus, iron and zinc intake compare to secretory phase was detected. Although energy, carbohydrates and protein intakes increased in menstruation phase, and fat intake was higher in proliferative phase, these changes were not statistically significant.
Conclusion
Women who participated to this study had changes in moods and appetite but not in anthropometric measurements during a menstrual cycle. Understanding these changes is of great importance for women's and menstrual health. Keywords: Dietary Intake; Menstrual cycle; Women; Weight

Obesity in 3q29 microduplication syndrome: An inherited case report and literature review

Carlos Manuel Alzás Teomiro, Mireia García-Ramírez, Ángel Rebollo-Román, Ana María Moyano-Sánchez & María José Molina Puerta
Reina Sofía University Hospital, Endocrinology and Nutrition, Córdoba, Spain

Background
3q29 microduplication syndrome is a very uncommon genetic disorder with fewer than 40 cases reported, although the wide and heterogenous clinical features make this syndrome hard to diagnose. This syndrome is clinically milder than the 3q29 microdeletion syndrome, which contributes to the high rate of underdiagnosed cases that may exist. Patients affected with this syndrome have a complex phenotype, with non-specific clinical features such as autism spectrum disorders, psychiatric comorbidities, intellectual disability, overweight and craniofacial dysmorphisms, among others. Apart from the previously described ones, obesity, muscular hypotonia, speech delay, microcephaly and ventricular defects are often reported.
Objective
We report the clinical case of a 15-year-old male with a 3q29 microduplication syndrome diagnosed while ruling out a Prader-Willi syndrome. We summarize the literature, and compare our patient phenotype with the previously reported cases.
Methods
Genome-wide copy number analysis was carried out using single-nucleotide polymorphism microarray. The study revealed a 3q29 microduplication with a 1.5 Mb length, affecting DLG1 gene.
Results
A 15-year-old male who was sent to the Endocrinology and Nutrition department due to his overweight, in order to discard secondary causes of obesity and offer treatment. The main medical history of the patient included an early diagnosis of autism with low IQ (<70) in cognitive tests, dysfunctional personality with obsessive-compulsive tendencies and a mixed anxious-depressive syndrome. The patient referred an important and progressive weight gain since he was 8 years old with bad dietetic habits. Physical examination was unremarkable. Low-set ears were the unique facial dysmorphism present in the patient. His height was 1.79 m (85th centile), weight was 117.7 kg (99th centile) and BMI was 36.7 kg/m^2 (99th centile). The genetic study revealed a 3q29 microduplication affecting DLG1 gene, which could potentially explain the patient's clinical features. Same mutation was found in the mother. 3q29 microduplication phenotype is widely variable. There are very few clinical cases series published in medical literature, but as reported in some reviews obesity is found in 50% of the cases described.
Conclusions
Our patient showed moderate intellectual disability, autism, psychiatric disorders, obesity and chronic constipation as main feautres of this syndrome. The management of patients affected with this syndrome depends on the moment of diagnosis but includes ophthalmological, cardiac and auditory evaluation, with psychiatric/psychological support when needed. Genetic counselling should be made.

Autoimmune polyglandular syndrome type 3: A case report

Nino Turashvili

Tbilisi State Medical University's and Ingorokva's University Clinic of High Medical Technologies'', Tbilisi, Georgia

Introduction
Autoimmune polyglandular syndromes are characterized by the coexistence of two or more autoimmune endocrine diseases, however, coexistence of various non-endocrine disorders is also possible. Autoimmune polyglandular syndrome type 3 (APS-3), is the co-occurrence of autoimmune thyroid disease (AITD) with diabetes type 1, but without Addison disease. The coincidence of AITD and latent autoimmune diabetes of the adult (LADA) is relatively less described.
Case Report
We present the case of a 50-year-old female patient with APS-3 associated with Hashimoto's thyroiditis, latent autoimmune diabetes of adult and vitiligo. A 50-year old woman presented to the clinic with a few months history of complaints: Increased thirst, frequent urination, weight loss. Hyperglycemia was revealed. HbA1c - 12.7%. C peptide was very low. Glutamic acid decarboxylase antibodies (GAD 65-Ab) were measured- >250 IE/ml ($n<10$); Latent autoimmune diabetes of the adult (LADA) was diagnosed and insulin therapy was started. Personal history revealed vitiligo within the past 5 years. With additional studies patient was also diagnosed with Hashimoto's thyroiditis: TSH, FT4- within normal reference ranges, the level of anti-TPO - 1685 (N 0-5.61 IU/ml), anti-TG- also elevated- 6.76 (N 0-4.11 IU/ml). Dyslipidemia was also diagnosed. Currently, the patient is on regular follow-up. LADA and dyslipidemia are well controlled; She still remains euthyroid.
Conclusion
APSs are rare conditions characterized by autoimmune disorder of multiple endocrine glands, with or without autoimmune disease of non-endocrine organs. The hypothesis of APS should be raised in patients with one autoimmune endocrine disease.

Pedal acrometastasis secondary to transitional cell carcinoma of the bladder masquerading as Charcot arthropathy in a patient with type 2 diabetes

Calvin Coe[1], Susan Mathew[1], Kedar Chirputkar[2] & Edward Jude[1]
[1]Tameside and Glossop Integrated Care NHS Foundation Trust, Endocrinology and Diabetes, Ashton-Under-Lyne, United Kingdom; [2]Tameside and Glossop Integrated Care NHS Foundation Trust, Trauma and Orthopaedics, Ashton-Under-Lyne, United Kingdom

Background
Metastatic disease is common in bone, with the majority occurring in the spine, pelvis, and long bones such as the femur and humerus. Acrometastasis, a term used to describe malignant spread distal to the elbow and knee, is a pattern less commonly seen. Its rarity often leads to delayed diagnosis; the condition may be confused with more common conditions such as inflammatory arthritis and Charcot neuroarthropathy, the latter especially in particular in patients with diabetes mellitus. This can lead to poor patient outcomes, with a serious impact on survival.
Case Presentation
An 80-year-old lady with type 2 diabetes mellitus and a history of previous non-invasive papillary carcinoma of the bladder, previously documented to be in remission, presented to her general practitioner with left foot pain following trauma. Initial radiographs were normal, prompting a diagnosis of a simple sprain. 3 months later, the patient was referred to the orthopaedic team due to worsening pain. Examination revealed erythema and swelling, but pulses were present and no neuropathy was detected. Repeat x-rays revealed lytic lesions in the talus and navicular bones. MRI confirmed a lytic and proliferative defect and was reported as likely acute Charcot arthropathy with superimposed infection, leading to subsequent referral to the diabetes team. Charcot arthropathy was also considered the most probable diagnosis when imaging was reviewed by specialists in two separate multidisciplinary team meetings. Bone biopsy was recommended as part of the further work-up given the patient's history; this demonstrated sheets of malignant tumour cells in keeping with metastatic transitional cell carcinoma. The patient was subsequently diagnosed with pedal acrometastasis from her existing malignancy, an infrequently described entity within the medical literature.
Discussion
This case identifies and draws awareness to a rare complication of malignancy, as well as highlights the importance of maintaining an open differential diagnosis in suspected Charcot arthropathy; a complication of diabetes that is often misdiagnosed, impacting patient morbidity and mortality[1]. Clinicians should maintain a low threshold for ordering a biopsy to permit the histological exclusion of other diagnoses, particularly in individuals with known malignancy; this patient's case emphasises the potential for diagnostic uncertainty even with advanced imaging and expert interpretation.

Severe Hypoglycemia after Levofloxacin Use: A case report

Muge Yasar[1], Ensar Aydemir[1], Coskun Ates[1], Filiz Mercan Saridas[1], Erhan Hocaoglu[1], Mehmed Said Aydın[2], Soner Cander[1], Ozen Oz Gul[1], Erdinc Erturk[1] & Canan Ersoy[1]
[1]Uludag University Faculty of Medicine, Department of Endocrinology and Metabolism, Bursa, Turkey; [2]Uludag University Faculty of Medicine, Department of Internal Medicine, Bursa, Turkey

Introduction
Levofloxacin is a fluoroquinolone group antimicrobial agent widely used in the treatment of community- and hospital-acquired infections. There have been reports of glucose homeostasis abnormality associated with the use of fluoroquinolones including gatifloxacin, levofloxacin and ciprofloxacin. This report presents the case of a patient with type 2 diabetes mellitus who developed severe hypoglycemia following oral levofloxacin use.
Case
A 77-year-old female patient was being followed for chronic atrial fibrillation, heart failure, asthma, hypothyroidism, and type 2 diabetes mellitus. For treatment of her diabetes, she was receiving intensive insulin therapy (a total of 110 units daily) and metformin, sitagliptin and empagliflozin. Two months ago, the patient was treated in an external center for COVID pneumonia, and was discharged on oral levofloxacin 500 mg/day two days before admission to our center. Following discharge, the patient developed confusion at home, and her blood glucose level was found to be 52 mg/dl, upon which she was admitted to our clinic for further investigations. We discontinued the antidiabetic medications. Differential diagnosis was performed to identify the causes of hypoglycemia, which ruled out adrenal insufficiency. The detailed history of the patient revealed that her complaints started on the second day of levofloxacin use. Levofloxacin was thought to be the possible cause of hypoglycemia and was discontinued. During the first three days, she had normal blood glucose levels. Starting from day four, her blood glucose started to increase up to 300 mg/dl. She was initially started on basal insulin; basal insulin was gradually increased and insulin aspart boluses were added. The patient was stabilized with basal bolus insulin therapy and was not given oral antidiabetics due to her GFR and serum creatinine levels. Her overall condition remained stable and her complaints regressed. She was discharged with a total daily insulin dose of 82 units (3×14 units of insulin aspart, 40 units of U300 insulin glargine).
Discussion
Levofloxacin-induced hypoglycemia is a rare complication, and although few cases have been reported in previous studies, some patients were reported to have severe and fatal hypoglycemia. Although levofloxacin is widely used, there is limited awareness of its possible hypoglycemic effects. Increased awareness of this side effect of levofloxacin may reduce the mortality and morbidity rates associated with the rare but life-threatening side effect of this widely used antibiotic. When selecting drugs for comorbidities in diabetic patients, it is crucial to consider potential effects of medications on glucose metabolism.

Differential performance in SIMBA simulation-based training sessions between healthcare professionals from low-and-middle income and high income countries suggests targeted education is needed to reduce the gap

Harshin Pallathoor Balakrishnan[1], Emily Warmington[2], Dengyi Zhou[3], Carina Synn Cuen Pan[2], SIMBA and CoMICs Team[4] & Punith Kempegowda[4,5]
[1]Far Eastern Federal University, School of Medicine, Vladivostok, Russia; [2]University of Birmingham, College of Medical and Dental Sciences, Birmingham, United Kingdom; [3]Imperial College London, Department of Metabolism, Digestion and Reproduction, Faculty of Medicine, London, United Kingdom; [4]University of Birmingham, Institute of Metabolism and Systems Research, Birmingham, United Kingdom; [5]University Hospitals Birmingham NHS Foundation Trust, Queen Elizabeth Hospital, Birmingham, United Kingdom

Introduction
The global migration of healthcare professionals has enabled those trained in low-and-middle income countries (LMICs) to move and work in high-income countries (HICs) and vice-versa. While medical licensing exams in HICs are designed to assess competency of the immigrating HCPs, there is limited literature on the differences in approach to manage clinical cases between those from LMIC and HIC. Simulation via Instant Messaging – Birmingham Advance (SIMBA) is a simulation-based training model using real-life clinical cases simulated via WhatsApp and Zoom. Participants from all over the world have been attending the sessions since its inception in 2020. In this study, we investigated if there was a difference in performance during SIMBA between participants depending on their country of residence.
Method
All participants who attended and completed both pre- and post-SIMBA surveys in 17 SIMBA sessions from 2020 to 2022 were included in this study. Participants were grouped into those from LMICs and HICs according to their country of residence based on the 2022 World Bank report. Participants' performance was assessed using the Global Rating Scale (GRS) adapted for each session, which scored the participant on a scale of 1 (poor) to 5 (excellent) in 6 domains: History Taking, Physical Examination, Investigations, Result Interpretation, Clinical Judgement, and Management. The mean GRS domain scores were calculated using multiple linear regression models, adjusting for sex, country, training, and number of WhatsApp messages. Mean difference between performance scores was calculated using a paired *t*-test.
Results
A total 281 participants ((HICs – 191 (67.9%), LMICs – 90 (32.0%)) from 49 countries ((HICs – 18(36.7%), LMICs – 31(63.2%)) were included in this analysis. Participants from LMICs scored lower in History Taking (LMICs: 3.5 vs HICs: 3.8; $P=0.0117$), Investigations (LMICs: 3.1 vs HICs: 3.6; $P=<0.0001$), Clinical Judgement (LMICs: 2.9 vs HICs: 3.4; $p=<0.0001$), and Management (LMICs: 2.3 vs HICs: 2.9; $P=<0.0001$). The performance was similar for participants across all countries in Physical Examination (LMICs: 3.5 vs HICs: 3.6; $P=0.2335$) and Result Interpretation (LMICs: 2.6 vs HICs: 2.8; $P=0.3264$).
Conclusion
There is a difference in performance of solving clinical cases between participants from LMICs and HICs which may reflect the difference in clinical training in their local region. Future research whether serial simulation-based learning can reduce this difference is currently underway.

Standard deviation

Soichi Takeishi & Tatsuo Inoue
Inuyama Chuo General Hospital, Diabetes, Inuyama-City, Japan

We studied regarding simplifying standard deviation (SD) and useful metrics for achieving target SD. In a cross-sectional study, we analyzed 24-h glucose levels measured using continuous glucose monitor (CGM) [iPro2] in 150 patients with type 2 diabetes. We analyzed 51 time in range (TIR) (reference ranges: mean glucose level (M)±20, M±21 … M±69, M±70 mg/dl [we referred to the underlined numbers as "Margin"]). We analyzed optimal cutoff values of TIR to predict SD below target, corresponding to 51 TIR × 26 target SD (25, 26 … 49, 50 mg/dl), using receiver operating characteristic analysis. Of the 51 reference ranges, the reference range for which TIR had the largest AUC for each target SD was referred to as "optimal reference range 1". We arranged the patients in ascending order of SD, ranking from 1 to 150. Consecutive 110 patients were selected 41 times while shifting one by one (from "1–110" to "41–150": 41 groups). Of the 51 reference ranges, the reference range for which TIR most correlated to SD for each group was referred to as "optimal reference range 2". Mean absolute deviation (MAD) correlated to SD ($r=0.995$, $P<0.001$; MAD = 0.87 × SD - 1.22) ($n=150$). "Margin" of "optimal reference range 1" (M1, mg/dl) tended to increase with increased target SD (mg/dl), from 42 for "target SD of 25" to 66 for "target SD of 50". Target SD correlated to M1 ($r=0.92$, $P<0.001$; M1 = 1.31×target SD + 5.56) ($n=26$). The optimal cutoff values of TIR for "optimal reference range 1" was 86.8±4.6 in 26 target SD. "Margin" of "optimal reference range 2" (M2) tended to increase with increased mean of SD, from 35 for "mean of SD of 30.6" to 64 for "mean of SD of 47.7". Mean of SD correlated to M2 ($r=0.96$, $P<0.001$) ($n=41$). SD means difference from M. If "optimal reference range 1" is used as an alarm threshold in a personal CGM and TIR for "optimal reference range 1" > 80–90% is achieved, SD below the target may be achieved. The mean of SD in study participants may affect the M2.

Ultrasound of sternocleidomastoid muscle may predict and diagnose type 2 diabetes mellitus and prediabetes

Mahmoud Younis
Egyptian Ministry of Health, Kafr El-Shaikh, Egypt

In order for type 2 diabetes to occur, insulin resistance occurs first, which often occurs from an increase in fat deposition in the liver and the pancreas, and with this resistance. It is universally agreed that diabetes diagnosis is by analyzing blood glucose. The ultrasound technology often helps in diagnosis and quick decision-making in the treatment of many diseases. It can tell us about the muscles' echogenicity.
Materials and Methods
400 patients followed in a private clinic in observational prospective study. Patients have been categorized into 4 groups. making neck ultrasound for all participants.
Results
The results exhibit a statistically notable difference between prediabetic patients and normal weight control as regards sternocleidomastoid muscle echogenicity with increased muscle echogenicity in prediabetic group and normal echogenicity in normal weight control group with P value less than 0.0001.The results exhibit a statistically notable difference between prediabetic patients and obese control as regards sternocleidomastoid muscle echogenicity with increased muscle echogenicity in prediabetic group and normal echogenicity in obese control group with P value less than 0.0001. The results exhibit a statistically notable difference between diabetic patients and normal weight control as regards sternocleidomastoid muscle echogenicity with increased muscle echogenicity in diabetic group and normal echogenicity in normal weight control group with p value less than 0.0001. The results exhibit a statistically notable difference between diabetic patients and obese control as regards sternocleidomastoid muscle echogenicity with increased muscle echogenicity in diabetic group and normal echogenicity in obese control group with P value less than 0.0001.
Conclusion
As we are in great need of new ways to diagnose and treat type 2 diabetes mellitus. Ultrasound of sternocleidomastoid muscle provides an effective way of predicting and diagnosing type 2 diabetes.

Keywords: type 2 diabetes mellitus, sternocleidomastoid, ultrasound

H syndrome presenting as juvenile diabetes in algerian man

Zeghouane Oussama, Mouna Mezoued, Bessaid Khadidja & Malha Azzouz
Bologhine Hospital, Endocrinology, Alger, Algeria

Introduction
H syndrome is a non-Langerhansian histiocytosis secondary to a mutation in the SLC29A3 gene encoding the nucleotide transport protein hENT3, It is a rare disease with a prevalence of 1 case 1,000,000 mainly characterized by hyperpigmentation, hypertrichosis and hepatosplenomegaly with endocrine manifestations including hypogonadism, short stature and insulin dependent diabetes mellitus. We report the case of a 20-year-old male who was admitted to our endocrinology department for chronic glycemic imbalance. Clinical case: This is a 20 year old patient, with a history of Mutism with deafness diagnosed at the age of 2 years, known type 1 diabetic since the age of 10 years put on insulin therapy basal bolus scheme. In addition, the patient presents a picture of exocrine pancreatic insufficiency under creon since 5 years. We had evoked a wolfram diabetes, in front of the presence of the deafness and the diabetes type 1. During the clinical examination we noticed hyperpigmented patches on the thighs and legs, as well as hypertrichosis. This led to the consideration of syndrome H as a possible diagnosis. A skin biopsy was performed on the hyperpigmented patch, which came back positive for markers: PS100 and CD68, confirming the diagnosis. The genetic study could not be done.
Conclusion
Although considered a very rare disease, this syndrome is probably not diagnosed and therefore not reported. The characteristic skin manifestation as well as genetic testing are essential for diagnosis. The hearing loss also varies in severity and may go unrecognized.

Meningoencephalitis revealing type 1 diabetes

Imane Boubagura, Sana Rafi, Ghizlane El Mghari & Nawal El Ansari
Department of Endocrinology, Diabetology and Metabolic Diseases, University Hospital of Marrakech, Marrakech, Morocco

Introduction
Meningoencephalitis (ME) is defined as an inflammatory process of the brain and meninges, most often secondary to an infection, or more rarely to a dysimmune process. From a clinical point of view, ME is defined by the association of a neurological disorder (disorder of consciousness, convulsion) with a febrile meningeal syndrome.
Case Report
The patient was 24 years old and had no previous medical history. He was admitted to the emergency room with abdominal pain and vomiting, which had been present for 2 days prior to his admission in a febrile context. On examination, the patient was initially conscious, dehydrated, with meningeal stiffness, capillary blood glucose was 3.56 g/l, urine dipstick showed glycosuria with 3 criss-cross of acetone. The workup showed a hyperglycemia at 4.8 g/l, a normal ionogram, CRP at 320 and hyperleukocytosis at 130,000 predominantly PNN, a urinary tract infection at ECBU with leukocyturia at 22,000 and presence of BGN, the workup was completed by a cerebral CT scan which came back normal, and a lumbar puncture in favor of bacterial meningitis, the patient was put on rehydration, The patient was put on rehydration, insulin therapy, and C3G meningitis dose, the evolution was marked by the appearance of consciousness disorders, the patient was transferred in intensive care unit, intubated, sedated, and put on insulin therapy in SAP, the culture of the ECBU and lumbar puncture objective a sensitive Escherichia coli infection. It is therefore a meningoencephalitis complicating a urinary infection with E-coli and revealing a type 1 diabetes.
Discussion
Infectious etiology of meningoencephalitis was found in 42% of cases, a dysimmune etiology was identified in 21% of cases and in 37% of cases the etiology remained undetermined (1). The most frequent infectious causes were HSV-1, followed by VZV and Mycobacterium tuberculosis, while E-coli meningoencephalitis remained relatively rare. Cerebral CT scan is not very helpful for encephalitis and must be systematically performed before any lumbar puncture.
Conclusion
The search for meningeal stiffness in diabetic ketosis should be systematic, as should the search for a pulmonary, urinary or digestive infection. Neuro-meningeal infection can complicate a urinary infection; thus, the mortality rate of E- coli meningitis and meningoencephalitis remains very high.

Stiff person syndrome revealing a LADA

Talbi Dounia, Kaoutar Elmoatamid, Ikram Amira, Manal Azriouil, Kaoutar Rifai, Iraqi Hinde & Mohamedelhassan Gharbi
Hospital Ibn Sina, Endocrinology, Rabat, Morocco

Introduction
Stiff-Person Syndrome (SPS) is a rare autoimmune neurological disorder that can be associated with other autoimmune diseases including type 1 diabetes mellitus (T1DM). The presence of alternative forms of autoimmune diabetes, such as latent autoimmune diabetes in adults (LADA) in SPS, is not well described.
Case Report
A 63 years old male patient, his medical and family histories were non-specific.He developed progressive rigidity in truncal and lower-limb musculature and episodic brief truncal associated to polyuro-polydipsic syndrome.MRI of the brain and spinal cord was without anomalies, the diagnosis of stiff person syndrome was suspected, an anti GAD assay was requested returning >3000 units/ml.As part of exploration of polyuro polydipsic syndrome, a glycated hemoglobin was done returning to 8%.
Discussion
Stiff-person syndrome (SPS) is a rare neurological disorder, which is an autoimmune disorder frequently associated with the presence of serum anti-glutamic acid decarboxylase (GAD) antibody. Solimena et al was the first to describe the important link between insulin-dependent diabetes mellitus, and SPS in 1988. GAD is an endogenous enzyme that catalyzes the production of γ-aminobutyric acid (GABA), a major neurotransmitter of the central nervous system, and it is also found in pancreatic beta cells.it is a common autoantigen in SPS and type1 diabetes mellitus. They are detected in 80% of patients with newly diagnosed T1DM; but the titer of anti-GAD is much higher (around 50-100 fold) in SPS than in Type1 diabetes mellitus. The presence of the autoimmune anti-GAD may lead to disruption of neuron ,beta cell function and destructs insulin secretion.
Conclusion
Despite the fact that LADA and Stiff Person Syndrome are both autoimmune diseases characterized by the presence of anti-GAD, the rates of co-occurrence of SPS and LADA remain unknown.

Case report: Inaugural ketosis revealing diabetes secondary to Klinefelter's syndrome

Ekoundzola Joel Rudy, Ghizlane El Mghari & Nawal El Ansari
CHU Mohammed VI Hospital, Endocrinology, Diabetology, Metabolism and Nutrition, Marrakesh, Morocco

Introduction
Klinefelter's syndrome is the most common male chromosomal abnormality. Several metabolic manifestations are observed during this syndrome including diabetes mellitus. We report the case of a patient who presented with inaugural ketosis revealing diabetes secondary to Klinefelter syndrome.
Observation
38-year-old patient followed for primary infertility for 6 years, alcoholics and smokers who have been weaned for 3 years, two sisters with a T2DM profile. He presented for 3 weeks a polyuro polydipsia syndrome without weight loss, vomiting or abdominal pain, referred after testicular biopsy for hyperglycemia at 4 g/l, glycosuria and acetonuria at 2× and bicarbonates at 25. The clinical examination noted a Klinefelter's profile, protruding superciliary arches, BMI at 31 kg/m^2, a pathological waist circumference at 102 cm, bilateral gynecomastia, micropenis and a Tanner stage at G2P4. On work-up: CRP: 6 mg/l; TSH = 1.93 µg/ml, cortisol: 120 µg/l; FSH: 36.8 UI/l; LH: 14.9UI/l; Testosterone: 0.08 µg/l; prolactin: 5.19 ng/ml; calcemia: 92 mg/l, Creatinine = 5 mg/l (GFR: 170 ml/mn), CT: 1.96 g/l; TG: 2.92 g/l; HDL: 0.34 g/l; LDL: 1 g/l. HbA1c = 14.8%. Testicular ultrasound showed small testicles. Spermogram: total azoospermia; Karyotype: homogeneous klinefelter 47, XXY. The treatment consisted in the correction of ketosis and then put on Mixtard30 (30-0-18), and Metformin 1000mg in progressive dose. The evolution was favorable with normalization of the glycemic values.
Discussion and Conclusion
In Klinefelter's syndrome, type 2 diabetes and carbohydrate intolerance are observed, with frequent hyperinsulinism and a peripheral insulin resistance mechanism, the clinical expression of which is a metabolic syndrome. Klinefelter's syndrome, although rare, is the most frequent male chromosomal abnormality, which is diagnosed late and often at the time of primary infertility. It may be associated with metabolic disorders and particularly diabetes due to insulin resistance observed in Klinefelter.

Glucocorticoid-induced diabetes

Siddiqa Soomauroo[1], Raida Ben Salah[1], Faten Haj Kacem Akid[2], Mohamed Abid[2] & Zouheir Bahloul[1]
[1]Hedi Chaker University Hospital, Department of Internal Medicine, Sfax, Tunisia; [2]Hedi Chaker University Hospital, Department of Endocrinology, Sfax, Tunisia

Introduction
The aim of this study was to investigate the characteristics of glucocorticoid-induced diabetes (GCID) in 18 non-diabetic patients before the initiation of corticosteroid therapy.
Patients and Methods
It is a retrospective study including non-diabetic hospitalized patients who developed diabetes after initiation of corticosteroid therapy.
Results
Eighteen patients (5 males/13 females) with a mean age of 59.5 years were included. A family history of diabetes was noted in 7 cases. Associated

cardiovascular risk factors were hypertension in 4 patients (18%), dyslipidaemia in 3 patients (16%), obesity in 7 patients (38%). Corticosteroid therapy was initiated with methylprednisolone boli in 18% of cases. In 72% of cases, patients received oral prednisone at a dose of 1 mg/kg/day. The median time to onset of GCID was 130 days (range 3-510 days). Thirteen patients (72%) developed an early GCID (within the first 3 months). The mean dose of prednisone at the time of the diagnosis was 0.7 mg/kg/day. Of these 18 patients, 7 received insulin therapy, and 6 received oral antidiabetic drugs. Five patients were managed by a diet only. The mean glycated haemoglobin was 7.3%.
Conclusion
GCID is a common complication occurring often after the age of 55 years and within 3 months of starting corticosteroid therapy. A later onset is also possible. A high initial dose of corticosteroids increases the risk of early GCID.

Glycemic variability in a group of Tunisian adolescents with type 1 diabetes mellitus

Faten Mahjoub[1], Ines Bani[1], Nadia Ben Amor[1], Abir El Amri[2], Ramla Mizouri[1], Rym Ben Othman[1] & Jamoussi Henda[1]
[1]National institute of Nutrition of Tunis, Department A, Tunis, Tunisia; [2]University of Medicine of Tunis, Tunis, Tunisia.

Introduction
Glycemic variability (GV), defined as an integral component of glucose homeostasis, is emerging as an important metric to consider when assessing glycemic control in clinical practice. The aims of our study were to study glycemic variability among a group of adolescents with type 1 diabetes and to determine the factors influencing this parameter.
Method
This is a cross-sectional analytical study, conducted at the National Institute of Nutrition in Tunis during the year 2021, including type 1 diabetic patients who underwent continuous glucose monitoring for 6 days. We analyzed the continuous glucose monitoring CGM data for each patient and we calculated the coefficient of variability by dividing the S.D. by the mean glucose and multiplying by 100 to get a percentage.
Results
Our study included 81 patients with type 1 diabetes, of which 47 are girls and 34 are boys. The average age was 16.6 ± 2 years and the mean duration of diabetes was 6.26 ± 4 years. The age of onset of diabetes varies between 1 and 18 years with an average of 10.4 ± 4 years. Patients with glycated hemoglobin (HB1AC) greater than 7% had an average coefficient of glucose variability (CV) of $39 \pm 12\%$ while those with a HB1AC less than 7% had an average CV of $40 \pm 11\%$. The majority of patients had glycated hemoglobin greater than 7% (89% of patients). Furthermore; More than half of the patients had a coefficient of variation of glucose (CV) greater than 36%. The average CV was $39 \pm 12\%$. The CV was significantly correlated to the age of patients ($r=0.25$ $P=0.025$) and to the duration of diabetes ($r=0.35$ $P=0.001$). However, CV was negatively correlated with age of diabetes onset ($r=-0.23$ $P=0.036$). The glycated hemoglobin was correlated to the CV ($r=0.22$ $P=0.049$).
Conclusion
HbA1c was traditionally considered as the gold standard for assessing glycemic control. GV is a more meaningful measure of glycemic control than HbA1c in clinical practice, and is without doubt now being recognized.

Assessment of laboratory characteristics of patients with severe COVID-19 infection: focus on in-hospital hyperglycemia

Yuliya Dydyshka[1,2], Mariya Efremava[3], Alla Shepelkevich[1], Elena Brutskaya-Stempkovskaya[3] & Veranika Lobashova[2]
[1]Belarusian State Medical University, Endocrinology Department, Minsk, Belarus; [2]Republic Center of Endocrinology and Medical Rehabilitation, Endocrinology Department, Minsk, Belarus; [3]Belarusian State Medical University, Minsk, Belarus.

Both hyperglycemia and in-hospital hypoglycemia are associated with poor hospital outcomes and increased healthcare costs. The effect of hypoglycemia may be due to the severity of the infectious disease and the high incidence of comorbidity. **The aim** of the study was to study the possible relationship between the severity, duration and compensation of hyperglycemia with the course of Covid-19.
Materials and methods
A retrospective analysis of data from primary medical records of 320 patients with Covid-19 infection, who, taking into account their severity of condition, received medical care in the intensive care unit of the infectious hospital in Minsk from June 2020 to March 2022, was carried out. There were 3 groups: 224 people with hospital hyperglycemia – the main group; 51 patients with a history of DM and/or newly diagnosed DM (comparison group); 45 people without glycemic disorders (control group).
Results and discussion
In patients with HH, a more frequent used of tocilizumab and remdisivir, what may indicate a higher severity of the disease course Patients in HH and DM groups showed similar results according to the studied criteria, which confirms the significance of the selected glucose level (more than 7.8 mmol/l) as a threshold for verifying glycemic disorders. In 15.6% of patients with normoglycemia, glycemic levels were less than 4.0 mmol/l. In the present study, lethality in the HH group was the highest and exceeded the control group by 3.5 times, and the indicator of the group with DM by 1.3 times ($P<0.001$). Comparing glycemia levels was found that in the DM group the glucose value was the highest (7.7 (6.1; 12.9) mmol/l vs. 7.0 (5.9; 8.4) mmol/l in the in HH group). Patients with HH and DM had higher levels of procalcitonin, CRP, LDH, neutrophils, more pronounced lymphopenia, which indicated a more pronounced inflammatory process. The level of D-dimers was also higher in the groups of patients with DM and HH.
Conclusions
According to the study, 70% of patients with severe COVID-19 had newly diagnosed hyperglycemia, 15.6% of patients in the control group had glycemia less than 4.0 mmol/l. The data obtained indicate the need for screening of glycemia and its multiple studies during the day in hospitalized patients with severe COVID-19.

Eating disorders in patients with type 1 Diabetes

Hana Ben Jemaa, Chaima Jemai, Mariem Letaief, Asma Cherni, Yosra Htira, Zohra Hadj Ali & Feika Ben Mami
National Institute of Nutrition of Tunis, C, Tunis, Tunisia.

Introduction
Eating disorders (ED) are common in type 1 diabetes (T1D). The aim of our study was to determine the frequency of eating disorders in a T1D population.
Methods
This was a descriptive prospective study conducted in Department C of the National Institute of Nutrition in Tunis, including 52 patients with T1D. We evaluated the prevalence of eating disorders using the 'Eating Disorder screening DEPS-R Scale'. A score $>$ 20 indicates an ED. Clinico-metabolic characteristics were collected from medical records. Glycemic imbalance was defined by an HbA1C$>$7%.
Results
The average age was 28 ± 12 years. The sex ratio was 0.57. The body mass index (BMI) was between 16.72 and 29.6 kg/m^2. 10.1% of patients were overweight. The average duration of diabetes was 10 ± 6 years. 48% of patients were treated with insulin analogues. Micro and macro vascular degenerative complications were frequent at 40.3% and 7.6% respectively. Diabetes was unbalanced in 76.9% of cases with an average HbA1C of 10.3%. ED were frequent by 80.7%. In patients with an ED, diabetes was unbalanced in 72% of cases. We did not show a significant association between BMI and ED. However, glycemic imbalance and ED were significantly associated ($P<10^{-3}$).
Conclusion
ED could disrupt glycemic control in patients with T1D. Thus, their systematic screening is essential.

Hyperglycemia in patients with severe COVID-19

Elena Brutskaya-Stempkovskaya[1], Natallia Darmayan[2], Yuliya Dydyshka[1] & Sergii Senetskkyi[1]
[1]Belarusian State Medical University, Minsk, Belarus; [2]Minsk City Maternity Hospital N2, Minsk, Belarus.

Objective
Stress hyperglycemia and decreased control of diabetes mellitus are recorded in severely hospitalized patients and are associated with an increased complications level, length of hospitalization and mortality. Clinical evidence suggests an increased prevalence of hospital hyperglycemia in patients with COVID-19 and a difference from typical stress hyperglycemia.
Materials and methods
We studied 219 moderate and severe hospitalized COVID-19 patients at Minsk City Maternity Hospital N2 in October-November 2021. A retrospective analysis from medical documents was performed.
Examination
Albumin, total calcium, creatinine, alkaline phosphatase, total protein, urea, creatinine, procalcitonin, CRP, total bilirubin, glucose, ALT, AST, ferritin, cretincrinase, uric acid, PCR-test, KT.
Results
All patients were PCR positive, average age 61.1 ± 10.19 years. Patients were hospitalized with moderate or severe COVID-19 pneumonia on days 2–16 of illness. BMI = 28.4 (26.3–32.0) kg/m2, glucose = 6.1 (5.4–7.3) mmol/l. Type 2 diabetes mellitus was registered in 31 (14.2%) patients; type 1 diabetes mellitus was registered in 3 (1.4%) patients. Hyperglycemia was registered in 163 patients (74.4%), including patients with type 2 diabetes mellitus and type 1 diabetes mellitus. 21 patients with newly reported hyperglycemia (15.9%) had glucose > 11.1 mmol/l and basis-bolus insulin therapy was prescribed. Analysis of the medical data of these patients and HbA1c < 5.7% indicate that these patients did not have diabetes mellitus before COVID-19. At the end of COVID-19 treatment, 14 (66.7%) patients did not require glucose-lowering treatment.
Conclusion
The results of the study indicate a high prevalence of newly diagnosed hyperglycemia in moderate and severe COVID-19. The identified hyperglycemia in COVID-19 differs from typical stress hyperglycemia and from the manifestation of type 2 diabetes mellitus and type 1 diabetes mellitus and needs further analysis.

EP505

Prevalence of hypokalemia in patients with diabetic ketoacidosis

Mohsen Ayadi[1], Rim Marrakchi[1], Sana Chbili[1], Mariem Boudaya[1], Kamel Jamoussi[1], Mouna Turki[1], Faten Haj Kacem Akid[2] & Mohamed Abid[2]
[1]Hedi Chaker Hospital, Biochemistry Departement, Sfax, Tunisia; [2]Hedi Chaker Hospital, Endocrinology Departement, Sfax, Tunisia.

Background/aims
Although patients with diabetic ketoacidosis (DKA) are expected to have total body potassium depletion, measured levels may be normal or elevated due to extracellular shifts of potassiumsecondary to acidosis. We aimed to examine the prevalence of hypokalemia in patients with DKA at presentation and during the treatment.
Methods
This is a retrospective cross-sectional descriptive study concerning all patients hospitalized in the Endocrinology Department for DKA between October 2021 and January 2022. Initial kalemia levels (k+) on presentation and those after treatment were determinated on AU 680® Beckman Coulter. Hypokalemia was defined using the criteria set forth by the American Diabetes Association (ADA) as measured serum potassium less than 3.3 mmol/l. The data were analyzed using SPSS26.
Results
A total of 30 patients were hospitalized for DKA. The mean age of the group was 26.73 ± 10.41 years. The mean potassium level was 3.73 mmol/l (range 2.3 to 5.3; s.d. ± 0.72). Among patients, 26.66%had hypokalaemia (k+ < 3.3 mmol/l), 16.66% had k+ between 3.3 and 3.5 mmol/l. In 26.66% of cases the k+ was between 3.5 and 4 mmol/l and 16.66% of patients had k+ between 4 and 4.5 mmol/l. In 10% of patients the k+ was between 4.5 and 5 mmol/l. Only one patient was presented with hyperkalemia. The mean age of the group who presented hypokalemia was 27 125 years ± 8.62 and 50% of them were Type 1 diabetes. None of the patients had neuromuscular or electrical signs of dyskalemia. During treatment, the mean k+ was 3.43 mmol/l (range 2.5 to 4.1; s.d. ± 0.4). The prevalence of hypokalemia was 33.33%. Among the patients who had hypokaliemia at presentation, 75% of them developed an hypokaliemia during treatment. And among the patients who had normal values of k+, 18.18% of them developed an hypokaliemia during treatment. The mean of duration of insulin therapy were 38.5 (± 24.21) hours and 30.69 (±18.77) hours ($P = 0.039$) respectively for the group who presented hypokalemia and for the group with normal k+ during the treatment. Also the group who presented hypokalemia during the treatment received higher total insulin dose infusion (85.09 ± 47.30 units vs 52.66 units ± 29.80);($P = 0.039$).
Conclusion
Hypokalemia was observed in 26.66% of patients with DKA. Further research is needed to better determine the risks and benefits of administering insulin before obtaining serum potassium values. The strategy of lowering insulin infusion rate in patients with significant hypokalemia during DKA treatment should require further evaluation.

Celiac disease in adult patients with type 1 diabetes: screening and clinical and paraclinical profile

Nadia Ben Amor, Youssef Karboul, Faten Mahjoub, Berriche Olfa, Zeineb Zemni, Imen Ouderni, Rym Ben Othman, Ramla Mizouri, Ines Lahmar, Amel Gamoudi & Jamoussi Henda
National Institut of Nutrition, A, Tunis, Tunisia.

Aims
Screening for celiac disease in adult type 1 diabetics and studying its clinical and paraclinical profile.
Patients and methods
Cross-sectional descriptive study conducted among 150 adult type 1 diabetic patients followed in Department A of the National Institute of Nutrition of Tunis. All patients underwent serological screening for celiac disease.
Results
The prevalence of histologically confirmed celiac disease was 3.33% while 4% had positive celiac disease serology. The average age of patients with celiac disease was 34.8 years with an average BMI of 22.71 ± 2.76 kg/m^2 and four out of five patients had a normal BMI and diabetes evolving for more than 5 years. Three out of five patients had uncontrolled diabetes and two had recurrent hypoglycaemia. Among the five diabetics with confirmed celiac disease, only one patient showed classic signs of celiac disease. Of the others, one patient was asymptomatic and three showed non-classical signs of celiac disease.
Discussion
The recommendations of the various learned societies on the methods of screening for celiac disease in adult patients with type 1 diabetes are still controversial, hence the need for more studies on this subject [1-7].

Diabetes and fasting during the SARS-COV 2 pandemic

Ben Ali Khaoula, Eya Safi, Berriche Olfa, Olfa Lajili, Bel Hadj Sliman Chayma, Oueslati Insaf, Hajer Moalla, Rym Ben Othman, Faten Mahjoub & Jamoussi Henda
National Institute of Nutrition, Service A of Diabetology and Nutrition, Tunis, Tunisia.

Introduction
The covid-19 pandemic has affected the diabetic population and their glycemic control, in particular Muslim diabetics fasting during the month of Ramadan. Our objective was to assess the glycemic control between Ramadan 2020 (April) and Ramadan 2021 (April) and to determine the impact of the pandemic on the Fasting authorization.
Methods
This is a prospective study including 30 diabetic patients followed at department A, at the National Institute of Nutrition in Tunis. Each patient underwent a clinical examination and a blood test.
Results
The mean age was 59.53 + 11.16 years. The mean diabetes duration was 9.7 ± 6.9 years. The majority of patients were type 2 diabetics (93%). More than a quarter were on insulin (27%) ($n = 8$). Only three patients (10%) had a SARS-cov2 infection. Before Ramadan 2020, the mean fasting Glycemia was 9.47 + 2.8 mmol/l and the mean HbA1c was 8.25 + 1.52%. Among our patients, 43% ($n = 13$) had HBA1c in the objectives. Ramadan 2020 fasting was authorized in 43% of patients (those with HBA1c in target) and antidiabetic treatment was appropriate in 90% of cases. The 2020 Ramadan fasting was complicated by hypoglycemia and hyperglycemia in 7% and 13% of cases respectively. only one patient stopped the fasting. Before Ramadan 2021, the mean fasting Glycemia was 10.51 + 3.2 mmol/l and the mean HBA1C was 8.15 + 1.6%. Before Ramadan 2021, glycemic target was reached in 48% of patients ($n = 14$), with an improvement of 5%.
Conclusion
The period of the pandemic has influenced the glycemic control in our diabetic population who practice Ramadan fasting. More studies will be needed to further assess this interference.

Type 2 diabetics on high doses of insulin: what therapeutic solution?

Chaima Sdiri, Yosra Htira, Hana Ben Jemâa, Chaima Jemai, Zohra Hadj Ali, Hedfi Imene & Feika Ben Mami
National Institute of Nutrition, Department of Nutritional Diseases and Dietetics Therapy (C), Tunis, Tunisia.

Introduction
Glycemic control in type 2 diabetics on insulin is a real therapeutic challenge. The aim of this study was to determine the clinical profile of type 2 diabetic patients on high doses of insulin and to assess their glycemic control after a reduction in insulin doses.
Method
It was a prospective study conducted in the Diabetology Department of the National Institute of Nutrition in Tunis with type 2 diabetic patients (T2DM) hospitalized on a high dose of insulin (≧ 0.5 IU/kg/d). Insulin dose reduction and dietary education were performed in all patients included in the study. Insulin doses were subsequently adjusted according to pre- and postprandial capillary blood glucose levels.
Results
We included 48 patients with a mean age of 59 ± 11 years [22;78] and a sex ratio (M/F) of 0.37. The mean age of diabetes was 19 ± 8 years. The mean time of permanent insulin therapy initiation was 12 ± 8 years. Metformin was prescribed in 56% of T2DM patients. Poor adherence to dietary rules was found in the majority of T2DM patients (91%), most of whom were sedentary (82%). Obesity was present in 67% of diabetics: it was abdominal in 75% of cases. Hypertension, dyslipidaemia and hypothyroidism affected 67%, 81% and 19% of diabetics, respectively. The mean glycated haemoglobin level was 10.4 ± 1.9%. The mean insulin dose at admission was 1.14 ± 0.26 IU/kg [0.8;2.21]. A mean rate of insulin dose reduction was 30.6 ± 14.2%. At the end of the hospitalization period: a statistically significant decrease in preprandial ($P = 0.007$) and postprandial ($P = 0.002$) blood glucose levels was noted.
Conclusion
Insulin overdose is common in insulin-requiring type 2 diabetics without any real benefit for glycemic control, but with a risk of aggravating the often present overweight.

DOI: 10.1530/endoabs.90.EP508

EP509

Metabolic profile of T2D patients on liraglutide: About 31 cases

Nana Aichatou Harouna, Nassim Essabah Haraj, Siham El Aziz & Asma Chadli
CHU Ibn Rochd, Endocrinologie-Diabétologie et Maladies Métaboliques, Casablanca, Morocco.

Introduction
Liraglutide has shown several benefits in diabetic patients, both in terms of glycemic profile and metabolic control. The objective of our work is to show the effects of liraglutide on the metabolic profile of obese T2D patients.
Materials and methods
This is a prospective study involving 31 obese T2D patients followed at the Department of Endocrinology and Metabolic Diseases CHU IBN ROCHD from January 2018 to December 2022. The data analysis was done with the Excel software in its 2021 version.
Results
The mean age was 49.44 years, Sex Ratio: M/F of: 1/4, the duration of diabetes was on average 12.17 years, the mean duration of treatment with liraglutide was 3 years. All our patients were obese with an average BMI of 39 kg/m2 and a waist circumference of 121 cm. All of our patients were unbalanced with an average Hb1c of 10%. The metabolic balance objectified dyslipidemia in 24 patients or 82.7% with a mean cholesterol level of 1.9 g / l, mean triglyceride of 1.47 g / l, mean HDL of 0.49 g / l and mean LDL level of 1.11 g / l. Arterial hypertension was objectified in 13 patients or 44.8% all monotherapy, hyperuricemia was objectified in 4 patients or 13.8% with an average uric acid level of 58.91 mg / l. The majority of patients or 75.8% were on insulins either in basal bolus or bed time regimen in combination with metformin and sulfonamide and 24.2% are on dual therapy metformin sulfonamide. After the introduction of liraglutide treatment, there was a decrease in BMI to 37.74 (−1.26), a decrease in waist circumference to 111.25 (−5.39), a decrease in Hba1c to 7.47 (− 2.53%), a decrease in uric acid to 55.33 (−3.58), an improvement in lipid profile with a decrease in LDL to 0.89 g / l (−0.22), a decrease in CT to 1.72 g / l (−0.18), a decrease in TG to 1.4 (−0.05) and an improvement in HDL to 0.52 (+0.03). Regarding the treatment of diabetes, 23.33% of our patients had benefited from insulin withdrawal.
Conclusion
Treatment with GLP-1 analogues offers a new therapeutic option of major interest in the management of type 2 diabetes.

New indication for long-acting second-generation basalinsulin analog?

Mouna Elleuch[1], Cyrine Chehaider[1], Maalej Souhir[1], Nabil Lachiheb[1], Dhoha Ben Salah[1], Rim Atheymen[2], Nadia Charfi[1], Mouna Mnif[1], Fatma Mnif[1], Abderrahmen Masmoudi[3], Naourez Gouiaa[4], Zouhair Sahnoun[2], Faten Haj Kacem Akid[1] & Mohamed Abid[1]
[1]CHU Hedi Chaker, Endocrinology, Sfax, Tunisia; [2]Medicine of Sfax, Pharmacology, Sfax, Tunisia; [3]CHU Hedi Chaker, Dermatology, Sfax, Tunisia; [4]CHU Habib Bourguiba, Anatomic Pathology, Sfax, Tunisia.

Introduction
Although skin reactions relating to insulin injection have decreased since the prescription of human insulin and the use of highly purified insulin, they are still described in the literature. They can lead to significant problems with glycemic control. The challenge is to recognize the type of reaction that is occurring and identify the type of insulin formulation that avoids these reactions.
Case-report
A 64-year-old patient, with type 2 diabetes for 24 years on premixed human insulin for 10 years, presented with pruritic erythematous lesions at insulin injection sites that appear few hours after the injection and persist for a few days. They improved under topical corticosteroids. IgG-mediated delayed hypersensitivity (type III hypersensitivity) was suspected. The reaction was induced bythe different formulations of insulin and we could not recognize whether the insulin or an excipient was incriminated. We eliminated an allergy to protamine, metacresol and zinc as well as a dermographism. This left us questioning the diagnosis of allergic reaction and we resorted to a skin biopsy. It showed a cutaneous panniculitis which is an inflammation of the subcutaneous fat that results from local trauma caused by both physical and chemical insults. Initially, the management wasto split the total daily dose of Insulin glargine 100 units/ml LANTUS®in two different sites at the same time. There action was less severe. Then, the use of Insulin glargine 300 units/ml TOUJEO® allowed to avoid this reaction.
Discussion and conclusion
The most frequent skin reactions relating to insulin injection are allergic. However, it is important for healthcare professionals to be mindful of cutaneous panniculitis as apossible complication of insulin injections. Very few similar case reports were published. It remains possible that it is under-recognized. The absence of reaction under the long-acting second-generation basal insulin analog

TOUJEO® (Insulin glargine 300 units/ml)may be explained by the fact that this type of Insulin formulation allows continuous release of insulin from the adipose tissue. This allows to avoid the local trauma caused by the peaks of Insulin-release.

Autoimmune polyendocrinopathy syndrome type 4

Hind Ouakrim, Sana Rafi, Ghizlane El Mghari & Nawal El Ansari
Chu Mohamed Vi Marrakesh – Drh, Marrakesh, Morocco.

Introduction
Autoimmune polyendocrinopathy syndrome (APS) type 4 is rare, characterized by an association between an autoimmune endocrine disease with another endocrine or non-endocrine autoimmune disease, and this association cannot be attributed to APS type 2 or 3. We report the observations of 3 cases with APS type 4.
Cases presentations
Case N 1:
Patient 16 years old, type 1 diabetic for 9 years under insulin therapy, with alopecia areata for 4 years under Methotrexate 25 mg/week and folic acid 5 mg/week
Clinical examination showed alopecia of the scalp, the eyelashes and the eyebrows. Screening for other polyendocrinopathies was normal.
Case N 2:
24-year-old female patient, type 1 diabetic for 16 years on insulin therapy, treated for celiac disease on a gluten free regime for 14 years.
Case N 3:
Patient aged 54, followed for primary biliary cholangitis (PBC) at the stage of cirrhosis, who reported signs of hypothyroidism, on clinical examination: bradycardia at 55 bpm, palpable thyroid. The workup revealed autoimmune Hashimoto's thyroiditis.
Discussion
Autoimmune polyendocrinopathies (APS) represent a heterogeneous group of diseases characterized by two or more endocrine deficits related to an autoimmune mechanism, often associated with other non-endocrine autoimmune diseases. The classification by Neufeld and Blizzard identifies four types: APS type 1 is defined by the presence of at least two manifestations of a triad: adrenal insufficiency, hypoparathyroidism and mucocutaneous candidiasis. APS type 2 is the most common, and combines adrenal insufficiency with either type 1 diabetes or dysthyroidism, or both. APS type 3 is the combination of a dysimmune endocrinopathy (other than adrenal insufficiency) and dysthyroidism, and APS type 4 includes any other combination of autoimmune diseases. Our first two patients had T1DM associated with another non-endocrine autoimmune disease, and our third patient had Hashimoto's thyroiditis associated with PBC, this combination leads us to a diagnosis of APS type 4.
Conclusion
In any patient with autoimmune disease, a regular follow-up is indicated to identify the emergence of new autoimmune diseases.

Evaluation of Socio-demographic, clinical and biochemical characteristics of patients with Non Alcoholic Fatty Liver Disease and Diabetes who are attending the diabetic clinic in a tertiary care institute in Colombo, Sri Lanka

Ishara Ranathunga, J P Naveenkumar, T G Athukorala,
Manilka Sumanatilleke & Noel Somasundaram
NHSL, Diabetes and Endocrinology, Colombo, Sri Lanka.

Background and objectives
Non-alcoholic fatty liver disease (NAFLD) is highly prevalent in patients with diabetes as well as the vice versa. It is crucial to identify the characteristics of this group of patients in order to prevent the development, the progression as well as the complications of the disease. We have studied characteristics of patients having both NAFLD and diabetes who are attending a tertiary care institute in Sri Lanka.
Methods
A descriptive cross sectional study was conducted from August 2020 to March 2021 at the Diabetes Unit of the National Hospital of Sri Lanka. All the patients who met the inclusion and exclusion criteria who met the diagnosis of NAFLD according to the NHANES III criteria or/and the USS criteria were recruited in to the study. After obtaining informed written consent, the data was collected using an interviewer administered questionnaire. Categorical and numerical variables were analyzed using Chi-square and independent sample t-tests respectively.
Results
Seventy fur patients who met the diagnostic criteria of NAFLD were enrolled in to the study. The mean age was 56.8 years (range 23–79) and 77% were females. The mean weight was 66.6 (s.d. = 12.1)kg and BMI was 27.4 (s.d. = 4.7)kg/m^{-2}. 47.3% met both biochemical and USS criteria. Furthermore, 12.2% ($n = 9$) met only the biochemical criteria while 40.5% ($n = 30$) met only the USS criteria. Majority (67.6%) were receiving a monthly income of SLR $< 30\,000.00$ per month and majority were unemployed (73%). A larger proportion were having type 2 diabetes for > 10 years. Mean HbA1c was 8.9 (s.d. = 1.9)%.
Conclusions
NAFLD with diabetes is associated with overweight, poor glycaemic control, poor income and unemployment indicating the future focus groups for disease prevention and management. Further large scale studies are needed to evaluate the risk factors in more detail.

Can prebiotics improve weight loss in obese patients?

Rym Ben Othman, Zeineb Zemni, Chaima El Ghali, Wafa Douiri, Berriche Olfa, Ramla Mizouri, Nadia Ben Amor, Faten Mahjoub & Jamoussi Henda
National Institute of Nutrition of Tunis, Obesity Research Unit, Bab Saadoun, Tunis, Tunisia.

Background
Prebiotics are compounds in food that induce the growth of beneficial microorganisms such as bacteria and fungi, which are essential for the proper functioning of the microbiota. The objective of our work was to evaluate the effect of prebiotics intake on anthropometric parameters in addition to a weight loss program.
Methods
This is an interventional study involving 30 obese patients consulting the obesity unit of the Institute of Nutrition of Tunis during the period from May to August 2022. Patients were divided into 2 groups matched for age, sex and BMI: diet alone and prebiotics (30 g of carob/d). Anthropometric measures (weight, waist circumference, BMI), body composition, and muscle strength (using handgrip dynamometer) were assessed at T0 and at one month after the intervention (T1).
Results
The mean age was 40.3 ± 6.7 years with a female predominance (80% of women). For the diet alone group, there was a significant decrease in body weight (-2.5 kg, $P = 0.001$), BMI (-0.9 kg/m^2, $P = 0.001$) and waist circumference (-1.7 cm, $P = 0.01$) between T0 and T1. For the prebiotic group, in addition to the significant decrease in weight (-2.2 kg, $P = 0.003$), BMI (-0.9 kg/m^2, $P = 0.001$) and waist circumference (-4 cm, $P = 0.03$), we have noticed a significant decrease in fat mass (-2.9 kg, $P = 0.001$) and percentage fat mass (-1.8%, $P = 0.001$), as well as a significant improvement in muscle strength ($+1.4$ kg, $P = 0.008$). Although the decrease in body fat and body fat percentage and the increase in muscle strength were significant in the prebiotic group and not in the diet alone group, the difference between the two groups was not significant.
Conclusion
For anthropometric parameters, the prebiotic group was not superior to the diet alone group.

Can prebiotics improve daytime sleepiness in obese patients?

Rym Ben Othman, Zeineb Zemni, Chaima El Ghali, Berriche Olfa, Ramla Mizouri, Wafa Douiri, Nadia Ben Amor, Faten Mahjoub & Jamoussi Henda
National Institute of Nutrition of Tunis, Obesity Research Unit, Bab Saadoun, Tunis, Tunisia.

Background
Excessive daytime sleepiness is a common complaint in obese patients affecting life quality. The objective of our work was to evaluate the impact of prebiotics intake on daytime sleepiness in addition to a weight loss program.

Methods
This is an interventional study involving 30 obese patients consulting the obesity unit of the Institute of Nutrition of Tunis during the period from May to August 2022. Patients were divided into 2 groups matched for age, sex and BMI: diet alone and prebiotics (30 g of carob/d). No patients took antibiotics during the intervention period and no patient stopped taking carob. Daytime sleepiness was assessed at T0 and at one month after the intervention (T1) using the Epworth sleepiness scale. A score ≥ 10 indicates excessive daytime sleepiness (EDS). The statistical level of significance was defined as $P<0.05$.
Results
The mean age was 40.3 ± 6.7 years with a female predominance (80% of women). EDS was found in 46.7% patients in each group at T0. There was a significant weight loss in each group (diet only group: -2.5 kg $P=\mathbf{0.001}$ and prebiotic group: -2.2 kg, $P=\mathbf{0.003}$). However, there was no statistically significant difference in weight loss between the two groups ($P=0.7$). For the diet alone group there was an improvement in the Epworth score between T0 and T1 that was not statistically significant (9.8 vs 8. 6, $P=0.06$). For the prebiotic group, we have noticed a statistically significant decrease in Epworth score (8.7 vs 7, $P=\mathbf{0.02}$) however, when comparing both groups, the difference was not significant ($P=0.06$).
Conclusion
It seems that prebiotics improve excessive daytime sleepiness in obese patients. Further studies are needed to understand the underlying mechanisms.

Endocrine-disrupting chemicals and transgenerational inheritance of obesity

Hassan Heshmati
Endocrinology Metabolism Consulting, LLC, Anthem, United States.

Introduction
Epigenetics is defined as heritable changes in gene expression without changes in the DNA sequence. The transgenerational epigenetic inheritance of diseases is an emerging area of research. Multiple environmental factors including toxicants are associated with the transgenerational inheritance of increased disease susceptibility. Endocrine-disrupting chemicals (EDCs) are a heterogeneous group of exogenous chemicals or chemical mixtures that interfere with the action of hormones. The obesity pandemic cannot be explained solely by alterations in food intake and/or decrease in exercise. The present review explores the literature on transgenerational inheritance of obesity caused by EDCs.
Methods
A systematic search of literature was conducted using the search terms epigenetics, EDCs, obesogens, pregnancy, embryonic/fetal development, transgenerational inheritance, and obesity.
Results
By inducing epigenetic changes in germ cells (egg or sperm), the environment directly influences genetic variation, inheritance, phenotypic variation, and adaptation. The changes propagate through multiple generations without any new exposure to the initiating factor. The obesity pandemic coincides with the exponential increase in the number of EDCs present in the air, water, and food. Some EDCs called obesogens can promote weight gain despite normal diet and exercise. At least 50 obesogens have been identified. Exposure to obesogens (e.g., bisphenol A, tributyltin, and phthalates) during critical windows of embryonic/fetal development (e.g., Weeks 4–8) can induce transgenerational inheritance of increased obesity risk. Even if the exposure is removed, the transgenerational phenotype can persist through multiple generations. The proposed mechanisms implicated in transgenerational inheritance caused by EDCs include DNA methylation (the most studied mechanism), histone methylation, histone retention, chromatin structure alteration, and non-coding RNAs expression. With a direct exposure of the parents (considered the F0 generation) and the fetus (considered the F1 generation), the true transgenerational transmission is the F3 generation and beyond for the exposure of a pregnant female and the F2 generation and beyond for the exposure of a non-pregnant female or a male. Most reported human studies on transgenerational epigenetic inheritance are up to the F2 generation.
Conclusion
Exposure to a subset of EDCs called obesogens causes the metabolic programming of obesity and its transgenerational inheritance. Bisphenol A is one of the most widespread obesogens affecting humans. A better understanding of the mechanisms of the transgenerational inheritance is critical for the implementation of preventive strategies in the fight against obesity. Every effort should be made to minimize or avoid the exposure to obesogens, especially during the windows of sensitivity of the embryo/fetus.

EP516

Impact of morbid obesity on kidney function in type 2 diabetic patients (Experience of the obesity unit CHU Mohammed VI; Marrakech) (About 31 cases)

Imane Boubagura, Sana Rafi, Ghizlane El Mghari & Nawal El Ansari
Department of Endocrinology, Diabetology and Metabolic Diseases, University Hospital of Marrakech, Marrakech, Morocco.

Introduction
Excess weight has become a major public health problem. Type 2 diabetes and obesity are known risk factors for kidney disease. The aim of this study is to determine the effect of obesity on glomerular filtration rate (GFR) and microalbiminuria in patients with diabetes.
Methods
This is a descriptive cross-sectional study conducted over three years in obese and type 2 diabetic patients hospitalized in the Endocrinology and Diabetology Department of the Mohamed VI University Hospital in Marrakech.
Parameters studied
* BMI, BP, Waist circumference, lipid balance. * Renal function. * GFR was determined by measuring plasma creatinine clearance (MDRD). * Microalbiminuria was measured on a 24-hour urine sample.
Results
-Population: 31 obese
-Sex ratio: 0.32
-Predominance: female
-Average age: 55.5 years (42–69 years).
- prevalence: severe obesity: 13.6% of diabetics morbid obesity: 86.36% of diabetics
-Average BMI: severe obesity: 38.1 kg/m2 morbid obesity: 52.5 kg/m2
-Average duration of diabetes: 8.4 years.
-The average GFR: 76.70 ± 20.41 ml/min for BMI $>$ 30 64.49 ± 13.26 ml/min for BMI $>$ 40
-. Prevalence of microalbiminuria:
* in type 2 diabetics with severe obesity: $21.13 \pm 6.85\%$
* in type 2 diabetics with morbid obesity: $55 \pm 11.45\%$.
Discussion
Obesity contributes to the parallel increase in the prevalence of chronic kidney disease, through: nephropathy associated with type 2 diabetes and hypertension. The existence of a metabolic syndrome, as well as the constant inflammatory state in obese type 2 diabetics, contributes to the development of glomerular sclerosis lesions. In our series we observed an interaction between the effect of obesity and type 2 diabetes on GFR. We also observed a strong interaction between the effect of obesity and T2DM on renal function with a reduction in GFR and an increase in microalbiminuria in morbidly obese patients.
Conclusion
Obesity is not only a cardiovascular risk factor, but also a renal risk factor. It is therefore essential to detect and treat high-risk patients. Therefore, testing for proteinuria and measuring renal function is indicated in all obese patients.

Obesity and metabolic syndrome in patients with non-functioning pituitary adenomas

Abdel Mouhaymen Missaoui, Nabila Rekik Majdoub, Siddiqa Soomauroo, Faten Haj Kacem Akid, Dhoha Ben Salah, Fatma Mnif, Nadia Charfi, Mouna Mnif, Mouna Elleuch & Mohamed Abid
Hedi Chaker University Hospital, Department of Endocrinology, Sfax, Tunisia.

Objective
To assess the prevalence of obesity and metabolic disorders in patients with non-functional pituitary adenomas (NFPA)
Patients and methods
A retrospective descriptive study of 35 patients followed for NFPA between 2000 and 2022. Metabolic syndrome was established according to the National Cholesterol Education Program Adult Treatment Panel III criteria.
Results
The mean age was 52.1 ± 11.4 years, with a male predominance (61.3%). Ninety percent were macroadenomas. The mean weight was 76.8 ± 15 kg corresponding to a mean BMI of 28.3 ± 5 kg/m^2. Obesity (40%) or overweight (26.7%) was frequently reported. The majority of obese patients were classified as grade 1 (66.7%). The mean waist circumference was 99.8 ± 13.4 cm with an android distribution of fat in 54.5% of

the patients with NFPAs. The frequency of hypertension was 16.1%. Glucose metabolism disorders were diagnosed in 34.5% of patients with a mean fasting blood glucose level of 5.7±2.4 mmol/l. Lipid metabolism was disturbed in 53.8% of cases. HypoHDLaemia and hypertriglyceridemia were observed in 36.4% and 11.5% of cases, respectively. Mixed hyperlipidemia affected 15.4% of patients. The overall prevalence of metabolic syndrome in our series is estimated at 16.7%.

Discussion

The mass effect of NFPAs is thought to be the cause of numerous hypothalamic dysregulations altering the biological circadian rhythm (waking-sleep, hunger-satiety, energy balance, etc...). These hypothalamic disturbances aggravate the metabolic risk in this population, who is particularly exposed to obesity and dyslipidemia. This situation would be further exacerbated by physiologically imperfect (glucocorticoids) or neglected (GH substitution) hormone substitutions.

EP518

The effectiveness of a comprehensive rehabilitation program on the balance function in patients with obesity

Valeriia Vasileva & Larisa Marchenkova
National Medical Research Center for Rehabilitation and Balneology, Moscow, Russia.

Objectives

The study of the influence of a new complex method of physical therapy with the inclusion of balance therapy with biofeedback and kinesihydrotherapy on the human balance function.

Material and methods

The study included men and women aged 40 to 65 years with a body mass index $\geq$30 kg/m^2. Research methods included anthropometry, stabilometry. The patients were further divided into two groups by simple randomization. Patients of both groups underwent a two-week course of medical rehabilitation. Patients of the main group received 4 methods of physical therapy: balance therapy, group classes in kinesihydrotherapy, group classes in a special complex of therapeutic exercises in the hall, aerobic exercises on a stationary bike or treadmill. The patients of the comparison group were treated only with the use of aerobic exercises and therapeutic exercises in the hall according to the same methodology and with the same number of procedures as in the main group. Dynamic observation was carried out at the beginning and after 14 days.

Results

According to the data, we obtained an improvement in the balance function on the 14th day of the study in terms of spread along the front ($P=0.028$) and the spread along the sagittal ($P=0.043$). Significantly improved indicators in the main group in terms of the average speed of movement of the center of pressure ($P=0.018$) and the speed of movement of the statokinesiogram ($P=0.028$), indicators of the area of the ellipse ($P=0.018$).

Conclusions

The new comprehensive program, including aerobic and strength physical training, kinesihydrotherapy and balance therapy, showed a more significant effect on the balance function after completion of the rehabilitation, rather than the standard rehabilitation method.

EP519

The effectiveness of a comprehensive rehabilitation program including interactive balance therapy with biofeedback and kinesihydrotherapy in reducing body weight and changing the body composition in patients with obesity

Valeriia Vasileva & Larisa Marchenkova
National Medical Research Center for Rehabilitation and Balneology of Ministry of Health of Russian Federation, Moscow, Russia.

Objectives

To evaluate the effectiveness of a new comprehensive rehabilitation program on weight dynamics and body composition indicators using different methods after the rehabilitation stage and long-term results.

Material and methods

The Research includes men and women aged 40 to 65 with a body weight index more than 30 kg/m^2. Patients of the main group (Group 1) received 4 methods of physical therapy: balance therapy, group sessions of kinesihydrotherapy, group sessions with a special complex of therapeutic exercises in the hall, aerobic exercises on a bike or treadmill. Patients of the comparison group (group 2) were treated only with the use of aerobic exercises and therapeutic exercises in the hall according to the same methodology and with the same number of procedures as in the main group.

Results

According to the data obtained, in both groups, after the completion of the treatment phase, body weight significantly decreased in both groups, $P=0.0001$, waist circumference ($P=0.0001$ in group 1 and $P=0.005$ in group 2) and hip circumference ($P=0.0001$ in group 1 and $P=0.0003$ in group 2). In the main group, the thickness of the triceps fat fold decreased significantly ($P < 0.05$) after 14 days, 3 and 6 months, respectively (from 36.0 [28.0; 39.5] to 32.0 [24.0; 46 0] to 28.0 [20.5; 37.5] to 29.0 [19.0; 45.0] mm, respectively), the thickness of the abdominal fat fold decreased after 14 days, 3 and 6 months (from 67.5 [50.0; 77.5] to 56.0 [50.0; 68.0] to 46.0 [37.0; 50.0] to 50.0 [38.0; 70.0] mm, respectively. We received a significant ($P < 0.05$) decrease in fat mass according to bioimpedancemetry in the main group after 14 days and 3 months, respectively (from 65.7 [49.2; 72.1] to 60.9 [42. 2; 66.7] to 55.3 [39.3; 62.2] kg, respectively). In group 1, the decrease in adipose tissue according to the data of air-replacing body platysmography also significantly ($P < 0.05$) differed after 14 days, 3 months, respectively (from 56.8 [41.3; 77.5] to 49.7 [40.1; 57.1] to 44.4 [34.4; 64.4] kg, respectively).

Conclusions

The new complex program, including aerobic and strength physical training, kinesihydrotherapy and balance therapy in combination with a low-calorie diet, showed a more significant effect than the standard rehabilitation method on reducing body weight, reducing the thickness of fat folds, as well as changing the composition of the body, including 3 and 6 months follow-up.

Prevalence of hirsutism in obese Tunisian women

Bel Hadj Sliman Chayma, Nadia Ben Amor, Faten Mahjoub, Berriche Olfa, Ben Ali Khaoula, Rym Ben Othman, Ramla Mizouri, Gammoudi Amel, Kacem Awatef & Jamoussi Henda
National Institute of Nutrition, Service A of Diabetology and Nutrition, Tunis, Tunisia.

Introduction

Hirsutism is clinically defined as presence of excessive body hair in women in androgen-dependent areas. The aim of our study was to determine the prevalence and the characteristics of hirsutism in obesity.

Patients and methods

This was a descriptive cross-sectional study including 65 obese Tunisian women of reproductive age conducted in the obesity unit of the national Institute of nutrition of Tunis. The Ferriman-Gallwey score was used to evaluate hirsutism.

Results

The mean age of the patients was 33.36±10.76 years. The mean body mass index was 37.13±7.31 kg/m^{2}with morbid obesity in 32.3% of patients. The mean body fat percentage was 45.69±5.89% with a mean waist circumference of 110.43±21.86 cm. Diabetes, hypertension and dyslipidemia were found in respectively 23.1%, 16.9% and 15.4% of cases. The mean age at menarche was 11.94±2.46 years. Irregular menstrual cycles and amenorrhea was reported in respectively 28.1% and 17.5% of patients. Hirsutism was found in 41.5% of the patients: mild in 59.3% of cases, moderate in 7% and severe in 3.7% of cases. The mean blood testosterone level was 0.34±0.22 ng/ml [0.03–0.94]. Of the hirsute patients, blood testosterone level was below 0.6 ng/ml in 87.5% of cases and between 0.6 and 2 ng/ml for 3 patients. No patient had a testosteronemia above 2 ng/ml. Causes were dominated by polycystic ovary syndrome in 55.6% of cases.

Conclusion

Hirsutism is a frequent complication in obese women requiring a rigorous etiological investigation.

Altered metabolism as a modified adolescent biomechanics component

Liza Mirkovskaya
San Diego State University, San Diego, United States.

Obese teenagers are likely to become obese adults in the future. Obesity affects various bodily systems, including the musculoskeletal system, both biochemically and mechanically. These negative consequences are ultimately connected to wrongful muscle loading and unloading patterns. Pediatric obesity is especially dangerous. This study examined adolescents with BMI ranging from average weight to morbidly obese; various locomotion parameters were measured in adolescents. The study found numerous biomechanics parameters, including weight acceptance and push-off peak forces, stance time, and step length, were significantly modified in obese teenagers. The pattern of alterations suggests that muscular loading and unloading in obese adolescents changes to accommodate energy expenditure during locomotion. The study concludes by analyzing various metabolism changes that might contribute to the altered movement. Such adaptations, while seemingly allowing for locomotion adjustment in the short term, might perpetuate musculoskeletal and other systems pathologies if obese adolescents remain obese as adults.

Iron deficiency anemia in pregnancy

Hana Ben Jemâa, Chaima Jemai, Chaima Sdiri, Dorra Ben Salem, Yosra Htira, Hedfi Imene, Zohra Hadj Ali & Feika Ben Mami
National Institute of Nutrition, Tunis, Tunisia.

Introduction
Iron deficiency is common in pregnant women, and it causes an increased risk of premature delivery and fetal death. The aim of this study is to determine the prevalence of iron deficiency in pregnant women and find out the most common risk factors associated with anemia.
Methods
We performed a retrospective study on 52 pregnant women hospitalized in the c nutrition department. The definition of anemia as well as the objectives of the different parameters of the iron balance are retained referring to the recommendations of the world health organization.
Results
The age of our patients ranges between 21 and 36 years old. it was noted that 23% of women had a normal build before pregnancy 42% were overweight and 35% obese. Twenty-nine percent of patients were primiparous. The prevalence of anemia was 40%. Among them the anemia was mild in 76% and moderate in 24%. No severe anemia noted. The averages of hemoglobin and ferritin levels were respectively 10.26+- 1.21 g/dl and 18.23+-1.03 umol/l in anemic women and 12.34 g/dl, 33.81 umol/l in non-anemic women. Among anemic women 5% were in the 1st trimester 43% in the second trimester and 28% in the 3rd trimester. Ninety-five percent of women were symptomatic. The most common symptoms were: fatigue and dizziness in 67%, paleness and dyspnea in 62% and tachycardia in 57%. In our study a significant correlation was found between iron deficiency and personal history of prematurity ($r=0.301$, $P=0.03$), family history of anemia ($r=0.437$,$P=0.001$) and abandonment of menstruation ($r=0.301$, $P=0.03$). However, there were no significant differences with the parity of women ($r=0.082$, $P=0.566$), and the duration of menstruation ($r=-0.86$, $P=0.566$).
Conclusion
Screening for anemia in pregnant women is simple and essential to prevent its maternal and fetal consequences.

Tissue-specific, adipose insulin resistance leads to hypertriglyceridemia

Song Jae Lee[1] & Sang Won Shin[2]
[1]Integrated Research Institute, First Department, Seoul, South Korea; [2]Korea University Hospital, Internal Medicine, Seoul, South Korea.

Hypertriglyceridemia (HTG) is known to be a risk factor for cardiovascular diseases, such as atherosclerosis and hypertension. Although the association between insulin resistance (IR) and HTG has long been recognized, the causal relationship between them has not been elucidated yet. Proper understanding of the effect of IR on HTG may better start with the realization that IR implies much more than mere impairment of glucose uptake in tissues. Given that the role of insulin is widely different from tissue to tissue, metabolic disruptions due to IR would be very tissue-specific. Furthermore, IR would not necessarily develop simultaneously in the whole body but instead develop first predominantly in the muscle tissue with a low cell turnover and then progress to the adipose tissues and to the liver with higher cell turnovers. This may warrant that IR be subdivided better into tissue-specific IRs, such as the muscle insulin resistance (MIR), adipose insulin resistance (AIR), and hepatic insulin resistance (HIR). It is believed that HTG is related particularly with AIR. The AIR – failure of insulin action in adipose tissues – would not only impair glucose uptake into adipose tissues thereby elevating plasma glucose (PG) significantly, but also let adipose tissue lipases, such as hormone sensitive lipase (HSL) and adipose triglyceride lipase (ATGL), be inhibited not enough even in the fed state. Consequently, adipose tissues under AIR would not only undergo uninhibited lipolysis to release constantly fatty acids (FAs) into the plasma but also fail to entrap the fatty acids (FAs) released from the triglyceride-rich lipoproteins (TRLs), such as very low-density lipoproteins (VLDLs) and chylomicrons, that undergo, with the help of lipoprotein lipase (LPL), delipidation, which elevates severely the plasma fatty acid (PFA). Then, a significant fraction of severely elevated PFAs would also transport into the liver and subsequently, along with the FAs being released when the remnant TRLs taken up by the liver undergo hepatic breakdown, be formed into VLDLs and secreted back into the plasma, thereby contributing to severe elevation of plasma triglyceride (PTG), i.e., hypertriglyceridemia (HTG). As well known, chylomicrons of dietary fat origin delipidate much faster than VLDLs, which explains why VLDLs constitute the major component of PTG. In summary, AIR renders adipose tissues unable to esterify FAs into fats, which inevitably elevates PFA severely, which in turn enhances hepatic VLDL generation and secretin, thereby elevating PTG severely and thus leading to HTG.

Biermer anemia in a type 2 diabetic not treated with Metformin

Elleuch Mouna, Wissal Ghamgui, Hadj Kacem Faten, Maalej Souhir, Mnif Mouna, Mnif Fatma, Charfi Nadia, Rekik Nabila & Abid Mohamed
Endocrinology and Diabetology Service, CHU Hedi Chaker, University of Sfax, Sfax, Tunisia.

Introduction
Anemia is defined by the World Health Organization as a hemoglobin concentration less than 120 g/l in women outside of pregnancy, and less than 130 g/l in men over 15 years of age. It is common in diabetics. It can be due to an autoimmune disease associated with type 1 diabetes, whereas the inflammatory cause is the primary cause in type 2 diabetes.
Observation
This is a 75 year old patient, type 2 diabetic for 21 years on insulin analogues without metformin; He presented with diabetic nephropathy and coronary insufficiency. In July 2022, the patient presented intense asthenia with anorexia and severe hypoglycemia of 0.3 g/l. In this context, a blood cell count was done showing anemia of 90 g/l with a mean blood volume of 109 fl. The etiological investigation confirmed a hypovitaminosis B12 with a normal folate level. The antiintrinsic factor antibodies were strongly positive. The diagnosis of Biermer anemia was retained and the patient was put on vitamin supplementation. Clinical and biological improvement and disappearance of hypoglycemia (assessment after one month of of vitamin B12 supplementation: hemoglobin 110 g/l with VGM 97 fl) were observed in our patient.
Conclusion
Beyond the search for a cause in order to ensure its treatment, the discovery of anemia in diabetic patients must systematically raise the question of its influence on glycemic control and the interpretation of glycated hemoglobin tests.

EP525

The sociodemographic and metabolic factors associated with severe insulin resistance in individuals with type 2 diabetes mellitus

Diana Simoniene[1], Emilę Rudminaitę[2] & Gabrielę Čypaitę[2]
[1]Lithuanian University of Health Sciences, Endocrinology, Kaunas, Lithuania; [2]Lithuanian University of Health Sciences, Medical Academy, Kaunas, Lithuania.

Some patients with type 2 diabetes mellitus (T2DM) suffer from severe acquired insulin resistance (IR). There is still a shortage of research analyzing the T2DM patients with severe IR and identifying their risk factors.
Aim
To evaluate how selected sociodemographic and metabolic factors are linked to severe IR among patients with T2DM.
Methods
It was a case control study. If T2DM patients received high insulin doses (> 1 IU/kg/day) and their HbA1c $\geq$ 9%, they were assigned to the case group ($n=58$). Patients with lower insulin requirements (< 1 IU/kg per day) and HbA1c

$< 8\%$ were assigned to the control group ($n=62$). Participants of control group were matched by gender and BMI with the case group. Data was analyzed using SPSS 27.0 software. The level of statistical significance was set as $P < 0.05$.
Results
The data of 120 patients with T2DM was analyzed (Table 1and Table 2).
Conclusions
1. T2DM patients with severe insulin resistance (case group) were younger and their diabetes duration was shorter compared to the control group.
2. The case group subjects had a higher prevalence of metabolic syndrome and dyslipidemia itself, exclusively hypertriglyceridemia.

GAZA study (Glycémie Améliorée Zéro Antidiabétique), a new antidiabetic therapeutic approach without pharmacoligical treatment

Ismail Nasri
Dr Nasri Ismail Endocrinologue Diabétologue, Chlef, Algeria.

Introduction
In diabetology all the recommendations insist on the intensification of the antidiabetic treatment with the maintenance of the same treatment if the type 2 diabetes mellitus is balanced. Our work insists on dietary treatment and focuses on weight loss in order to degress antidiabetic treatment until cessation.
Patients and methods
This is a prospective interventional study. Type 2 diabetes mellitus on pharmacological treatment: treatment is reduced if HbA1c $\leq$ 6.5%, until treatment is stopped in order to integrate the study. Type 2 diabetes mellitus without pharmacological treatment are monitored quarterly for 24 months, based on weight, fasting blood sugar and HbA1c.
Results
Our work brought together 289 patients with a sex ratio of 0.85 and an average age of 52 years and an average BMI of 29.6 kg/m^2, the average duration under antidiabetic treatment is 15 months, 74% under mono or dual therapy, 4 patients on insulin. 4% refused to stop treatment, 20% failed to stop treatment, 71% are still without pharmacological treatment, of which 49% exceeded 12 months and 20% exceeded 24 months. During the 24 months of follow-up: the average weight loss compared to the initial weight varied between −3 kg and −4.4 kg, the average fasting blood sugar varied between 1.10 and 1.19 g/l and HbA1c varied between 6.1% and 6.4%
Conclusion
As the intensification of the antidiabetic treatment is essential in the management of the patients with type 2 diabetes mellitus, the degression must be integrated into the therapeutic strategy in order to preserve the pancreatic capital and ensure a better quality of life.

Diabetes and Ramadan, special Ramadan blood glucose self-monitoring table

Ismail Nasri
Dr Nasri Ismail Endocrinologue Diabétologue, Endocrinology, Chlef, Algeria.

Background
International Diabetes Federation (IDF), in collaboration with the Diabetes and Ramadan (DAR) International Alliance proposed in 2021, IDF-DAR Practical Guidelines with a score that allows certain patients even on insulin to fast which requires regular and appropriate blood glucose monitoring.
Aim
Develop a special Ramadan blood glucose self-monitoring table in order to limit the risk of acute compilations during this month.
Method
Our work is a literature review and analysis of the pharmacokinetics of antidiabetics in order to determine the critical moments during Ramadan. It should be noted that, IFTAR: evening meal, SUHOOR: dawn meal.
Results
Our table contains 5 columns: Pre-SUHOOR, post-SUHOOR, at 1600 hours (frequent moment of hypoglycemia), Pre-IFTAR, post-IFTAR (Table 1A/ Non-insulin antidiabetics: the essential moments are: 1/ post-SUHOOR: to find out if the patient can continue fasting. 2/ at 1600 hours: the most critical period for hypoglycemia. 3/ post-IFTAR to correct dietary deviations in the event of hyperglycemia, and readjust the doses of antidiabetics in the event of hypoglycemia. B/ Basal insulin: will be readjusted according to blood glucose at 1600 hours and Pre-IFTAR. C/ short-acting insulin: the dose of IFTAR will be readjusted according to the blood glucose level post-IFTAR, the dose of SUHOOR will be readjusted according to the blood glucose post-SUHOOR. D/ Premixed insulin: the dose of IFTAR will be readjusted according to the blood glucose level post-IFTAR and Pre-SUHOOR, the dose of SUHOOR will be readjusted according to the blood glucose post-SUHOOR, at 1600 hours and Pre-IFTAR.
Conclusion
Fasting during Ramadan constitutes a major risk for diabetic patients, appropriate and regular blood glucose self-monitoring can help diabetics to manage treatment and diet well.

Table 1

Pre-Suhoor		Post-Suhoor	1600 hours	Pre-Iftar	Post-Iftar		
Blood Glucose	Short acting/ premixed insulin	Blood Glucose	Blood Glucose	Blood Glucose	Short acting/ premixed insulin	Blood Glucose	Basal insulin

The effect of hypoglycemic therapy on functional state of the kidneys in patients with type 2 diabetes mellitus

Sitora Muminova[1], Khurshida Nasirova[1] & Dilafruz Maksudova[2]
[1]Tashkent Pediatric Medical Institute, Endocrinology, Uzbekistan;
[2]Tashkent Pediatric Medical Institute, Uzbekistan.

The purpose of the study was to assess the functional state of the kidneys in patients with type 2 diabetes, depending on hypoglycemic therapy.
Material and research methods
60 patients with type 2 diabetes with CKD. The mean age of the patients was 54± 2.5 years, the experience of diabetes was 11.7±0.18, the mean Hb1C was 9.1%, and the mean fasting glycemia was 11.2 mmol/l. The patients were divided into 2 groups: group 1-30 patients on the iSGLT-2+ metformin, group 2–30 patients on the iDPP-4+metformin. The observation period was 6 months.

Research results and discussion
In patients with type 2 diabetes with diabetic nephropathy (CKD 2,A2), iSGLT 2 after 6 months of observation effectively reduced the level of glycated hemoglobin (Hb1C) by 1.0% and fasting plasma glucose was 8.4 mmol/l, in patients taking iDPP-4 10 mmol/l. A significant improvement in GFR is observed after 6 months of taking iSGLT-2, at the 1st visit 69.2 ± 0.08 ml/min per 1.7 m^2 after 6 months 82.7 ± 2.85 ml/min per 1.7 m^2. According to our results, IGLT2 reduces the risk of progression of albuminuria, 68% of patients reported MAU – 32.01 mg/day at the 1st visit, after 6 months 28.5 mg/day.
Conclusions
The use of iSGLT-2 in DM2 patients with nephropathy not only improves glycemic control and slows down the development of diabetic kidney damage (reduces the rate of increase in albuminuria and improves GFR).

EP529

The efficacy of regimens for sodium-glucose countertranspoter 2 inhibitor (Emaglyf) with metformin and DPP-4 inhibitor (Januvia) in patients with DM 2 and stage 1-3 chronic kidney disease

Mokhira Teshabekova
Republican Specialized Scientific Practical Medical Center of Endocrinology of Public Health Ministry named by acad. Ya.Kh. Turakulov, Department of Diabetic Nephropathy, Tashkent, Uzbekistan.

Aim of the study
To study the effectiveness of combination therapy of sodium-glucose countertranspoter 2 inhibitor -SGLT-2 – (Emaglyf) with metformin and DPP-4 inhibitor (Januvia) in patients with stage 1–3 chronic kidney disease associated with DM 2.
Material and research methods
A total of 40 patients with type 2 diabetes and CKD grades 1–4 were selected. To study the effect of various schemes of nephroprotective therapy on the functional state of the kidneys in DM 2, patients were divided into 2 therapeutic groups: Group 1 consisted of 20 patients with DM 2 and CKD 1–3 tbsp. receivingSGLT-2 (emoglyph) + metformin Group 2 consisted of 20 patients with DM 2 and CKD 1–3 tbsp. receivingSGLT-2 (Emoglyph) + DPP 4 (Januvia). In the work, general clinical, clinical and biochemical (AL, AST, bilirubin, PTI, urea, creatinine, GFR, C-reactive protein, etc.), hormonal (insulin, C-peptide), immunological (uromodulin) methods of blood tests, as well as instrumental methods of examination – ultrasound of internal organs, Ultrasound and dopplerography of renal vessels, as well as statistical methods. We also evaluated the results of ECG in 12 conventional leads and echocardiography (EchoCG) (dimensions of the chambers of the heart, the thickness of its walls and myocardial contractility). The control group consisted of 20 healthy individuals.
Research results
The initial data of carbohydrate metabolism indicated its decompensation in the studied groups. There were no significant differences between the Doppler values of the renal arteries in the groups. At the same time, the indicators significantly differed from those of the control group.
Conclusions
1) After 6 months of therapy, the indicators of carbohydrate metabolism reached normalization in both groups, while the best results were observed when using the SGLT-2+ DPP4 regimen
2) After 6 months of treatment, significant differences were found between the Doppler values of the renal arteries in the groups, namely, when using the SGLT-2+ DPP4 scheme

Diabetic osteoarthropathy: A case report

Ahmed Boukhalfa, Zahra Ismail, Sana Rafi, Ghizlane El Mghari & Nawal El Ansari
Mohammed VI University Hospital Center, Endocrinology, Diabetology and Metabolic Diseases Department, Marrakech, Morocco.

Introduction
Diabetic osteoarthropathy (D.O) commonly referred to as Charcot's foot is a complication secondary to neuropathic and inflammatory osteolysis, occurring in a setting of old and/or poorly controlled diabetes. Its pathophysiology remains poorly understood and its diagnosis must be systematically evoked in the presence of any inflammatory sign that localised to the foot or ankle occurring on a background of diabetic neuropathy.
Clinical case
Sixty four year-old female patient, diabetic since the age of 48 years on 2 premixed and rapid analogue. Her diabetes was unbalanced and she was already at the stage of degenerative complications, with the notion of amputation of the 3rd toe of the right foot following gangrene. The patient was admitted with pain in the left foot that had been evolving for 5 months, occurring in the context of prolonged walking and without any notion of trauma. Clinically, the foot was deformed, painful, with enlargement of its anteroposterior and lateromedial diameter. Biological tests revealed a high CRP and LDH without hyperleukocytosis. An X-ray of the left foot showed secondary ossifications with marginal sclerosis and exostoses. A CT scan showed hypertrophy and destruction of the bone with infiltration of the periarticular soft tissues in favour of a Charcot foot. The left foot was immobilised in a plaster cast and offloaded with the patient being put on a progressive dose of pregabalin with improvement of her pain.
Discussion
Currently diabetes is the leading cause of diabetic osteoarthropathy. Unilaterality of the disease is dominant. Intense bone demineralisation is evidence of significant autonomic damage. Our patient had a delay in diagnosis which could be explained in part by the rarity of this pathological entity and the lack of specificity of its clinical picture. The cornerstone of management is an early clinical and radiological diagnosis strict unloading of the foot, appropriate analgesia with a careful discussion of the surgical indication in the state phase in order to prevent the development of ulcerations, a major cause of amputation.
Conclusion
D.O is often under-diagnosed due to the non specificity of the clinicobiological picture. It is characterised by irreversible osteoarticular complications, hence the importance of early diagnosis with adequate management based on offloading and early immobilisation in parallel with good therapeutic education.
Key words: diabetes-osteorthropathy-unloading-surgery.

Emphysematous cystitis in diabetics

Kadiri Chaimae & Lachkar Hassan
Hospital Cheikh Zaid, Endocrinology, Rabat, Morocco.

Introduction
Emphysematous cystitis is a rare rare condition encountered mainly in poorly balanced diabetic patients. It represents a rare cause of septic shock and is characterized by the presence of air in the wall and/or the bladder lumen. Abdominopelvic computed tomography remains the key examination to confirm the diagnosis.
Observation
We report the case of a 65-year-old patient with a history of non-ill-controlled type 2 diabetes on sulfonylureas and complicated by diabetic retinopathy and diabetic neuropathy. He was admitted for management of a glycemic imbalance associated with urinary burning and vomiting. Clinical examination found pelvic tenderness. The balance shows neutrophilic polymorphonuclear leukocytosis with white blood cells at 11550/ul and a CRP at 24.8 mg/l. He has unbalanced diabetes (HBA1C = 9%) and functional renal failure (creatinine = 76.13 mg/l). Thoraco-abdomino-pelvic CT demonstrates emphysematous cystitis. The evolution is favorable under antibiotic therapy, insulin therapy and bladder drainage.
Conclusion
Urinary tract infections are more frequent and more serious in diabetic patients. They can have a severe prognosis, hence the need for early diagnosis and rapid treatment.

Pregnancy after exposure to GLP-1 receptor agonists. A case report and literature review

Olga Wajtryt[1] & Marek Dedecjus[2]
[1]Maria Sklodowska-Curie National Research Institute of Oncology, Department of Oncological Endocrinology and Nuclear Medicine, Warsaw, Poland; [2]Maria Sklodowska-Curie National Research Institute of Oncology, Department of Oncological Endocrinology and Nuclear Medicine, Warsaw, Poland.

GLP-1 receptor agonists have become an important group of drugs used in the treatment of type 2 diabetes and then obesity. There are also many reports of very beneficial effects, e.g. in the treatment of polycystic ovary syndrome.

Multidirectional metabolic impact, weight loss, menstrual regularity, and therefore fertility, when used in a group of young women, the possibility of pregnancy should always be taken. We present a case report of the patient which is the starting point for a review of the current state of the art, a review of the literature, and the proposed management of GLP-11 analogs treatment among women of reproductive age. A 43-year-old patient with type 2 diabetes treated with metformin and semaglutide in the fifth pregnancy, in the seventh week of pregnancy, came to a gynecologist and diabetologist, which meant several weeks of exposure to semaglutide in the first trimester of pregnancy. In the obstetric history – 2 deliveries and 2 miscarriages, history of irregular menstruation. A patient with a diagnosis of diabetes in pregnancy during a second pregnancy, was treated with metformin after delivery, and then semaglutide was added. Semglutide for 6 months. The patient did not use oral contraception, because she planned the implantation of intrauterine device. Glycated hemoglobin was 5.4%. Semaglutide was discontinued and the patient quickly required the functional insulin therapy. The reference ultrasound examinations of the first and second trimesters did not reveal any fetal defects. In subsequent trimesters, HBA1c-5.2–5.4%. The girl The fetus was through a transverse incision in the lower uterine segment. The fetus was a female delivered at 35 gestational age, weighing 2750 g. GLP-1 agonists have been classified by the FDA and EMA as group C, which means that they are contraindicated during pregnancy. From preclinical studies, we know about skeletal defects in rodents and rabbits. There is a recommendation to use contraception in the pre-pregnancy women and a time of wash-out recommendation. For semglutide it is- 2 months. There are only single cases describing pregnancy during exposure to GLP-1RA. Most likely, in the coming years the data will be more accurate because the increasing use of GLP-1 receptor agonists in treatment provide data in cases of unplaned pregnancies. We will also need a long-term observation of those patients and their offspring.

Hyperhomocysteinemia in post-covid diabetic patients in Adjara Region, Georgia (Country)

Ketevan Dundua[1,2], Liana Jashi[3], Tamar Peshkova[4], Rusudan Kvanchakhadze[5] & Eter Margalitadze[4]
[1]BAU International University Batumi, Basic Medicine, Batumi, Georgia; [2]David Aghmashenebeli University Of Georgia, School of Medicine, T'bilisi, Georgia; [2]David Aghmashenebeli University Of Georgia, School of Medicine, T'bilisi, Georgia; [4]Batumi Shota Rustaveli State University, Medicine, Batumi, Georgia; [5]David Aghmashenebeli University Of Georgia, Medicine, T'bilisi, Georgia.

Objective
Post Covid Syndrom (PCS) after Covid Pamdemic is a major couse of morbidity for Diabetic patients. In the last 30 years, a new metabolic risk factor for vascular damage – hyperhomocysteinemia (HtHcy) has been identified and is considered as an independent risk factor for the development of cardiovascular pathologies and the possible lethal outcome.
Aim of study
This study was undertaken to check association of plasma Hcy level in post covid diabetics with increased risk of CVD. That's why, due to the growing number of patients with T2DM with Long Covid symptoms and complications we decided to study non-insulin-dependent diabetics in this area to determine the correlation between Covid infection and HtHcy and give some evidence about correlation between CVD high risk.
Keywords: homocysteine; Post Covid Syndrome (Pcs), plasma, type 2 diabetes mellitus, cardiovascular disease CVD.
Method and design
Case-control study, was conducted to assess the effect on plasma homocysteine (Hcy) in 74 type 2 diabetic out-patients with anamnesis of Covid 19 only who did not require hospitalization for COVID-19 disease were included this study. Clinical data and laboratory results of 74 RT-PCR-positive COVID-19 cases were collected, aged between 65 > years old man and woman, ambulatory visited 6 endocrinologist and 3 cardiologists in 3 primary care clinic, city Batumi, period between March 10 – to November 23, 2022. 34 of these patients had a history of cardiovascular complication, or Heart Bypass Surgery CABG(7 pts) before Covid-19 disease. Test results of metabolite panel: B12, folate and homocysteine, which were run in the immunochemistry module of Cobas®8000 analyzer using Electro Chemi Luminescence technology (Roche diagnostics, Mannheim, Germany).
Results
74 Post COVID-19 diabetic patients (43 males, 31 females) were enrolled in the study. Laboratory results: Homocysteine (μmol/l) – 15.62±1.37; Folate (mg/l) – 4.59±0.41; B12 (ng/l) –531.50±62.20.
Summery points
Hyperhomocysteinemia was observed in post COVID diabetic patients included in the study; We recommend analysis of homocysteine levels to predict the course of the post Covid syndrome; Homocysteine levels in post COVID-19 NIDDM patients can be evaluated for a predictive, preventive and personalized medical approach.
Conclusion
Homocysteine levels can be used as a prognostic parameter that can predict the severity of post COVID-19 disease. We believe that studies on disease severity and predictive medicine in the field of biomarkers will increase in the future.

Metabolic profile and clinical hyperandrogenism in Cushing's disease

Hanae Rachedi[1], Dounia Zerrouki[1], Nabila Zeryouh[1], Rania El Amel[1], Siham Rouf[2] & Hanane Latrech[2]
[1]Endocrinology, Diabetology and Nutrition Department, University Hospital Center Mohammed VI, Oujda, Morocco; [2]Endocrinology, Diabetology and Nutrition Department, Laboratory of Epidemiology, Clinical Research and Public Health, Faculty of Medicine and Pharmacy, Mohamed I University, Oujda, Morocco.

Introduction
Cushing's disease is a rare condition that represents the most common cause of endogenous Cushing's syndrome. Its severity is due to cardiovascular complications, with high morbi-mortality rates. This study aims to evaluate the specific features of metabolic disorders in females having Cushing's disease and presenting a clinical hyperandrogenism.
Materials and methods
Retrospective and descriptive study, including 12 female patients with Cushing's disease presenting a clinical hyperandrogenism, recruited in the Endocrinology-Diabetology-Nutrition department of university hospital center Mohammed VI of Oujda between 2016 and 2022. Statistical analysis was performed by SPSS version 21 software.
Results
The mean age was 30.3±11.8 years, with age ranging from 14 to 54 years. The average BMI was 32.7±8.1 kg/m^2, obesity was observed in 41.6% of our patients. The mean waist circumference was 107.4±13 cm. Dyslipidemia was found in 66.7% of patients: mixed dislipidemia was noted in 58.3% of them, hypercholesterolemia was found in 91.6% and hypoHDLemia was described in 83.3% of cases. In addition 33.3% of our patients were diabetics with a mean HBA1c of 6.5±1.3%, requiring insulin therapy in 50% and metformin in monotherapy in 50% of cases. Twenty-five percent of our patients had an association of diabetes and arteriel hypertension. In total, 58.3% of our patients had a metabolic syndrome.
Discussion-conclusion
In Cushing's disease, hypercortisolism leads, through a combination of effects on the liver, muscles, adipose tissue and pancreas, to an augmentation of gluconeogenesis and an alteration of insulin sensitivity, causing glucidic metabolism disorders. The therapeutic approach to these patients must be comprehensive, including the control of associated cardiometabolic diseases, in order to reduce morbidity and mortality rates. (1)

Parathyroid hormone level in people on programmed hemodialysis

Ju Seunghwan[1], Said Ismailov[1] & Zulaykho Shamansurova[1,2]
[1]Tashkent Pediatric Medical Institute, Endocrinology with Pediatric Endocrinology, Tashkent, Uzbekistan; [2]Institute Biophysics and Biochemistry at the National University of Uzbekistan, Metabolomics, Tashkent, Uzbekistan.

Introduction
The purpose of this work was monitor the frequency of determination and compare the levels of parathyroid hormone in blood plasma in people on programmed hemodialysis.
Material and methods
Data from medical records of 465 patients on programmed hemodialysis who were admitted to the Republican Centre of Nephrology and Kidney Transplantation were analyzed. Patients according to reason of end stage of renal failure were divided into 3 groups due to chronic glomerulonephritis, diabetes mellitus and other reasons.

Results
The level of glycemia was significantly higher in the group of patients with DM, the level of creatinine, urea nitrogen, calcium, phosphorus in the blood plasma was high and no differences were found between the groups. Only 15% patients on Programmed hemodialysis PTH level in blood plasma, while 48% of them have a normal range and 52% have a higher levels of hormone.
Conclusion
Determination of the PTH level in blood plasma and early diagnosis of hyperparathyroidism in people on programmed hemodialysis were performed at an insufficient level in our study. Eliminating this fault will undoubtedly help to improve the effect of treatment and increase the life expectancy of patients.

Increased Visceral to Subcutaneous Fat Ratio is the Key to Type 2 Diabetes Pathogenesis and Treatment: New Hypothesis

Mahmoud Younis
Egypt Ministry of Health, Kafr El-Sheikh City, Egypt.

Introduction
Many researchers are linking diabetes with obesity, which has become very prevalent now, but we see large numbers of diabetics with normal weight as we see obese persons, but they are not necessarily diabetics, which calls us seriously to review this matter, taking into account that obesity is a factor in the occurrence of diabetes. Many studies have talked about visceral fat, as well as about the ratio between visceral fat and subcutaneous fat and its role in the occurrence of insulin resistance and diabetes. Here, we consider that the increase in the percentage of visceral fat, that is, the fat that is not in its right place, is an important indicator of the occurrence of this major defect in the metabolism process, which represents severe stress on the genes responsible for the metabolism process and represents severe stress on the beta cells in the pancreas.
Materials and methods
600 patients followed in a private clinic in observational prospective study. Patients have been categorized into 6 groups according to being diabetic, prediabetic, control, with normal body mass index or high body mass index.
Results
The results exhibit a statistically notable difference between overweight diabetic patients and overweight control as regards increased visceral fat to subcutaneous fat ratio with *P* value less than 0.0001. The results exhibit a statistically notable difference between overweight prediabetic patients and overweight control as regards increased visceral fat to subcutaneous fat ratio with *P* value less than 0.0001. The results exhibit a statistically notable difference between normal weight diabetic patients and normal weight control as regards increased visceral fat to subcutaneous fat ratio with *P* value less than 0.0001. The results exhibit a statistically notable difference between normal weight prediabetic patients and normal weight control as regards increased visceral fat to subcutaneous fat ratio with *P* value less than 0.0001. Most patients with diabetes and prediabetic have visceral to subcutaneous fat ratio more than 0.6 which can be considered as a cutoff point to type 2 diabetes mellitus diagnosis.
Conclusion
As type 2 diabetes grows in an epidemic way, it is a must to know the pathogenesis and find new treatment pathways. Epigenetics explain most of type 2 diabetes cases by increasing visceral to subcutaneous fat ratio.
Keywords: type 2 diabetes, visceral fat, subcutaneous fat, and epigenetics.

EP537

Keto-acidosis decompensation and centropontic myelinolysis: incidental finding-a case report

Asmae El Hafiani[1], Iraqi Hinde[1], Mohamedelhassan Gharbi[1], Rifai Kaoutar[1], Toulali Fatima[1] & El Harouni Soukaina
Ibn Sina University Hospital, Endocrinology, Rabat, Morocco.

Introduction
Centropontic myelinolysis (CPM) is a neurological pathology related to axonal demyelination lesions, often localized at the pontine level. For a long time, this condition was attributed to rapid correction of hyponatremia. A few cases of PCM with normal natraemia have been described, in a context of undernutrition, chronic alcoholism, hypokalaemia or hyperglycaemia.
Patient and observation
We report the case of an 18 years old patient, type 1 diabetic for 8 years, admitted for keto-asidosis decompensation. On admission, the patient was conscious, hemodynamically and respiratorily stable, capillary blood glucose was elevated to 6 g/l, with the presence of 3 crosses of acetone and sugar on urine dipstick. The biological workup showed a venous glucose level of 6.16 g/l, a corrected natraemia of 137 mmol/l, a kalemia of 3.7 mmol/l, and low alkaline reserves of 13 meq/l. The emergency was resolved and the patient underwent a thorough clinical examination, which revealed FTT severe staturo-ponderal delay, a micro penis and bilateral paresthesias in all 4 limbs. A hypothalamic-pituitary MRI in search of a central cause of FTT was performed, showing the presence of a pontine lesion suggestive of PCM.
Discussion
PCM was first described in 1959. Microscopically, it is a symmetrical destruction of myelin involving all nerve bundles associated with a loss of oligodendrocytes. Often, it has been attributed to a rapid correction of hyponatremia. In the case of normal natraemia, it can be hypothesized that rapid elevation of blood glucose has the same effect as a rapid infusion of hypertonic saline. MRI remains the imaging technique of choice. An effective but slow correction of the blood sugar level allows a good evolution of the clinical picture.

Morphofunctional assessment of nutritional status in patients with type 1 diabetes mellitus

Mireia García-Ramírez[1], Carlos Manuel Alzás-Teomiro[1], Ángel Rebollo-Román[1], Ana María Sánchez-Moyano[1] & Aura Dulcinea Herrera-Martínez
Hospital Universitario Reina Sofía, Unidad de Gestión Clínica de Endocrinología y Nutrición, Córdoba, Spain.

Objective
To evaluate the nutritional status in patients with type 1 diabetes mellitus (DM1) or latent autoimmune diabetes in adults (LADA).
Methods
Observational transversal clinical study in patients with DM1/LADA. Nutritional assessment was performed using bioelectrical impedance analysis (BIA), dynamometry, ultrasound of rectus femoris muscle and subcutaneous fat tissue, functional tests and laboratory parameters. Statistical analysis was performed with SPSS v.25.
Results
In our cohort, thirty-nine males were included. Mean age: 51.5 ± 13.3 years, with a mean DM evolution time of 22.2 ± 14.7 years. The prevalence of microvascular or macrovascular complications were 66.7%. 30.8% and 61.5% of the patients had high and very high cardiovascular risk, respectively. Mean BMI: 26.8 ± 3.9 kg/m2. 66.7% of patients were overweight or obese. According to the GLIM criteria, 3 patients, aged over than 60 years and with other comorbidities, were classified as malnourished. Mean value of body cell mass (BCMe) measured by bioelectrical impedance was 40.5 ± 5.3%. 35.1% of patients presented decreased standardized phase angle (SPA) (Mean 5.8 ± 1.35°). Mean lean mass: 72.8 ± 12.5%. Mean fat mass: 21.5 ± 7.4%. Mean calf circumference: 37.5 ± 3.8 cm. 12.8% had decreased hand dynamometry values (according to references values by aged groups) and the mean of the Up and Go test was 8.9 ± 2.2 seconds. In our cohort, there were not altered serum nutritional parameters. Mean value of adipose tissue thickness in rectus femoris (measured by ultrasound) was 0.8 ± 0.3 cm, with a median circumference of 9.5 ± 1.5 cm and an area of 7.1 cm^2. Abdominal adipose tissue ultrasound revealed a total thickness of 2.5 ± 0.9 cm, the median values were: superficial adipose tissue 0.69 ± 0.31 cm, deep adipose tissue 0.86 ± 0.40 cm and preperitoneal adipose tissue 0.89 ± 0.69 cm.
Conclusion
The role of morphofunctional assessment of nutritional status in the follow-up of patients with DM1/LADA is not fully established. It is necessary to continue the study of the application in daily clinical practice of emerging techniques such us nutritional ultrasound in these patients.

False informations about diabetes in arabic speaking YouTube Videos

Radhouen Gharbi, Hadami Ben Yamna, Marwa Chiboub, Sahar Abidi, Hajer Kandara, Manel Jemel & Ines Kammoun
Institut De Nutrition, Tunis, Tunisia.

Introduction
Nowadays, social media has become a valuable source of health-related information which can have an important impact on people's behaviors and

decisions regarding their diseases. To improve management of diabetes, patients often seek health information in social media platforms, including Youtube. However, the nature of its content, which anyone can upload, isn't always reliable and scientifically accurate, sometimes even misleading. The aim of this study is to analyse false informations in diabetes related youtube videos.
Methods
A YouTube query using the *search* terms "diabetes treatment" in arab language was performed at the date of January 17th 2023. The most viewed 50 videos which first appeared in the search results were included in the analysis. We assessed the veracity of informations contained in every video. The nature, publisher, and supposed aim of false informations was noted.
Results
The percentage of videos containing false informations was 63% of the total; The titles contained 75% and the "poster" 75% of misleading data. 77% of the videos were published by profiles presenting themselves as doctors. The topics containing the highest percentage of false infomaiotns were alternativs medicine (100%), dietetics (76%), Treatement (72%) and pathophysiology of type 2 diabetes (52%). 37% of the videos contained religious content, 63% encouraged diabetics to stop their medications. 49% of the posters declared negative opinions about the medical community, and the same percentage had anti-conspiracy opinions.
Conclusion
False and misleading informations are widespread in Arabic speaking diabetes related videos of youtube. Patient education should therefore include awareness that this social media should not be considered a reliable source of diabetes information and management.

Assessment of metabolic profile in type 2 diabetic patients after 12 weeks of treatment by Liraglutide

Zouaoui Chadia, Bel Hadj Sliman Chayma, Bchir Najla, Baltagi Myriam, Annam Benchhida & Haroun Ouertani
Military Hospital of Tunis, Endocrinology, Tunis, Tunisia.

Introduction
Liraglutide has been shown to have a positive effect on the glycemic and lipidic profile of diabetic patients. We aimed to assess the metabolic profile in type 2 diabetic patients after 12 weeks of treatment by Liraglutide
Methods
This is a prospective study performed at the endocrinology department of the Military Hospital of Tunis. We recruited 22 patients with type 2 diabetes (T2D) treated with insulin and/or oral antidiabetics. Liraglutide 1.2 mg was initiated subcutaneously once daily for 12 weeks to these patients. Anthropometric parameters and blood samples were collected at 0 and 12 weeks.
Results
The study population consisted of 8 male and 14 female individuals, with a mean age of 53.8 years with extremes ranging from 32 years to 66 years.. All of the patients had a body mass index indicative of overweight status, with 20 obese patients. Eight patients had hyperlipidemia, fifteen patients had hypertension and seven patients had coronary artery disease. There was no significant reduction in weight (110.7 kg vs 110.3 kg, $P=0.639$) but the reduction of body fat percentage was significant (40.7% vs 38.4%, $P=0.046$). HbA1c was significantly reduced at 12 weeks with Liraglutide (9.7% vs 8.4% $P=0.022$) but there were no significant reduction in fasting plasma glucose (12.2 vs 10.2 mmol/l, $P=0.113$). Regarding the lipidic profile, there was no significant modification in total cholesterol (4.5 vs 4.3 mmol/l, $P=0.318$), LDL cholesterol (2.41 vs 2.28 mmol/l,, $P=0.569$), Triglycerides (2.4 vs 2.3 mmol/l, $P=0.835$) and HDL cholesterol (1.1 vs 1.1 mmol/l, $P=0.71$).
Conclusion
Studies have shown that treatment with Liraglutide can lead to significant weight loss, reduction in HbA1c levels and decrease in total cholesterol, LDL cholesterol and triglycerides, which are all markers of cardiovascular risk. Liraglutide also increases HDL cholesterol. Our study supports these results in terms of glycemic control, but we did not find an improvement in the lipid profile. A study with a larger sample size is needed.

Insulin intolerance: Adipose panniculitis

Nabil Lachiheb, Elleuch Mouna, Chehaider Cyrine, Charfi Nadia, Hadj Kacem Faten & Abid Mohamed
Hedi Chaker, Department of Endocrinology, Sfax, Tunisia.

Introduction
Besides insulin allergy, several other forms of insulin intolerance are possible. Adipose panniculitis (AP) is an acute form.
Purpose
Describe the clinical, paraclinical and evolution of AP.
Clinical case
64-year-old patient, type 2 diabetic for 24 years on premixed human insulin for 10 years. He consults for itchy erythematous lesions at the insulin injection sites. The lesion begins with an immediate pruritus then appearance a few hours later of a local inflammation which increases in diameter. The examination finds an induration of 10 cm in diameter of necrotic aspect with improvement under topical corticosteroids. Several types of human insulin and analogues have been used. We eliminated an allergy to protamine, metacresol and zinc. likewise, dermographism has been eliminated. The pharmacovigilance investigation incriminated INSULATARD, ACTRAPID, APIDRA and LANTUS. Skin biopsy showed fatty panniculitis. The management was to put the patient on Lantus and Apidra with dose splitting on different sites. The evolution was favorable.
Discussion
Manifestations of insulin intolerance can occur several weeks, months or sometimes years after the start of insulin therapy. The time to onset of symptoms was very suggestive of drug origin. The evolution when the injections were stopped was marked by a regression of the inflammatory signs. Re-administrations at other sites reproduced the same lesions. It is an inflammatory panniculitis compatible with type III delayed hypersensitivity. For our patient: favorable evolution under fractionated LANTUS + APIDRA with topical corticosteroid.
Conclusion
Insulin allergy requires prompt diagnosis and management to ensure safe glycemic control.

DOI: 10.1530/endoabs.90.EP541

Hospitalization of diabetic patients: What impact on their metabolic profile?

Chaima Sdiri, Yosra Htira, Hedfi Imene, Chaima Jemai, Zohra Hadj Ali, Hajer Tertek & Feika Ben Mami
National Institute of Nutrition, Department of Nutritional Diseases and Dietetics Therapy (C), Tunis, Tunisia.

Introduction
Persons with diabetes may need to be hospitalized in order to improve diabetes balance. We aimed to evaluate the benefits from hospitalization in a diabetes department on glycemic parameters.
Method
It was a descriptive cross-sectional study conducted on diabetic patients consulting for the first time after a hospitalization in the department (C) of the National Institute of Nutrition of Tunis for the management of a poorly controlled diabetes.
Results
We included 60 diabetic patients with a mean age of 49.1 ± 16.8 years and a sex ratio (M/F) of 0.28. Type 2 diabetes affected 66% of the patients. The mean body mass index increased from 28.2 ± 5.9 kg/m^2 during hospitalization to 29 ± 5.7 kg/m^2 at the follow-up visit ($P=$NS). The mean fasting blood glucose remained stable: 11.6 mmol/l during hospitalization VS 11.2 mmol/l at the consultation while glycated haemoglobin decreased significantly from 10.2% to 9.1% ($P=0.009$). The lipid profile showed a non-significant decrease in triglyceride levels from 1.6 mmol/l to 1.4 mmol/l, a non-significant increase in total cholesterol levels from 4.5 mmol/l to 5 mmol/l.
Conclusion
Therapeutic and dietary education is a pillar of care for all hospitalized diabetic patients to achieve good glycemic control while maintaining regular outpatient monitoring.

Association of ABO blood groups with diabetic microvascular complications

Sevgul Faki[1,2], Nurcan Ince[2], Abbas Ali Tam[2], Beril Turan Erdogan[2], Neslihan Çuhacı Seyrek[2], Oya Topaloglu[2], Reyhan Ersoy[2] & Bekir Cakir[2]
[1]Ankara City Hospital, Departments of Endocrinology and Metabolism, Ankara, Turkey; [2]Ankara Yıldırım Beyazıt University, Faculty of Medicin, Departments of Endocrinology and Metabolism, Ankara, Turkey.

Background
Micro vascular complications are the major outcome of Type 2 Diabetes Mellitus progression, which reduces the quality of life and increases diabetic morbidity & mortality. As the incidence of type 2 diabetes is growing day by day; our search for its aetiology and pathogenesis is also ever growing to predict its risk factors and early screening for better care and prevention of its complications. Many studies have tried to link susceptibility of type 2 diabetes with ABO blood group though results have been inconsistent. The present study aims to analyse association of micro vascular complication with different blood groups if any.
Methods
The study included the paitents with diabetes who were hospitalized and followed up in our clinic form Dec. 2019 to April 2022. Information such as age, sex, and family history of diabetes was scanned from medical records. The blood group was determined by standard serological methods. Screening of microvascular complications done by appropriate clinical examinations and laboratory investigations.
Results
There was 348 patients with type 2 diabetesin this study, the average age of the patients was 59.3±12.8, male to female ratio was 142(40.8%)/204 (59.8%) reapectively. 246 (70.68%) patients had one or the other complications. Diabetic nephropathy, rethinopathy and neuropathy ratio was 31.3%, 35.20% ve %52.0% respectively. None of the type of micro vascular complication was found to be significantly associated with different blood groups. In addition we found that Rh (−) group had significantly low Diabetic nephropathy, rethinopathy compare to Rh (+) group ($P=0.044$ ve P 0.041).
Conclusions
Although we didn't finde a relationship between ABO blood group and diabetic microvascular complications, Rh (+) was found to be a risk factor for developing nephropathy and retinopathy.

Diabetes health promotion self-care scale: Reliability and validity of the Turkish Version

Ayfer Peker Karatoprak[1], Selda Mert[2], Yeliz Demirhan[3], Canan Baydemir[4], Mehmet Sözen[3], Levent Aydın[1], Berrin Cetinarslan[3], Zeynep Canturk[3] & Alev Selek[3]
[1]Kocaeli University, Podiatry, Kocaeli, Turkey; [2]Kocaeli University, Health Services, Kocaeli, Turkey; [3]Kocaeli University, Endocrinology, Kocaeli, Turkey; [4]Kocaeli University, Biostatistics and Medical Informatics, Kocaeli, Turkey.

This study was carried out to put the Diabetes Health Promotion Self-Care Scale for patients with Type 2 diabetes mellitus (DM) into use for nursing and medical literature. The sample of this methodological design research consisted of 620 patients diagnosed with type 2 DM. The data were collected with Personal Information Form and the Diabetes Health Promotion Self-Care Scale. In the validity and reliability stage of the scale, exploratory and confirmatory factor analyzes, and structural equation modeling was used for the item analyzes, internal consistency, and structural validity. The statistical analysis showed that the reliability coefficient of the scale was Cronbach $\alpha=0.922$. The sub-factors of the Diabetes Health Promotion Self-Care Scale consisting of 27 items and 7 sub-factors were determined as 'Interpersonal Relationships', 'Blood glucose self-monitoring', 'Personal Health Responsibility', 'Exercise', 'Diet', 'Adherence to the Recommended Regime', and 'Foot Care'. As a result of the analysis, the Diabetes Health Promotion Self-Care Scale was found as a valid and reliable scale to be applied to Turkish society.

The activation value of the renin-angiotensin-aldosterone system in the pathogenesis of late complications of DM 2

K.K. Mirzaev & Muzaffar Khaydarov
Andijan State Medical Institute, Department of Surgical Diseases and Civil Defense, Andijan, Uzbekistan.

Aim
To study the indicators of RAAS in patients with DM 2 with chronic heart failure (CHF) and diabetic foot syndrome (DFS).
Material and methods
We observed 75 patients with DM 2, CHF and DFS. Patients were distributed into 3 groups: 1 gr – patients with 2 t and neuroichemic form of DFS and CHF – 22 patients, 2 groups – patients with DM 2 and neuroichemic form of DFS without CHF – 28 patients, 3 groups – patients with CHF without DM 2 –25 patients Patients performed general clinical, biochemical, hormonal, genetic blood tests, as well as an ECG, Echo-ECG, etc. Instrumental studies, as well as statistical methods.
Results
In the study of aldosterone, its increased average values were found in all groups. In patients with CHF, the indicators are reliable than in the group of patients with DM 2. In the group of patients with DM 2 in combination with CHF, the indicators were the highest, reliably different from the indicators of patients with diabetes and unreliable in comparison with the CHF group. Renin levels in groups were significantly higher than the upper limit of the norm lying. However, it should be noted that in the DM 2+CHF group, indicators statistically reliably exceeded the indicators in the first two groups.
Conclusions
Chronic hyperglycemia and RAAS activation are pathogenetic factors that aggravate the course of CHF in patients with DM2. This, in turn, accelerates the development and progression of the late complications of DM 2, worsening the prognosis of both DFS and CHF.

DOI: 10.1530/endoabs.90.EP545

EP546

The effect of chronic kidney disease on cardiovascular outcomes in patients with DM 2

Feruza Khaydarova[1] & Kamola Alimova[2]
[1]Republican Specialized Scientific Practical Medical Center of Endocrinology of Public Health Ministry named by acad. Ya.Kh. Turakulov, Tashkent, Uzbekistan, [2]Republican Specialized Scientific Practical Medical Center of Endocrinology of Public Health Ministry named by acad. Ya.Kh. Turakulov, Department of Diabetic Nephropathy, Tashkent, Uzbekistan.

Aim
To study the role of chronic kidney disease (CKD) for cardiovascular outcomes in patients with DM 2
Material and methods
50 male patients (average age from 40 to 65 years) were identified at the time of diagnosis of DM2 with CRS from the databases of the department of diabetic nephropathy of the Center of Endocrinology named by Acad. Yo.Kh. Turakulov for the period 2022. Patients were under supervision after the diagnosis of adverse cardiovascular events – ACE- (myocardial infarction, stroke, AG, mortality), heart failure (HF) and CRC. Patients were distributed to 2 groups: 1 group – these are patients with DM2+ CKD (24 patients), 2 group – DM2+ CKD + HF + hypertension + hyperlipidemia (26 patients)
Results
CKD was associated with a higher risk of HF, mortality and ACE. This risk was more pronounced in elderly patients with the ACE in the history. ($P<0.05$). When analyzing in a general cohort in patients with DM2+ CKD + HF + hypertension + hyperlipidemia, the risk of the frequencies of the ACE was increased, HF compared to patients with DM2+ CKD. ($P<0.05$)
Conlusion
In patients with DM2, the presence of CKD was associated with a higher risk of ACE, HF and mortality.

Mediastinitis complicating cervical cellulitis in a diabetic patient

Houas Jihene[1], Bergaoui Emna[1], Ghammam Monia[1], Naouar Maroua[1], El Omri Malika[1], Bellakhdher Mouna[1], Hasni El Abed Yosra[2], Meherzi Abir[1], Kermani Wassim[1] & Abdelkefi Mohamed[1]
[1]ENT Department and Neck Surgery of Farhat Hached Hospital, Sousse, Tunisia; [2]Endocrinology Department Farhat Hached Hospital, Sousse, Tunisia.

Introduction
Cervicofacial cellulitis represents one of the most worrying infectious emergencies in ENT despite their frequency which has clearly decreased since the advent of antibiotics. From a simple infection, most often dental or in the ENT sphere, it produces an infiltration of the cellulo-adipose tissue of the face and neck with extensive necrosis of the cervical and even mediastinal aponeurotic spaces especially in diabetic patients. The management must be rapid and efficient since the vital prognosis is engaged.

Aim
To study the clinical, radiological and the therapeutic modalities of mediastinitis complicating cervico-facial cellulitis in a diabetic patient.
Observation
This is a 62-year-old diabetic man, who consults ENT emergency for a left cervical mass associated with fever and asthenia since 2 days. Respiratory and hemodynamic status were preserved. The oral examination showed a defect oral hygiene with a decayed of the 41 tooth. The left cervical swelling was 10 cm, indurated and with inflammatory signs. The initial biological assessment shows a hyper leukocytosis at 327OO, a CRP at 319 mg/l and a blood sugar level at 12 mmol/l. Cervico-thoracic scan reveals a collection in the left anterolateral cervical spaces with wide pharyngeal communication, piriform sinus, extending to the thyroid cartilage taking off the thyroid gland, perioesophageal and reaching the anterior and posterior mediastinum. The dental panoramic shows a deterioration of the 41. An emergency flattening was performed after notifying cardiovascular surgeons for a possible thoracotomy. Bacteriological examination showed a very abundant and mixed bacterial flora reminiscent of anaerobic germs. Bi-antibiotic was initiated immediately. The dental treatment was carried out. Postoperative follow-up showed an improvement of the local condition and normalization of the inflammatory assessment.
Conclusion
Cervical cellulitis in diabetics is a serious condition requiring urgent and multidisciplinary care. The clinical presentation may sometimes underestimate the extent of the infection, causing life-threatening mediastinitis.

Ramsay Hunt syndrome in a diabetic patient: A case report

Houas Jihene[1], Naouar Maroua[1], Ghammam Monia[1], Bergaoui Emna[1], El Omri Malika[1], Bellakhdher Mouna[1], Hasni El Abed Yosra[2], Meherzi Abir[1], Kermani Wassim[1] & Abdelkefi Mohamed[1]
[1]ENT Department and Neck Surgery of Farhat Hached Hospital, Sousse, Tunisia; [2]Endocrinology Department, Farhat Hached Hospital, Sousse, Tunisia.

Introduction
Ramsay Hunt syndrome or Herpes Zoster Oticus is characterized by reactivation of latent varicella zoster virus in the geniculate ganglion and subsequent spread to cranial nerve. The diagnosis is mainly clinical. The facial paralysis seen in Ramsay Hunt syndrome is often more severe with the increased rate of late neural denervation and the decrease chance of complete recovery especially in diabetic patients. The aim of this study is to focus on the association between diabetes mellitus and Ramsay Hunt syndrome.
Case presentation
A 38-year-old woman with history of diabetes mellitus, on oral antidiabetic drugs and insulin, presented to ENT emergency with 4 days history of right-sided earache followed by the development of vesicular rash involving the right pinna. Physical examination revealed right-sided grade IV facial nerve palsy. The right ear had a cluster of vesicles on the concha and antihelix associated to perforated tympanic membrane in the otoscopy. Audiometry was normal. Random blood sugar was 18.3 mmol/l. We made a diagnosis of Ramsay Hunt syndrome and administered acyclovir 500 mg 4 times daily for 12 days and solumedrol 80 mg daily for 10 days. Two weeks after initiation of the treatment vesicular lesions disappeared but neurological examination revealed right-sided grade II facial nerve palsy. Blood sugar was well controlled.
Conclusion
Ramsay Hunt syndrome is one of the least frequent causes of facial palsy, inducing severe dysfunction and of poorer prognosis for the facial nerve than Bell's palsy. Associated acyclovir and high-dose corticosteroids with well controlled blood sugar improve facial nerve functional recovery in diabetic patients.

Nasal septal abscess in patients with type 2 diabetes mellitus: A report of 2 cases

Houas Jihene[1], Naouar Maroua[1], Ghammam Monia[1], Bergaoui Emna[1], El Omri Malika[1], Bellakhdher Mouna[1], Hasni El Abed Yosra[2], Meherzi Abir[1], Kermani wassim[1] & Abdelkefi Mohamed[1]
[1]ENT Department and Neck Surgery of Farhat Hached Hospital, Sousse, Tunisia; [2]Endocrinology Department Farhat Hached Hospital, Sousse, Tunisia.

Introduction
A nasal septal abscess (NSA) is defined as a collection of pus between the cartilage or bony septum and its mucoperichondrium or mucoperiostium. NSA caused by uncontrolled diabetes mellitus are rare. The aim of this study is to focus on the association between diabetes mellitus and NSA.
Materials and methods
We report two rare cases of NSA in patients with type 2 diabetes mellitus collected in ENT department of Farhat Hached Hospital of Sousse over a period of 10 years.
Results
Case one was a 80-year-old woman, with history of diabetes mellitus, hypothyroidism and on oral hypoglycemic medication, presented with a nasal block and purulent nasal discharge for 6 days. There was no history of trauma, sinusitis or any surgical procedures. Direct nasoendoscopy showed a bilateral septal swelling at the anterior aspect. Random blood sugar was 20.3 mmol/l. She had a surgical incision and drainage. The patient was started on IV cefotaxime and metronidazole than Clindamycin. She was started on sliding scale insulin for rapid blood sugar control. The microbiological examination showed *Staphylococcus aureus*. The follow-up was marked by the recurrence of the NSA leading to a revision surgery. No reccurence was noted. The second case was a 47-year-old man, with history of diabetes mellitus, on oral hypoglycemic medication, presented with an inflammatory nose swelling associated with bilateral nasal obstruction. He had no history of sinusitis, trauma or surgery. On examination, the patient had a fever at 39°c. The tip the nose showed localized edema and erythema with a healed carbuncles. Direct nasoendoscopy revealed bilateral septal swelling at the anterior aspect and bilateral inferior turbinate hypertrophy. Random blood sugar was 23 mmol/l. The treatment consisted on a surgical drainage and intravenous antibiotic therapy (cefotaxime and metronidazole). He was started on sliding scale insulin for rapid blood sugar control. Bacteriological examination showed *Staphylococcus aureus*. We noted the recurrence of the NSA within 7 days leading to a revision surgery. No reccurence was noted.
Conclusion
Nasal septal abscess is a rare condition. However uncontrolled diabetes should be considered as a condition in any patient with nasal septal abscess when trauma is excluded. Therefore prompt treatment should be given to prevent serious cosmetic nasal deformity and intracranial complications.

Hypoglycemia in type 2 diabetes: Assessment of knowledge and fears

Sabrina Ayari, Faten Mahjoub, Selma Mohsen, Nadia Ben Amor, Ramla Mizouri, Rym Ben Othman & Jamoussi Henda
Institut de Nutrition de Tunis, Service A, Tunis, Tunisia.

Recurrent hypoglycemia is a major clinical problem. In fact, it disrupts blood glucose regulation and greatly impacts the daily lives of those affected. Maintaining glycemic balance is a real challenge indiabetic patients. The objectives of the study were to determine the prevalence of hypoglycemia in type 2 diabetics and to evaluate their knowledge.
Patients and methods
This was a cross-sectional study conducted among 120 type 2 diabetic patients followed at the outpatient clinic of the A service at the National Institute of Nutrition in Tunis. We evaluated the prevalence of hypoglycemia, their knowledge, clinical and biological characteristics of the patients, as well as methods of first line treatment of hypoglycemia and assessing fear of the risk of hypoglycemia using the HFS-II (Hypoglycemia Fear Survey-II) questionnaire.
Results
Our population consisted of 46 men and 74 women. The mean age was 58.4 ± .13.9. The average duration of diabetes was 12.1 years, the mean HbA1c was 9.85%. Only 25% of patients knew the definition of hypoglycemia and only 50% of them had a glucose meter. Among the studied patients, 43.3% had at least one episode of hypoglycemia in the month preceding the study. Adequate first line treatment in hypoglycemia was performed by only 16.6% of patients. Furthermore, the higher the HFS 2 Score, the more unbalanced the diabetes was ($P = 0.02$).
Conclusion
Preventing hypoglycemia is necessary in order to achieve good glycemic balance, hence the interest in therapeutic education that must be established early and regularly re-evaluated.

Retropharyngeal abscess in diabetic patient: Management challenge

Houas Jihene[1], Lazid Sarra[1], Ghammam Monia[1], Kechiche Jawaher[1], El Omri Malika[1], Bellakhdher Mouna[1], Hasni El Abed Yosra[2], Meherzi Abir[1], Kermani Wassim[1] & Abdelkefi Mohamed[1]
[1]ENT Department and Neck Surgery of Farhat Hached Hospital, Sousse, Tunisia; [2]Endocrinology Department Farhat Hached Hospital, Sousse, Tunisia

Purpose
Retropharyngeal abscesses are rare in adults. They most commonly occur in immunocompromised patients as well as older one with systemic diseases like diabetes mellitus. The aim of this study is toidentify the clinical presentation of retropharyngeal abscesses and therapeutic challenges in diabetic patient.
Case report
It is about a 50-year-old man, diabetic (DNID) who consulted us for intense cervicalgia, odynophagia and mixed high dysphagia associated with fever. The patient received oral antibiotic treatment without any improvement. The physical examination found an apyretic and eupneic patient. Oropharynx examination noted halitosis and bulging of the anterior left wall. Neck examination revealed a tender left sided mass of 4 cm. Biological assessment revealed increased white blood cell counts and high sugar blood level. An urgent neck and chest CT scan showed a retropharyngeal circumferential fluid collection more pronounced on the left from the oropharynx down to the hyoid bone, with an important oedema of the vallecula and the epiglottis. Without extending into the mediastinum. The patient underwent early transoral drainage under general anaesthesia with intravenous antibiotic therapy (ceftriaxione + flagyl). Through the first week of hospitalization, blood sugar rates were out of balance. We noted the decrease of the cervical mass however the patient still complained about difficulty swallowing in solid food. A CT scan control at j10 of treatment revealed the increase of the retropharyngeal collection responsible for a significant mass effect on the aero digestive chain. That extend into the superior and posterior mediastinum. Revision surgery was required with transoral drainage and insertion of a tube feed. It was imperative to have the patient restrict oral intake until swelling resolves completely. Per operative bacteriological samples isolated klebsiella pneumonia resistant to cerftriaxone, thus we had to change the treatment by piperacillin–tazobactam. After one month of intravenous tazoactam therapy, we noted a visible clinical improvement and Cervical CT control showed total resolution of the retropharyngeal collection. The patient was discharged after 40 days of hospitalization. One month follow up, the outcome was favourable.
Conclusion
Retropharyngeal abscesses can quickly become a life-threatening emergency. Treatment consists of broad-spectrum antibiotics along with surgical drainage. Management in diabetic patient remains an interdisciplinary challenge including the expertise of specialists in otorhinolaryngology,endocrinologist, radiology, and microbiology.

EP552

Multiple fingers with multiple endocrine disorders

Omer Elawad
Faculty of Medicine, University of Gezira, Internal Medicine, Sudan

Background
Bardet–Biedl syndrome is a rare multisystem autosomal recessive disorder that falls under the spectrum of ciliopathy disorders. This ciliopathy is characterized by rod–cone dystrophy, renal malformations, polydactyly, learning difficulties, central obesity, and hypogonadism [1]. It was first described by Bardet [*2*] in 1920 and then by Biedl [*3*] in 1922. Its prevalence in Europe and North America is 1:100 000 [*4*]. The incidence of this syndrome is higher in the Faroe Islands and Kuwait, with 1:3700 and 1:17 000 live births, respectively [*5*]. According to the diagnostic criteria published by Beales *et al*., the diagnosis of BBS is based on the presence of at least four primary features or three primary features and at least two secondary features [*2*]. The management of BBS is supportive through a multidisciplinary team approach.
Case presentation
A 50-year-old single man presented to a university hospital, complaining of easy fatigue. The patient began to develop night blindness at the age of 7 years, and by the age of 15, he had entirely lost his vision. He had been diagnosed with diabetes mellitus for the preceding 6 years, and he had been managing it with insulin therapy and was experiencing frequent attacks of hypoglycemia. There is a history of polydactyly and visual impairment in the family. On physical examination, the patient was pale. He was 175 cm tall and 96 kg heavy, with a BMI of 31.3 kg/m^2, indicating obesity. His vital signs were normal. Fundus examination showed features of retinitis pigmentosa. Examination of the extremities showed post-axial polydactyly in both the upper and lower limbs. Laboratory investigations showed normochromic normocytic anemia, features of subclinical hypothyroidism, and a high renal profile. Abdominal ultrasonography revealed bilateral small kidney size, and echocardiography showed left ventricular hypertrophy. The diagnosis of BBS was made on the basis of the presence of four items of primary features (obesity, retinitis pigmentosa, post-axial polydactyly, and renal abnormalities) in addition to two secondary features (diabetes mellitus and left ventricular hypertrophy).
Conclusion
BBS is a rare clinical syndrome that may go unnoticed by many clinicians. Increased awareness among physicians is required for the early diagnosis and treatment of Bardet–Biedl syndrome and to avoid complications and mortality. The combined presence of post-axial polydactyly, blindness, learning disabilities, renal malformations, and obesity in a diabetic patient should alert to the possibility of BBS.

Criteria for metabolic syndrome and assessment of biochemical indicators

Olga Moskalenko & Edward Kasparov
Research Institute of Medical Problems of the North – a separate subdivision of the FRC KSC SB RAS, Krasnoyarsk, Russia

Metabolic syndrome (MS) is an actual problem of modern medicine. It is known that the prevalence of MS varies depending on the criteria used to determine it. It should be noted that the main criterion for MS is the central (abdominal) type of obesity. It is necessary to adapt the existing diagnostic criteria for MS in Russia, because it is necessary to take into account ethnic and genetic differences, national nutritional characteristics in the Russian population, lifestyle and economic opportunities. The purpose of the study: to evaluate the biochemical parameters and criteria for the metabolic syndrome.
Materials and methods
The study included 76 MS patients and 41 apparently healthy volunteers. The glucose level was determined by the glucose oxidant method, the lipid profile was assessed, and standard test systems were used. Insulin was determined by enzyme immunoassay using the DRG test system. All study participants signed an informed consent approved by the ethics committee. Statistical data processing was carried out using the application packages "Statistica for Windows 8.0".
Results
The results obtained show an increase in insulin resistance index (HOMA-IR) values with an increase in glucose or fasting insulin levels. This coefficient is of the greatest diagnostic value and has received wide practical application. The calculation of HOMA-IR revealed an almost 2-fold increase in this indicator in patients with MS ($P<0.05$), which is a predictor of the risk of developing vascular and diabetic complications. The level of NEFA in patients with MS was increased in 95% of cases and was almost 2 times higher than the norm. Also, in patients with MS, there was an increase in the level of insulin and glucose in the blood in comparison with the control group ($P<0.05$).
Conclusion
The study shows that early diagnosis of MS is important for providing timely medical care and lifestyle correction (weight loss, dietary changes, regular physical activity) and preventing the development of severe vascular and diabetic complications.

Metabolic profile of morbid obesity compared with moderate and severe obesity: About 72 cases

Hanae Bakmizi[1], Hanae Rachedi[1], Siham Rouf[2] & Hanane Latrech[2]
[1]Endocrinology, Diabetology and Nutrition Department, University Hospital Center Mohammed VI, Oujda, Morocco; [2]Department of Endocrinology, Diabetology And Nutrition, Laboratory of Epidemiology, Clinical Research and Public Health, Faculty of Medicine and Pharmacy, Mohamed I University, Oujda, Morocco

Introduction
Obesity is currently a public health problem due to its worrying increase in prevalence over the last ten years. The management of obesity and associated comorbidities is therefore a priority. The WHO classification distinguishes 4 types of obesity according to BMI in terms of severity.
Patients and methods
Retrospective study including 72 obese patients hospitalized and followed at the Endocrinology-Diabetology and Nutrition Department of the Mohamed VI

university hospital Oujda Morocco, divided into 2 groups, G1: 36 cases (BMI: 30 to 40 kg/m^2), G2: 28 cases (BMI $\geq$ 40 kg/m^2). Over a period of 2 years (from September 2020 to September 2022). Clinical and paraclinical data were collected from the patients' medical records. The analysis was performed by SPSS Version 21 software, and the threshold: $P<0.05$ was considered significant.
Results
In G1, the mean age of the patients was 33.19 $\pm$ 15.78 years and 39.61 $\pm$ 13.82 years in G2. A female predominance was noted in both groups, sex ratio F/H (G1): 3 and (G2): 8.33. The mean BMI in G1 was 35.56 $\pm$ 2.87 kg/m^2 and 47.01 $\pm$ 5.16 kg/m^2 in G2. The mean waist circumference was higher in G2: 131.98 $\pm$ 14.99 cm compared to G1: 113.71 $\pm$ 13.94 cm. The prevalence of diabetes was 27.77% (G1) and 28.57% (G2) ($P > 0.05$). The prevalence of hepatic steatosis was 52.94% (G1) and 48% (G2). The mean uricemia was 54.42 $\pm$ 14.59 mg/l (G1) and 65.47 $\pm$ 12.41 mg/l (G2). In contrast, the prevalence of dyslipidemia was significantly higher in the morbidly obese group (35.71%) compared to the moderate to severe obesity group (30.55%).
Conclusion
About Obesity is a complex chronic disease in which abnormal or excessive body fat (adiposity) impairs health, increases the risk of long-term medical complications and shortens life span. Our study demonstrates obesity increase metabolic risk whatever its severity.

The association of cortisol secretion and body weight in overweight and obese patients

Angelika Buczyńska[1], Katarzyna Łuka[2], Ewa Duraj[3], Maria Kościuszko[2], Paweł Mierzejewski[2], Aleksandra Wiatr[1], Agnieszka Adamska[2], Katarzyna Siewko[2], Adam Krętowski[1,2] & Anna Popławska-Kita[2]
[1]Medical University of Bialystok, Clinical Research Centre, Bialystok, Poland; [2]Medical University of Bialystok, Department of Endocrinology, Diabetology and Internal Medicine, Bialystok, Poland; [3]Medical University of Bialystok, Department of Periodontal and Oral Mucosa Diseases, Bialystok, Poland

Recently, 59 percent of European adults was diagnosed with obesity or overweight according to the 2022 Regional Obesity Report presented by the World Health Organization (WHO). Thus, insight into factors implicated in overweight and obesity may have important therapeutic implications. Interestingly, increased cortisol secretion and psychosocial stress have been demonstrated to be related with body weight-dependent insulin resistance and beta cells failure. Thus, the study was performed to assess the association of cortisol secretion, insulin resistance, and pancreatic beta cell failure occurrence. For the purpose of this study, 200 overweight and obese subjects (BMI $>$ 25 kg/m^2) and 50 healthy volunteers (BMI $<$ 25 kg/m^2) were enrolled. Study population was divided according to BMI values (into overweight (O1; BMI $>$ 25 kg/m^2) and obesity (O2; BM $>$ 30 kg/m^2)), homeostatic model assessment (HOMA) for insulin resistance (HOMA-IR) results (cut of 2). Simultaneously, among O1 and O2 study groups, the beta-cell function was assessed, and patients with pancreatic beta cell failure were appointed following HOMA estimates steady state beta cell function (HOMA-B) levels. The cortisol and adrenocorticotropic hormone (ACTH) concentrations were determined at Cobas E411 Roche device. The HOMA-IR and HOMA-B values were increased among O1 and O2 study groups comparing to control group ($P<0.05$, all). The cortisol concentration was increased in O2 comparing to control group ($P<0.001$). There were no differences in cortisol secretion in the O1 and control group. Nevertheless, comparing result obtained from patients among O1 and O2 groups with insulin resistance, the O1 patients were characterized with higher cortisol concentrations ($P<0.03$). Moreover, similar result was obtained among O1 and O2 patients characterized by pancreatic beta cell failure occurrence, where O1 patients were observed with increased cortisol secretion ($P<0.05$). The studied groups did not differ in ACTH concentrations. Based on the presented results, it can be assumed that obesity combined with insulin resistance or pancreatic beta cell insufficiency is associated with increased cortisol secretion.

Child nutrition and the prevalence of obesity among the youth in Uzbekistan

Malika Rakhmetova
Tashkent Medical Academy Urgench Branch, General Medicine, Urgench, Uzbekistan

We examined the nutrition of 300 children aged 5–7 in households, preschool and school institutions and established that, surprisingly, that children's prescribed diet in the institutions includes a daily consumption of sweet tea, fruit compotes, cocoa and sweet carbonated drinks, and that the favorite food of children is sweet and fatty confectionery. An indispensable attribute of a typical school is a nearby retail outlets that profit from the desire of children to buy bright, cheap, but unhealthy low-quality sweets. Earlier studies of obese adults show that up to 35% of them suffered from obesity from early childhood. Considering that Uzbekistan is a country with a relatively young population (the average age in 2017 being 28.5 years), one can extrapolate a significant increase in obesity levels given these diets. In addition to school and household diets, the rollback of breastfeeding practices and the early introduction of complementary foods and cow milk contributes significantly to the predominance of childhood obesity. In Uzbekistan, the traditionally favored family model being many children (mostly one every two years), full breastfeeding of the newborn becomes a challenge, contributing to childhood obesity.

Correlation of education levels with obesity and its treatment in Uzbekistan

Malika Rakhmetova
Tashkent Medical Academy Urgench Branch, General Medicine, Urgench, Uzbekistan

We studies the correlation between levels of educational attainment and the prevalence of obesity, as well as the effectiveness of its treatment surveying 200 patients of the Khorezm endocrinology dispensary in Urgench, Uzbekistan in March-October 2022. Lowest prevalence of obesity is, unsurprisingly, observed among the group with the highest educational attainment – in this group pre-obesity and 1st degree obesity prevail. Noteworthy, however, is a trend towards higher obesity among the educators and medics in that group, presumably due to the spread of IT technologies in Uzbekistani healthcare and educational facilities and its contribution to sedentary workplace. Professions typically associated with high levels of physical activity registered lowest levels of obesity prevalence – notably construction workers with only 0.09%. Among the professions cited obesity was most prevalent (78%) among drivers, with cooks (72%) and entertainers (67%) following them. Among state officials and public employees, a decrease in obesity prevalence could be registered, while the unemployed did not exhibit any significant trend. For the latter, given the predominance of housewives among the unemployed of Uzbekistan and given that they typically are not university graduates, one could extrapolate a trend towards obesity also in that group.

Hirsutism and anthropometric parameters in obese Tunisian women: A correlation study

Bel Hadj Sliman Chayma, Nadia Ben Amor, Faten Mahjoub, Berriche Olfa, Ben Ali Khaoula, Rym Ben Othman, Ramla Mizouri, Gammoudi Amel, Kacem Awatef & Jamoussi Henda
National Institute of Nutrition, Service A of Diabetology and Nutrition, Tunis, Tunisia

Introduction
Hirsutism is a common disorder that occurs in 5% to 10% of women of reproductive age. The aim of this study is to evaluate the relation between anthropometric parameters (AP) and hirsutism in Tunisian obese woman.
Methods
A descriptive cross-sectional study was conducted at the obesity unit of the national institute of nutrition of Tunis including 65 obese women of reproductive age. data were collected by questioning, examining the patient and from medical records. The Ferriman-Gallwey score was used to evaluate hirsutism. Hirsutism was defined by a score higher than eight. Our population was divided into 2 groups: 26 hirsute women (H+) and 39 healthy women as a control group (H−). The AP considered were: weight, body mass index (BMI), waist circumference (WC) and body fat percentage (BFP). Testosteronemia was measured in hirsute women.
Results
The mean age of patients was 33.3 $\pm$ 10.8 years. Menstrual disorders were reported in 32.3% of cases. Morbid obesity was found in 34.9% of cases. Significantly higher differences between H+ and H− groups were shown regarding mean weight

(107.3 ± 25.5 versus 93.6 ± 14.7 kg; $P = 0.005$), mean BMI (40.5 ± 8.4 kg/m^2 versus 35.4 ± 5.5 kg/m^2; $P = 0.008$), WC (121.3 ± 17.1 cm versus 107.2 ± 11.7 cm; $P = 0.005$) and BFP (48.2 ± 7.1% versus 44.3 ± 4.6%; $P = 0.03$). A BMI above 36.9 kg/m^2 (OR = 5.4; $P = 0.004$), a WC above 109 cm (OR = 9.3; $P = 0.004$) and a BFP above 109 cm (OR = 6.9; $P = 0.005$) were significantly associated with the presence of hirsutism. In hirsute women, The mean blood testosterone level was 0.3 ± 0.2 ng/ml and there was a correlation between Testosteronemia and Weight ($P = 0.019$).

Conclusion

Our study clearly shows that hirsute women had higher AP. In fact, adipose tissue is implicated in the production of androgens. Therefore, weight loss of obese and overweight is strongly recommended.

Eating disorders in an obese Tunisian population: Clinical and nutritional aspects

Zeineb Zemni, Nadia Ben Amor, Faten Mahjoub, Imen Ouderni, Eya Safi, Ben Ali Khaoula, Rym Ben Othman, Ramla Mizouri, Berriche Olfa & Jamoussi Henda

National Institute of Nutrition of Tunis, Obesity Research Unit, Bab Saadoun, Tunis

Introduction

Eating disorders (ED) are very frequent in the obese population. Our objective was to describe the relationship between ED and the characteristics of an obese population (food intake, anthropometric measurements, cardiometabolic complications).

Methods

Cross-sectional descriptive study of 100 obese Tunisian patients followed at the obesity unit of the National Institute of Nutrition of Tunis.

Results

The mean age was 46.66 ± 12.32 years. The sex ratio M/F was 0.23. The average BMI was 40.3 ± 6.58 kg/m^2. Obesity class I, class II and morbid obesity were noted in 23.5%, 30.5% and 46% of cases, respectively. ED was noted in 84.3% of the cases and was dominated by snacking, compulsive eating, binge eating, night eating syndrome and bulimia in 53%, 52%, 48%, 36.3% and 22.5% respectively. We noted a significant association with the presence of at least one ED and the stage of obesity ($P = 0.036$). Patients with at least one ED had significantly higher energy, carbohydrate and simple carbohydrate intake than those without ED ($P = 0.011$, 0.001, 0.011 respectively) reflecting the poor dietary quality associated with ED. No significant association was found between APCs, anthropometric measurements and metabolic and cardiovascular complications apart from hypertriglyceridemia ($P = 0.012$).

Conclusion

The prevalence of APD is high in obese patients and is associated with poor dietary quality that leads to therapeutic failure. Our results are in agreement with those of DEDENON-MAYER(1).

Complications of obesity in adolescents: About 18 cases

Hanae Bakmizi[1], Soumiya Berrabeh[1], Salma Derbel[1], Hanae Rachedi[1], Siham Rouf[2] & Hanane Latrech[2]

[1]Endocrinology, Diabetology and Nutrition Department, University Hospital Center Mohammed VI, Oujda, Morocco; [2]Department of Endocrinology, Diabetology and Nutrition, Laboratory of Epidemiology, Clinical Research and Public Health, Faculty of Medicine and Pharmacy, Mohamed I University, Oujda, Morocco

Introduction

Adolescent obesity is a public health problem because of its prevalence and severity. It is a phenotypically heterogeneous disease and evolving in several phases (constitution, maintenance, aggravation) whose determinants are multiple. The great diversity of comorbidities and complications that can be experienced as a result of obesity makes all seriousness.

Patients and methods

Retrospective study including 18 obese adolescents hospitalized and followed at the Department of Endocrinology-Diabetology and Nutrition of the CHU Mohamed VI OUJDA, over a period of 2 years (from September 2020 to September 2022). Patients received an interview, a clinical examination and a biological assessment to rule out secondary obesity. Data were collected from medical records. The analysis was performed by SPSS Version 21 software, and the threshold: $P < 0.05$ was considered significant.

Results

The median age was 15.33 ± 3.30 years. The average BMI was 35.05 ± 6.61 kg/m^2. 6% of patients had overweight, 33% of patients had moderate obesity and 27% had severe obesity and 33% had morbid obesity. % of adolescents were in the dynamic phase of obesity. Complications were dominated by metabolic syndrome (29.41%), the average waist circumference was 110.29 ± 19.24 cm, 33.3% had hypoHDLemia, 22.2% had hypertriglyceridemia, 26.6% had prediabetes and 47.05% had hyperuricemia. Osteoarticular and pulmonary complications affected 17.6% and 17.6% of adolescents, respectively. Digestive complications such as fatty liver disease and GERD were noted in 5.8% and 11.1% of cases, respectively. None of the patients had Obstructive sleep apnea syndrome (OSAS) however 35.29% suffered from nocturnal snoring. The immediate consequences are often psychosocial.

Conclusion

These results justify the imperative of early and adequate management of obesity better than prevention, which must begin very early. Given the emergence of obesity among adolescents, preventive strategies are necessary, particularly targeting high-risk youth.

The interplay between vitamin D deficiency and tuberculosis in patient with type 2 diabetes

Iryna Kostitska[1] & Iryna Makoida[2]

[1]Ivano-Frankivsk National Medical University, Endocrinology, Ivano-Frankivsk, Ukraine, [2]Ivano-Frankivsk National Medical University, phthisiology and pulmonology with the course of occupational diseases, Ivano-Frankivsk, Ukraine

Introduction

The world medical community is strongly concentrated on the fight against infectious diseases, such as COVD-19, HIV/AIDS and tuberculosis (TB), but non-communicable diseases diabetes and complications "have relatively imperceptibly come to the fore in developing countries, becoming a global problem." The common multimorbidity disorders are evidence to suggest that, TB and vitamin D deficiency in patients with type 2 diabetes leads to disease clustering, frailty, and poor health-related quality of life.

Case report

A 62-year-old male has been suffering from type 2 diabetes for a long time complained of non-productive mild cough, low-grade fever, fatigue. A nasopharyngeal swab test for SARS-CoV-2 was negative. The patient consulted a tuberculotherapist. After the follow-up examination complete blood cell count, chest X-ray, sputum smear microscopy, genetic-molecular study with GeneXpert-test and culture test on the BACTEC system, the subject was diagnosed with disseminated TB with bacterial excretion, susceptible. The level of glycosylated hemoglobin (HbA1C) was 8.4%, glucose in the blood levels ranged from 3.2 to 15.4 mmol/l, 25-(OH)D_3 − 9.2 ng/ml, that severe vitamin D deficiency. The patient received treatment according to the 2HRZE 4HR scheme. At the patient's request, he continued to receive of antihyperglycemic drugs: metformin 2000 mg/day, sitagliptin 100 mg/day, but after one month therapy patient was given injection degludec/liraglutide at a daily dose of 10 units administered subcutaneously. The person is prescribed 20 000 IU/daily during 3 months. The result – the treatment was completed, whereas the cavern was preserved, the patient refused to undergo surgical treatment. After 3 months repeated laboratory tests were normal levels HbA1C was 7.1% without episodes of hypoglycemia and 25-(OH)D_3 − 20.2 ng/ml. The therapy resulted in patient's improvement of the general conditions and compensation of carbohydrate metabolism and vitamin D status.

Conclusion

Our clinical case suggests that the temporal relationship between significant deficiency vitamin D and the poor glycemic profile (HbA1C) in person with type 2 diabetes. TB programmes need to pay more attention to vitamin D status in the patients if there is coexisting diabetes. Particularly the association between vitamin D deficiency with prognosis of tuberculosis in patients with type 2 diabetes should be addressed through a future studies.

Case of Severe (Familial) Hypertriglyceridemia with Metabolic Syndrome

Naia Lataria
Acad. Bochorishvili Clinic, Endocrinology, Tbilisi, Georgia

Introduction
Severe hypertriglyceridemia is a condition when triglycerides levels are over 500 mg/dl. It is serious risk-factor for cardiovascular disorders and acute pancreatitis. Especially in combination with glucose intolerance, abdominal obesity, and fatty liver.
Case
We present case of 27 y.o male with Severe Hypertriglyceridemia and Metabolic syndrome. 27 y.o male presented to clinic with several years of untreated Severe Hypertriglyceridemia history. He refused to take fenofibrate for years, but his triglycerides levels even on fenofibrate were never below 500 mg/dl.
Family history
Mom and Dad with Slightly elevated triglycerides and little brother with severely elevated triglycerides. Although Genetic testing was not done, we suppose that it is Familial Hypertriglyceridemia. He gained 20 kg past year. Height – 186 cm, Weight – 100 kg, BMI – 28.9 kg/m2. Waist circumference – 115 cm.
Laboratory Data: Triglycerides – >2625 mg/dl,
T-Cholesterol – 249 mmol/l,
HDL – 13 mg/dl,
LDL – 30.16 mmol/l,
VLDL – No results,
AI – 17.42.
HBA1c – 5.4%,
Glucose – 5.38 mmol/l,
Insulin Resistance index – 2.4,
Basal Insulin – 127.9 pmol/l.
TSH – in normal range.
Prescription
1. Lifestyle intervention (Healthy Eating Plan)
2. Fenofibrate – 145 mg daily
3. Rosuvastatin – 20 mg daily
4. Fish Oil – 4 g. daily
5. Metformin – 1000 mg daily
Follow-up after 2 months (January, 2023): 1. Weight loss – 10 kg. Height 186 cm, weight – 90 kg, BMI – 26.0 kg/m^2. Waist Circumference – 107 cm.
T-Cholesterol – 157.77 mg/dl
HDL – 27.456 mg/dl,
LDL – 69.6 mg/dl,
Triglycerides – 313.55 mg/dl,
VLDL – 62.64 mg/dl
AI – 4.75.
HBA1c – 5.4%,
Glucose – 4.95 mmol/l,
Insulin Resistance index – 2.19,
Basal Insulin – 119.6 pmol/l.
Patient continues healthy lifestyle modifications in his everyday living and Pharmacologic therapy without changes. Follow-up check-up in 3 months.
Conclusion
It is very important to increase awareness about hypertriglyceridemia and importance of dietary changes and pharmacological therapy especially in patients with familial hypertriglyceridemia and metabolic syndrome.

EP563

Finerenone reduces Albuminuria in a non-diabetic female with congenital lipodystrophy

Rana Almudhammed
Diyala College of Medicine, Baghdad, Iraq

Introduction
Chronic Kidney disease is one of the leading causes of morbidity and mortality worldwide especially among people with diabetes. Finerenone is non-steroidal emerging mineralocorticoid receptor Finerenone has proved to reduce albuminuria and delay the progression of CKD and reduce the cardiovascular risk in non-diabetic population. It is not known whether finerenone has the same effect in non-diabetic CKD. I used finerenone in a case of microalbuminuria in a female diagnosed with congenital lipodystrophy (images available) with normal HbA1c and preserved e GFR. Congenital Lipodystrophy is a group of genetic disorders characterized by severe insulin resistance and loss of adipose tissue with subsequent fat accumulation in the heart, kidneys, liver and ovaries. 22-year-old female presented with acromegalic facies lean body habitus and severe acanthosis nigricans. Her labs showed significantly elevated triglyceride more than 1000 mg/dl HbA1c 5.7%, Albumin-creatinine ratio was 50 mg/g, e-GFR was 120 ml/min, replacement of metreleptin isn't available in my country so I had to delay the progression of her albuminuria. She was given Finerenone 20 mg based on her serum potassium once daily for 3 months. After 3 months her albuminuria declined to 23 mg/g.

New onset diabetes mellitus after dexamethasone treatment for intracranial hypertension in a case of severe acromegaly

Daniela Telehuz[1,2], Ioana Rada Ilie[2], Cornelia Bala[3] & Gabriela Roman[1]
[1]Emergency Clinical County Hospital Cluj, Diabetes and Nutrition Diseases, Cluj-Napoca, Romania; [2]Emergency Clinical County Hospital Cluj, Endocrinology, Cluj-Napoca, Romania

Introduction
Glucocorticoids are hormones that are used extensively in medicine for their anti-inflammatory and immunomodulatory effects. New onset diabetes mellitus is a frequent complication and is the result of an activation of glucocorticoid receptors which stimulate hepatic gluconeogenesis, adipose tissue lipolysis and increase the insulin resistance.
Case presentation
We present a case of a 49-year-old Ukrainian female who in 2015 started having headaches and a decrease in visual acuity. The dysmorphic features at the clinical exam were suggestive of acromegaly and an invasive 3 cm pituitary adenoma was found. The tumor was partially resected in 2015 in Ukraine, then the patient stopped seeing her endocrinologist until 2020, when an MRI showed an invasive 4 cm pituitary tumor. A somatostatin analogue treatment was introduced with poor medical adherence. The treatment was again interrupted in February 2022 due to drug shortage after the outbreak of Ukraine War. In April 2022 the patient was hospitalized in Romania and an IGF-1 of 837 ug/ml was detected. The MRI showed a minimal tumoral growth compared to 2020. A second neurosurgical intervention was refused because of major risks. A somatostatin analogue treatment was reintroduced along with growth hormone receptor antagonist and a dopamine agonist. Conventional radiotherapy was conducted during which the patient developed intracranial hypertension that required Dexamethasone. Blood sugar was monitored regularly during corticoid treatment and in July 2022 the patient developed diabetes mellitus (glycaemia 600 mg/dl, HbA1c 7.78%) that required basal bolus insulin regimen and Metformin. Dexamethasone was switched for Prednisone then it was gradually reduced and interrupted in august 2022. The insulin was interrupted in October 2022 and the Metformin treatment was continued because of a persistent impaired fasting glycaemia. The MRI at 3 months after radiotherapy shows a tumoral reduction compared to April 2022 (35/28/40 mm vs 35/30/47 in April 2022) and an IGF-1 value of 258 ng/ml, still slightly above the upper limit, so Pegvisomant was increased.
Conclusion
Glucocorticoids are very useful for their anti-inflammatory effect but they are associated with a wide range of side effects including disturbances of the carbohydrate metabolism, due to their stimulation of glucocorticoid receptors with a diabetogenic effect in different organs. New treatments that could retain the anti-inflammatory properties without having the diabetogenic effects are currently being researched. Selective glucocorticoid receptor agonists and 11beta-Hydroxysteroid dehydrogenase type 1 inhibitors are currently being tested in clinical trials but they show limited efficacy.

A case report on hypertriglyceridemia induced pancreatitis

Furhana Hussein[1], Man-Yan Cheung[2], Gideon Mlawa[3] & Mahamud Bashir[4]
[1]Queen's Hospital, Endocrinology and Diabetes/Acute Medicine, London, United Kingdom, [2]Queen's Hospital, Acute Medicine, London, United Kingdom, [3]Queen's Hospital, Endocrinology and Diabetes, London, United Kingdom, [4]Queen's Hospital, London, United Kingdom

Introduction
Acute pancreatitis is an inflammatory disease of the pancreas that can lead to necrosis of the pancreas and if infected could lead to multi-organ failure. Common cause of acute pancreatitis are gallstones and excess alcohol consumption. Hypertriglyceridemia is becoming an increasing cause of acute pancreatitis and is diagnosed with serum triglyceride levels >1.7 mmol/l. It is associated with high morbidity and mortality.
Case presentation
38-year-old male was admitted with left upper quadrant abdominal pain radiating to the back and vomiting. He was haemodynamically stable but was tachycardiac and

pyrexic. Past medical history of Diabetes Mellitus type2 on gliclazide and metformin, hypercholesteremia and hypertriglyceridemia on atorvastatin. However, he was not compliant with medication. He would on occasions consume alcohol in excess.
Investigations
Blood test showed raised inflammatory markers, WBC 15.2, CRP 220. Serum triglycerides were elevated 28.77 (normal limit < 2.26 mmol/l). Hyperglycaemia with blood glucose level of 17 and HbA1c 111. Amylase was raised at 378. The patient underwent CT Abdomen and Pelvis showing acute pancreatitis. No features of pancreatic necrosis or pseudocyst formation.
Management
Patient was initially managed conservatively with insulin sliding scale, intravenous fluids, analgesia and pabrinex. Started on Atorvastatin 80 mg and Fenofibrate 200 mg.
Discussion
Hypertriglyceridemia is a common form of dyslipidaemia that carries a high risk of cardiovascular disease such as atherosclerosis and hypertension. Hypertriglyceridemia results from environmental and genetic factors and is associated with other conditions such as obesity, diabetes mellitus, hypothyroidism and excess alcohol consumption. Chylomicrons are triglyceride-rich lipoprotein particles that are present when triglyceride are > 10 mmol/l and could occlude the pancreatic capillaries leading to ischaemia and enhanced lipolysis leading to release of free fatty acids, inflammatory mediators and free radicals that lead to inflammation, oedema or necrosis of pancreas. Hypertriglyceridemia induced acute pancreatitis associated with high morbidity and mortality risk and may lead to multi-organ failure. It is important to check lipid profile when a patient presents with acute pancreatitis. This can be managed with lifestyle changes and medications such as fenofibrate to help lower serum triglyceride levels below 4.5 mmol/l.
Conclusion
Hypertriglyceridemia is increasingly becoming a cause of acute pancreatitis which carries a high morbidity and mortality risk. It is important to consider this in patients presenting with acute pancreatitis and lipid profile should be requested as initial work-up. This could provide the opportunity to early diagnose hypertriglyceridemia and start treatment earlier to help prevent complications of pancreatitis and further episodes in the future.

EP566

Major hypertriglyceridemia complicated by acute pancreatitis

Kadiri Chaimae & lachkar hassan
Hospital Cheikh Zaid, Endocrinology, Rabat, Morocco

Introduction
Major hypertriglyceridemia is a rare pathology associated with severe acute complications. We report the case of a patient with major hypertriglyceridemia complicated by acute pancreatitis.
Observation
This is a 51-year-old patient with a history of hypertriglyceridemia on fenofibrate 160 mg per day and an attack of acute pancreatitis on chronic alcoholism. He consults for transfixing epigastric pain. The clinical examination found overweight (BMI at 29 kg/m^2) and android obesity. The biological assessment shows hyperleukocytosis with neutrophils, a CRP at 304 mg/l, a hypertriglyceridemia at 15.55 g/l, a hypercholesterolemia at 10.20 g/l, serum with a chylous appearance. Abdominal CT confirmed stage D acute pancreatitis. Treatment was started urgently with intensive rehydration, suspension of food, basal insulin therapy under cover with 5% serum glucose and heparin therapy at a preventive dose associated with analgesics. The patient also received treatment with fibrates and statins. The evolution is favorable clinically and biologically with a drop in triglycerides.
Discussion and conclusion
Major hypertriglyceridaemia is exceptional. Their severity is linked to the high risk of acute pancreatitis requiring early management.

Why not MODY monogenic diabetes? A case report

Salma Mohsen, Chaima Jemai, Hana Ben Jemaa, Dorra Ben Selem, Skander Msolly, Zohra Hadj Ali, Yosra Htira, Imen Hedfi & Feika Ben Mami
National Institute of Nutrition of Tunis, C, Tunis, Tunisia

Introduction
Monogenic diabetes MODY is common but remains under diagnosed because genetic study is expensive in our country.
Method
We report the case of an 18-year-old patient with no personal pathological history admitted in October 2022 for diabetes management. Her diabetes was diagnosed accidentally on July 2022: Systematic capillary blood glucose done when she had a Hysteria's crisis revealed values higher than 2 g/l. From July to October, the patient did not received any antidiabetic treatment and never had any acute complication, especially ketoacidosis one. Our patient did not have cardinal signs of diabetes. The physical examination showed acanthosis nigricans and overweight (BMI = 25.7 kg/m^2). HbA1c was 9.9%, insulinemia and C-peptide were normal, and HOMA index was 2.52. Thyroid parameters and basal cortisolemia were normal. There were no pancreatic autoimmunity (negative anti-GAD 65, anti-islets and anti-insulin antibodies). The "MODY RISK" score was at 75%. The association of polycystic ovary syndrome or polycystic kidney disease was ruled out by radiological examinations. The patient was put on Glimepiride 1 mg/d and Metrormine 850 1 cp/d with achievement of glycemic targets. The genetic study was requested in progress.
Conclusion
Monogenic diabetes MODY has common characteristics with T1D and T2D. It is often underdiagnosed due to the cost of genetic study but it should be evoked when diabetes presentation is atypical.

Type 2 diabetes and human immunodeficiency virus infection

Hind Ouakrim[1], Zineb Ait Si Ali[2], Sana Rafi[1], Ghizlane El Mghari[1] & Nawal El Ansari[1]
[1]Chu Mohamed Vi Marrakesh – Drh, Endocrinology, Marrakesh, Morocco; [2]Chu Mohamed Vi Marrakesh Drh, Marrakesh, Morocco

Introduction
Human immunodeficiency virus (HIV) infection and certain antiretroviral (ARV) treatments are associated with an increased risk of developing certain chronic comorbidities including type 2 diabetes, which is more prevalent in HIV-infected individuals. The coexistence of diabetes and HIV infection makes the standard of care more complex. The objective of this work is to discuss the relationship between these two comorbidities and to update physicians on the diagnosis of type 2 diabetes (T2DM) in HIV-infected patients.
Case presentation
A 40-year-old female patient, followed for HIV infection for 23 years under antiretroviral treatment, including protease inhibitors (PIs) and nucleoside analogues (NRTIs). Eight years later, the patient consulted with vaginal pruritus with profound asthenia. The workup showed fasting hyperglycemia at 3 g/l with hbA1c at 12%. She was put on insulin therapy and metformin with good evolution.
Discussion
It has been reported that diabetes is up to four-fold more common in HIV infected patients on retroviral therapy than in HIV seronegative patients. It is noted that glucose intolerance and insulin resistance are the main mechanism, the exact causes of which have not yet been defined, but several risk factors for the development of diabetes in HIV-infected individuals have been identified, such as duration of HIV infection, viral load, low CD4 count, and inflammation caused by HIV. However, the main factor that contributes to hyperglycemia in HIV is iatrogenic. Certain classes of AVR have been shown to increase the likelihood of developing diabetes in HIV-infected patients, such as protease inhibitors (PIs) and nucleoside analogues (NRTIs). And since HIV-infected patients have a more rapid turnover of red blood cells. It is suggested that fasting blood glucose should be used as a screening and diagnostic tool for diabetes in these patients, and postprandial blood glucose or oral glucose tolerance testing can also be performed as part of the screening measures.
Conclusion
As a result, the least toxic ARVs should be chosen and metabolic abnormalities should be detected early. Management should be multidisciplinary.

Emotion sharing posts related to diabetes in Instagram

Senda Ben Rebai, Radhouen Gharbi, Sahar Abidi, Marwa Chiboub, Hajer Kandara, Manel Jemel & Ines Kammoun
Institut De Nutrition, Tunis, Tunisia

Introduction
Diabetes is a disease affecting quality of life of millions of persons worldwide. Instagram is one of the most successful social media network. It influences, via its

posts, thoughts, emotions and decision making of many topics, including health related ones. The aim of this review to analyse the emotional sharing content of diabetes related posts in Instagram.
Methods
An Instagram query using the *search* term "diabetes" in arab language was performed between the 13th and th 23th January 2023. The first 10 posts appearing everyday of the study were included in the analysis. The publishing profiles, the nature and the content were assessed.
Results
70% of the overall diabetes related videos had emotional sharing content. Posts containing emotions sharing content had on average 932 likes and 132 commentaries; those with information sharing had 852 and 50, respectively. 32% of the videos shared positive emotions; it included mainly describing "success stories" of people living with diabetes, and "deculpabilisation" of diabetics. 7% contained negative emotions, mainly expressing difficulty of living with diabetes, and the insulin daily injection burden. 61% had neutral emotional content, mainly experiences sharing. 58% of positive emotions sharing was posted by diabetics profiles, and 15% by health professionnals.
Conclusion
The emotional sharing posts are popular among diabetes related content in Instagram. The posts published by diabetics had more positive percentage than other sharing profiles, and thus may be useful to help the diabetics improve their perception of their disease.

Assessment of anthropometric parameters in type 2 diabetic patients on Liraglutide

Zouaoui Chadia, Bel Hadj Sliman Chayma, Bchir Najla, Youssef Gharbi, Annam Benchhida & Haroun Ouertani
Military Hospital of Tunis, Endocrinology, Tunis, Tunisia

Introduction
Glycemic control and weight management are crucial considerations in the treatment of type 2 diabetes (T2D). Liraglutide, an incretin-based therapy, has been demonstrated to not only effectively maintain glycemic control but also promote weight loss in type 2 diabetic patients. Our study aims to evaluate the impact of Liraglutide on body weight and body composition parameters in patients with T2D.
Methods
This is a prospective study, carried out in the in the department of Endocrinology of the Military Hospital of Tunis. We administrated Liraglutide 1.2 mg daily at 22 patients with T2D. Weight and impedance measurements were performed on each patient before starting Liraglutide and after 6 to 12 months of treatment.
Results
Patients were 8 males and 14 females with a mean age of 53.8 ± 8.9 years. Our patients had dyslipidemia, hypertension, heart failure and coronary artery disease in respectively 16, 14, one and seven patients. Twenty patients were obese, with morbid obesity in 16 patients. The mean weight was 109.7 ± 17.9 kg before starting Liraglutide and 107.5 ± 18.6 kg after 6 to 12 months of treatment ($P = 10^{-3}$). The mean BMI was 40 ± 7.1 kg/m^2 before starting Liraglutide and 39.3 ± 7.4 kg/m^2 after 6 to 12 months of treatment ($P = 0.834$). The percentage of body fat decreased significantly after 6 to 12 months of treatment ($44.1 \pm 7.7\%$ vs $43.7 \pm 2.5\%$, $P = 0.046$). There was no significant change in lean body mass ($56.5 \pm 8.7\%$ vs $56.6 \pm 8.7\%$, $P = 0.930$).
Conclusion
Our study shows the effectiveness of Liraglutide in reducing weight and body fat percentage in patients with T2D.

Reasons of Liraglutide discontinuation in Tunisian type 2 diabetic patients

Zouaoui Chadia, Bel Hadj Sliman Chayma, Bchir Najla, Kalboussi Chanez, Sassi Eya, annam benchhida & Haroun Ouertani
Military Hospital of Tunis, Endocrinology, Tunis, Tunisia

Introduction
Liraglutide is an anti-diabetic drug that has been shown to be effective for glycemic control and weight loss. However, factors such as unavailability, high cost, and side effects may make it challenging for patients to continue treatment. Our study aims to identify these barriers to treatment adherence and to understand the factors contributing to the discontinuation of Liraglutide therapy in Tunisian patients with type 2 diabetes (T2D).
Methods
A prospective descriptive study was conducted at the endocrinology department of the Military Hospital of Tunis, including 23 patients with T2D who were naïve to glucagon-like peptide-1 receptor agonists. Our study involved a progressive dosing regimen for Liraglutide, starting at 0.6 mg/day for one week, before increasing to the final dose of 1.2 mg/day. We have followed our patients for 12 months.
Results
Our population included 8 men and 15 women with a mean age 54.5 ± 9.5 years old. Mean duration of diabetes was 12.7 ± 8.2 years. Obesity, dislipidemia, and hypertension were found in respectively twenty, sixteen and 15 patients. Eight patients had a history of coronary artery disease. Four patients reported epigastralgia after the introduction of Liraglutide, associated with diarrhoea in one patient which persisted despite the reduction of the Liraglutide dose to 0.6 mg/day. Liraglutide treatment was discontinued in nine patients. The cause of withdrawal was digestive intolerance in two patients, lack of glycemic control with lack of weight loss in three patients, unavailability of treatment in three patients and death in one patient.
Conclusion
It is important to check the availability and tolerance of Liraglutide in diabetic patients, as this can help to better manage their diabetes and ensure that they are taking the most appropriate treatment.

Therapeutic developments in diabetes mellitus

Dimitra Psychogiou[1,2] & Kostoglou Athanasiou Ifigenia[2,3]
[1]Pharmacist, Athens, Greece, [2]Hellenic Open University, Patras, Greece, [3]Asclepeion Hospital, Voula, Department of Endocrinology, Athens, Greece

Introduction
Diabetes mellitus (DM) treatment has recently undergone major developments which have dramatically changed the management of the disease. During the twentieth century major changes in the treatment of DM have transformed the disease from an uncurable disease to a chronic one. However, some of the major drugs used for its treatment have remained stable, while others have now almost gone into disuse.
Aim
The aim was to show the recent therapeutic developments in DM as depicted in everyday clinical praxis during the period 2016–2021.
Methods
The data of sales of antidiabetic medications in two medium sized pharmacies in central Athens during the years 2016 and 2021 were recorded.
Results
An increase in the sales of metformin by 22.2% was observed either alone or in combination with other orally administered antidiabetic medications. A major decrease in the sales of pioglitazone alone and in combination with other medications was observed. A major decrease in the sales of sulfonylureas was observed and glinides almost disappeared from the market. The sales of DPP-4 inhibitors either alone or in combination with metformin remained stable. A major increase in the sales of GLP-1 receptor agonists and of a combination of a GLP-1 receptor agonist and a long-acting insulin analog was found. A major increase in the sales of SGLT2 inhibitors was observed. The sales of human biosynthetic insulins decreased while the sales of long-acting insulin analogs increased.
Conclusions
In this report therapeutic developments in DM as depicted in the sales of antidiabetic medications in two pharmacies in central Athens are shown. Metformin continues to play a lead role in first-line treatment of DM 2. The sales of metformin increased and in 2021 they were 50% of orally administered antidiabetic medications and 40% of the total sales of antidiabetic medications. The sales of DPP-4 inhibitors alone or in combination with metformin remained stable, while GLP-1 receptor agonists and SGLT2 inhibitors increased dramatically. In this paper the major therapeutic developments in DM as they are depicted in clinical application in the urban multinational environment of central Athens, which may lead to the final cure of the disease are shown.

The lipid spectrum of patients with diabetes mellitus 2 type and morbid obesity

Maryam Dadakhanova
Tashkent Pediatric Medical Institute, Endocrinology, Tashkent, Uzbekistan

Aim of the study
To study the lipid profile of patients with diabetes mellitus 2 type (DM 2) and morbid obesity before bariatric surgery.
Material and methods
We evaluated 35 patients (15 women, 20 men) with DM 2 type and morbid obesity during October-December 2021. Mean age of patients was 48.3 years-old. Control group constituted by 20 healthy patients with same age. The patients were divided by BMI into 2 groups:
Group 1 – 17 patients with grade II obesity
Group 2 – 18 patients with grade III obesity
All patients underwent clinical and biochemical evaluations including endocrine check, lipids profile, hormonal profile (TSH, LH, FSH, prolactin, free testosterone, estradiol, progesterone, prolactin, etc), genitalia's ultrasonography, height (sm), weight (kg), BMI, waist circumference (WC), hip circumference (HC), waist–hip ratio, questioning and other studies.
Results
The study of anthropometry indicators revealed that 3 degree of obesity in all groups dominated:: in 1 gr - 64% of patients, 2 gr – 68%. The biochemical profile studies revealed violations of lipid metabolism – 84.6%: hypercholesterolemia –73.1%, reduced level of high density lipoproteins (HDL) – 73.1%, increased maintenance of low density lipoproteins (LDL) – 55.8%, hyperitriglyceridemia – 34.6%. A carbohydrate exchange disorders were found in all groups – insulin resistance – 88.5% of the total number of patients, hyperinsulinemia – 76.9%, violation of glucose tolerance – 46.2%.
Conclusions
1. In patients with Morbid obesity, 3 degree of obesity dominated in all surveillance groups. 2. The biochemical profile studies revealed violations of lipid metabolism – 84.6%: hypercholesterolemia – 73.1%, reduced level of HDL – 73.1%, increased maintenance of LDL – 55.8%, hyperitriglyceridemia – 34.6%

The evaluation of anthropometric indicators after bariatric surgery in patients with DM type 2 and morbid obesity

Maryam Dadakhanova
Tashkent Pediatric Medical Institute, Department of Endocrinology, Tashkent, Uzbekistan

Aim
To study the dynamics of anthropometric indicators 3 months after bariatric surgery in patients with DM type 2.
Material and methods
We evaluated 35 patients (15 women, 20 men) with DM 2 type and morbid obesity during October–December 2021. Mean age of patients was 48.3 years-old. Control group constituted by 20 healthy patients with same age. The patients were divided by BMI into 2 groups:
Group 1 – 17 patients with grade III obesity.
Group 2 – 18 patients with grade IV obesity.
All patients underwent clinical and biochemical evaluations including endocrine check, lipids profile, hormonal profile (TSH, LH, FSH, prolactin, free testosterone, estradiol, progesterone, prolactin, etc), genitalia's ultrasonography, height (sm), weight (kg), BMI, waist circumference (WC), hip circumference (HC), waist–hip ratio, questioning and other studies.
Results
In 1 and 2 groups of patients we found a reliable decrease in BMI III and IV degrees 3 months after bariatric surgery.. In 1 and 2 groups of patients, a reliable improvement in indicators were noted compared to the average data of BMI.
Conclusions
Three months after the bariatric surgery in patients with DM 2 type, there is a reliable improvement in anthropometry indicators compared to the data before surgery.

Lipemia interferences in clinical biochemistry parameters: a case report

Ines Mezghani[1], Rim Marrakchi[1], Faten Hadj Kacem[2], Mariem Boudaya[1], Mariem Gassara[1], Kaouthar Feki[1], Kamel Jammoussi[1], Mohamed Abid[2] & Mouna Turki[1]
[1]Hedi-Chaker University Hospital of Sfax, Biochemistry Department, Sfax, Tunisia, [2]Hedi-Chaker University Hospital, Tunisia, Endocrinology Department, Sfax, Tunisia

Introduction
Lipemic specimens could be a source of significant analytical errors. The aim of this study was to examine the effect of lipid removal using ultra-centrifugation of lipemic samples, on some routine biochemistry parameters.
Observation
A 53-year-old man hospitalized in endocrinology department for treatment of severe hypertriglyceridemia (21.3 mmol/l). All the patient's routine biochemical parameters were held on AU 680® Beckman Coulter before and after ultracentrifugation of the plasma sample. We determined total bilirubin, glucose, gamma-glutamyl transferase (GGT), aspartate aminotransferase (AST), alanine aminotransferase (ALT), alkaline phosphatase (PAL), amylase, lipase, creatine kinase (CK), lactate dehydrogenase (LDH), iron, cholesterol, triglycerides, HDL cholesterol, phosphorus, creatinine, urea, total protein, albumin, uric acid and magnesium. The percentage of differences (bias) was calculated and compared with the allowable inaccuracy. Clinically significant interferences were found in AST (14.81%), Total bilirubin (23.08%), lipase (27.06%), Total protein (1.47%) and magnesium (12.5%).
Conclusion
Lipemia causes clinically significant interferences for AST, Total bilirubin, lipase, Total protein and magnesium measurement on AU 680® Beckman Coulter and those interferences could be effectively removed by ultracentrifugation.

The state of central hemodynamics in patients with diabetic foot syndrome is associated with chronic heart failure

Muzaffar Khaydarov & K.K. Mirzaev
Andijan State Medical Institute, Department of Surgical Diseases and Civil Defense, Andijan, Uzbekistan

Aim
Study results of ultrasound dopplerography of the heart in patients with neuroischemic form of diabetic foot syndrome associated with chronic heart failure.
Material and methods
We examined 64 patients with DM 2 and DFS in the neuroischemic form on the basis of the Department of Surgery of the AndesMI. The patients were divided into 4 groups:1 gr – patients with neuroischemic form of DFS and CHF– 15 patients,gr. 2 – patients with neuroischemic form of DFS without CHF – 18 patients,Gr. 3 – patients with neuroischemic form of DFS, CHF and dyscirculatory encephalopathy stage 2–3 – 16 patients, gr. 4 – persons with CHF without D 2 15 patients. All patients were subjected togeneral clinical, biochemical, hormonal (IRI, C-peptide, inflammation marker-pro-inflammatory cytokine TNF-a, vascular endothelial growth factor (VEGF-A),and instrumental research methods – Doppler ultrasound of the vessels of the brain, lower extremities, ECG, Echo-ECG, bacteriological analysis of discharge from the wound, as well as statistical methods.
Results
There is a significant difference in the indicators of central hemodynamics in the studied groups compared with the norm: for example, LV EDR, ESV, EDV, LV EFR ($P < 0.05$), data on the average pressure in the pulmonary artery, the time of slowing the blood flow of early diastolic filling, TZSLV ($P < 0.001$);Thus, in patients of the studied groups, significant deviations of the Echo-ECG, which requires further study.
Conlusion
1. Among the risk factors, hereditary burden for DM dominated – only 21 cases out of 60 (35%), smoking – only 49 cases (81.6%), alcoholism

The results of the early postoperative period in patients with DM 2 subjected to aorto-coronary bypass

Diera Inogamova & Feruza Khaydarova
Republican Specialized Scientific Practical Medical Center of Endocrinology of Public Health Ministry named by acad. Ya.Kh. Turakulov, Tashkent, Uzbekistan

Aim
To study complications in the early postoperative period in patients with DM 2 subjected to ACB

Material and methods
60 patients (prospectively) with CHF were examinedafter endovascular revascularizationin the period of 2021 at the Center of Surgery named after acad. V.V. Vakhidov. All observed patients were divided into 2 groups: 1 gr. – 35 patients with DM2 with CHF and undergoing ACB, 2 gr. – 25 patients with CHF without DM2 who underwent ACBThe control group consisted of 20 patients with type 2 diabetes without CHF. To characterize the examined patients were used: general clinical, biochemical and instrumental examinations.
Research methods
General clinical, biochemical (bilirubin, direct, indirect, lipid spectrum, ALT, AST, coagulogram, blood sugar, glycated hemoglobin, urea, creatinine, GFR, galectin-3, insulin, renin, aldosterone in the blood) and instrumental: ECG, Echo-ECG, cardiac angiography, Dopplerography of the main vessels of the heart and legs, ultrasound of internal organs, fundus.
Results
We studied the systemic risk factors of atherosclerosis, such as age, gender, diabetes, hypertension and dyslipidemia, are to varying degrees of rejection of the graft. In the early postoperative period, these characteristics remained normal. In the early proverbial period, after A?B, our observation of complications was not observed.
Conlusion
Technical factors, such as the method used to harvest the conduits, the vasodilatory protocol, the storage solution, and the anastomotic technique, also play a major role in determining graft success.

DOI: 10.1530/endoabs.90.EP577

EP578

The role of risk factors in patients with Diabetes mellitus 2 and chronic kidney disease before hemodialysis

Feruza Khaydarova & Mokhira Teshabekova
Republican Specialized Scientific Practical Medical Center of Endocrinology of Public Health Ministry named by acad. Ya.Kh. Turakulov, Department of Diabetic Nephropathy, Tashkent, Uzbekistan

Aim
To study the role of risk factors in patients with DM 2 and chronic kidney disease I–IV degree
Material and methods
The study was carried out in 30 patients with type 2 diabetes mellitus (DM 2) treated in the Diabetic Nephropathy Department 2019 – 2021. Healthy volunteers ($n=20$) amounted to a control group. The paper included general-clinical, clinical and biochemical, hormonal, immunological methods of blood testing, as well as instrumental methods of I investigation -ultrasound of internal organs, ECG, ECHO-ECG, indicators of the quality of life of patients (questionnaire), as well as statistical techniques.
Results
We analyzed 30 patients with DM 2, complicated by chronic kidney disease CKD 1–4 degree.. Of these, women – 12, men – 18. The average age of patients amounted to 56.3 / 67.5 years, respectively, among men and women. The following accompanying diseases were identified as the progression factors of the CKD: hypertonic disease – 74%, ischemic heart disease – 68%, chronic hepato cholecisto-pancreatitis – 62.7%, anemia – 45%, urine-stone disease – 25%, obesity – 17%, diseases of the spine –18.7%, transferred stroke – 9%, ovarian polycystic syndrome – 5%, etc.
Conlusion
Among the risk factors of CKD 1–4 degree. In patients with DM 2 first place was hypertonic disease and ischemic heart disease.

Mathematical model for preoperative differential diagnosis for the parathyroid neoplasms

Julia Krupinova, Alina Elfimova, Ekaterina Kim, Anna Eremkina, Irina Maganeva, Elena Kovaleva & Natalia Mokrysheva
Endocrinology Research Centre, Moscow, Russia

Backgrounds
Preoperative diagnosis of parathyroid carcinoma (PC) is critical for the determination of the scope of surgical intervention. Nowadays, specific diagnostic markers for differentiation of PC and benign tumors are unknown, and less than half of patients with PC undergo necessary en bloc surgery.
Aims
To develop the instrument for preoperative diagnosis of PC.
Materials and methods
A multi-center retrospective study included 242 patients with primary hyperparathyroidism: 50 patients with PC, 30 with ?typical adenoma (AA), and 162 with adenoma of the parathyroid glands. We compared laboratory, instrumental and clinical characteristics. Comparison of two independent groups for quantitative data was performed using the Mann–Whitney test (U-test). Comparison of three independent groups for quantitative data was conducted using the Kruskal–Wallis ANOVA. The frequencies of binary variables were compared using the two-tailed Fisher exact test and Freeman–Halton test. The critical level of statistical significance for statistical hypotheses testing was taken as 0.05. CatBoosting algorithm was conducted to construct mathematical models for the differential diagnosis of PTG neoplasm types. Twelve factors were chosen by expert method for the model construction. At the first step, we reduced the dimension of feature space using sklearn.feature_selection, module ExtraTreesClassifier and SelectFromModel. Then we constructed the first model to differ PA and (PC or AA). At the second step, we also reduced feature space and constructed the second model to differentiate PC and AA.
Results
Patients with PC and AA had higher levels of PTH, ionized and albumin-corrected calcium, alkaline phosphatase, volume and the largest diameter of neoplasm, and the higher frequency of glomerular filtration rate decrease less than 60 ml/min per 1.73 m^2 compared to patients with adenoma. The frequency of low-energy fractures was higher in the carcinoma group versus the adenoma group (32% vs 8%). Heterogeneous structure and indefinite contour of glands detected by ultrasound were more typical for PC than for AA and adenomas. The mathematical model was developed using CatBoost gradient boosting algorithm for the noninvasive preoperative differential diagnosis of PC, AA, and adenoma.
Conclusions
Model can predict adenoma with PPV 100% and PC with PPV 81–92%. Using model clinicians could plan extended en bloc resection for PC and selective parathyroidectomy for adenoma. If AA is predicted, he has to make a decision on the choice of the necessary volume of parathyroidectomy based on his experience, because AA are the zone of uncertainty.

Real world efficacy and safety of multikinase inhibitors in patients with advance differentiated thyroid cancer

Suset Dueñas-Disotuar, Juan Manuel Canelo-Moreno, Irene De Lara-Rodríguez, Ana Romero-Lluch & Elena Navarro-González
Virgen del Rocío University Hospital, Endocrinology and Nutrition, Sevilla, Spain

Purpose
To establish the safety and efficacy of multikinase inhibitors (MKIs) treatment in real life.
Methods
This retrospective observational descriptive study included patients with advanced differentiated thyroid cancer in treatment with MKIs as first and second line treatment. From November 2011 to May 2022. Clinical variables, efficacy and adverse events (AE) were collected. Variables are expressed as median and interquartile range.
Results
First line. $n=30$. 21 sorafenib, 6 lenvatinib, 2 axitinib, 1 pazopanib. Second line, $n=11$ lenvatinib. 46.7% were women. Papillary thyroid cancer 73.3%. Age of onset of MKIs 67 years. Time from metastasis to IMK start 24 (9.2–74) months. Lung metastasis 66.7%, bone metastasis 3.3%, lung and bone metastasis 20%.
Safety
AEs occurred in 96.7% of patients in first line treatment. The most common was asthenia in 70% of patients. Severe AE, grade 3 or 4, occurred in 30% of patients, the most common was palmar-plantar erythrodysesthesia syndrome. All patients in second line of treatment presented AEs. Asthenia was the most common AE (72.7%) followed by hypertension (63.6%). Severe AE occurred in 54.5% of patients.
Efficacy
MKIs as first line. The median progression-free survival (PFS) was 23 months (CI 95% 11.2–34.8). Median overall survival (OS) was not reached. Mean overall survival was 71.13 months (CI 52–90.1). Median duration of treatment 331 days. Sorafenib as first line. Median PFS was 16 months (CI 95% 4.8–27.2). Median overall survival (OS) was not reached. Mean overall survival was 64.3 months (CI 42.5–86.2). 3 patients died. Dose withdrawal because of AE occurred in 10

(47.6%) of patients. The rest had disease progression. Lenvatinib as first line. Median PFS was not reached. 1 patient died and 5 patients had not disease progression. Median duration of treatment 383 days. Lenvatinib as second line. Median PFS was 24 months (CI 16.6–31.4). Median overall survival (OS) was not reached. Mean overall survival was 36.3 months (CI 30.9–42.2). 2 patients died. Dose withdrawal because of AE occurred in 5 (45.5%) of patients who had disease progression. 2 patients suffered disease progression. Partial response occurred in 1 patient, 1 had stable disease.
Conclusions
With Lenvatinib as first line treatment, most patients reached stable disease. With sorafenib as first line treatment we got similar results to clinical trials. AE were common, 30% as first line and 54.5% as second line.

A rare association of glucagonoma and gastric gastrinoma

Senda Ben Rebai, Imen Rojbi, Sabrine Mekni, Essayah Sawsen, Ibtissem Ben Nacef & Karima Khiari
Charles Nicoles Hospital, Endocrinology Department, Tunis, Tunisia

Introduction
Glucagonomas are rare functioning pancreatic neuroendocrine tumours that secrete glucagon. Gastrinomas are neuroendocrine tumours that secrete gastrin and are rarely located in the stomach. We report an extremely rare case of concomitant gastric gastrinoma and glucagonoma.
Case presentation
A 64-year-old-man with a history of digestive haemorrhage and gastrectomy presented with weight loss, asthenia, anorexia and abdominal pain. Esophagogastroduodenoscopy revealed severe erosive gastritis on gastrectomy stump, biopsy confirmed a grade 1 neuroendocrine neoplasm. Computed Tomography (CT) scan showed a 70-mm solid mass of the lesser curvature of the gastric stump, multiple liver metastases, multiple coelio-mesenteric adenopathies and partial thrombosis of the spleno-mesenteric trunk. A positive octreoscan was diagnostic for neuroendocrine tumour. Serum gastrin level was 108 pmol/l (normal $<$ 60 pmol/l). Once the diagnosis of metastatic gastric gastrinoma was made, the patient was put on somatostatin analogues. At one-year follow up, the patient reported itching cutaneous eruptions in his groin area treated with topical steroids with no improvement. These skin lesions were associated with weight loss, anorexia, glossitis and newly discovered diabetes mellitus. On physical examination, the lesions were suggestive of necrolytic migratory erythema. Laboratory tests indicated elevated blood glucose (12 mmol/l) and anemia (11 g/dl). Fasting glucagon level was elevated ($>$ 150 pmol/l, normal $<$60). Abdominal MRI showed a 10 mm peripheral nodule in the body of the pancreas.
Conclusion
The most interesting aspect of this case is the diagnosis of glucagonoma in a patient diagnosed with metastatic gastrinoma already treated with somatostatin analogues.

Clinical characteristics and survival of patients with functional lung neuroendocrine tumors

Bojana Popovic[1], Sanja Ognjanovic[1], Dusan Ilic[1], Valentina Elezovic Kovacevic[1], Milica Opalic[1], Lena Radic[1], Marijan Micev[2] & Djuro P. Macut[1]
[1]Clinic for Endocrinology, Diabetes and Metabolic Diseases, Department for Endocrine Tumors and Hereditary Cancer Syndromes, Belgrade, Serbia; [2]Clinic for Digestive Surgery, Department for Pathohistology, Belgrade, Serbia

Aim
Functional neuroendocrine tumors (NETs) represent a specific diagnostic and therapeutic challenge. Hormonal clinical syndrome can severely complicate clinical picture and affect treatment. Functional pancreatic NETs have been extensively studied. Our aim was to analyze functional lung NETs in terms of clinical characteristics and survival.
Materials and methods
We retrospectively analyzed data from 230 patients with lung NETs treated at our department from 2005 till 2022. The patients underwent standard radiological, pathohistological and hormonal evaluation. All tumors were graded according to current guidelines to typical carcinoids (TC), atypical carcinoids (AC), large cell neuroendocrine carcinomas (LCNEC) and small cell lung carcinomas (SCLC). Disease stage was defined according to the ENETS/AJCC TNM staging system. Differences between functional and non-functional tumors were analyzed by non-parametric tests, overall survival was analyzed by Kaplan–Meier method, and differences by Cox-regression analysis. Statistical analysis was performed by SPSS software.
Results
Functional tumors were diagnosed in 53 patients (23%): 20 serotoninomas (8.7%), 15 with ectopic Cushing's syndrome (6.5%), 11 calcitonin secreting (4.8%), 6 with SIADH (2.8%), and 2 with ectopic acromegaly (0.9%). Sex distribution was almost equal in the entire group (female 50.4%), and in the subgroup of functional tumors (female 45.3% female). The mean age was 55.3 ± 13.6, with no significant difference between groups ($P=0.443$). Majority of functional NETs were well differentiated (TC 18.4%, AC 49.0%, LCNEC 22.4%, SCLC 10.2%), and this distribution was similar to patients with nonfunctional NETs ($P=0.127$). There were no significant differences in primary tumor size ($P=0.705$), and presence of MEN1 syndrome, but metastatic disease was less frequent in functional tumors ($P=0.01$), and consequently functional tumors more frequently presented in lower disease stages ($P=0.02$). Median overall survival in the entire group was 66.0 months (95%CI 35.7–96.3), and in the group of functional NETs 36.0 months (95%CI 4.7–67.3). Survival was significantly shorter in functional NETs compared to nonfunctional ($P=0.02$). When groups of different tumor grades were analyzed separately, significantly shorter survival of functional NETs was confirmed in well-differentiated tumors ($P=0.011$ for TC, and $P=0.009$ for AC), while poorly-differentiated tumors of both groups had similar survival ($P=0.585$ for LCNEC, and $P=0.632$ for SCLC).
Conclusion
Almost one quarter of patients with lung NETs have some form of recognizable hormonal syndrome. Even though functional lung NETs metastasized less frequently compared to non-functional, overall survival of these patients was significantly shorter, namely in groups of well-differentiated tumors. Treatment of these patients requires improvement of therapeutic strategies.

Recurrent parathyroid cancer in a child associated with mutation in CDC73 gene

Ekaterina Kim[1], Julia Krupinova[1], Anna Eremkina[1], Natalya Kalinchenko[2] & Natalia Mokrysheva[1]
[1]Endocrinology Research Centre, Pathology of the Parathyroid Glands and Disorders of Mineral Metabolism, Moscow, Russia; [2]Endocrinology Research Centre, Moscow, Russia

Background
Parathyroid cancer (P?) in children is extremely rare, more often sporadic, but may be associated with a germline mutation. The only effective treatment is surgical approach due to the chemo-radio-resistance of PC.
Clinical case
A 6-years-old girl presented with weakness, gait disturbance, pain in the limbs, an X-shaped curvature of the legs. At the age of 12, the patient's well-being worsened sharply. The laboratory examination revealed primary hyperparathyroidism (PHPT): PTH 208 pmol/l, phosphorus 0.8 mmol/l, calcium ionized 1.76 mmol/l, alkaline phosphatase 4779 U/l. Ultrasound (US) showed a nodule $29 \times 17 \times 17$ mm near to the left lobe of the thyroid gland. At the age of 13, she underwent a selective parathyroidectomy with the achievement of remission. The histological structure was more consistent with a parathyroid adenoma (tumor structures in the lumen of some blood vessels were regarded as introduced during the preparation of the histological specimen). A germline heterozygous mutation c.70 G$>$T, p. Glu24Ter in exon 1 of the *CDC73* was identified. At the age of 15 years, there was a relapse of PHPT: PTH 527 pg/ml, Ca$++$1.4 mmol/l, total calcium 3.05 mmol/l. US visualized an hypoechoic lesion $8 \times 4 \times 6$ mm in the area of the removed PTG which accumulated ^{99m}Tc-MIBI on scintigraphy with SPECT-CT. The tumor of the left upper PTG with adjacent tissue was removed. Pathology examination showed invasive growth of PC into skeletal muscles and loss of parafibromin expression. One year later the patient underwent left hemithyroidectomy with ipsilateral lymphadenectomy, partial excision of the muscles, tissue and fascia to another recurrence of PC. Because of the PHPT persistence, a total thyroidectomy with pretracheal lymphadenectomy and the removal of lymph nodes, soft tissue on the right was subsequently completed followed by supraclavicular lymphadenectomy on the right. US and ^{99m}Tc-MIBI scintigraphy visualized an intramuscular neck lymph node (metastasis) $9 \times 12 \times$ 8 mm on the right accumulating the isotope. The ineffectiveness of the previous surgical treatment led to subsequent local radiotherapy (SOD 50 Gy) without remission achievement, however, in combination with cinacalcet 45 mg/day allowed to maintain mild hypercalcemia.

Conclusion
The bone deformities in childhood require calcium and PTH levels to be checked. If the diagnosis of PHPT is confirmed, a genetic study is necessary to exclude hereditary forms. A mutation in the *CDC73* gene should be aware of an increased risk of PC.

Patient-derived three-dimensional model of papillary thyroid cancer for personalized medicine and testing of novel therapies

Daria Petrova[1], Asya Bastrich[1], Zaur Abilov[1], Ekaterina Bondarenko[2], Liliya Urusova[2], Petr Nikiforovich[1], Dmitry Belcevich[2], Svetlana Pylina[1], Anna Eremkina[2], Ekaterina Kim[1] & Natalia Mokrysheva[2]
[1]Endocrinology Research Center, National Center for Personalized Medicine of Endocrine Diseases, Moscow, Russia; [2]Endocrinology Research Center, Moscow, Russia

Introduction
Over the last decades, there has been a significant increase in the incidence of thyroid cancer. Papillary thyroid cancer (PTC) is the most common histopathological type with often a favorable prognosis. Conventional therapies include surgical resection, adjuvant therapy with radioactive iodine, and suppressive therapy with thyroid hormones. However, the prognosis for iodine-resistant/refractory thyroid cancers or the advanced metastatic cancer is less favorable. We present the patient-derived three-dimensional (3D) model of PTC, which can be used to test novel therapies.
Results
3D cancer organ-like cultures (organoids) can be obtained from tumor resections or biopsies, propagated *in vitro*, frozen and thawed at any time. Organoid culture preserves genetic and cellular heterogeneity and allows determining individual responses of a tumor to drug therapies. To complement the existing protocols (Sondorp et al., 2020; Chen et al, 2021), we have developed an effective patient-derived 3D PTC models both for primary tumors and metastases. Pretreatment of cancerous tissue, culture medium, extracellular matrix and method of passaging are crucial for successful establishment of stable organoid cultures. Optimization of all the stages resulted in obtaining self-sustaining PTC organoid lines. Immunohistochemical analyses (anti-Ki-67, anti-TTF-1, anti-Thyroglobulin) and H&E staining of organoids and original tumor confirmed the malignant nature of the organoids, their heterogeneity and proved that PTC organoids recapitulate features (such as papillary, follicular or cystic structures) of the parental tumor tissue. The analyses were performed after at least three passages of the PTC organoid lines *in vitro*.
Conclusion
The presented model can be used for personalized medicine and development of optimal therapies for PTC.

Phenotypic presentation of MEN1 (NM_130799.2):c.758delC (p.Ser253CysfsTer28) rs1592648765 pathogenic mutation of MEN-1 gene: a case report

Edoardo Vergani[1], Paola Concolino[2], Emanuela Traini[3], Giuseppe Macis[4] & Antonio Mancini[1]
[1]Fondazione Policlinico Universitario A. Gemelli IRCCS, Università Cattolica del Sacro Cuore, Abdominal and Endocrine Metabolic Medical and Surgical Sciences, Rome, Italy; [2]Fondazione Policlinico Universitario A. Gemelli IRCCS, Università Cattolica del Sacro Cuore, Laboratory and Infectious Disease Sciences, Rome, Italy; [3]San Carlo di Nancy, GVM Care and Research, Endocrine Surgery UOC, Rome, Italy; [4]Fondazione Policlinico Universitario A. Gemelli IRCCS, Università Cattolica del Sacro Cuore, Diagnostic Imaging, Oncological Radiotherapy and Hematology, Rome, Italy

Multiple endocrine neoplasia (MEN) 1 is a rare hereditary autosomal dominant tumor syndrome characterized by two or more endocrine tumors. Non-endocrine neoplasms have been described as well. MEN1 is caused by inactivating mutations of the onco-suppressor gene MEN-1 (chromosome 11q13) which encodes the protein menin. Currently, 897 public variants of MEN-1 gene are reported. We present the case of a recently discovered pathogenic mutations of MEN-1 gene. A 32-year-old Italian male patient, admitted to our outpatient for osteopenia and nephrolithiasis in hypercalcemia and hypophosphatemia. Primary Hyperparathyroidism, confirmed both biochemically and morphologically (neck ultrasound plus ^{11}C-methionine PET-CT), was sustained by left superior parathyroid gland. The patient, after ruling-out pheochromocytoma diagnosis, underwent subtotal parathyroidectomy (left superior and inferior, right superior) since three hyperplastic parathyroid were found during the surgery. Pituitary hormones were evaluated, with no sign of pituitary hyper/hyposecretion, except for a single finding of high ACTH level. Pituitary MRI showed an 8 mm lesion suggestive for microadenoma. Cushing syndrome biochemical assessment was equivocal. The concomitant detection of high level of chromogranin A prompted us to perform an abdominal MRI, in the suspicion of neuroendocrine tumor (NET). The MRI showed three pancreatic lesions (12 mm in the pancreatic head, 8 and 3 mm in the pancreatic tail); moreover, it showed a 4 cm lesion of the medial lip of the left adrenal gland. ^{68}Ga PET-CT was performed, showing high radionuclide uptake, suggestive of high expression of somatostatin receptors, in the pancreatic area and left adrenal gland. Ultrasound endoscopy and subsequent biopsy of the pancreatic lesions confirmed the diagnosis of pancreatic NET G1. As regard the left adrenal nodule, no signs and symptoms of adrenal hormones hypersecretion were detected. The ^{131}I-Norcholesterol scintigraphy revealed a unilateral left adrenal gland uptake. The patient underwent left adrenal surgery due to the dimension of the nodule. Histology confirmed left adrenal adenoma. Genetic testing (MEN-1 gene exon 2-10 DNA-sequencing) identified a missense MEN1 heterozygous pathogenic variant MEN1(NM_130799.2):c.758delC (p.Ser253CysfsTer28) rs1592648765 in exon 4. The patient is now under somatostatin analogues and monitored by MRI and hormonal follow-up. Genetic inheritance is under investigation. We have described for the first time the clinical consequence of a recently discovered pathogenic mutation associated with four different endocrine neoplasms. MEN1 represents a complex syndrome, as it has plenty of possible clinical manifestations and a deep and still surprising panel of mutations and genetic variants. A potential genotype-phenotype correlation is still far to be recognized.

EP586

Parathyroid carcinoma in a patient with both MEN1 and RET mutations

Svetlana Pylina, Ekaterina Kim, Ekaterina Bondarenko, Julia Krupinova, Anna Eremkina & Natalia Mokrysheva
Endocrinology Research Centre, Moscow, Russia

Background
MEN1-related primary hyperparathyroidism (PHPT) characterised by benign course, whereas malignant transformation is extremely rare. The diagnosis of parathyroid carcinoma (PC) within the MEN-1 syndrome is a challenge for a range of specialists.
Clinical case
A 47-year Eastern European female. PHPT had been revealed during examination for multinodular goitre: PTH 614 nmol\l, calcium 3.06 mmol\l. Results of imaging methods were controversial (multiple lesions). The patient underwent total thyroidectomy and parathyroidectomy. Histological and immunohistochemical (IHC) examinations confirmed parathyroid carcinoma with the vascular and capsular invasion, spread to adjacent adipose tissue ??1N???Pn0LV, positive for PTH and Chromogranin A. The other parathyroid glands were described as adenomas. At the same time a neuroendocrine tumour of the lung (NET) 32×27×30 mm. (G2) was revealed. The patient refused surgery and further was treated with lanreotide 120 mg every 28 days. Hypercalcemia, hypercalciuria and low level of PTH were detected four years after primary surgery herewith she did not receive calcium and active vitamin D supplements. Bone scintigraphy excluded the osteoblastic process. 68Ga-DOTA-TATE PET/CT showed a lung tumour with increased growth up to 49×45 mm. IHC analysis of the bronchoscopic samples confirmed the highly differentiated lung NET expressing PTH. There was genetic screening at the age of 52 revealing mutations in the *MEN1* (1308G>A ?.W436X(NM_130799.2, pathogenic) and *RET* genes (HG38, chr10:43105062C>T, c.736C>T, with unknown clinical significance). The same MEN1-mutation was identified in her daughter, who was diagnosed with PHPT (parathyroid adenoma) and non-functioning pituitary microadenoma. Other components of syndrome manifested consistently. At the age of 50 she was diagnosed with pancreatic head tumour 31×34 mm, treated first with etoposide, carboplatin. Later pancreas body NET (19×13 mm., SUV=6.64), tail (11×9 mm., SUV =23.28 and 15×12 mm., SUV 15.22) were visualised on PET/CT. Pituitary macroadenoma 5.5×15×10 was identified at the age of 51. Due to an elevated level of IGF-1 and the absence of a decrease of tumour size, lanreotide dose had been increased to 120 mg every 21 days with the addition of cabergoline 0.5 mg once a week. The conservative treatment and follow-up are ongoing.
Conclusion
This case demonstrates the atypical genetic background in a patient with MEN-1 and PC. Despite the presence of *RET* mutation, components of MEN-2 syndrome

were not confirmed. The revealed hypercalcemia and hypercalciuria accompanied by suppressed iPTH allow us to assume the ectopic production of parathyroid hormone-related protein in the lung NETs.

EP587

Prognostic impact of the tumor immune microenvironment in adrenocortical cancer

Nano Pachuashvii[1] & Liliya Urusova[2]
[1]Institute of Clinical Morphology and Digital Pathology, I.M. Sechenov First Moscow State Medical University, Moscow, Russia; [2]Endocrinology Research Centre, Moscow, Russia

Background
Adrenocortical carcinoma (ACC) is an uncommon endocrine malignancy, usually characterized by a late detection, aggressive clinical course, and poor outcome. The tumor microenvironment (TME) which includes infiltrating immune cells plays a critical role in tumor growth, survival, and prognosis in cancer patients. The presence of tumor-infiltrating immune cells (TIIC) affect the clinical benefit from novel strategies of immunological checkpoint blockade. Anti-immune pathways like PD-L1 are used by the tumor to overcome immune system and they serve as immunotherapy targets.
Methods
The study included tumor tissue samples from 75 patients with ACC, which treated at the Endocrinology Research Centre (Russia, Moscow) between 2010 and 2022: 47 cases of conventional (62.7%), 18 cases of oncocytic (24%), and 9 cases of myxoid (12%) and 1 case of sarcomatoid (1.3%) variants of ACC. Immunohistochemical analysis of tumor tissue sections was carried out according to the standard technique with a peroxidase detection system with DAB on an automatic Leica BOND III IHC staining system using Leica reagents and protocols. Each of the 75 patients underwent histological diagnostics and a series of immunohistochemical stains for the markers of the main immune cell subsets: CD45, CD3, CD4, CD8, and CD68. The impact of PD-L1 expression and the number of TIIC considering the intratumoral and stromal distribution on pathological characteristics and clinical outcomes were analysed.
Results
The number of ?D45+ immune cells in tumor parenchyma and stroma was 189 and 268 cells/mm^2, respectively. However, the number of immune cells from all the analyzed populations in tumor parenchyma was higher in oncocytic compared to conventional ACC cases. The analysis of the relationship of survival with the studied factors showed that the overall survival and progression-free survival between conventional and oncocytic histological variants differ significantly. The differences in survival between conventional and oncocytic histological variants of ACC were statistically significant (P-value < 0.05). PD-L1 expression does not affect prognosis.
Conclusions
Rich T-lymphocyte response is a good prognostic factor in ACC. The study of TIIL subpopulations can be used to predict ACC outcomes.

EP588

An unusual association of a familial MEN1 with renin co secretion form a glucagonoma

Daniel Mihai[1,2], Poalelungi Ramona[1] & Corin Badiu[1,3]
[1]National Institute of Endocrinology, Thyroid Related Disorders, Bucharest, Romania, [2]C.I. Parhon National Institute of Endocrinology, Thyroid Related disorders, Bucureşti, Romania; [3]"C.Davila" University of Medicine and Pharmacy, Endocrinology, Bucharest, Romania

Introduction
Multiple endocrine neoplasia type 1 (MEN1) is an autosomal dominant disorder consisting in the development of primary hyperparathyroidism (PHPT), pancreatic neuroendocrine tumors, and pituitary adenomas. Occurrence of glucagonoma in MEN1 patients is rare (3%) and metastatic disease is present in 50% to 80% of patients at the time of diagnosis. The association of adrenal nodules/tumors and MEN1 is also rare.
Case report
We present the case of a 37-year-old female patient with a personal history of type II diabetes mellitus and severe hypokalemia who presented to the "C.I Parhon" National Institute of Endocrinology for further investigations of hypopotasemia. She had normal blood pressure, weakness and fatigue. Laboratory showed high values of renin and aldosterone (renin >300 pg/ml, aldosterone 547 pg/ml) with persistence of severe hypopotasemia (K = 2.30 mmol/l), hyperparathyroidism (PTH = 324.10 pg/ml with normocalcemia), hyperprolactinemia (PRL = 91.93 ng/ml), without hypercortizolism. Chromogranin A = 1.700.00 ng/ml and glucagon were high, with normal levels of 5HIAA, NSE and serotonin. Abdominal MRI reveals a pancreatic corporeal-caudal tumor mass whose appearance is compatible with a neuroendocrine tumour with secondary lymph node and liver determinations. Parathyroid scintigraphy identified an aspect suggestive of lower left parathyroid gland. It was decided surgery, with enucleoresection of cephalopancreatic exopthytic tumour, corporal-caudal splenopancreatectomy en bloc with partial left adrenalectomy. Pathology certifies a well-differentiated neuroendocrine tumor G1pT3pN1pM1a and immunohistochemistry shows positivity for AE1-AE3, chromogranin and synaptophysin, negative staining for CD56, Ki67 $<1\%$. Microwave ablation of tumoral liver segment VII was performed considering secondary determinations in the liver. Medical management included somatostatin analogues.
Conclusions
The discovery of elevated levels of renin in the presence of glucagonoma in this patient suggests a tumoral co-secretion. This association is very rare and constitutes a life threatening situation, requiring multidisciplinary approach.

Alpelisib-induced severe hyperglycemia: A case report. Are we discontinuing the drug too soon?

Javier García Fernández & Marcos Perera Izquierdo
Our Lady of Candelaria University Hospital, Endocrinology and Nutrition, Santa Cruz de Tenerife, Spain

Background
Alpelisib is an α-selective PI3K inhibitor indicated for the treatment of postmenopausal women and men with hormone receptor-positive (HR+), human epidermal growth receptor 2-negative (HER2–), PIK3CA-mutated locally advanced or metastatic breast cancer following disease progression or after endocrine therapy. Hyperglycemia is the most common adverse event (up to 60%) associated with its use. It occurs more frequently and lasts longer in patients with prediabetes or type 2 diabetes (DM2) at baseline. 4 grades of Alpelisib-induced hyperglycemia are defined by the FDA. In grades 3 (>13.9–27.8 mmol/l) and 4 (>27.8 mmol/l), current guidelines recommend to interrupt or even discontinuate Alpelisib.
Case report
We present the case of a 58-year-old woman with a history of hypertension, dyslipidemia, obesity, and untreated type-2 diabetes. In 2010, she received surgery for breast cancer (HER2+, HR+, PIK3CA-mutated). Since 2018, lymph node and bone progression were discovered despite hormonal treatment and radiotherapy for symptomatic control. She started treatment with Alpelisib-Fulvestrant in July 2022, with grade 3–4 hyperglycemia (9–15 mmol/l) appearing after a week. She was referred to an Endocrinologist and began treatment with a low-carbohydrate diet, metformin titrated to a maximum dose of 1000 mg twice a day, linagliptin 5 mg once a day and insulin therapy in a basal-bolus regime at 0.2 IU/kg (Table 1). Despite this treatment, in the following months both fasting and postprandial blood glucose levels remained between 10 and 15 mmol/l, so it was necessary to increase the insulin dose progressively. In November 2022, high blood glucose levels persisted, with the control CT scan showing stable disease. She continued Alpelisib and kept increasing insulin dose up to 0.95 IU/kg. In January 2023, glycemic targets were achieved (preprandial 5–6.66 mmol/l, postprandial 5.55–9.99 mmol/l, HbA1c of 7.3%) and dose was even lowered up to 0.7 IU/kg to prevent fasting hypoglycemia.

Table 1 Hypoglycemic agents used in the case report. IU = international units.

	Aspart U100 (IU)					
	Breakfast	Lunch	Dinner	Glargine U300 (IU) at 2200 hours	TOTAL (IU/kg)	Other
07/2022	4	4	4	10	0.20	Metformin 1000 mg (1-0-1)
11/2022	16	16	16	38	0.95	Linagliptin 5 mg (0-1-0)
01/2023	11	10	16	30	0.70	Low carbohydrate diet

Conclusion
Grade 3–4 AIH management with low CH diet, metformin, linagliptin and basal-bolus insulin therapy at high doses has allowed our patient to accomplish hyperglycemia control after 6 months of treatment, without interrupting Alpelisib while achieving stable oncological disease to date.

DOI: 10.1530/endoabs.90.EP589

EP590

Incidental diagnosis of MEN2a in a patient with concurrent ovarian carcinoma presenting with cervical lymphadenopathies

Catalina Pena[1], Alina Sucaliuc[1], Ghemigian Mircea[2], Brezean Iulian[3], Alida Nicoleta Dumitru[4] & Grigorie Daniel[4]
[1]National Institute of Endocrinology C.I Parhon, Thyroid 2, Bucharest, Romania; [2]National Institute of Endocrinology C.I Parhon, Surgery, Bucharest, Romania, [3]Clinical Hospital DR. Ion Cantacuzino, Surgery; Bucharest, Romania; [4]National Institute of Endocrinology C.I Parhon, Bucharest, Romania

Introduction
Multiple endocrine neoplasia type 2A is an autosomal dominant disorder which is characterized by the occurrence of medullary thyroid carcinoma in association with pheochromocytoma and parathyroid tumors.
Case report
We present the case of a 64-year-old woman, with familial history of thyroid carcinoma, renal lithiasis and personal history of right nephrectomy for renal lithiasis, who presented for the investigation of a left lateral cervical mass. CT scan revealed bilateral thyroid nodules, multiple lateral cervical and supraclavicular lymph nodes metastasis, left ovarian tumor with lumbar, paraaortic and interaortocaval lymph nodes metastasis and small adrenal left nodule. Biochemistries revealed a high level of calcitonin 792 pg/ml, carcinoembryonic antigen 84 ng/ml, hypercalcemia 11 mg/dl, increased PTH 140 pg/ml, normal levels of plasma and urine metanephrines, normetanephrines. DNA testing of the RET proto-oncogene revealed the Cys634Arg mutation, confirming the MEN2 diagnostic. Bilateral ovariectomy, total hysterectomy and dissection of lomboaortic, interaortocaval lymph nodes were performed, testified by histopathological findings as high grade papillary serous ovarian carcinoma. Two months later, a total thyroidectomy, left superior parathyroidectomy and lateral neck dissection were performed. The histopathological examination confirmed bilateral medullary thyroid carcinoma, with 13 secondary metastatic lymphadenopathies due to ovarian carcinoma and parathyroid adenoma. Immediate postoperatively biochemistries were: calcitonin 41 pg/ml, PTH 10 pg/ml, normal total calcium, and at two months follow-up calcitonin 2.9 pg/ml, PTH 88.2 pg/ml, normal total serum calcium, carcinoembryonic antigen 2.23 ng/ml. Three years follow up CT scans showed no signs of relapse or secondary metastatic lesions.
Conclusions
When diagnosing a patient with MEN2A is important to look for clinical and biochemical features along with personal and family history and genetic testing. The incidental diagnosis of MEN2A allowed us to plan the genetic screening of the proband's family. We anticipate that the multidisciplinary approach for treatment and follow-up investigations will increase the survival prognosis of our patient.

Keywords: MEN2A, papillary serous ovarian carcinoma

The correlation between baseline calcitonin levels and the risk of metastasis in patients followed for medullary thyroid carcinoma

Nezha Raki, Nassim Essabah Haraj, Siham El Aziz & Asma CHADLI
UHC Ibn Rochd, Endocrinology, Diabétology, Nutrition and Metabolic, Casablanca, Morocco

Introduction
Medullary thyroid carcinoma (MTC) is a neuroendocrine tumor that represents the most aggressive form of thyroid carcinoma, usually diagnosed at advanced stages. Serum calcitonin (CT) is the sensitive and specific marker of sporadic and hereditary CMT. It is a diagnostic, prognostic and follow-up marker.
Purpose of the study
To investigate the correlation between the risk of metastasis and CT levels at the time of diagnosis of MTC.
Materials and methods
Retrospective study including patients followed for MTC in the endocrinology and diabetology department of the CHU Ibn ROCHD in Casablanca from 2007 to 2022. The statistical analysis was carried out by the SPSS 25.0 software.
Results
We recruited 25 patients followed for CMT; the average age was 46.9 years, with a female predominance (72%). All patients underwent total thyroidectomy, bilateral lymph node dissection was performed in sixteen patients and unilateral in three patients. The MTC was in the context of MEN in six patients (24%), the genetic study of mutations of the RET proto-oncogene was positive in three patients. Fifteen of the cases presented a metastatic form (60%), the lymph node localization of which was present in all patients and at a distance in ten patients (66.7%). The CT level at the time of diagnosis in patients with a metastatic form was $>$ 500 pg/ml (mean value 3855.6 pg/ml) in 66.6% of patients ($P<0.01$), while the CT level was $<$ 100 pg/ml in patients without metastases. Most had undergone a first incomplete thyroid surgery. Moreover, the tumors were larger, multifocal ($P<0.05$) and with capsular invasion ($P<0.02$). Among these patients, three benefited from chemotherapy sessions, radiotherapy was performed in two patients, one patient was put on targeted therapy with vandetanib and two patients are scheduled for treatment with sorafenib.
Conclusion
CT is a very sensitive biochemical marker. The absence of its preoperative assay leads to a delayed diagnosis of MTC and the initial surgery is often incomplete. Indeed, preoperative CT levels are strongly correlated with disease progression, which requires adequate management with close monitoring of the disease.

Ferroptosis in human adrenocortical cells and aldosterone-producing adenomas

Yingxian Pang[1], Martina Tetti[1,2], Siyuan Gong[1], Martin Reincke[1] & Tracy Ann Williams[1,2]
[1]Medizinische Klinik und Poliklinik IV, Klinikum der Universität München, LMU München, München, Germany; [2]Division of Internal Medicine and Hypertension, Department of Medical Sciences, University of Turin, Turin, Italy

Background
The role of ferroptosis – a regulated form of cell death – in the pathophysiology of aldosterone-producing adenomas (APA) is unclear.
Objective
To identify mechanisms of ferroptosis in human adrenal cells and translate these findings to APA pathophysiology.
Methods
Cell death detection, lipid ROS generation and mRNA sequencing were performed on HAC15 cells treated with the specific ferroptosis inducer RSL3 (1, 2 and 4 mM), in the presence and absence of the ferroptosis antagonist Liproxstatin-1. Volcano plots and heat maps were used to visualize RNAseq data from RSL3-treated HAC15 cells. Transcriptomics data of APAs versus adjacent cortex were mined from a publicly available transcriptome dataset (GSE60042). Spatial gene expression profiles of selected genes of interest were generated in 8 cryosections of APAs and paired adjacent cortex.
Results
RSL3 induced a liproxstatin-1 sensitive, dose-dependent effect on HAC15 cell death and lipid ROS generation. Genes which were differentially expressed in both RSL3-treated HAC15 and in APAs were identified and considered as genes of interest. RSL3 induced dose-dependent increases in *HMOX1*, *UNKL* and *TRIB1* gene expression in HAC15 cells. The spatial transcriptomics dataset showed decreased *HMOX1*, *UNKL* and *TRIB1* expression in APA tumor tissue relative to the adjacent cortex. Therefore, we identified genes with a putative function in the promotion of ferroptosis in human adrenal cells which were downregulated in APA tumors.
Conclusion
Suppression of cell death by ferroptosis may play a key role in APA pathophysiology.

Endocrinopathies in oncological patients treated with immunotherapy: A real world data study

Anna Angelousi[1], Athina Karampela[1], Spyridon Kazanas[2], Petros Papalexis[1], Alexandros Lafioniatis[1], Vasiliki Siampanopoulou[1], Chrysoula Mytareli[1], Maria Theochari[3], Dimitra Stephanou[3], Dimitrios Ziogas[3] & Helen Gogas[3]
[1]Laiko General Hospital, First Department of Internal Medicine, Unit of Endocrinology, Athina, Greece; [2]Laiko General Hospital, First Department of Internal Medicine, Greece; [3]Laiko General Hospital, First Department of Internal Medicine, Unit of Medical Oncology, Athina, Greece

Background
Immune checkpoint inhibitors (ICIs) (anti-CTLA-4, PD-1 inhibitors, PD-L1 inhibitors) are considered a widely used therapeutic choice for several cancer

types. However ICI therapy is frequently complicated by adverse events; endocrine toxicities are the most common ones.
Methods
To assess in a retrospective observational study in a tertiary hospital the incidence and the characteristics of the immunotherapy-related endocrine adverse events (irEAEs) in oncological patients treated with ICIs. All patients had baseline hormonal functional tests (before the initiation of ICIs) and during the follow-up (mean: 20 months).
Results
A total of 117 irEAEs cases were registrated out of 1077 (10.86%) oncological patients treated with ICIs (46% females). The mean time of diagnosis of irEAEs was 7.7 months after the onset of ICIs treatment with recovery in 9.4% of patients during the follow-up. The overall incidence of hypophysitis and thyroid dysfunctions was 6.9% and 4% respectively in patients treated with ICIs. Among the 117 irEAEs cases, 63.2% (74 cases) presented with hypophysitis followed by 24.8% with primary hypothyroidism (29 cases) and 10.3%with thyreotoxicosis (12 cases). Furthermore, one case developed diabetes insipidus, one case primary adrenal insufficiency and two cases primary hypogonadism. Hypophysytis was diagnosed in 75% of patients treated with anti-CTLA-4 inhibitors vs. 61.5% of patients treated with PD-1/PDL-1 and 72.4% with combination treatment. Thyroid disorders were noted in 36% of patients treated with PD-1/PDL-1 vs. 25% of patients with anti-CTLA-4 inhibitors and 25.5% with combination treatment. Hypophysitis was reversible in 9.5% of patients whereas primary thyroid disorders in 25.8% of cases with irEAEs. Interestingly reversibility was significantly associated with the time of diagnosis of irEAEs. Thyroid autoantibodies were found positive in 44% of cases with primary hypothyroidism and in 30% of cases with no thyroid dysfunction. No MRI was performed systematically among patients with hypophysitis. However in 20 out of 34 (58%) of patients with hypophysitis, MRI presented pathological findings.
Conclusions
irEAEs are relatively frequent in patients treated with ICIs, thus physicians should be aware of the clinical signs/symptoms in order to proceed to an early diagnosis and treatment. The complexity of the pathophysiological mechanisms of action of ICIs requires a multidisciplinary approach of these patients.

Psychiatric disorders in Cushing's syndrome and impact on follow-up

Sofia Ouhessaine, Nassim Essabah Haraj, Siham El Aziz & Asma Chadli
Ibn Rochd University Hospital of Casablanca, Morocco Neurosciences and Mental Health Laboratory Faculty of Medicine and Pharmacy-University Hassan II, Endocrinology, Diabetology, Nutrition and Metabolic Diseases Department, Casablanca, Morocco

Introduction
Cushing syndrome (CS) is a rare and serious disease with high mortality. Diagnosis and management of the disease are difficult, as CS is typically characterized by the presence of multiple symptoms hypertension, diabetes, weight gain, or osteoporosis, the psychiatric and neurocognitive consequences are just as important by a set of anxio-depressive disorders resounding on the quality of life but also on the management of the disease.
Objective
Describe the association of Cushing's syndrome with anxiety and depression disorders and retention on adherence to treatment and follow-up of the disease.
Methods
Descriptive retrospective study of patients hospitalized for endogenous hypercortisimes in the endocrinology and metabolic diseases department between 2018 and 2022.
Results
Our study included 64 patients, the average age was 29.6 years, with a clear female predominance. memory loss with difficulty concentrating was noted in 95%, insomnia with difficulty falling asleep in 80%, depression in 75%, a psychiatric consultation was carried out in the majority of our patients, 50% were put under anxiolytic and antidepressant treatment, only one case of visual hallucination was recorded. As for adherence to treatment and follow-up, 82% showed up regularly for consultation, 6% intermittently and 12% were lost to follow-up.
Conclusion
Psychological management is part of the multidisciplinary management of Cushing's syndrome. Psychological interventions may be required to treat depression and to improve long-term prognosis, subjective wellbeing and quality of life.

Immune checkpoint inhibitors induced endocrinopathies: a possible indicator of improved survival

Mariana Ornelas[1], Marta Borges-Canha[2], Pedro Gouveia[1], Margarida Maria Morna Ferreira[1], Eduarda Resende[1], Elena Maritza Pontes Santos Sa[1] & Francisco Silvestre Abreu[1]
[1]Hospital Dr. Nélio Mendonça, Funchal, Portugal; [2]São João Universitary Hospital Center, Porto, Portugal

Background
Immune checkpoint inhibitors (ICI) are an innovative oncologic therapy used in several types of solid and hematological neoplasms. This treatment enables the antitumoral immune system response and results in significant improvement of clinical outcomes and survival rate. However, endocrine related adverse effects (ERAE) have been related, with thyroid and pituitary dysfunction being the most common endocrine diseases described. An association between the surge of endocrinopathies and better overall survival rate has been suggested.
Aim
To evaluate the association between patients' features and the development of endocrine toxicity and to assess the association between ERAE development and mortality.
Methods
A retrospective observational study was conducted in 98 patients submitted to immunotherapy in our center since its introduction in 2015 until March 2021. We excluded patients who had missing data regarding the corticotroph axis evaluation. We used linear and logistic regression models to address our aims.
Results
We observed a significant negative association between ERAE development and death (OR 0.32; $P=0.028$). We detected no associations between ERAE and the following characteristics: age at ICI initiation, sex, diabetes *mellitus*, medical history, immunotherapy duration and ICI type.
Conclusion
The development of an ERAE may be associated with a better overall survival rate in advanced oncologic disease supporting the role of an unleashed immune system response to malignant cells.

Case Report: Successful treatment of an atypical lung neuroendocrine neoplasm with PRRT

Vanessa Guerreiro[1], Inês Lucena[2], Ana Paula Santos[3], Inês Próspero[2], Gonçalo Ferreira[2], Sara Gil Santos[3], Joana Oliveira[3], Paula Freitas[4], Isabel Torres[3] & Hugo Duarte[2]
[1]Alameda Professor Hernâni Monteiro, Endocrinology, Porto, Portugal; [2]R. Dr. António Bernardino de Almeida 865, Nuclear Medicine, Porto, Portugal; [3]R. Dr. António Bernardino de Almeida 865, Endocrinology, Porto, Portugal

Neuroendocrine neoplasms (NENs) arise from specialized cells called neuroendocrine cells spread through the body, mainly in the gastrointestinal tract, pancreas and lung. Pathological classification of Lung NENs include well differentiated NENs, that can be classified as typical or atypical carcinoids, and poorly differentiated neuroendocrine carcinomas (NECs), classified as small-cell lung carcinoma (SC-NEC) or large-cell neuroendocrine carcinoma (LC-NEC). We present a case of a 59-year-old female patient, who was referred to our hospital in 2012, for treatment with Peptide Receptor Radionuclide Therapy (PRRT) with ^{177}Lu-DOTATATE, due to progressive metastatic NEN lung disease. The patient had previously been submitted to primary tumour ressection, in 1999, with histopathological diagnosis of an atypical lung carcinoid. Due to metastasis in liver (2008), bone (2009) and kidney (2012), the patient underwent various treatments, namely somatostatin analogues (2008); chemotherapy (may 2008-June 2009); anti-algic radiotherapy (2009) and sunitinib (July 2009-february 2012). She was referred to IPO Porto, due disease progression despite multiple treatments. As she had high expression of somatostatin receptors on ^{68}Ga-DOTA-NOC-PET/CT, the patient underwent 3 cycles of PRRT treatments from 2012 to 2013 (Before NETTER-1 results). A dose adjustment in the administered activity was made, due to higher treatment toxicity risk of the patient, given her clinical background of chronic kidney disease (GFR ~48 ml/min). Despite the reduced treatment activity (total: 14.99 GBq), treatment response was obtained (imaging improvement, with visualization of fewer foci of ^{68}Ga-DOTANOC PET/CT uptake at liver and bone level). No renal or hematological toxicity occurred. Disease progression was diagnosed in ^{68}Ga-DOTANOC PET/CT in may 2016, with new bone and hepatic lesion detected however not detectable by CT imaging. After 10 years, the patient remains clinically stable, under treatment with cold somatostatin analogues. Despite PRRT with ^{177}Lu-DOTATATE not being yet approved by the EMA for treatment of lung NETs, this case illustrates the potential clinical benefit of this treatment in this group of patients. Besides, chronic kidney disease (CKD) patients should have

individualized approach as they can benefict from PRRT at lower doses, with clinical and imagiological response. Randomized clinical studies are needed to validate PRRT in lung NENs.

Diagnostic efficacy of tumor markers in the detection of metastatic pancreatic neuroendocrine neoplasms

Violetta Rosiek, Anna Zemczak, Magdalena Londzin-Olesik & Beata Kos-Kudła
Medical University of Silesia, Department of Endocrinology and Neuroendocrine Tumors, Department of Pathophysiology and Endocrinology, Katowice, Poland

Introduction
Neuroendocrine neoplasms (NENs) are rare heterogenous tumors which prevalence is increasing. Functional pancreatic neuroendocrine neoplasms (p-NENs) develop characteristic clinical syndromes in contrast to non-functional tumors that are diagnosed accidentally or at an advanced stage due to the lack of sensitive and specific biomarkers that could predict their clinical course.
Aim
This study aimed to assess tumor markers (TMs) in patients with p-NENs and their association with disease extent (metastatic vs. nonmetastatic disease).
Methods
115 patients with p-NENs and 40 patients from the control group were enrolled. TMs levels, such as cytokeratin 18 (CY18), ferritin, carbohydrate antigen 19-9 (CA19-9), cancer antigen 125 (CA125), alpha-fetoprotein (AFP), carcinoembryonic antigen (CEA), and beta-2-microglobulin (BMG) were determined.
Results
The majority of the patients with p-NENs were non-functional (108/115) and well-differentiated (NET G1 (60/115) and NET G2 (47/115)). TMs levels in the patients with p-NENs were significantly higher than in the control group ($P < 0.01$), except for CA125 and AFP. The area under the curve (AUC) for CY18, CA19-9, and ferritin in patients with p-NENs was significantly higher than in the control group ($P < 0.001$), and their accuracy for detecting patients with p-NENs cases compared to the control group was 68%, 73%, and 77%, respectively. The CY18, CA125, and CEA levels were elevated in metastatic disease irrespective of PNEN grade (M-WU/t, $P=0.01$, $P=0.02$, and $P=0.01$, respectively). The AUC for differentiating metastatic from nonmetastatic disease in p-NENs was < 0.7 in these markers ($P < 0.05$).
Conclusions
The CY18, CA19-9, and ferritin can be used as additional tumor markers in diagnostics patients with p-NENs. The CY18, CA125, and CEA could be useful for diagnostic and prognostic purposes in patients with metastatic disease.

Adverse events to mitotane therapy in adrenocortical carcinoma

Eider Pascual-Corrales[1], Ignacio Ruz-Caracuel[2], Teresa Alonso-Gordoa[3], Javier Molina-Cerrillo[3] & Marta Araujo Castro[1]
[1]Ramón y Cajal Hospital, Endocrinology and Nutrition, Madrid, Spain; [2]Ramón y Cajal Hospital, Anatomic Pathology, Madrid, Spain; [3]Ramón y Cajal Hospital, Oncology, Madrid, Spain

Introduction:
Adrenocortical carcinoma (ACC) is a rare tumor, often with an unfavorable prognosis. The management of ACC is challenging due to its low frequency and limited experience. The objective of this study was to describe the adverse events (AE) in patients diagnosed with ACC treated in the Divisions of Endocrinology and Oncology at the Ramón y Cajal University Hospital (Madrid, Spain) in the last seven years.
Methods
Records of patients with ACC from 2016 to 2022 were retrospectively reviewed including clinical and biochemical data, management and follow up. Only patients with available information about mitotane therapy were included.
Results
A total of 8 patients with ACC (4 females and 4 males; median age at diagnosis 51.2 [38.2–73.9] years) were studied, including 4 hormonally inactive, 3 androgen-secreting and 1 cortisol-secreting ACC. All patients underwent surgery. The ENSAT tumor stage was II in 3 patients, III in 1 patient and IV in 4 patients. 2 patients were treated with mitotane in mononotherapy(stage II) and 6 in combination with other treatments (2 radiotherapy, 5 chemotherapy, 1 immunotherapy and 1 lung metastasis surgery). The median duration of mitotane therapy was 8.0 [3.8–38.6]months (4 patients are still under treatment at the time of analysis, 7 January 2023). During follow-up, all patients achieve the therapeutic range after 5.4 [4–6.1]months of treatment, with a median dose of 4.5 [3-5]gr/day and mitotane levels of 15 [12.4–19.7] mg/dl, except one patient due to therapeutic non-compliance. All patients had at least one AE during mitotane therapy. The time to first AE was 23 ± 8.75 days. The most common AE were digestive and hepatotoxicity in 100%, and neurotoxicity in 63% ($n=5$). Considering individually, asthenia, hypercholesterolemia and GGT increase were the most common AE ($n=8$), followed by nausea and anorexia with weight loss ($n=7$). The AE median number was 14 [9–16]. No correlation was found between the number of AE and the mitotane dose when therapeutic levels were achieved ($r=-0.46$,$P=0.251$). Neither with the duration of mitotane therapy ($r=0.32$,$P=0.435$) or mitotane plasmatic levels ($r=-0.32$, $P=0.442$). After a median follow-up of 17.7 [7.4–84.6] months, 2 patients(stage IV) died and 6 are still alive, including 3 with persistent/recurrent disease. There were two patients with ENSAT II stage treated in monotherapy who had to withdraw mitotane due to neurotoxicity. The time to first ACC recurrence/progression during Mitotane treatment was 18 ± 15.93 months.
Conclusions
The most frequent AE with mitotane were digestive, hepatotoxicity and neurotoxicity, which are not associated with the level, dose or duration of mitotane therapy.

Treatment with 177Lu-dotatate in metastasic advanced neuroendocrine tumors with positive expression of somatostatin receptors, in a third level hospital in Spain from 2015–2022

Giselle Giron[1], Lorena Hernandez[1], MARIA ISABEL DEL OLMO GARCIA[1], Rosa Camara-Gómez[1], Pilar Bello[2], Stephan Prado[2], Angel Segura[3] & Juan Francisco Merino Torres[1,4]
[1]University and Polytechnic La Fe Hospital, Endocrinology and Nutrition, Valencia, Spain; [2]University and Polytechnic La Fe Hospital, Nuclear Medicine, Valencia, Spain; [3]University and Polytechnic La Fe Hospital, Medical Oncology, Valencia, Spain; [4]University of Valencia, Medicine, Valencia, Spain

Introduction
^{177}Lu-Oxodotreotide(PRRT-Lu) has the approval by EMA and FDA since 2017 for the treatment of patients with gastro-entero-pancreatic neuroendocrine tumors(GEP-NET). However, in daily clinical practice it has also been used in other NET tumors such as paragangliomas, lung NET, medullary thyroid cancer, and others. The aim of this study is to describe the characteristics and follow-up of patients treated with PRRT-Lu in a third level hospital in Spain from 2015-2022.
Methods
Descriptive and transversal study of 103 patients with NET and positive expression for somatostatin receptors, in advanced stage or progressive disease treated with PRRT-Lu. Characteristics and follow-up of the patients are expressed as media or percentage (SPSSv26.)
Results
– Mean age at treatment was 63 years(SD14). 49.5% were men. PRRT-Lu was administered in 85% NETs, 10.2% PG/PHEO, 0.9% medullary thyroid cancer.
– Primary tumor localization: 36.5% pancreas, 23.4% small intestine, 13.1% lungs, 7.5% suprarenal glands, 8.4% unknown primary.
– The treatment was administered every 8 weeks following standard PRRT-Lu recommendation: 60.7% received 4 doses, 10.3% 3 doses, 9.3% 2 doses, 12.1% 1 dose. 4 patients have been retreated during follow-up.
– 99% of the patients received prior treatments, 87% SSA, 23% chemotherapy, 40.7% everolimus, 23.3% sunitinib. PRRT-Lu was used as 1st line of treatment in 1 patient, 2nd line in 44 patients (42.3%), 3rd line in 75 patients (72.1%), 4th line in 12 patients (11.5%), and as 5th line in 10 patients (9.6%).
– Median follow-up is 17.9 months(IQR 25.6), with a maximum follow-up 68 months. During follow up according to RECIST criteria: 38.3% Stable Disease, 29% progressive disease, 7.5% partial response, and 21% NA (6.5% lost follow-up, 14.5% have just started treatment).
– Adverse effects: 60.7% did not have any adverse event, 11.2% gastrointestinal, 5.6% hematologic, 10% asthenia, all of them G1-G2. Only one patient had a severe adverse event, a medullary aplasia that caused death. Metabolic complications presented with the administration of the medication were: diabetic ketoacidosis, severe hyperkalemia, hypertensive crisis, and uncontrolled VIPOMA crisis.
Conclusion
– Treatment with 177Lu-Dotatate must be considered as a treatment of advanced NETs with positive expression of somatostatin receptors, because of the favorable results in PFS and safety.
– Patients should be assessed within a multidisciplinary committee and framed in Reference Units, given their therapeutic complexity.
– The endocrinologist's role in monitoring the patient must be a cornerstone, in order to detect and treat endocrinological complications before, during and after treatment.

Experience with variants of the SDH gene related to paraganglioma in the Southern Health Area of Seville (Spain)

Jose Antonio Ariza Jimenez, Eyvee Arturo Cuellar Lloclla & J. Ignacio Fernández Peña
Virgen de Valme University Hospital, Endocrinology and Nutrition, Seville, Spain

Introduction
Paragangliomas are rare tumors originated from extraadrenals chromaffin cells. Most are sporadic, but between 30% and 50% are associated with hereditary syndromes. Mutations in the succinate gene dehydrogenase (SDH) have been identified as a cause of the hereditary paraganglioma-pheochromocytoma syndrome.
Material and methods
Descriptive study of case series of patients belonging to the Southern Health Area of Seville with mutations in the SDH gene associated with hereditary paraganglioma syndrome.
Results
There were 22 patients belonging to four different families, who were carriers of genetic mutations in SDH gene. 27.27% (6/22) of them have developed tumors related to these genetic variants. Median age of patients at diagnosis of tumors was 35 years. The heterozygous mutation in exon 2, c.79>T of the SDHB gene was the most frequent, affecting 45.45% (10/22) patients; 3/10 of them (33.33%) presented paraganglioma and 1/10 adrenal hyperplasia. On the other hand, c.293G>A mutation in SDHB gene affected to 5/22 patients (22.72%); 1/5 of them presented paraganglioma. Thirdly, c.761C>T mutation in the SDHB gene affected to 4/22 patients (18.18%); 1/4 of them presented paraganglioma. Lastly, c.1A>G mutation in SDHC gene affected 3/22 patients (13.63%); 1/3 of them developed paraganglioma. All cases were asymptomatic. None was functional and only 1 case presented slightly increased levels of chromogranin A. All cases required surgical treatment and only 1 needed chemotherapy.
Conclusions
– Despite its rarity, we should not forget to include paraganglioma in the differential diagnosis of patients with compatible symptoms.
– Once diagnosed, it is essential to consider genetic tests in order to establish a possible hereditary origin.
– If the hereditary origin is confirmed, it should be considered to extend the study to relatives to diagnose more cases and to supervise carriers of the mutation.

EP601

An Oestrogen-secreting neuroendocrine tumour in the lung

Najeeb Shah & Jonathan Thow
York & Scarborough NHS Foundation Trust, Diabetes & Endocrinology, York, UK

Case:
A 59-year-old female with a past medical history of surgically treated primary hyperparathyroidism (PHPT) and breast cancer presented with irregular periods, post-menstrual bleeding, hot flushes, fatigue, and left loin pain. Furthermore, she reported weight gain of approximately 8 lb over 6 months and easy bruising in the absence of antiplatelet and anticoagulant therapy. There were no central, respiratory, or gastrointestinal symptoms. She was normotensive, and the clinical examination was unremarkable. She was established on Tamoxifen therapy. Her father had colonic polyps, while her mother suffered from a uterine malignancy. Initial blood work is detailed in Table 1. For loin pain, the ultrasound scan of the renal tract showed mild dilatation of the right renal pelvis. An overnight dexamethasone suppression test showed undetectable serum cortisol (<30 nmol/l), and a genetic screen for multiple endocrine neoplasia (MEN-1) returned negative. A CT thorax, abdomen & pelvis (CT TAP) showed a left lower lung lobe mass measuring 43 mm with no radiological evidence of metastases. Cranial imaging was unremarkable. The lung mass did not demonstrate FDG uptake on PET CT, and there was no evidence of FDG avid nodal or distant metastasis. It was felt that the lung mass represented an oestrogen-secreting neuroendocrine tumour, and a left lower lobectomy was planned. The biopsy results were deemed unusual and difficult to interpret. The post-operative oestrogen levels were undetectable (Table 2), and patient symptoms resolved. A follow-up CT TAP 6 months post-op showed no new lesions. The patient remains under Endocrinology follow-up with persistently suppressed oestrogen and gradually rising gonadotrophin levels.

Learning points:
1. Significantly elevated oestrogen levels in this age group should prompt clinicians to search for central and peripheral causes.
A systematic approach under MDT guidance is imperative to investigate atypical and vague symptoms of rare pathologies.

Table 1 Initial blood test results

Blood test	Result	Normal range
FSH	10.2 IU/l	25.8–134.8
LH	7.7 IU/l	7.7–58.5
Oestradiol	***4155 pmol/l***	***<505***
TSH	1.9 mU/l	0.27–4.2
PRL	451 mIU/l	102–496
Sodium	142 mmol/l	133–146
Potassium	4.1 mmol/l	3.5–5.3
Urea	4.5 mmol/l	2.5–7.8
Creatinine	70 μmol/l	45–84
Haemoglobin	139 g/l	115–165
Platelets	263 × 10^9/l	150–450

FSH; follicle-stimulating hormone, LH; Luteinizing hormone, TSH; thyroid stimulating hormone, PRL; prolactin.

Table 2 Post-operative blood results

Revision of the histopathological examination following 68 Ga DOTA-FAPI-04 PET/CT of a Neuroendocrine breast tumor diagnosed as Invasive Ductal Carcinomatosis initially

Ömer Sönmez[1], Kaan Akcay[2], Gamze Beydağı[2], Nalan Alan Selçuk[2] & Ezgi Hacıhasanoğlu[3]
[1]Yeditepe University Hospital, School of Medicine, Istanbul, Turkey; [2]Yeditepe University Hospital, Nuclear Medicine, Istanbul, Turkey; [3]Yeditepe University Hospital, Pathology, Istanbul, Turkey

Neuroendocrine tumors (NETs) of the breast are very rare. They represent less than 1% of breast carcinomas. It is important to differentiate metastatic neuroendocrine neoplasia from primary neuroendocrine neoplasia of the breast. Histopathological misinterpretation of a breast NET is common. In a study of 18 NET cases that metastasized to the breast, it was found that 62% of these tumors originated from the gastrointestinal tract and 28% from the lung. Forty-four percent of these tumors were incorrectly diagnosed as primary breast carcinoma We present you a case of a 59-year old female patient who visited the clinic due to occasional vomiting and nausea for the last year. Her examination revealed a breast mass, which had been initially diagnosed as Invasive Ductal Carcinoma by histopathological examination (Figure-1). After that, a Fluorodeoxyglucose (FDG) – Positron Emission Tomography (PET)/Computer Tomography (CT) was ordered to investigate the lesions. But the scan did not reveal any pathology. Subsequently, the patient underwent [68Galium (Ga)]Ga-Fibroblast Activation Protein Inhibitor (FAPI) PET/CT which demonstrated pathological uptake in the mesenteric root and breast (Figure 2-B). Due to the conflicting findings, histopathological examination of the tru-cut biopsy was repeated and it has confirmed the diagnosis of NET (Figure-3). Therefore, 68Ga-DOTATATE PET/CT was performed. Multiple lesions with increased DOTA activity were illustrated in bilateral breast, mesenteric root, bones and liver (Figure 2-C). Consequently, the revised diagnosis of grade 2 NET was confirmed by histopathology. Although the FAPI uptake pattern of NETs is not exactly established, heterogeneous uptake was reported. In addition to that, [68Ga]Ga-FAPI PET/CT's utility in primary and metastatic NETs was previously demonstrated in case reports. It is also important to note that, although [68Ga]Ga-FAPI PET/CT has shown promising results in tumors of epithelial origin, these scans might be non-pathological depending on the tissue of NET. Our case demonstrates very useful information regarding unusual presentations of NETs. In the light of our case and previous research, we strongly believe that after further evaluation and investigation FAPI-PET/CT might have a beneficial role in the management of NETs.

Clinicopathological Features of Insulinoma case series

Mehmet Sözen[1], Zeynep Canturk[1], Alev Selek[1], Berrin Cetinarslan[1], Baldan Huri Eryılmaz[2], Emre Gezer[1] & Damla Köksalan[1]
[1]Kocaeli University Faculty of Medicine, Endocrinology and Metabolism, Turkey; [2]Kocaeli University Faculty of Medicine, Internal Medicine, Turkey.

Introduction
Insulinoma is the most common functional pancreatic neuroendocrine tumor (PanNET), accounting for more than 50% of all cases. Diagnosis of insulinomas may be challenging. In this study, we aim to discuss the clinicopathological features and long-term follow-up results of insulinoma cases followed up in our clinic.
Material and Methods
It is a descriptive and retrospective study of 13 insulinoma cases diagnosed over 10 years. All data of the patients were obtained retrospectively from the hospital registry system and patient follow-up files. 72-hour prolonged fasting test was performed as a diagnostic test. CT, MRI, Ga-68 DOTATATE PET/CT, EUS, and selective arterial calcium stimulation methods were used for insulinoma localization.
Results
The mean age of the patients was 53.9 ± 19.7 years, and the mean age at the time of diagnosis was 52.9 ± 18.2 years. There was only one patient diagnosed with MEN-1 syndrome. The mean time from the onset of symptoms to the diagnosis was 15 (7-27.5) months. Symptomatic hypoglycemia occurred in eight patients in the first 6 hours (61.54%) during the test. Symptomatic hypoglycemia develops in only one patient t (7.69%) after the first 24 hours. The median size of lesions identified radiologically by MRI was 15 (12-24) mm, and 46.2% of these lesions were isolated in the pancreatic tail. Multiple lesions in the pancreas were detected in 15.4% of the cases. Invasion into fatty tissues surrounding the pancreas was detected radiologically in 1 patient and pathologically in 2 patients. Only one of these patients had liver metastases as distant organ metastases at the time of diagnosis. According to WHO pancreatic neuroendocrine tumor classification, 5 patients had grade 1, 4 patients had grade 2 and 1 patient had grade 3 disease. Surgery could not be performed because 2 of 13 patients refused to have surgery. Nine patients who underwent surgery were in remission in the postoperative period and no recurrence was observed during the 31 ± 28 month follow-up. Octreotide LAR was started in one of the patients who did not accept surgery.
Conclusion
In recent years, thanks to non-invasive imaging methods that have increased in parallel with technological developments, it has been possible to diagnose insulinoma cases, most of which are smaller than 2 cm, earlier and to treat them appropriately. Our experience also highlights that Ga-68 DOTATATE PET/CT may be useful when cross-sectional imaging fails to localize the pancreatic lesion.

An unusual etiology of primary hyperparathyroidism in a young woman

Dan Alexandru Tutoveanu, Adina Simona Dragomir, Dana Roxana Boanţă, Anda Simona Dumitraşcu & Dumitru Ioachim
C.I. Parhon National Institute of Endocrinology, Bucureşti, Romania

Introduction
Parathyroid carcinoma represents a very rare cause of primary hyperparathyroidism. It can be sporadic (most of cases), but also can occur in association with certain syndromes (multiple endocrine neoplasia, hyperparathyroidism-jaw tumor syndrome or isolated familial hyperparathyroidism).
Case report
An 18-year-old woman was referred to the endocrine clinic because of a severe hypercalcemia, detected in the orthopedic surgery department, where she was hospitalized for surgical correction of a frailty right hip and femur fracture. For a few months, she has been complaining of muscle and bone pain (particularly at the left lower limb) and decreased muscle strength; also, her past medical history included a left thyroid nodule and a hypercalcemia of 13.54 mg/dl two years before, that was not further investigated. At admission, she had a PTH of 1157 pg/ml (NV: 15-65), a calcium of 14.7 mg/dl, a low phosphorus (2 mg/dl), and a 25-OH-vitamin D of 21 ng/ml (NV: 30-100), with normal thyroid and renal function. The diagnosis of primary hyperparathyroidism was established. The values for calcitonin and metanephrines were within the normal range, ruling out MEN 2 syndrome. Also, the normal value for chromogranine A and the absence of clinical features of a pituitary adenoma made the MEN 1 syndrome unlikely. A neck ultrasound revealed 2 hypoechoic nodules, one within the left thyroid lobe and another located under the lobe. A neck and thoracic CT scan showed a left lateral cervical, paratracheal, heterogenous mass of 4.313.233.17 cm, possibly a parathyroid tumor. RX scans of the left lower limb revealed brown tumors. An abdominal US was performed and showed kidney stones, without nephrocalcinosis. After fluid therapy for hypercalcemia, it was performed an "en bloc" resection of the left paratracheal mass and left thyroid lobe. The histological and immunohistochemical studies confirmed 3 foci of parathyroid carcinoma, pT3pN0, with vascular invasion, with positivity for the expression of GATA3, chromogranin A, PTH and parafibromin. Also, genetic testing for hyperparathyroidism-jaw tumor syndrome (HRPT2/CDC73 germline mutation) and MEN 1 gene sequencing have been taken into consideration. After surgery, the PTH dropped to 4.46 pg/ml, with a calcium of 10.5 mg/dl. Then, the patient developed "hungry bone syndrome" and hypothyroidism, necessitating high doses of vitamin D and calcium supplements and L-thyroxine substitution. She had a favorable evolution, with fractures consolidation, PTH and calcium within the normal range and without other signs of tumor recurrence at more than 2 years after parathyroid carcinoma resection.

Pitfalls in diagnosis and treatment of parathyroid cancer

Nataliya Druzhkova[1,2], Anastasiia Dulesova[3] & Zinaida Afanasieva[1,2]
[1]Republican Clinical Oncological Dispensary of the Ministry of Health of the Republic of Tatarstan, Department of endocrine tumors, Kazan, Russia; [2]Kazan State Medical Academy — Branch Campus of the FSBEI FPE RMACPE MOH, Kazan, Russia; [3]Republican Clinical Oncological Dispensary of the Ministry of Health of the Republic of Tatarstan, Department of pathohistology, Kazan, Russia.

Introduction.
Parathyroid carcinoma (PC) is the one of the rarest endocrine malignances and occurs in 0.5–5% of cases among patients with primary hyperparathyroidism (PHPT). Diagnosis of PC can be challenging and often made after surgery or while local or distant metastases detection. We present a case of a patient with a large intrathyroid PC, which was initially identified as a malignant thyroid nodule.
Case report.
59-old caucasian women was diagnosed with 3.2 cm cystic-solid nodule in the right thyroid lobe with irregular margins and increased blood flow in Jun? 2020. FNAB was performed and papillary cancer suggested (Bethesda V). At presentation: TSH – 1.01 mME/ml (RR: 0.4–4.0), calcitonin < 2.0 pg/ml (RR: 0–5), Ca – 3.19 mmol/l (RR: 2.0–2.57), PTH – not defined. Thyroidectomy and central neck lymph node dissection were performed. Intraoperative cytology suggested a follicular neoplasia. Follicular variant papillary thyroid cancer with no signs of lymph node lesion was confirmed histologically (pT3N0M0). Immunohistochemistry was not performed. In September 2020 patient underwent adjuvant RAI ablation (I-131, 3.7 GBq). In February 2022 hypercalcaemia with Ca 3.15 mmol/l (RR: 2.0–2.65), Ca^{2+} – 1.75 mmol/l (RR: 1.12–1.32) was detected and PHPT suspected. PTH – 1424 pg/ml (RR: 12–88) when measured. Neck US, 99mTc-sestamibi parathyroid SPECT scintigraphy, ?ontrast-enhanced Neck and Chest CT showed no evidence of disease in the neck and chest. The hypervascular liver tumor 33 × 23 mm with irregular margins was detected during abdominal CT.
In April 2022 the liver resection (segment VIII) was performed. Severe hypercalcemia before surgery was corrected with intravenous bisphosphonates and cinacalcet. Hungry bone syndrome after surgery confirmed a successful outcome.
Positive immunostaining for GATA-3, CKpan, CD56, PAX8 in the liver tumor, positive immunostaining for GATA-3, CKpan, CD56, PAX8 and negative immunostaining for thyroglobulin and TTF-1 in the primary thyroid tumor confirmed the diagnosis of intrathyroid PC with single liver metastasis 2 years after the initial surgery.
Conclusion.
Our case demonstrates, that cytology and routine histology are poor at distinguishing malignant thyroid and parathyroid tumors. To avoid faults in treatment, it is extremely important to exclude PHPT before surgery in hypercalcaemic patients with suspected thyroid cancer.

Leydig Cell Tumor – a Case of Postmenopausal Hirsutism

Koba Kamashidze[1], Tamar Peshkova[2], Liana Jashi[3] & Ketevan Dundua[4]

[1]University of Georgia, Clinical Medicine, T'bilisi, Georgia; [2]Batumi Shota Rustaveli State University, Clinical Medicine, Batumi, Georgia; [3]David Aghmashenebeli University Of Georgia, T'bilisi, Georgia; [4]David Aghmashenebeli University Of Georgia, T'bilisi, Georgia.

Background
Progressive hirsutism and moderate to severe male-pattern balding in women requires exclusion of an adrenal or ovarian tumor.
Case Presentation
A 51-year-old lady presented with excessive hair on her face and lower abdomen of 1 year duration which affected her quality of life. Her menopause started 3 years ago. Her body mass index was 28.6 kg/m^2. She had hair on her upper lip, chin, and lower abdomen; she had a Ferriman–Gallwey score of 18. On examination the patient was normotensive, with male pattern baldness. A hormone profile revealed a markedly elevated serum testosterone of 3.7 μg/l (< 0.47), androstenedione of 6.1 ng/ml (0.35–2.49 ng/ml) and a free androgen index 67% (0.19–3.63%). Cortisol, prolactin, growth hormone and thyroid function tests, glycemic profile were normal. A CT scan of the abdomen and pelvis revealed a 21 mm right ovarian mass and multiple uterine fibroids with normal adrenal glands. The patient underwent total laparoscopic hysterectomy with bilateral salpingo-oophorectomy. Histology confirmed the presence of a Leydig cell tumour, confined to the right ovary, with no malignant features. Post-operatively her androgen levels normalized and symptoms resolved within 10 weeks.
Conclusion
In postmenopausal women with new onset of hirsutism that is severe or rapidly progressive, the possibility of an androgen-secreting tumor must be suspected and detailed history and physical examination, substantiated by focused biochemical and morphological confirmation is necessary.

Extra-adrenal adrenocortical cancer (ACC) associated with multiple endocrine neoplasia type 1

Deirdre Green[1], Chris Thompson[1,2], Arnold Hill[3,4], Michael O'Reilly[1,2] & Mark Sherlock[1,2]
[1]Beaumont Hospital, Department of Endocrinology, Dublin, Ireland; [2]Royal College of Surgeons in Ireland, Academic Department of Endocrinology, Dublin, Ireland; [3]Beaumont Hospital, Department of Surgery, Dublin, Ireland; [4]Royal College of Surgeons, Department of Surgery, Dublin, Ireland.

Adrenocortical carcinoma (ACC) is a rare malignant tumour arising from the adrenal cortex, with an estimated annual incidence of one to two patients per million. Ectopic ACCs are extremely rare. They are believed to arise from cortical fragments arrested during embryologic migration and have been found close to the adrenal gland or along the path of gonadal descent. The majority of ACCs are sporadic, however, ACC has been linked with genetic disease processes, including multiple endocrine neoplasia type-1 (MEN-1). We present the case of a 66-year-old lady referred with newly diagnosed diabetes on a background of primary hyperparathyroidism. Examination revealed Cushingoid features and hormonal evaluation confirmed ACTH-independent Cushing's syndrome. 1 mg overnight dexamethasone suppressed 0900 h cortisol was 548 nmol/l [<50 nmol/l] with an undetectable ACTH <3.0 pg/ml (7.2 – 63.3 pg/ml). DHEAS 5.3 μmol/l (0.5–5.6μmol/l) and androstenedione 3.49 nmol/l (1.39 – 9.77 nmol/l) were normal. Testosterone was suppressed <0.4 nmol/l (0.1–1.4 nmol/l). Imaging revealed a 6×6×4.5 cm right-sided presumed adrenal lesion with Hounsfield units >20, a pancreatic lesion [2.5× 1.6 cm], and bilateral pulmonary nodules [0.9×0.8 cm, 0.7×0.6 cm, 0.3 cm]. Right adrenalectomy was performed and histology was consistent with an extra-adrenal ACC [Weiss score 5/9] within the peri-adrenal adipose tissue. The resected adrenal gland was normal. Lung biopsy confirmed metastatic ACC tissue and endoscopic ultrasound-guided biopsy of the pancreatic lesion revealed a pancreatic neuroendocrine tumour which was diagnosed biochemically to be an insulinoma. Genetic assessment confirmed MEN-1. Adrenal lesions in MEN-1 syndrome have significant malignant potential. ACCs are reported in 2.5–6% of MEN-1 patients. This case highlights the importance of screening for MEN-1 in at-risk patients and the need for close clinical follow-up. To our knowledge, this is the first case report of extra-adrenal ACC in MEN-1 syndrome.

Mesenteric paraganglioma with a late-onset metastases accelerated after delayed surgery

Ewelina Rzepka[1], Mari Minasyan[1], Elwira Przybylik-Mazurek[1], Magdalena Ulatowska-Białas[2], Marta Opalinska[1], Anna Sowa-Staszczak[1], Aleksandra Gilis-Januszewska[1] & Alicja Hubalewska-Dydejczyk[1]
[1]Jagiellonian University Medical College, Chair and Department of Endocrinology, Cracow, Poland; [2]Jagiellonian University Medical College, Department of Pathomorphology, Cracow, Poland.

Mesenteric paragangliomas are a rare entity; consequently, 20 cases have been reported to date. Although often found incidentally and considered benign, they have potential to metastasize. We present a case of 63-year old man with a 11-year history of the mesenteric paraganglioma. The lesion for the first time had been described on CT scan of the abdomen in 2010. However, the patient was lost to follow-up. In 2021 CT scan, followed by MRI of the abdomen, perfomed due to reccurent abdominal pain, revealed substantial progression of the tumour size (from 7×5×3 cm in 2010 to 13×10×10 cm in 2021). The patient was qualified for laparotomy. Because of difficult localization and risk of non-radical operation, the lesion was only biopted – the histopathological result was consistent with paraganglioma. Hormonal assessment showed significantly elevated urinary fractionated metanephrines. Genetic testing of SDHB/SDHD, VHL, RET, MEN1, MAX mutation was negative. Control CT scan revealed left hydronephrosis secondary to ureteral obstruction by the tumour mass and further slow progression of the tumour size. Preoperatively performed.

EP609

Mixed neuroendocrine-non-neuroendocrine neoplasm (MiNEN) of pancreas with typical insulinoma presentation

Maria Salomé Serranito, Nelson Cunha, Emanuel Vigia Duarte & José Silva-Nunes
Hospital Curry Cabral – Centro Hospitalar Universitário de Lisboa Central, Lisbon, Portugal.

Introduction
Mixed neuroendocrine-non-neuroendocrine neoplasms (MiNEN) of the pancreas are composed of two morphologically different components, each representing at least 30% of the tumor: ductal or acinar adenocarcinoma and neuroendocrine neoplasm (NEN). They are extremely rare tumors whose etiopathogenesis and biological behavior are not fully understood. Given its rarity, we describe a case of insulinoma in the context of MiNEN.
Clinical case
A 55-year-old woman with no relevant medical or family history was referred to our department due to symptomatic hypoglycemic episodes with one year of evolution. The episodes were more frequent in the morning, improved after ingestion of carbohydrates, and capillary blood glucose was between 38–55 mg/dL. She denied taking hypoglycemic agents. Physical examination showed BMI 30 kg/m^2 and was otherwise unremarkable. Laboratory evaluation with 12 h fasting was consistent with endogenous hyperinsulinism: glycemia 53 mg/dL, insulin 11.45 μUI/ml (3–25), C-peptide 3.62 ng/ml (0.93–3.73) and anti-insulin antibody was negative. Calcium metabolism and pituitary lab tests were normal. CT scan and MRI did not show neoformative lesions. Ultrasound endoscopy revealed a solid intrapancreatic formation in the body-caudal transition, hypoechogenic, with 8.8 mm, well-delimited and vascularized, with features suggestive of NEN. Given these results, a diagnosis of insulinoma was made and the patient underwent distal pancreatectomy. After the surgery, the hypoglycemia episodes resolved. Anatomopathological examination revealed a MiNEN of the pancreas with 1.5 cm, comprising a G1 NEN (~70%) and ductal adenocarcinoma (~30%) – staging (AJCC 8th edition): pT1aN0. In the remaining pancreatic parenchyma, a 0.3 cm neuroendocrine microadenoma was also identified. The patient is under surveillance at the Endocrinology and Medical Oncology outpatient clinic. One year after surgery, there is no clinical and laboratory evidence of hypoglycemia nor suspicious lesions on FDG-PET scan. Given the presence of two neuroendocrine pancreatic tumors, the patient underwent MEN1 genetic testing, however, results are still unknown.
Conclusion
The follow-up and prognosis of patients with MiNEN are not well understood. There are few cases of pancreatic MiNEN published in the literature, and their presentation is heterogeneous. However, in most of them, the neuroendocrine component is non-functional, and the diagnosis is made in the context of detection of incidental pancreatic lesion or mass effect. In this case, the neuroendocrine component was as insulinoma and the study of endogenous hyperinsulinism preceded the identification of

the tumor. With this exceptionally rare case, we intend to contribute to the body of knowledge about MiNEN, whose approach remains challenging for clinicians.

Pulmonary metastases in differentiated thyroid cancer

Rahal Amel[1,2], Samira Azzouz[3] & Lynda Benabed[3]
[1]Medecines, Endocrinology, Algiers, Algeria; [2]Hopital Bologhine Ibn Ziri, Endocrinology, Algiers, Algeria; [3]Medecines, Algiers, Algeria.

Introduction
The incidence of thyroid cancers is increasing; they are considered to have a very good prognosis with good survival The frequency of metastases is 5 to 10%. The most common locations are lung and bone. The morbidity of metastatic disease is related to the initial histological type, tumour mass, location of metastases, age, possible loss of iodine uptake and 18F-FDG uptake
Materials and methods
We collected 25 patients treated for hormone-dependent differentiated thyroid carcinoma with pulmonary metastases. We first evaluated the therapeutic response to radioiodine according to histological factors; age and location of the metastasis Secondly, we evaluated the evolution of these patients: remission or evolutionary progression as well as the transition to a refractory form.
Results
In patients with pulmonary metastases: The predominant histological type is papillary in 76% The average age is 45 years Morphological evaluation reveals micronodular lesions in 53%; infra radiological in 20% and macro nodular in 28% of cases 68% of patients with pulmonary metastases are iodo avid metastases After univariate analysis, papillary histology is significantly more frequent in iodo avid lung metastases and aggressive forms are significantly more frequent in non iodo avid lung metastases Complete biological and morphological responses are significantly more frequent in iodo lung avid metastases Progression to a refractory form is significantly more frequent in patients over 40 years old and in non iodo avid lung metastases
Conclusion
Our results are in agreement with the data of the literature in fact the patients of less than 40 years: having a more frequent infra radiological forms are better responders to the radioactive iodine and a contrario the refractory forms are more frequent in the patients of more than 40 years

Body Mass Index and sporadic Medullary Thyroid Cancer: insights from a large series

Alessandro Prete[1], Carla Gambale[2], Virginia Cappagli[2], Valeria Bottici[2], Rossella Elisei[2] & Antonio Matrone[2]
[1]Endocrinology Unit, Clinical and Experimental Medicine, Pisa, Italy; [2]Endocrine Unit, Clinical and Experimental Medicine, Pisa, Italy.

Introduction
An increased Body Mass Index (BMI) has been associated with higher prevalence of many cancers, including differentiated thyroid cancer. However, no data have been reported about potential impact of BMI on aggressiveness of presentation and clinical outcome of medullary thyroid cancer (MTC).
Aim
To evaluate the potential influence of BMI on clinical presentation and outcome of MTC.
Methods
We reviewed anthropometric and clinical data of 444 consecutive patients with sporadic MTC, surgically treated at the Endocrine Surgery Unit and followed at the Endocrine Unit of the University Hospital of Pisa, from 2000 to 2019.
Results
At time of surgery, 92/444 (20.7%) patients had BMI $\geqq 30 \times kg/m^2$ (Ob-group) and 352/444 (79.3%) $< 30\ kg/m^2$ (control group). Ob-group patients were significantly older (median 59.5 vs 54.0 years, $P=0.001$), whilemale gender prevalence did not differ (44.6% vs 45.1%, $P>0.4$). Ob-group showed a significantly smaller tumor dimension compared with control group (median 1 cm vs 1.3 cm, $P=0.001$). Particularly,micro-MTC ($\leq$ 1 cm)was present in 50/92 (54.3%) and 136/352 (38.6%), 1–2.5 cm tumors in 25/92 (27.2%) and 137/352 (38.9%), 2.5–4 cm tumors in 16/92 (17.4%) and 52/352 (14.8%) and tumors $>$ 4 cm in 1/92 (1.1%) and 27/352 (7.7%), in Ob-group and control group, respectively ($P=0.006$). MTCs of Ob-group had both significantly lower T and N stage compared with control group ($P=0.019$ and 0.013, respectively). Otherwise, minimal extra-thyroid extension and multifocality did not differ ($P>0.4$). Ob-group patients had significantly lower levels of pre-operative calcitonin compared with control group (median 67.2 vs 123.5 pg/ml, $P=0.036$). After surgery, the follow-up time did not differ between Ob-group and controls (5.2 vs 6.3 years, $P>0.1$). At the end of follow-up, Ob-group showed significantly lower rate of structural disease, compared with control group (12/92, 13%, vs 80/352, 22.7%, $P=0.036$).
Conclusions
At the time of surgical treatment, about 21% of all sporadic MTC patients were suffering from obesity. In our series, patients with obesity had smaller tumors and less metastatic lymph node involvement, probably due to more frequent and careful medical evaluations experienced by these population leading to an early detection of MTC. Moreover, Ob-group had less structural disease at the end of the follow-up confirming the importance of an early diagnosis of MTC.

A new pathogenic variant of MEN 1 gene causing pituitary, pancreatic, parathyroid, adrenal and middle ear neuroendocrine tumors

Sorina Schipor[1], Cristina Stancu[2], Oana Stanca[2], Andrei Muresan[1], Mirela Gherghe[3] & Corin Badiu[2,3]
[1]National Institute of Endocrinology, Molecular, Cellular and Structural Research Laboratory, Bucharest, Romania; [2]National Institute of Endocrinology, Thyroid Related Disorders, Bucharest, Romania; [3]"C.Davila" University of Medicine and Pharmacy, Endocrinology, Bucharest, Romania.

Multiple endocrine neoplasia type 1 (MEN1) is an autosomal dominant disorder caused by germline mutations of MEN1 gene, without genotype–phenotype correlation. It is defined as the occurrence of two or more primary neuroendocrine tumors (parathyroid, enteropancreatic, pituitary), or the occurrence of one of the MEN1-associated tumors in family members of a patient with a clinical diagnosis of MEN1. Multiple parathyroid tumors with hyperparathyroidism are the most common manifestation with highest penetrance between 40 to 50 years, followed by pancreatic neuroendocrine tumors. Our patient, 49 years old, had a family history positive for hyperparathyroidism, gastrinoma, pancreatic and adrenal tumor, (his brother), pancreatic tumor, subcutaneous lipomas, (his father), prolactinoma, (his daughter). He was diagnosed with primary hyperparathyroidism at 37 years, submitted in 2013 to parathyroidectomy that revealed three adenomas. In 2014, he was diagnosed with nonfunctioning pituitary macroadenoma. In 2015, an abdominal computed tomography scan revealed pancreatic tumors and bilateral adrenal adenomas which proved nonfunctional at biochemical evaluation. In 2021, IRM showed the gastric wall thickening and superior digestive endoscopy was performed. Gastric biopsy documented gastric neuroendocrine tumor grade 1. He then developed carcinoid syndrome and elevated levels of chromogranin A ($>$2800 ng/ml), serotonin (535.3 ng/ml), and 5-hydroxyindoleacetic acid (17.83 mg/24 h). Functional imaging (99mTcEDDA/HYNIC-TOC SPECT/CT) revealed gastric and pancreatic tumor with high expression of somatostatin receptors, with secondary lymph node and liver involvement, and a faint uptake in the middle ear. To rule out the existence of a phenocopy of this syndrome we analyzed *MEN1* gene by Sanger sequencing. Genetic analysis showed the occurrence of a new heterozygous mutation by the insertion of two nucleotides in exon 3 of *MEN1* gene at the position c.520_521insCA, resulting in a frame shift mutation (H174Pfs*12). This mutation is predicted as pathogenic and disease causing (MutationTaster). One previous report identified a pathogenic missense mutation at the same position, but in our case the alteration is different and not described yet.
We report a patient with a novel mutation in MEN1 gene presenting with primary hyperparathyroidism, a nonfunctioning pituitary macroadenoma, bilateral nonfunctioning adrenal adenomas, neuroendocrine gastric and pancreatic tumors with liver metastases, and middle ear neuroendocrine tumor. A higher risk of aggressive tumor phenotypes has been described in relation to frameshift and nonsense mutations, predominantly associated with aggressive gastroenteropancreatic neuroendocrine tumors (GEP NETs). Patients with aggressive phenotypes and genetically confirmed MEN1 should be carefully followed up in a multidisciplinary approach, preferably at 3 months interval for long-term.

A Rare Case; Ectopic ACTH Syndrome Caused by Metastatic Germ Cell Tumor

Ozlem Kanburoglu Meletli[1], Cigdem Birinci[1], Cuneyt Bilginer[2], Hulya Coskun[1], Irfan Nuhoglu[2], Ozge Ucuncu[1] & Mustafa Kocak[2]
[1]Karadeniz Technical University Faculty of Medicine, Department of Endocrinology and Metabolism, Trabzon, Turkey; [1]Karadeniz Technical

University Faculty of Medicine, Department of Endocrinology and Metabolism, Trabzon, Turkey.

Introduction
Although ectopic ACTH syndrome (EAS) is most commonly seen in cancers with neuroendocrine differentiation, it is not a common condition in germ cell tumors. Here we report a rare case of EAS due to metastatic germ cell tumor.
Case report
A 53-year-old male patient presented with fatigue, weakness, swelling in both legs and weight loss for 3 months. He had type 2 diabetes and no history of smoking or alcohol. In the physical examination, there were aphthous lesions in the mouth, widespread hyperpigmentation on the skin and pitting edema of the feet. In laboratory results hyperglycemia, severe hypokalemia and elevation in cholestasis enzymes were observed. Abdominal computerized tomography showed multiple metastatic masses and lymph nodes in the abdomen, the largest of which was in the liver. Needle biopsy of the liver mass resulted in metastatic germ cell tumor metastasis. No focus was detected in the imaging performed for primary focus scanning. Hypercortisolemia was found in the examinations performed due to severe hypokalemia resistant to treatment (Table 1). As a result of further investigations, although ACTH staining was negative in the immunohistochemical examination, the patient was considered to have EAS due to metastatic germ cell tumor, since it was clinically compatible. The patient was started on bleomycin-etoposide-cisplatin-based antineoplastic therapy for metastatic germ cell tumor and a steroid synthesis inhibitor was started for the treatment of hypercortisolemia. After 4 cycles of chemotherapy, the cortisol level was determined as 2.93 μg/dl because the patient had symptoms such as weakness, loss of appetite and hypotension. Adrenal insufficiency developed with the inhibition of steroidogenesis and control of the ACTH secreting focus with antineoplastic therapy. Therefore, the steroid synthesis inhibitor was discontinued and hydrocortisone replacement was started. It was planned to continue antineoplastic therapy until complete remission was achieved.

Table 1 Laboratory findings

Parameter	Result	Reference Range
Cortisol	26.48 μg/dL	
ACTH*	181 ng/l	<46
Mid-night Salivary Cortisol	43.45 ng/ml	0.7–2.2
Urine Free Cortisol	109.53 μg/24 h	3.5–45
2 mg DST** (Liddle test)	20.56 μg/dL	
Overnight 8 mg DST**	16.9 μg/dL	

*ACTH: Adrenocorticotrophic Hormone **DST: Dexamethasone Suppression Test.

Conclusion
When EAS is detected, identification and treatment of the ACTH-secreting focus is important in achieving remission. It should be kept in mind that immunohistochemical ACTH staining may be negative in metastatic foci. This case taught us that the etiology of hypercortisolemia should be addressed with a broad perspective and a multidisciplinary approach.

Pan-endocrine cancer pattern of somatic mutations: Toward Genotype–Phenotype correlation and machine learning methods

Liang Zhang & Joakim Crona
Department of Medical Sciences, Uppsala University, Uppsala, Sweden.

Background
Neuroendocrine tumors (NETs) and Adrenocortical carcinomas (ACCs) are rare and heterogeneous tumors entities. Advanced NETs and ACC own poor prognosis with less than 40% of five-year survival. There is a need for improved biomarkers to predict disease prognosis and treatment sensitivity. A broad overview of NETs and ACC genetics has never been explored.
Aim
To investigate genotype–phenotype correlations on a pan-endocrine cancer level with a focus on somatic mutations.
Methods
A litterature search identified papers utilizing Whole Exome/Genome Sequencing on NETs or ACCs since 2000. Key inclusion criteria were: 1. NETs from the gastrointestinal tract, lung, adrenal/paraganglia and thyroid as well as ACC; 2. Available data on patient characteristics and somatic mutations. Data on clinicopathological features and genetic variants were collected.
Results
1747 articles were screened and thirty-four publications were selected. Data from a total of 1209 patients were enrolled in this study. Among ACCs, 264 cases were included. 67.8% (145 out of 214) were females; median age was 49.6 (range,13–83) years; mean tumor size was 11.1 ± 4.9 cm; and 36.2% (76 out of 210) manifested malignant behavior with either local invasion, metastatic or recurrent disease. Among 945 NETs, we identified 304 pheochromocytoma/paraganglioma, 131 medullary thyroid carcinoma, 249 pancreatic NETs, 182 small intestinal NETs, 61 lung NETs, 6 breast NETs, 6 duodenal NETs and 6 unkonwn orign NETs. Among these, 50.3%(306 out of 608) were female patients. The median age was 52 (range,10–89) years; mean tumor size was 4.4 ± 2.6 cm and 35.6% (217 out of 609) were recorded with malignant behaviors.
Conclusion
This cohort may provide a first and broad overview of the genetic landscape among both NETs and ACCs. Future research will aim to identify genotype–phenotype correlations with a focus on the dicsocery of prognostic biomarkers.

DOI: 10.1530/endoabs.90.EP614

A case report – Should we start breast cancer screening earlier in the MEN-1 patients?

Henrique Pina, João Dinis Martins, Vitória Duarte, Sílvia Guerra, José María Aragüés & Cristina Valadas
Hospital Beatriz Ângelo, Endocrinology, Loures, Portugal.

Multiple endocrine neoplasia type 1 (MEN-1) is characterized by an increased predisposition to the development of tumors of the endocrine tissues, such as parathyroid glands, anterior pituitary, and duodenopancreatic neuroendocrine tumors. It is an autosomal dominant disorder due to germline mutations in the MEN-1 tumor suppressor gene. This gene encodes the menin protein, which is involved in cell growth and differentiation, and in sensing or repairing DNA damage. We present the case of a patient whose diagnosis of MEN-1 syndrome was made incidentally during staging for breast cancer. The patient is a female, 43 years old, with no relevant personal history, and a family history of consanguinity – the patient's parents are brother and sister. During the staging for breast cancer, the patient underwent breast mammography and biopsy after the detection of a 25 mm nodule in the right upper-external breast quadrant. The anatomopathological evaluation revealed invasive ductal carcinoma. Then, a genetic test was performed identifying a breast cancer pathogenic variant (CHEK2 c.1141 A>G VUS) and, incidentally, a MEN-1 pathogenic mutation (c.1117G>A). After the identification of the MEN-1 mutation, the patient was referred to an Endocrinology consultation. The initial laboratory evaluation accordingly to Clinical Practice Guidelines for MEN1 revealed no preliminary abnormalities: plasma calcium 9.3 mg/dl, albumin 4.2 g/dl, PTH 63.6 pg/ml, gastrin 23 pg/ml, glucagon 145 pg/ml, vasointestinal polypeptide 14 pmol/l, chromogranin A 7.3 nmol/l, insulin 16.0 μUI/ml, with an associated fasting glucose level of 90 mg/dl, prolactin 6.5 ng/ml, IGF-1 92 ng/ml, TSH 1.71 mUI/l, fT4 14.2 pmol/l, FSH 23.1 mUI/l, LH 7.6 mU/l, 17-Beta estradiol 80.6 pg/ml, ACTH 10.7 pg/ml, CA 125 11.7 U/ml. Imaging evaluation done during staging for breast cancer (including gynecological echography, thorax MRI and bone scintigraphy) showed no evidence of disease other than the referred nodule. There is growing evidence that MEN-1 increases the risk of development of breast tumors by at least two- to threefold (in frequency and in age of appearance) and several MEN-1 studies suggest the age of 40 years for the start of screening. However, Clinical Practice Guidelines for MEN-1 do not mention breast cancer and do not suggest changes in breast cancer screening compared to the general population. Since in Europe, the majority of countries conduct breast cancer screening programs starting at age 50, this case raises the question – Shouldn't we start breast cancer screening earlier in the MEN-1 subpopulation?

Posterior reversible encephalopathy syndrome (PRES) as a presentation of a metastatic pheochromocytoma (PHEO)

Simone Furio Collao, Irune Blanco Urbaneja, Maria Soledad Librizzi, Isabella Mattei, Noemi Jimenez Lopez, Ruben Carrasco Barria, Alvaro Mauricio Chavez Villegas & Maria Calatayud Gutierrez
University Hospital 12 de Octubre, Endocrinology and Nutrition, Madrid, Spain.

Introduction
PRES it's a neurologic syndrome with multiple manifestations, that includes high blood pressure with a variable range. It usually develops in the context of medications or an underlying condition. The treatment is usually symptomatic and determined by said disease.

Objective
We present the case of a patient with PRES linked to the diagnostic of a metastatic PHEO.
Case-report
A 72-year-old male underwent left adrenalectomy in 2016, because of a PHEO. Pathology findings included capsular invasion, necrosis, diffuse focal pattern, and nuclear pleomorphism without invasion of the perinephric fat. He had no evidence of disease until 2020, when he lost follow-up because of COVID-19 pandemic. In May 2022, he was admitted in Neurology because of a hypertensive crisis up to 205/97 mmHg, headache, an acute confusional state and transient cortical blindness, that lasted hours, compatible with PRES. He was discharged with hypertensive medication. He was readmitted in June 2022 because of deterioration of general condition and weight loss up to 10 kg. Computed tomography (CT) of the chest, abdomen and pelvis was performed, showing multiple pulmonary, pleural, hepatic and bone lesions, without clear evidence of primary tumor. Because of the history of the patient and symptoms presented in the previous hospitalization, 24 h catecholamines and fractionated metanephrines urine test was determined, presented in Table 1 After the results, we initiated and titrated alpha-blockade with Doxazosin until we achieved adequate blood pressure. We completed the study with 123I-Meta-Iodobenzylguanidine Scintigraphy and Ga-68 DOTATATE PET/CT Scan which revealed increased uptake in the CT lesions. Lanreotide 120 mg sc was initiated and after nuclear imaging was performed, radionuclide therapy was also initiated, but the patient presented liver failure and died after the 1st dose of Lutetium-177.

Table 1 24 h catecholamines and fractionated metanephrines in urine

	RESULTS (g/24 h)	NORMAL RANGE
Norepinephrine	**955.3**	**[23–105]**
Epinephrine	**69.9**	**[0.5–20]**
Dopamine	**9.678**	**[65–400]**
Normetanephrine	**195.379**	**[162–528]**
Metanephrine	**22.263,52**	**[64–302]**
3-Methoxytyramine	**60.522**	**[94–400]**

Conclusions
Even though neurologic complications are rare, in the presence of PRES or other atypical cerebrovascular symptoms, PHEO should be suspected. PHEO should have a lifelong follow-up to prevent complications and early detection of recurrence/malignancy.

Molecular predictors of response to the therapy with mitotane in adrenocortical cancer

Erika Porubayeva & Lilia Selivanova
Endocrinology Research Center, Department of Fundamental Pathology, Moscow, Russia.

Background
Adrenocortical cancer (ACC) therapy is characterized by insufficient effectiveness. Currently, mitotane, an adrenolytic drug, is the only drug approved for treatment of ACC and is used in the adjuvant setting and in case of metastatic or advanced disease. However, the administration of mitotane to certain groups of patients remains controversial due to the low response rates, high toxicity and limited data on the benefit of treatment. Expression levels of the large subunit of ribonucleotide reductase M1 (RRM1), cytochrome P450 2W1 (CYP2W1) and sterol-O-acyltransferase-1 (SOAT1) are considered as potential predictors of response to mitotane therapy. The aim of this study was to estimate the immunohistochemical expression of RRM1, CYP2W1 and SOAT1 in ACC as markers of clinical outcomes and response to the therapy with mitotane.
Methods
The study included 62 patients older than 17 years of age with a diagnosis of ACC confirmed histologically and immunohistochemically. Pathomorphological examination of surgical and consultative material from patients treated between 2005 and 2020 in Endocrinology research center and other health care centers of Russia was performed. Antibodies to SF-1, Ki-67, RRM1, CYP2W1, SOAT1 were used diluted in accordance with recommendations of firms-manufacturers for immunohistochemical detection. Kaplan–Meier method was used to estimate disease-free survival (DFS) and its predictors.
Results
Mitotane therapy was initiated in 29 patients in the postoperative period, the control group comprised 33 patients according to results of immunohistochemical examination (level of expression of Ki-67). In the control group of patients with low and moderate RRM1, CYP2W1 and SOAT1 immunoreactivity, a better DFS was observed ($P=0.037$, $P=0.020$ and $P=0.001$, respectively) compared to the study group at this level of marker expression. In case of high expression levels of the markers, no statistically significant differences were found.
Conclusion
In this study we have identified tendences in the correlation of the expression of potential prognostic markers and DFS in our sample of patients. Evaluation of RRM1, SOAT1 and CYP2W1 immunoreactivity opens new possibilities for personalized mitotane therapy in ACC.

Merkel cell carcinoma, experience of a single center

Dusan Ilic, Sanja Ognjanovic, Bojana Popovic, Valentina Elezovic Kovacevic, Milica Opalic, Lena Radic & Djuro P. Macut
Clinic for Endocrinology, Diabetes and Metabolic Diseases, University Clinical Centre of Serbia, Department for Endocrine Tumors and Hereditary Cancer Syndromes, Belgrade, Serbia.

Introduction
Merkel cell carcinoma is a rare and aggressive neuroendocrine skin cancer. It is characterized by a high rate of local recurrence after surgical resection as well as the occurrence of distant metastases. It mostly occurs in the elderly and the exact etiology is unknown. The most significant risk factors for its occurrence are exposure to ultraviolet light and the oncogenic effect of the Merkel cell polyoma virus.
Aim
Demographic and clinical characterization of patients with Merkel cell carcinoma as well as tumor characteristics and their impact on the outcome of the disease.
Methods
The retrospective study included 37 patients diagnosed with Merkel cell carcinoma who were treated in our department between 2001 and 2022.
Results
Most patients were male, 64.9%, while the average age at the time of diagnosis was 62.03 ± 12.03 years. The median follow-up of patients from the time of diagnosis was 24 (5–121) months. The primary site of the tumor was unknown in 32.4% of patients, while localization in the head and neck, upper extremities, lower extremities, and glutes was 12.9%, 19.4%, 12.9%, and 16.1%, respectively. Metastatic disease at the time of diagnosis was verified in 64.9% of patients, most often in locoregional lymph nodes 61.1%. In stage I the disease was diagnosed in 17.1% of patients, in stage II in 14.3%, stage III in 57.1% and stage IV in 11.4% of patients. Systemic chemotherapy was used in 82.9%, locoregional radiation therapy in 34.3%, and immunotherapy in 16.2% of patients. Survival was statistically significantly shorter in patients with stage III and IV disease compared to patients with stage I and II disease (P 0.04). The earliest death occurred 5 months after diagnosis. A trend in shorter survival was observed in male patients (P 0.06).
Conclusion
Advanced Merkel cell carcinoma is associated with a worse prognosis. The fact that in most patients at the time of diagnosis there is locoregional dissemination of the disease imposes the need for a greater degree of clinical suspicion among doctors of various specialties, as well as raising public awareness of this type of cancer with the aim of early diagnosis and treatment.

Malignant Struma Ovarii: Report of Two Cases Diagnosed with Follicular Variant Papillary Thyroid Carcinoma

Betül Gündüz, Sema Çapkinoğlu Türk, Yusuf Kayhan, Elif Kılıç Kan, Aysegul Atmaca & Ramis Çolak
Ondokuz Mayıs University – Faculty of Medicine, Endocrinology and Metabolic Diseases, Turkey.

Introduction
Malignant struma ovari is a rare ovarian mature teratoma. The diagnosis can be done histopathologically. There are no specific diagnostic findings in terms of imaging, clinical and laboratory. We present two cases of malignant struma ovarii in papillary follicular variant subtypes in this report.
Case report
Case 1; The patient was a 44 year old female, she had complaints of pelvic pain and a palpable lower abdominal mass. Pelvic MRI examination showed a semisolid mass of $90 \times 80 \times 103$ mm in the left ovarian region. Tumor markers

and thyroid tests were normal. Laparotomy was performed. Left salpingo-oopherectomy material was sent for frozen section and was reported to be malignant. Right salpingo-oopherectomy and total abdominal hysterectomy were performed. Histopathology results showed as follicular variant papillary thyroid carcinoma. There was minimal invasion in the tumor capsule. Thyroid ultrasonography examination showed a hypoechoic nodule without blood supply with measuring 3.5×3×3.5 mm. Total thyroidectomy followed by radioactive iodine treatment was offered for the patient. However the treatment could not be continued because the patient was out of follow-up.

Case 2; A 37 year old female, she had complaints of pelvic pain in the left lower quadrant and distention. Pelvic MRI examination showed two masses of 91×60×73 mm and 34×35×40 mm in the left ovarian region. Left salpingo-oopherectomy were performed. Histopathologic examination showed follicular variant papillary thyroid carcinoma in the struma ovari. Right salpingo-oopherectomy and total abdominal hysterectomy were performed. Thyroid ultrasonography examination and thyroid tests were normal. Total thyroidectomy followed by radioactive iodine treatment was offered for the patient. The patient was referred to general surgery for thyroidectomy.

Conclusions

Due to the rarity of malignant struma ovari and the lack of adequate case series, diagnosis and treatment are unclear. Bilateral salpingo-oopherectomy, total abdominal hysterectomy and I 131 ablation after thyroidectomy reduce the risk of recurrence and facilitate patient follow up with thyroglobulin.

Clinical Case: Missed Diagnosis of Poorly Differentiated Thyroid Cancer

Sandra Jokubauskaitę[1] & Diana Šimonienę[2]
[1]Lithuanian University of Health Sciences, Kaunas, Lithuania; [2]Hospital of Lithuanian University of Health Sciences Kaunas Clinics, Department of Endocrinology, Kaunas, Lithuania.

Introduction

Poorly differentiated thyroid cancer (PDTC) is a rare subtype of thyroid carcinomas, that diagnosis is difficult and often missed in daily routine. It is believed that most of them arise in well-differentiated thyroid carcinoma, although a subset of these lesions apparently also arise de novo.

Case report

In 2007, a 55-year-old man had a total thyroidectomy and received radioactive iodine treatment post-surgery due to well-differentiated papillary thyroid carcinoma (PTC) (pT2N0M0). An endocrinologist examined the patient several times for a possible recurrence of thyroid cancer, but there were no signs: thyroglobulin (TG) was <0.1 μg/l. The patient is currently on thyroxine replacement therapy (targeted thyroid-stimulating hormone <0.1 mIU/l). In 2019, an elevated TG level was detected (6.47 μg/l), and an ultrasound (US) of the neck showed a calcified lymph node in the III zone of the right side. Fine-needle aspiration of the calcified lymph nodes revealed any tumorous alterations and TG did not increase dynamically (4.5 μg/l). In 2020, the patient complained of pain in his left upper arm. A CT scan revealed a pathologic humeral fracture, and a bone tumor biopsy indicated PTC metastasis. CT scan of the neck, chest, abdomen, and pelvis revealed no primary tumor, therefore the right lung root and bronchopulmonary lymph nodes were more likely to be pathological, likewise, a blood test found an elevated TG level (637.5 μg/l). Hence, the humeral tumor was excised, followed by fracture fixation and cementoplasty; the histology of the tumor confirmed PTC metastasis in the bone. The patient was given radioactive iodine therapy in ablating dosages following surgery. Four months after, a CT scan shows slightly enlarged peribronchial and bronchopulmonary lymph nodes, and TG level increased over time up to 716.05 μg/l. After biochemical and radiological progression along with radioactive iodine resistance, the patient's medical records and cytological features were reviewed – PDTC was diagnosed. Kinase inhibitors have been initiated for cancer treatment (Lenvatinib). In 2022, on a CT scan, the disease has not progressed, and the level of TG has decreased (217 μg/l), indicating that the cancer is likely responding to biological therapy. This year, the patient feels better and has started the 20th cycle of Lenvatinib.

Discussion

PDTC accounts for 2–15% of all thyroid malignancies, consequently, PDTCs, which require a correct diagnosis in order to receive adequate treatment, are often missed in daily routine. In our case, a correct diagnosis was made 13 years after the PTC diagnosis.

Systemic manifestations of medullary thyroid cancer

Ana Matijaca
Clinical Hospital Dubrava, Zagreb, Croatia.

78-year old previously healthy man was reffered to Outpatient endocrinology clinic due to painful spine and shoulders. His lumbar and thoracic X-ray showed decreased lumbar and thoracic vertebrae (L1, L2 and Th 5) and densitometry indicated slightly decreased bone density with T score -1,0 in left femoral neck and L1 vertebra. Since patient mentioned recent unintentionally 10 kg weight loss he was processed to further work-up and additional blood tests were done. Secondary osteoporosis was ruled out. Levels of testosterone and cortisol as well as PTH, calcium and phosphate were normal. Slightly elevated PSA (6 μg/l) and significantly eleveted CEA 75.2 μg/l (n.v.< 5) were noticed, and TSH was 8 mIU/l. Patient had no history of thyroid disease earlier. Thyroid ultrasound showed hypoechoic nodule with smooth irregular capsule size 2.3×2.4×1.7 cm in right lobe and FNA was done. Cytological finding indicated medullary thyroid carcinoma. Neck ultrasound was repeated to evaluate lymph nodes and FNA of largest ipsilateral lymph node size 8×5 mm with visible hilus and reactive aspect was done preoperatively – no tumor cells were found. Additonal measurement of serum calcitonin and urinary fractionated metanephrines was done. Calcitonin was extremely high, 1998 ng/l (n.v. 8,31–14,3) and pheochromocytoma was ruled out. Since very high levels of serum calcitonin and CEA were found, CT of thorax and abdomen was done and no metastasis were found. Patient underwent total thyroidectomy with cervical lymph node dissection. Patohistology confirmed medullary thyroid carcinoma with 4/16 positive lymph node on ipsilateral site, contralateral lymph nodes were not positive for tumor. Postoperatively values of calcitonin was 10×05 ng/l (n.v. 8,31–14,3) and CEA was 31.8 ng/ml, but since postive lymph nodes patient was reffered to oncologist. According to current NCCN guidelines, after diagnosis of MTC was confirmed, screen for germline RET proto-oncogene mutations was done. It showed that patient had mutation c. 790 in 13. exsone of RET gene which is related with MEN2 syndrome. In conclusion, paraneoplastic syndrome is not so rare with MTC – literature refers flushing and diarrhea as most, and ectopic secretion of ACTH as less common. I wanted to show patient with systemic manifestation not commonly described with MTC as were weight loss and bone pain in patient whose age would not indicate thyroid tumor to be cause of these symptoms.

Primary multiple carcinomas: Papillary thyroid carcinoma and primary neuroendocrine liver carcinoma

Lali Tigishvili[1], Maya Mchedlishvili[2] & Giorgi Mchedlishvili[3]
[1]ENMEDIC Clinic, Endocrinology Deprt., Tbilisi, Georgia; [2]ENMEDIC, Tbilisi, Georgia; [3]ENMEDIC Clinic, Tbilisi, Georgia.

Liver neuroendocrine carcinoma is a relatively rare disease. There is lack of description due to prognostic information of the disease. Liver serves as an visceral organ, taking part in several endocrine functions, according to an investigations has produced specific proteins and activate thyroid hormones, glucocorticoids. This article describes clinical case of 54 years man with clinical diagnosis of Grave's disease. Liver examination showed normal liver hormones, radiology investigation revealed a nodule (size of the nodule 7.0–5.6 cm) localization in the right lobe of liver. Patient has no diagnosis of Hepatitis C virus, AFP was in normal range. According to liver postsurgical investigation the low Grade neuroendocrine carcinoma revealed. There are extremely rare cases of primary liver neuroendocrine carcinoma. Following our recommendations patient examined due to excluded metastatic lesions (colonoscopy procedure) and was revealed without tendency of cancer in the intestines. According to immune profile and histological examination neuroendocrine liver carcinoma Grade 1 revealed. Patient followed with thyroidectomy a year later with diagnosis of papillary thyroid microcarcinoma with multi centric growth and tendency in pre- and paratracheal lymph nodules (2 nodules). According to the literature, liver neuroendocrine carcinoma – Grade 1 don't characterized with aggressive behavior. Therefore in such case, liver neuroendocrine carcinoma metastasis developed in the retroperitoneum after thyroidectomy, three months later. Neuroendocrine liver cancer is more aggressive in association with papillary thyroid cancer. As a conclusion there are rare cases of primary multiple carcinomas associated with papillary thyroid microcarcinoma in the literature, and this article is an example of aggressive follow up of Primary Multiple

Carcinomas: liver neuroendocrine cancer with association of Papillary Thyroid Cancer.

Head circumferences measured during developmental monitoring visits before diagnosis of pediatric craniopharyngioma

Julia Beckhaus[1], Svenja Boekhoff[1], Leonie Krieger[1], Junxiang Peng[1,2], Carsten Friedrich[1] & Hermann Müller[1]
[1]Klinikum Oldenburg AöR, Oldenburg, Germany; [2]Nanfang Hospital, Department of Neurosurgery, Guang Zhou Shi, China.

Craniopharyngiomas (CP) are congenital, benign, embryonic malformations which arise from ectoblastic remnants of Rathke's pouch and are located in the (supra-)sellar region. Many patients show a reduced growth rate and an increased BMI early before the diagnosis of CP. However, it is unknown whether patients with CP present with increased head circumference before diagnosis. A cohort of 90 patients was screened for medical records of their developmental monitoring visits. In 83 patients, data on head circumferences was available. We observed that CP patients with hypothalamic involvement of their tumor tend to have an increased head circumference SDS before CP diagnosis. When comparing head circumference SDS before diagnosis at defined time points between birth and four years of age, all head circumferences were in the upper normal range. However, no statistically noticeable differences were found, comparing hypothalamic involvement and no hypothalamic involvement of the tumor. Congenital embryonic malformations such as CP located in the parasellar area can have impact on cerebrospinal fluid circulation and lead higher head circumferences due to hydrocephalus early before diagnosis. Our results show, that head circumference SDS could be an effective early-indicator for CP. A standardized procedure for head circumference measurements during developmental monitoring visits should be implemented in clinical care. We anticipate that our study is the starting point for prospective studies with larger sample size to assess the potential predictive value of head circumference measurements for an early CP diagnosis.

Factors associated with dysglycemia and its post-surgical resolution in patients with Pheochromocytomas and Paragangliomas

Lin Zhao[1], Yecheng Liu[2] & Xianliang Zhou[1]
[1]Fuwai Hospital, National Center for Cardiovascular Disease, Chinese Academy of Medical Sciences and Peking Union Medical College, Cardiology, Beijing, China; [2]State Key Laboratory of Complex Severe and Rare Diseases, Peking Union Medical College Hospital, Chinese Academy of Medical Science and Peking Union Medical College, Emergency, Beijing, China.

Background
Pheochromocytomas and paragangliomas (PPGLs) are a group of rare neuroendocrine tumors. Dysglycemia has been observed in patients with PPGLs in some small case series. However, few large studies, and none in China, have described the outcomes of dysglycemia after resection, and the factors associated with the development and resolution of dysglycemia in patients with PPGLs.
Methods
We retrospectively analyzed the clinical data of consecutive patients with PPGLs admitted between January 2018 and June 2020. Clinical characteristics were compared between patients with and without dysglycemia. Multivariable logistic regression analysis was used to identify independent predictors and the receiver operating characteristic curves was used to evaluate the diagnostic performance of the variables.
Results
Among 163 patients in this study, 47.9% had preoperative dysglycemia. Patients with dysglycemia were older at diagnosis and have a higher proportion of hypertension. The white blood cell counts and 24-hour urinary epinephrine (24hU-E) concentrations were higher in patients with dysglycemia. Multivariable logistic regression analysis showed that age [odds ratio (OR), 1.040; 95% confidence interval (CI), 1.011–1.070; $P = 0.006$], hypertension (OR, 3.318; 95% CI, 1.375–8.009; $P = 0.008$), and 24hU-E concentration (OR, 1.013; 95% CI, 1.005–1.022; $P = 0.016$) were independent risk factors of preoperative dysglycemia. Taking age, hypertension and 24hU-E into account in the same model, the area under the receiver operating characteristic curve of the model for predicting preoperative dysglycemia was 0.737. The proportion of patients with dysglycemia was significantly decreased after surgery ($P < 0.001$) and patients with postoperative dysglycemia in remission had larger preoperative tumor diameters ($P = 0.005$).
Conclusion
Dysglycemia affects almost half of patients with PPGLs. Age, hypertension, and 24hU-E concentration are independent risk factors of preoperative dysglycemia. Removal of PPGLs can improve dysglycemia in most patients, and the postoperative remission of dysglycemia is associated with the preoperative tumor diameter. These results are of great importance for risk assessment and selection of optimal therapy of dysglycemia in patients with PPGLs.

Insulinoma: 4 case reports

Ben Salem Maram, Marwa Chiboub, Wafa Ben Hilel, Hajer Kandara & Ines Kammoun
National Institute of Nutrition, Department of Endocrinology, Tunisia.

Background
Insulinoma is a rare variety of endocrine neoplasm and is usually benign, solitary, and small in size. It is responsible of endogenous insulin secretion resulting in development of symptoms of hypoglycemia.
Case presentation
We report 4 cases of insulinoma that were diagnosed and managed in the year 2022. Three women and one man aged respectively 76, 68, 60 and 42 years-old. All patients presented a long history of various adrenergic symptoms of hypoglycemia and one patient presented signs of neuroglycopenia including behavior changes and confusion. The mean duration of the symptoms was 8.7 years. Three patients presented spontaneous hypoglycemia with a mean plasma glucose levels of 0.3 g/l concomitant with inappropriately high insulin and C-peptide levels. The positive diagnosis was made in one patient after an 8 h fasting test. The tumors were located preoperatively in 3 cases using pancreatic MRI which have objective a unique nodule in all cases with a mean size of 2 cm. in one case, abdominal CT scan, pancreatic MRI and endoscopic ultrasonography were practiced but the tumor was not located. All patients underwent laparotomies and the tumors were localized peroperatively. Enucleation of the nodules were practiced and all the tumors turned out to be benign after histopathological examination. Symptoms disappeared postoperatively in all cases and the glucose plasma levels were normal.
Conclusion
Insulinomas are rare endocrine tumors that can be life-threatening by causing severe hypoglycemia. Clinical manifestations are diverse and the diagnosis is usually delayed. Biochemical diagnosis is easy, but the preoperative localization of the tumor can be challenging. Surgical resection of the tumor is the treatment of choice and should be done by an experienced surgeon. Risk of reoccurrence is rare after surgery and it usually concerns tumors with high histological grade.

DOI: 10.1530/endoabs.90.EP625

EP626

Large bilateral adrenal masses: interest of plasma LDH measurement to detect adrenal lymphoma

Urbain Tauveron-Jalenques[1], Aurelie Ravinet[1], Romain Guieze[1], Valentin Brusseau[2], Olivier Tournilhac[1], Jacques Olivier Bay[1] & Igor Tauveron[2]
[1]CHU de Clermont Ferrand, Service de Thérapie Cellulaire et Hématologie Clinique Adulte, Clermont Ferrand, France; [2]CHU de Clermont Ferrand, Service Endocrinologie, Clermont Ferrand, France.

Large adrenal masses are strongly suggestive of malignancy. Nevertheless, bilateral adrenal masses are less common (around 20% of incidental adrenal lesions). Metastases and lymphoma are more frequent (especially when aging), and not so easy to differentiate on CT or MRI. Simple biological markers, such as plasma LDH or beta2microglobulin, could help.
Case report
A 69-year-old patient was admitted for abdominal pain with progressive lethargy. Abdominal CT revealed heterogeneous necrotic bilateral adrenal lesions, measuring over 70 mm, invading the left diaphragmatic pillar and the gastric wall. Spontaneous density was above 10HU and wash out negative. Adrenal insufficiency was confirmed by low 0800 h cortisol and increased ACTH. After

ruling out pheochromocytoma, oncologists decided of adrenal biopsy before receiving increased levels of β2microglobulin and LDH. Adrenal biopsy diagnosed non centrogerminative diffuse large B cell lymphoma. In situ hybridization analyses showed a BCL6 rearrangement without BCL2 or MYC rearrangements. An 18FDG PET-CT revealed splenic invasion and multiple lymphadenopathies, which would have been easily accessible to biopsy. Further evaluation revealed marrow infiltration on bone marrow biopsy and a high risk of central nervous system invasion. Overall the age adjusted IPI score was 3 and CNS-IPI score was 6 (high risk). These conclusions led to 8 cycles of R-CHOP21 immuno-chemotherapy plus two cycles of high dose methotrexate regimen in conjunction with intrathecal methotrexate. Treatment was well tolerated and lead to complete remission on PET-CT, CT scan and bone marrow biopsy, still lasting 2 years after the end of treatment.

Discussion and conclusion

When facing bilateral adrenal incidentaloma, lymphoma must be evoked more commonly than with unilateral masses. Adrenal imaging (either CT, PET-CT, or MRI) or existence of adrenal insufficiency, have a limited role in guiding to etiology. Biopsy of adrenal mass is an exposed action that may lead to complications (hemorrhage, sepsis, tumor dissemination) or unhelpful conclusion due to necrosis. Therefore, simple markers such as LDH (and possibly other markers including beta2microglobulin) should be measured to suggest lymphoma (increased in over 70% of cases), and further lead to a screen (by CT and PET-CT if not obvious clinically) for associated lymphadenopathies which are much easier to biopsy than the adrenal gland or for lesions with a higher standardized uptake value which are more commonly conclusive for the pathological diagnosis of lymphoma.

A case of synchronous association of stomach neuroendocrine tumor and pernicious anemia

Ghada Sabbagh[1,2], Hamza Elfekih[1,2], Ghachem Aycha[1,2], Ghada Saad[1,2], Kenza Houd[1,2], Ach Taieb[1,2], Asma Ben Abdelkarim[1,2], Yosra Hasni[1,2] & Molka Chadli Chaieb[1,2]

[1]Farhat Hached Hospital, Endocrinology and Diabetology, Sousse, Tunisia; [2]Faculty of Medicine Ibn Al Jazzar, University Of Sousse, Sousse, Tunisia.

Introduction

Biermer's disease is a chronic inflammatory disease due to antibodies targeting parietal cells and intrinsic factor compromising vitamin B12 absorption leading to pernicious anemia, and gastric acid secretion leading to achlorhydria. Neuroendocrine tumors are rare neoplasms that have been reported during the evolution of chronic gastritis. We here describe a case of a type 1 gastric neuroendocrine tumor discovered alongside with Biermer's disease.

Case presentation

A 60-year-old patient with no medical history was first diagnosed with anemia. Hemoglobin levels were initially at 9 g/dl with macrocytosis, low levels of vitamin B12 and presence of intrinsic factor antibodies. Since the diagnosis of Biermer's disease was made, a lifetime vitamin B12 supplementation was prescribed. A gastroscopy was performed showing a 4 mm polyp in the gastric mucosa. Histopathology revealed a type 1 stomach neuroendocrine tumor. Since the tumor is well differentiated and nonfunctioning tumor, our decision was to follow up the patient and to monitor him by gastroscopic surveillance.

Discussion

Type 1 neuroendocrine tumors are known to occur in the setting of chronic autoimmune gastritis. Deprived gastric acid secretion due to parietal cell destruction results into continuous gastrin secretion leading to hyperplasia of both G cells and enterochromaffin like cells that could further induce gastric neuroendocrine tumors. Synchronous association of stomach neuroendocrine tumor and Biermer's disease is possible and clinicians should be aware of that.

Pancreas, An Unusual Metastatic Site In A Long-term Indolent Surviving Case, Under Somatostatin Analogues Therapy, Of Medullary Thyroid Carcinoma: A Case Report And Review Of Cases Documented In Literature

Salvatore Raia[1], Sabrina Chiloiro[1], Antonella Giampietro[1], Maria Grazia Maratta[2], Giovanni Schinzari[2], Fabia Attili[3], Maria Gabriella Brizi[4], Vittoria Rufini[5], Laura De Marinis[1], Alfredo Pontecorvi[1], Guido Rindi[6] & Antonio Bianchi[1]

[1]Agostino Gemelli University Policlinic, Endocrinology, Rome, Italy; [2]Agostino Gemelli University Policlinic, Oncology, Rome, Italy; [3]Agostino Gemelli University Policlinic, Digestive Endoscopy, Rome, Italy; [4]Agostino Gemelli University Policlinic, Radiology, Rome, Italy; [5]Agostino Gemelli University Policlinic, Nuclear Medicine, Rome, Italy; [6]Agostino Gemelli University Policlinic, Anatomic Pathology, Rome, Italy.

Medullary thyroid carcinoma (MTC) accounts for 1%–2% of thyroid cancers and has a variable clinical course. MTCs present with locoregional metastasis in 50% of patients and distant metastasis in 10% to 15% at the time of initial diagnosis. The lungs, liver, and bone are common metastatic sites, and distant metastasis is known to be a poor prognostic factor for long-term oncologic outcomes. We present the long course case, under somatostatin analogues (SSA) therapy, of a 72 years old woman, who underwent total thyroidectomy surgery for multinodular goiter in 2000 with subsequent histologic diagnosis of MTC RET wild type and histologic typing in 2022 of a pancreatic metastasis from known medullary thyroid carcinoma. Since 2005 she was treated with lanreotide autogel (ATG) 120 mg/every 28 days. In 2014 lanreotide ATG was administered with high frequency (every 14 days) for radiological progression. The use of SSA instead of tyrosine kinase inhibitors (TKI) was preferred in light of the symptom-free clinical condition. This case constitutes, to our knowledge, the seventh reported case of pancreatic metastasis from MTC in the literature and we performed a review of the other reported clinical cases. The present report is also significant given the few described recurrent MTC cases in a patient with clinical stable disease with slow radiological progression after surgery and under long-term SSA therapy. This case may suggest that prolonged SSA therapy is beneficial in MTC asymptomatic patients with slow radiological progression; further confirmatory evidence is required.

A retrospective study investigating the potential relationship between obesity and thyroid cancer

John Flood & Sara Mohamed

Royal College of Surgeons in Ireland – Bahrain, Medicine, Al Sayh, Bahrain.

Thyroid cancer is the most common endocrine malignancy, and accounts for between 5 and 10% of thyroid nodules biopsied in endocrine services. As per the Global Cancer Observatory, the incidence of thyroid cancer in Bahrain is 2.12 cases per 100 000 people, which is less than the neighbouring countries of Saudi Arabia and Kuwait. The purpose of the study is to investigate the relationship between thyroid cancer and obesity in Bahrain, where 28.9% of males and 38.2% of females are classified as obese. Other risk factors such as radiation exposure and genetics will not be explored from lack of data, but height and iodine concentration in the water will be explored. The study will also include the mode of presentation, histological subtypes, and management of thyroid cancer. The study is a retrospective cohort study of 179 patients who have been diagnosed with thyroid cancer and discussed in the National Tumour Board from the years 2019 to 2021. Access to their E-Files was granted by the Bahrain Oncology Centre. The population consistent mostly of Bahraini females with an age range of 18–88. Most of the study population (41%) presented with an asymptomatic neck swelling which was then investigated and diagnosed as thyroid cancer. The most common histological type of thyroid cancer in our study was papillary thyroid carcinoma (88%). The TNM staging showed that most of our patients had a T1 score, with 60 having N1 score and 9 having M1. Our results show that most of the patients with thyroid cancer ($n = 33$) had a body mass index (BMI) of 25–29.9 and only 25 patients had a BMI of 30–34.9. In previous studies obesity has been thought to contribute as a causative agent in 20% of cancers such as breast and colon. But in our study, we did not find a strong relationship between BMI and the tumour size. However, we were able to show a relationship between increasing age and metastatic disease. And finally, the vast majority of the patients in our study had BMI of overweight rather than morbid obesity. Currently, we are investigating a potential relationship between height and thyroid cancer, as well as low iodine levels in the water supply in Bahrain as possible etiological factors. Unfortunately, genetic studies are not available from our oncology service as part of the work up for thyroid cancer in Bahrain.

Angiosarcoma of the thyroid: a case report

Hajar Azagouagh[1], Karimi Meryem[1], Hasna Ouirar[1], Zaineb El Mazouni[1], Kaoutar Rifai[1], Iraqi Hinde[1] & Mohamedelhassan Gharbi[1]
Ibn Sina, Endocrinology, Rabat, Morocco.

Introduction
Angiosarcomas are aggressive malignant tumors but very rare especially when they are located in the thyroid, characterized histologically by their vascular differentiation and their polymorphic appearance.
Observation
We report the case of a 68-years-old female patient, from a mountainous region who has a history of cholecystectomy in 2018, she underwent a total thyroidectomy for a compressive goiter, the postoperative period was marked by an hypoparathyroidism which was substituted. The anatomopathological examination of the surgical specimen showed a thyroid localization of an angiosarcoma of 5 cm of large axis with extension to the fatty and muscular tissue around the thyroid. The CT scan which was performed two months after the surgery showed a left later tracheal formation measuring 9×5 cm suggesting a recurrence. Adjuvant radiotherapy was proposed to our patient.
Discussion
Angiosarcoma of the thyroid is a rare but very aggressive tumor. it affects more women than men with a sex ratio of 9/3 and an average age of 69 years. These tumors were initially described in the inhabitants of alpine regions where their frequency varies between 2 and 10% of all malignant thyroid tumors. This predilection for mountainous regions has been explained by the iodine deficiency leading to goiter, however, the existence of cases in non-mountainous regions without associated goiter suggests that there are other etiological factors not yet known. These tumors are most often revealed by a rapidly growing cervical mass that may be accompanied by signs of compression, as they can be revealed by metastases in particular pulmonary. Local recurrence and metastasis are frequent and early. The prognosis is poor and the average survival is 9 months.
Conclusion
Thyroid localization of angiosarcoma is exceptional but possible. The therapeutic difficulty is correlated to the frequency of recurrence and its metastatic nature.

The role of 131I whole body scan in post-operative assessment of patients with thyroid microcarcinoma

Agnieszka Suligowska[1], Agnieszka Walczyk[1,2], Danuta Gasior-Perczak[1,2], Iwona Palyga[1,2], Artur Kuchareczko[1,2] & Aldona Kowalska[1,2]
[1]Holycross Cancer Centre, Endocrinology, Kielce, Poland; [2]Jan Kochanowski University, Kielce, Poland.

Introdutcion
In recent years, thyroid microcarcinoma (TMC) predominates in the context of diagnosis and treatment of thyroid cancer. TMC has an excellent prognosis, its management is changed in the last few years, reducing surgical procedure and role of radioiodine ablation (RAI). Therefore, the question is what tests have a diagnostic value in patients with thyroid microcarcinoma after thyroidectomy
The aim of this study was to evaluate the role of 131 I whole body scan (WBS) in post operative assessment of patients with TMC.
Materials and methods
Retrospective analysis of the medical records of 446 consecutive patients with TMC. All patients were treated in one oncology centre between 2012 and 2021 with total thyroidectomy and were in low risk of recurrence group according to ATA stratification system (LR-ATA). During first assessment after the surgery ultrasound examination, stimulated thyroglobulin level, thyroglobulin antybody level and WBS were performed in all patients. Usefulness of WBS in planning further treatment was assessed.
Results
In all 446(100%) patients the radioiodine uptake in WBS was detected only in the thyroid bed. There was no pathological radioiodine uptake in any patients
Conclusion
Routine 131I WBS is not required for patients with LR-ATA TMC after total thyroidectomy. WBS does not affect further management.

The Thyroid extranodal marginal zone B-cell lymphoma of MALT: about 2 cases

Bellakhdher M[1], Jemli S[1], Ghammem M[1], El Omri M[1], El Abed Y[2], Meherzi A[1], Houas J[1], El Kermani W[1], El Euch K[2] & Abdelkefi M[1]
[1]ENT and Neck Surgery Department Farhat Hached Hospital, Sousse, Tunisia; [2]Endocrinology Department Farhat Hached Hospital, Sousse, Tunisia.

Introduction
Primary thyroid non-Hodgkin's lymphoma (PT-NHL), is a quite rare entity, accounting for 1.3–1.5% of thyroid neoplasm, and 0.5% of lymphoma. The extranodal marginal zone B-cell lymphoma of MALT, occurs in 23% of PTL. The aim of our work is to evaluate the clinicopathological features and treatment outcomes of patients with MALT primary thyroid lymphoma. We report two cases of MALT PTL taken care of in our department.
Observation 1
It was 56 years old man, with a history of hypothyroidism. Hospitalized in our department for management of an anterior basicervical swelling evolving for 4 years and rapidly increased associated with a recent deterioration in general condition as well as significant unquantified weight loss and intermittent dyspnea. The physical examination found a hard anterior basic cervical tumefaction, making 5 cm of MA associated with right jugular carotid adenopathy. Cervical ultrasound showed a multinodular goiter. Thyroid fine needle aspiration revealed a cluster of inflammatory cells with plasma cells without signs of malignancy. A lymph node biopsy found malignant cells in small clumps. The patient had a total thyroidectomy. The extemporaneous examination concluded a benign isthmic nodule. The definitive anatomopathological examination showed an aspect of low-grade MALT lymphoma rich in plasma cells. The patient was referred to hematology for additional treatment (chemotherapy). There was no relapse after 4 years of follow-up.
Observation 2
It was, 52 years old woman, with a medical history of adenocarcinoma of the colon in 2011 and neoplasia of the right breast in 2020, both treated by surgery and chemotherapy, who referred to our service for an anterior basicervical swelling evolving for 6 months rapidly increasing in size. The physical examination found a hard anterior basic cervical tumefaction, making 3 cm of MA associated with bilateral jugular carotid adenopathy. Cervical ultrasound showed a multinodular goiter. The patient had a total thyroidectomy. The extemporaneous examination concluded a benign nodule. The definitive anatomopathological examination showed an aspect of low-grade MALT lymphoma rich in plasma cells. The patient had a pet scan which was without abnormalities. Bone marrow biopsy showed non-infiltrated marrow. The hematologists decides then to monitor the patient and not administer chemotherapy because of the different arguments related to the patient and her tumor. There was no relapse after one year of follow-up.
Conclusion
Thyroid (MALT) is 23% of all thyroid lymphomas. The overall survival is estimated to be more than 90%. Its care is multidisciplinary.

Carcinological factors associated with adrenal metastases in bronchopulmonary cancer: a comparative study

Abdel Mouhaymen Missaoui[1], Fatma Hamza[2], Siddiqa Soomauroo[1], Hiba Noomen[2], Wafa Belabed[1] & Mohamed Abid[1]
[1]Hedi Chaker University Hospital, Department of Endocrinology, Sfax, Tunisia; [2]Habib Bourguiba University Hospital, Department of Nuclear Medicine, Sfax, Tunisia.

Objective
To study the carcinological factors associated with adrenal metastases (AMT) in bronchopulmonary cancer (PBC).
Patients and Methods
Case–control study analysing oncological data of 40 patients with PBC monitored by 18DFG PET/CT at the Nuclear Medicine Centre of Sfax, Tunisia. We compare the characteristics of 2 subgroups:
G1 ($n=17$): patients with PBC and META (cases)
G2 ($n=23$): patients with PBC without META (controls)
Results
The two groups were matched for age and gender. METAs were more common in patients with small cell carcinomas (G1: 17.6% versus G2: 0%; $P=$NS). A small, non-significant frequency of sarcomatoid carcinomas was observed in G1 (G1: 28.6% versus G2: 5.3%; $P=$NS). SUVmax (G1: 15.8±7.8 versus G2: 12.3±7)

and metabolic volume (G1: 35.6 ± 29.5 versus G2: 32.2 ± 4.8 cm^3) of PBC did not appear to influence its metastatic tropism to the adrenal glands.
According to logistic regression, the predictive factors for META were PBC size > 6 cm (OR = 0.063; CI95% = [0.012–0.33]; $P = 0.001$) and the number of pre-existing secondary sites (OR = 5.23; CI95% = [1.85–14.78]; $P = 0.002$).
Discussion
PBC is a neoplasm with a high metastatic potential, particularly in the adrenal glands. 18FDG PET/CT has become the gold standard for the initial assessment and monitoring of PBC. Adrenal involvement should be systematically investigated in the initial staging of PBC, particularly if it is larger than 6 cm and if another secondary location has already been established.

Vascular damage after craniopharyngioma – a literature review

Julia Beckhaus[1], Svenja Boekhoff[1], Brigitte Bison[2], Carsten Friedrich[1] & Hermann Müller[2]
[1]Klinikum Oldenburg AöR, Oldenburg, Germany; [2]University Hospital Augsburg, Augsburg, Germany.

Craniopharyngiomas are rare, embryonic, malformational tumors of the (supra-)sellar region. Due to tumor and/or treatment-related hypothalamic lesions, patients develop morbid obesity. As a major vascular risk factor, obesity leads to reduced 20-year overall survival and a 3- to 19-fold higher cardiovascular mortality after craniopharyngioma compared to the general population. This review studies craniopharyngioma-specific risk factors for vascular damages. Three databases (Pubmed, CINAHL and Web of Science) were searched and 49 articles were included after title and abstract screening. Eligible studies were case reports, cohort and cross-sectional studies. Neurovascular damages due to surgical interventions included cerebral infarcts, stroke, aneurysms, anterior/-middle cerebral artery syndrome (ACA/MCA), cerebral venous sinus thrombosis, and seizures. Radiation-induced vascular disease described Moyamoya syndrome, radionecrosis and thrombosis. Tumor-induced inflammation is suspected to play a causal role in the etiology of vascular complications in proximity of the tumor. Therefore, early diagnostics such as echocardiography or cardial MRI and risk-adapted prevention and treatment options for vascular disease are needed to improve long-term prognosis after craniopharyngioma treatment. This review summarizes the available evidence for vascular disease after pediatric- and adult-onset craniopharyngioma to derive possible treatment pathways. Individualized, tertiary prevention programs are required for craniopharyngioma patients and survivors to overcome or reduce the risk of vascular complications and elevate their quality of survival.

Multiple endocrine neoplasia type 1: a case report

Hatice Sebile Dökmetaş[1], Hikmet Zeynep Ağaoğlu[2], Onur Şahin[2], Meriç Dökmetaş[2], Esma Eren[2], Ayşenur Akkoyun[2] & Oğuz Kaan Türk[2]
[1]Istanbul Medipol University, Endocrinology, Istanbul, Turkey; [2]Istanbul Medipol University, Internal Medicine, Istanbul, Turkey.

Introduction
Multiple endocrine neoplasia type 1 (MEN1) is a rare, heritable syndrome characterized by a hyperparathyroidism, pituitary adenoma and pancreatic islet cells.
Case
A 56-year-old male patient had a single parathyroid excised for primary hyperparathyroidism 10 years ago. He was further investigated due to hypoglycemia and a mass was found in the head of the pancreas on MRI. It was reported as neuroendocrine tumor and no recurrence was found in the 7-year follow-up. The patient who applied to our hospital for further examination in 2020 has been having intermittent diarrhea attacks for 3 years. In the CT examination, hemangioma in the liver, well-circumscribed tumor in the pancreatic head, and right adrenal nodule were detected. Considering a neuroendocrine tumor, Ga-68 PET/CT examination was performed. High GaTaTe uptakes were detected in the head of the pancreas and in the second part of the duodenum. In addition, nodular thickening was detected in the right adrenal gland, but GaTaTe uptake was not observed. Metanephrine and normetanephrine were examined and found to be normal. PTH: 165.1 (15–65) pg/ml Ca: 11.39 (8.6–10) mg/dl and other tests including pituitary hormone panel, insulin, c-peptide and gastrin were found to be normal. Nephrolithiasis was detected in the CT scans of the patient. There are ulcers in the small intestine on gastroscopy. No adenoma was detected in the pituitary MRI examination. Later, the patient was referred to general surgery for excision. The remaining parathyroid glands were excised. The pancreatic head tumor was found to be compatible with insulinoma, and involvement in the duodenum was found to be compatible with gastrinoma.
Conclusion
The clinical diagnosis of MEN1 is based on the formation of two or more primary MEN1-related tumors (parathyroid gland, anterior pituitary, and enteropancreatic). Our patient is a classic example of MEN1 syndrome with tumors in 2 defining endocrine organs.
Key words
MEN1, Hyperparathyroidism, pancreatic islet tumor.

MiNEN of the proximal colon – a strange case

Diana-Georgiana Lazar[1], Andreea Raluca Petria[1], Sabina Elena Oros[1,2], Anda Dumitrascu[1], Larisa Buduluca[1], Teodor Ionut Constantin[1], Iulia Grigore[1], Daniel Grigorie[1,2], Iulian Brezean[2,3], Sorin Dumitru Aldoescu[3] & Daniela Degeratu[3]
[1]National Institute of Endocrinology "C.I. Parhon", Bucharest, Romania, [2]"Carol Davila" University of Medicine and Pharmacy, Bucharest, Romania, [3]"Dr. Ion Cantacuzino" Clinical Hospital, Bucharest, Romania.

Introduction
Ectopic ACTH syndromes account for 5–10% of Cushing syndrome, with intrathoracic and gastrointestinal–pancreatic neuroendocrine tumors being the most common causes, followed by small cell lung cancer, adrenal paraganglioma and medullary thyroid carcinoma.
Case report
A 50-year-old male hypertensive and diabetic patient was transferred to our clinic for emergency endocrine care for hypokalemia. He had mild hypercortisolism and liver metastases. We admitted a patient with normal body mass, facial and thoracic hyperemia, lower muscle weakness and a right hypochondriac sensitive normal volume abdomen, without muscular defense signs or stretch marks. Biochemistry tests revealed hypokalemia ranging between 2.5 and 3.7 mEq/l, despite the intensive treatment with potassium chloride and spironolactone, and mild hepatic cytolysis. Hormonal tests confirmed ACTH-dependent hypercortisolism (ACTH > 2000 pg/ml, cortisol > 63.4 mg/dl) and high NET markers-chromogranin A > 900 ng/ml, neuron-specific enolase > 200 µg/l, and CEA (59.18 ng/ml). The CT scan showed hyperplasia of the adrenal glands, a solid nodule of the uncinate process and multiple hepatic tumors suggesting metastases. Ketoconazole failed to control hypercortisolism due to hepatic side effects. The patient was referred for bilateral adrenalectomy, performed in association with right hemicolectomy and ileo-transversal anastomosis, with a slightly favorable evolution afterwards, on gluco and mineralocorticoid replacement therapy with improvement of the ionogram, blood pressure and glycaemia. The histopathological exam confirmed proximal colon carcinoma-ulcerated adenocarcinoma, mucinous component (~35–40%) and large cell neuroendocrine carcinoma (~35%) suggesting a MiNEN (mixed NET and non-NET). The immunohistochemistry (IHC) exam showed positive staining for synaptophysin and chromogranin A, MMR protein (MSH2, MSH6, MLH1, PMS2), intense positive diffuse p53, CK20 and SATB2, a ki67 of 80–85%, but negative staining for ACTH.
Particularities
Despite the negative staining for ACTH, Cushing's syndrome symptoms improved after tumor resection and adrenalectomy. A large tumor may harbor different ACTH expression in different areas, which can be the cause of ACTH negative IHC sample. The age at diagnosis was lower than the known mean age (60 years) and the symptoms onset and evolution were fulminant in this case, almost one month, despite all medical intervention.
Conclusion
Management of ectopic ACTH syndrome due to neuroendocrine tumor is complex. The gold standard is the complete surgical resection of the primary tumor. If the surgery fails, it is important to control hypercortisolemia and prevent its complications. The severity and histological pattern of the tumor is related with the ectopic ACTH syndrome prognosis.

Neuroendocrine carcinoma of the vagina in a young patient – a rare entity

Simona Gabriela Duta[1], Teodor Dumitras[1], Carmen Sorina Martin[1,2], Luminita Cima[1,2], Cornelia Nitipir[1,2], Dana Terzea[2,3] & Simona Fica[1,2]
[1]Spitalul Universitar de Urgenţă Elias, Bucureşti, Romania; [2]Carol Davila University of Medicine and Pharmacy, Bucureşti, Romania; [3]C.I. Parhon National Institute of Endocrinology, Bucureşti, Romania.

Primary vaginal malignancy is uncommon, accounting for about 2% of all gynecological tract cancers, with small-cell neuroendocrine carcinoma of the vagina being exceptionally rare and aggressive. They display similar histological and immunohistochemical features to small-cell carcinomas of different origin. Few cases are reported in the literature so far and therefore, there is no current treatment protocol consensus. We report the case of a 34-year-old nulliparous patient, who presented for evaluation in May 2022 after palpatory detection of a vaginal mass during ovule treatment, following an annual Pap smear, that showed nonspecific inflammation and was negative for squamous intraepithelial lesion. She was otherwise asymptomatic and had a medical history of two surgically removed polypoid uterine adenomyomas. Family history was also positive for genital and gastrointestinal malignancy. Upon gynecological examination, a highly vascularized, friable, 5 cm mass was identified, located on the posterior vaginal wall, occupying almost the entire vagina. The histopathological biopsy report showed a poorly differentiated carcinoma and immunohistochemistry confirmed a neuroendocrine carcinoma, with SSTR2 expression. The following imagistic screening revealed secondary pulmonary determinations and metastatic adenopathies, and also a solid 6 cm mass on the left ovary. PET-CT scan also showed some metabolically active bone lesion, one on the tenth costal arch. The multidisciplinary team decided initiation of cisplatin and etoposide combination chemotherapy. After 8 cycles, the patient had a good response to the treatment, with normalization of tumoral markers (initially high CA125, CA15-3, CEA) and dimensional regression of the primary tumor, some metastases and of the ovarian tumor. The patient underwent whole-body octreotide scintigraphy with SPECT/CT and is currently being evaluated for surgical excision and radiotherapy of bone determinations. In conclusion, we present the unique case of advanced, metastatic neuroendocrine carcinoma of the vagina in a young patient with associated genital malignancy family history, emphasizing the necessity of a multidisciplinary approach, genetic screening and further study of the disease. Small-cell neuroendocrine carcinoma of the vagina is extremely rare, with aggressive behavior and poor prognosis. Histological recognition of this separate entity is important and multimodality treatment could improve patient outcomes.

Multiple endocrine neoplasia: about 9 cases

Siddiqa Soomauroo[1], Fatma Mnif[1], Abdel Mouhaymen Missaoui[1], Dhouha Ben Salah[1], Kawthar El Arbi[1], Yosra Lajmi[2], Faten Hadj Kacem[1], Mouna Elleuch[1], Nadia Charfi[1], Mouna Mnif[1], Fatma Abdelhedi[2], Nabila Rekik[1] & Mohamed Abid[1]
[1]Hedi Chaker University Hospital, Department of Endocrinology, Sfax, Tunisia; [2]Hedi Chaker University Hospital, Department of Genetics, Sfax, Tunisia.

Introduction
Multiple endocrine neoplasia (MEN) is a group of inherited syndromes of autosomal dominant transmission characterized by the development of endocrine tumors.
Materials and methods
It is a retrospective study collecting data of 9 patients with MEN, during a 30-year period.
Results
The mean age at diagnosis was 34.6 years with a clear female predominance. The majority of our patients were from Gabes (4 cases). Seven patients had MEN1. The different pathologies described in MEN1 were: primary hyperparathyroidism (PHP/100%), macroprolactinoma and multi-nodular goiter(57%), adrenal adenoma(42.8%) and insulinoma(14.2%). The genetic study was done for all patients except one who died. It revealed the presence of a mutation in the gene coding for Menin in three cases. A new missense mutation at exon-4 of the MEN1 gene, not previously described in literature, was found in our series. Two patients had MEN2. In MEN2A (1 case), PHP was the revealing condition followed by medullary thyroid carcinoma (MTC) and then pheochromocytoma. In MEN2B (1 case), pheochromocytoma was the initial manifestation followed by MTC. Molecular study of the RET gene carried out in both patients (result in progress for MEN2A) showed a mutation in exon-16 (codon,M918T).
Discussion/conclusion
The diagnosis of MEN can be made on a range of clinical arguments but molecular study remains essential to confirm the diagnosis and to give appropriate genetic counselling. The risk of recurrence is high (50% for the offspring of an affected individual). The genetic study also makes it possible to indicate surveillance and early management of asymptomatic family cases carrying the mutation.

Neuroendocrine tumors of the head and neck: our experience

Houas Jihene[1], Kechiche Jawaher[1], Ghammam Monia[1], Belhadjmiled Heyfa[1], El Omri Malika[1], Bellakhdher Mouna[1], Hasni El Abed Yosra[2], Meherzi Abir[1], Kermani Wassim[1] & Abdelkefi Mohamed[1]
[1]ENT Department and Neck Surgery of Farhat Hached Hospital, Sousse, Tunisia; [2]Endocrinology Department Farhat Hached Hospital, Sousse, Tunisia.

Introduction
Neuroendocrine tumors of head and neck region are rare and heterogeneous. it can arise in all the different organs of this region, including the nasal cavity, paranasal sinuses,, larynx,,thyroid, can be divided into two broad groups: those with epithelial differentiation, and neurally derived tumours, including paragangliomas and olfactory neuroblastomas. Their morphological and clinical features mainly depend on the degree of differentiation and on the site of origin.
Method
A retrospective study was conducted on 37 patients identified with neuroendocrine tumors of the head and neck over a period of 32 years, from 1990 to 2022. Presentation, Clinical examination, evaluation, medical and surgical treatments, histological examination were reviewed.
Results
The average age was 44 years ranging from 11 to 83 years with a sex ratio of 1.2. The average consultation delay was 8 months. We identified 12 patient with paraganglioma and as chief complaint of neck mass, Olfactory neuroblastoma in 7 cases presented with epistaxis and nasal obstruction, neuroendocrine tumors arising from the larynx in 5 cases, consulted for dysphonia and dysphagia, medullary thyroid carcinoma in 12 cases and neuroendocrine carcinoma of the thyroid in 1 case presented for cervical swelling. Treatment courses varied across patients and included combinations of surgery, and/or radiotherapy. Average follow-up time was 2 years. 6 Patients were lost to follow-up. 2 had evidence of known metastases to various sites including bone, and brain. A tumor recurrence was noted in 5 cases.
Conclusion
Neuroendocrine tumors are a heterogeneous group of neoplastic proliferations showing different morphological features, clinical presentation, and treatment outcomes.

Parathyroid cancer and of primary hyperparathyroidism

Mouna Elleuch[1], Maalej Souhir[1], Wissal Ghamgui[1], Dhoha Ben Salah[1], Trigui Souleima[1], Nadia Charfi[1], Mouna Mnif[1], Fatma Mnif[1], Nabila Rekik Majdoub[1], Fatma Hamza[2], Fadhel Guermazi[2], Faten Haj Kacem Akid[1] & Mohamed Abid[1]
[1]CHU Hedi Chaker, Endocrinology, Sfax, Tunisia; [2]CHU Habib Bourguiba, Nuclear Medicine, Sfax, Tunisia.

Parathyroid cancer is a rare cause of primary hyperparathyroidism (PPH). The objective of this work is to discuss clinical and therapeutic specificities of these tumors.
Case n°1
51-year-old woman from a consanguineous marriage, with a family history of recurrent renal lithiasis, neoplasia, and a personal history of breast neoplasia and uterine fibroid, consulted for abdominal pain, vomiting and weight loss. The diagnosis of primary hyperparathyroidism was made in view of hypercalcemia (3.65 mmol/l), hypophosphatemia (0.62 mmol/l), PTH = 2701 pg/ml (41*N), hypovitaminosis D < 8 ng/ml, Clcreatinine = 86 ml/min. A left retro-thyroid nodule and 2 right sub-thyroid nodules on cervical ultrasound were noted. The Technetium-99m-sestamibi scan showed a left retro-thyroidal mass 21 × 16 × 37 mm and a right inferior latero-tracheal nodule 13 × 16 mm fixing MIBI. Hyperparathyroidism-jaw tumor-syndrome was strongly suspected; mandibular radiography didn't show any ossified fibroids. The

search for HRPT2 gene mutation is in progress. A left lobo-isthmectomy with homolateral mediastino-recurrential evacuation and a right and left upper parathyroidectomy were performed. anatomopathology examination revealed a 5 cm left upper parathyroid carcinoma with oxyphilic cells and 2 atypical parathyroid nodules of the right upper pole of 1.5 cm.
Case n°2
Sporadic PPH complicated by recurrent lithiasis and osteoporosis in a 68 year old man secondary to a necrotic cervical-mediastinal ectopic right lower parathyroid mass. Malignancy was suspected due to the large size (8 cm), and a PTH of 16 times normal. The patient underwent carcinological surgery and total thyroidectomy for a multinodular goiter. Anatomopathology examination is in progress
Case n°3
57-year-old patient, with a personal history of hypertension and primary infertility, consulted for incoercible vomiting, asthenia and fever.The bilogy: hypokalemia (2.7×mmol/l), renal insufficiency (clcréat = 29 ml/min), hypophosphoremia (0.45 mmol/l), hypercalcemia (4.02 mmol/l) with electrical signs (QT shortening) requiring an emergency hemodialysis session. Primary hyperparathyroidism was diagnosed with a PTH = 570 pg/ml (8.7*N), a plunging cystic mass with some parietal calcifications, measuring 40×56×90 mm and largely necrotic, not fixing MIBI. The evolution was marked by the appearance of epileptic seizures, followed by an alteration of his state of consciousness in relation to a Wernicke's encephalopathy on MRI.

Cervical paragangliomas: clinical presentation and Managment modalities

Houas Jihene[1], Kechiche Jawaher[1], Ghammam Monia[1], Lazid Sarra[1], El Omri Malika[1], Bellakhhder Mouna[1], Hasni El Abed Yosra[2], Meherzi Abir[1], Kermani Wassim[1] & Abdelkefi Mohamed[1]
[1]ENT Department and Neck Surgery of Farhat Hached Hospital, Sousse, Tunisia; [2]Endocrinology Department Farhat Hached Hospital, Sousse, Tunisia.

Introduction
Paragangliomas are a diverse group of neuroendocrine tumors arising from chromaffin cells within paraganglionic tissues of the autonomic nervous system. The aim of this study is to review our experience in the management of these tumors.
Methods
The medical records of 12 patients with 13 paraganliomas was performed in a a single academic hospital over a period of 32 years from 1990 to 2022.
Results
There were 10 women (83.3%) and 2 men (16.6%) with a mean age of 47 years. A painless lateral neck mass was the main finding in 10 cases. There was no evidence of a functional tumor. Computed tomography was performed in 8 cases and MRI in 11 cases.The majority of the lesions were paragangliomas of the carotid bifurcation (7 cases), while 5 patients with a vagal paraganglioma. Bilateral vagal paragangliomas were detected in one case. Secretory activity was studied in 6 patients. All patients had normal level of metanephrines. For patients treated with radiotherapy, Radiotherapy was able to control growth in all treated tumors. 8 patients treated surgically. The most commonly affected structures were the facial nerve, the vagus nerve and the hypoglossal nerve and Sympathetic chain palsy as a sequela of the surgery. Average follow-up time was 36 monthes and there were no regional recurrence.
Conclusion
Surgery and radiation therapy represent the main treatment modalities for paraganglioma. Although surgical resection has remained the mainstay of treatment for paragangliomas, the need for preoperative embolization remains controversial. Secretory and malignant tumors are extremely rare and requires active management.

Syndrome of inappropriate antidiuretic hormone secretion associated with olfactory neuroblastoma

El Omri Malika, Marwa Ben Njima, Jihen Haouas, Meherzi Abir, Ghammam Monia, Mouna Bellakhdhar, Kermani Wassim & Abdelkefi Mohamed
Hospital Farhat Hached, ENT, Sousse, Tunisia.

Introduction
Olfactory neuroblastoma causing syndrome of inappropriate antidiuretic hormone (SIADH) as paraneoplastic syndrome is very rare. There have been only 10 cases with antidiuretic hormone (ADH) producing olfactory neuroblastoma in the literature. The syndrome is due to ectopic production of protein hormones, hormone precursors, or hormone-like substances by the tumor tissue. Here, we report the case of olfactory neuroblastoma associated with SIADH.
Observation
Patient S.D., 25 years old, with a history of inappropriate ADH secretion syndrome (SIADH) under NaCl, had consulted for unilateral left nasal obstruction evolving for five months. Examination revealed a fleshy, richly vascularized tumor mass filling the entire left nasal cavity. The right nasal cavity and the cavum were free. A biopsy was performed and the diagnosis was an inverted papilloma. The CT scan of the facial mass revealed a 23×41 mm hyperdense nasosinusal tumor formation with blowing calcifications extending to the maxillary sinus and to the homolateral ethmoidal cells coming in contact with the papyraceous lamina and the roof of the ethmoid. MRI of the facial mass showed a left maxillary tissue process of 40×25×45 mm. The walls of the left maxillary sinus are thinned but continuous. Retentional filling of the maxillary and left frontal sinuses and no brain abnormalities. The patient underwent a middle meatotomy, anterior and posterior ethmoidectomy and left sphenoidotomy by endonasal approach removing the tumor. The immediate postoperative course was simple. The extemporaneous examination was in favor of a massive tumor, non vascular, without histological signs of malignancy. The final anatomopathological examination concluded to an olfactory aesthesioneuroblastoma stage II of Hyams. The patient was proposed for postoperative RT, but the patient did not reconsult.

atypical revelation of anaplastic thyroid cancer

Moncef Sellami[1], Mohamed Amin Chaabouni[2], Ons Kharrat[2], Faten Haj Kacem Akid[3], Mohamed Abid[3] & Ilhem Charfeddine[2]
[1]Habib Bourguiba University Hospital, Sfax, Tunisia; [2]Department of Otorhinolaryngology, Head and Neck Surgery, Sfax, Tunisia; [3]Hedi Chaker University Hospital, Department of Endocrinology, Sfax, Tunisia.

The aim of this study is to report a case of an unusual presentation of anaplastic thyroid carcinoma and describe its clinical, radiological and management particularities. Observation: We report the case of a 60 year-old female patient who presented with a two-week history of progressive aphagia, associated with hemoptysis. She also described recent shortness of breath, and a painless cervical mass evolving for 10 months, rapidly enlarging during the last four weeks. Her medical history was uneventful. Physical examination found bilateral fixed hard masses of the cervical sectors II and III, measuring 5 cm on the left, and 10 cm on the right with an extension to sector III. Nasofibroscopy revealed a suspect left subtonsillar mass, hiding the hypopharyngeal and laryngeal structures. Its biopsy showed unspecific necrotic tissues. CT scan objected a hypopharyngeal mass, measuring 102×78×62 mm, extending inferiorly to the larynx, posteriorly to the prevertebral space, invading anteriorly the right thyroid lobe and reaching laterally the subcutaneous tissues. Multiple cervical necrotic lymph nodes and thrombosis of the right internal jugular vein were associated. On thoracic images, pulmonary metastases were found. Due to aggravation of her dyspnea, the patient underwent tracheotomy, during which a second biopsy was done. Anatomopathological study with immunohistochemistry (PAX8, cytokeratin and TTF1) discovered an anaplastic thyroid carcinoma. Palliative radio and chemotherapy were indicated, but the patient was lost of sight. Conclusion: Considering the rapidly lethal potential of anaplastic thyroid carcinomas, it is important to have in mind this entity as a differential diagnosis for head and neck tumors.

Mixed papillary–medullary thyroid carcinoma and cystic adrenal mass

Christina Limniati[1], Eleni Papagianni[2], Magdalini Smarda[3], Maria Kaza[1] & Charalampos Tsentidis[1]
[1]Nikea General Hospital "Agios Panteleimon", Piraeus, Greece, Department of Endocrinology, Diabetes and Metabolism, Nikea-Piraeus, Greece; [2]Evangelismos General Hospital, Department of Pathology, Athina, Greece; [3]General Hospital of Nikea, Department of Computed Tomography and Magnetic Resonance, Nikea, Greece.

Introduction
Regardless of the fact that the incidence of thyroid cancer has increased significantly in recent years, the simultaneous occurrence of multiple tumors in

one thyroid gland is still a rare phenomenon. These tumors have the morphology, either of a single mass with mixed histological features, or of a single lesion consisting of two distinct cell-populations, or of two different tumors between which normal thyroid tissue is interposed. Various theories have been proposed as causes for the co-existence of papillary and medullary thyroid carcinoma, however the exact mechanism remains unclear.
CASE REPORT
A 42-year-old man referred to our department, for thyroid ultrasound evaluation, that had shown two large nodules in the right lobe (3×2.29 cm, TIRADS-4 and 4.6×2.01 cm, TIRADS-3). Laboratory evaluation showed normal thyroid function, but high calcitonin values 108.9 ng/ml(<14), which raised a strong suspicion of medullary carcinoma. The patient was advised that the best therapeutic approach was surgery, after performing laboratory and imaging tests related to Multiple- Endocrine-Neoplasia-syndromes (MEN). Free 24-hour urinary metanephrines, as well as other indicators of endocrine neoplasms were within normal limits. However, adbominal Computed-Tomography(CT) revealed a mass 2 cm in the left adrenal gland, with increased Hounsfield-units(HU) and absolute-late-washout>50. An additional Magnetic-resonance-imaging(MRI) was deemed necessary, which, due to the SARS-COV-2 pandemic, was not performed immediately. The patient underwent total thyroidectomy, and histology examination revealed mixed thyroid carcinoma with papillary (80%) and medullary (20%) components. Immunohistochemistry was positive for BRAFV600E mutant protein in all neoplastic cells. The patient was treated with ^{131}I administration, and Whole-Body-Scan(WBS) showed no abnormal findings. Thyroglobulin values with TSH>100 was undetectable, while calcitonin and CEA at 6 and 12 months postoperatively were within normal limits. An abdominal MRI was performed, which did not rule out cystic pheochromocytoma. However, that was not confirmed by the other laboratory and imaging tests(MIBG), nor by clinical symptoms.
Conclusion
Measurement of calcitonin during initial thyroid nodule workup, is helpful in detecting medullary carcinoma. Mixed-medullary-follicular-thyroid-carcinoma(MMFCC) is an extremely rare form of thyroid malignancy and prognostically, the behavior is usually analogous to medullary component. The therapeutic approach is based on the partial treatment of each neoplasm separately. Cystic pheochromocytomas have atypical imaging and clinical features, while symptoms from catecholamine hypersecretion is proportional to the size of the solid part, so these are often silent. In the coexistence of medullary thyroid carcinoma and cystic adrenal lesions, testing for pheochromocytoma is necessary.

Tall cell variant of papillary carcinoma on ectopic thyroid tissue

Maali Ben Nasr, Ben Sellem Dorra, Ons Ben Hamida, Rihen Belayouni, Lamia Zaabar & Aida Mhiri
Salah Azaiz Institute, Nuclear Medicine, Tunis, Tunisia.

Introduction
Ectopic thyroid tissue is a rare developmental abnormality due to aberrant embryogenesis and/or migration of the thyroid gland. Although rare (<1%), papillary thyroid carcinoma is the most common malignant transformation.
Aim
Report a case of Tall cell variant of papillary carcinoma occurring on ectopic thyroid tissue in the thyroglossal duct.
Observation
A 56-year-old male patient consulted for a cervical mass appearing two years before, with progressive dysphonia. On physical examination, the patient had a firm tumefaction in the anterior cervical region, with undetermined limits, measuring approximately 7 cm. The thyroid gland was in the normal position. The thyroid function was normal. Neck ultrasound showed a heterogeneous hyperechoic left paramedian cervical mass with much vascularization on Doppler examination. No focal lesion in the thyroid gland was revealed. Cervical MRI provided a more precise assessment of the extension of the mass and confirmed the integrity of the other structures. The tumor was totally resected via a cervical approach. Histological examination confirmed its thyroidal nature, with the presence of tall cell variant of papillary carcinoma without capsular or vascular embolism. The treatment was completed by a total thyroidectomy and bilateral central lymph node dissection. The histological results were normal. The patient underwent radio-iodine therapy, 6 months after the surgery, with elevated initial thyroglobulin at 60 ng/ml. Later on, he developed lung and pleural metastases refractory to iodine. Thyroid suppression therapy was prescribed as an adjuvant treatment.
Conclusions
Although rare, papillary carcinoma on ectopic thyroid should be evoked before any mass of the hyoidal region. Its diagnosis is histological, only after surgical excision of the lesion. The treatment is primarily surgical associated with radioiodine I-131 therapy and suppressive hormone replacement therapy.

Multiple Neuroendocrine tumours and role of clinical screening versus genetic testing

Waqas Ilyas[1], Fahmy Abdelrehman[2] & Safwan Adam[1]
[1]Christie Hospital NHS Trust, Manchester, UK; [2]Royal Blackburn Hospital, Blackburn, UK.

Neuroendocrine neoplasms (NENs) are rare but diverse group of malignancies that can arise from gastroenteropancreatic tract and lungs. NENs can be clinically symptomatic (functioning) or silent (non-functioning). We present a case found to have multiple NENs in the absence of known clinical syndrome and discuss role of genetic testing versus clinical screening. 54 Female, referred to endocrine team for investigation of hypoglycaemic symptoms and suspected insulinoma. Routine biochemistry and 0900 h cortisol was normal. 72 h fasting revealed severe hypoglycaemia (blood glucose of 2 mmol/l) with inappropriately normal insulin levels. No Past medical history or family history. No clinical features of VHL syndrome, Neurofibromatosis and Tuberous sclerosis. Other Fasting gut hormones, 24-hour urinary 5HIAA was all normal. CT scan of Abdomen Pelvis showed 1.3 cm arterial enhancing lesion in body of pancreas and a lesion in terminal ileum with mesenteric lymph nodes involvement. Colonoscopy showed Random terminal ileum biopsy showed inflammation only. Octreotide scan revealed positive uptake in ileocecal lesion and adjacent nodes. No uptake in pancreas. EUS showed 1.1 cm hypo echoic lesion in body of pancreas, 2 cm distal to confluence area. MEN 1 screen (Calcium, PTH, pituitary profile) and MEN 2 screen was negative. plasma metanephrine and normetanephrine were normal. After discussion in GIT MDT, Distal pancreatectomy and ileocecal resection for 2× NENs was done. Histopathology showed Well differentiated NEN terminal ileum Ki67 1%, G1, 9 out of18 lymph nodes involved. T4, N1 R0. And Well differentiated NEN pancreas, Grade 1, pT1 Nx R0. Histology revealed insulin positive staining in keeping with insulinoma, proliferation index Ki67 < 1%. Patient had uneventful surgery but developed post operative collection managed successfully with surgical drain and antibiotics. Patient had dietician and MDT input clinically improved and discharged with endocrine team follow-up.
Discussion
We are aware that rare genetic mutations can lead to multiple NENs include MEN 1, MEN 2, NF1, VHL, TSC1 and TSC2. Clinical screen for these syndromes should be done in such patients to help us decide surveillance and follow-up. Suspected patients should be tested for these genetic mutations. Although there are no guidelines or studies to suggest whether doing genetic testing, in the absence of negative clinical screen, would be of any additional benefit. We will discuss role of each in details. Further studies are needed to see if there are other genes that can play role in development of multiple NETs.

Recurrent insulinoma: Case report

Ben salem Maram, Marwa Chiboub, Chayma Besrour, Manel Jemel, Hajer Kandara & Ines Kammoun
National Institute of Nutrition, Department of Endocrinology, Tunis, Tunisia.

Background
Insulinoma is a rare neuroendocrine tumor that causes inappropriate secretion of insulin resulting in hypoglycemia. The diagnosis of insulinoma may be difficult. Recurrence after surgery is rare and it usually concerns tumors with high histological grade.
Case presentation
We report a case of a 52-year-old woman with recurrent episodes of symptomatic hypoglycemia. The laboratory investigations showed high insulin (20 IU/ml) and C-peptide levels (5.02 ng/ml) concomitant with low blood sugar levels (38 mg/dl) and absence of plasma sulfonylurea. Preoperative pancreatic imaging was negative. Exploratory surgery was performed and the peroperative ultrasound showed a pancreatic tumor of 1 centimeter. Enucleation of the tumor was performed and histopathology confirmed the diagnosis of a grade 1 insulinoma (Ki 67 <1%). Ten years later, she started experiencing symptomatic episodes of hypoglycemia with inappropriately elevated insulin (16 IU/ml) and C-peptide levels (3.03 ng/ml). Pancreatic MRI showed an 11×16 mm tumor. Splenectomy was performed and

histology confirmed the diagnosis of insulinoma. Workup for multiple endocrine neoplasia turned out to be negative.
Conclusion
Insulinoma is a rare tumor that may be life-threatening by causing severe hypoglycemia. Although recurrence of sporadic insulinoma is rare, a clinical follow-up is necessary after surgery.

Insulinoma in elderly
Chayma Besrour, Marwa Chiboub, Ben Salem Maram, Meriem Adel, Manel Jemel, Hajer Kandara & Ines Kammoun
National Institute of Nutrition, Endocrinology, Tunis, Tunisia.

Introduction
The insulinoma is a rare neuroendocrine tumor derived from the beta islet cell of the pancreas. It is usually sporadic and benign in 90% of the cases. It occurs more often in women in their fifties.
Observation
We report the case of 76-year-old women with a medical history of hypertension and dyslipidemia, who was transferred to our department from the emergency unit after a diagnosis of severe episode of hypoglycemia (glucose level at 0.2 g/l) with neurologic manifestations resistant to intra venous glucose supplementation. Indeed, these episodes began in the previous six months with symptoms worsening over time. During her hospitalization, the patient presented a spontaneous hypoglycemia with a glucose level at 0.43 g/l, the insulin level was high at 21.6 µUI/ml > 3 µUI/ml and the peptide C level was at 4.10 ng/ml > 0.6 ng/ml in favor of an endogenous hyperinsulinism. The dosage of hypoglycemic sulfonamides was negative. An abdominal MRI was performed showing a 25 mm exophytic and hyper vascularized mass of the pancreas corresponding to an insulinoma. The patient was referred to surgery which was performed with no complications and the histopathological examination of the removed tissue confirmed the diagnosis of a G2 neuroendocrine tumor.
Discussion
Insulinoma is the most frequent neuroendocrine pancreatic tumor. Surgery represents the first line treatment. Others options such us diazoxide and octreotide can be discussed especially if the malignancy is suspected.

Asymptomatic Pheochromocytoma in a patient with Adrenal Incidentaloma
Aoife Raja[1], Conor Meehan[2], Rachel Crowley[3] & Ma Pyeh Kyithar[1]
[1]Midlands Regional Hospital Portlaoise, Diabetes and Endocrinology, Portloaise, Ireland; [2]Midlands Regional Hospital Portlaoise, Radiology, Portloaise, Ireland; [3]St Vincent's University Hospital, Endocrinology, Dublin, Ireland.

Background
While the classic presentation of pheochromocytoma includes a triad of episodic headaches (90%), diaphoresis (60–70%), and palpitations (70%), literature has suggested 10% to 17% of patients with pheochromocytoma are either asymptomatic or mildly symptomatic; thus, highlighting the importance of appropriate endocrine work up of adrenal incidentalomas.
Case
We report a 37-year-old male with a long-standing history of nocturia and dysuria, who was managed by a urologist for prostatitis. Further evaluations with CT-kidneys, ureters and bladder showed an incidental rounded left 3×2 cm mildly hyper-attenuating adrenal mass, and the patient was referred to Endocrinology clinic for assessment of the adrenal incidentaloma. Other than dysuria and nocturia, no history of headache, diaphoresis, palpitations, or hypertension were of note. There was no family history for pheochromocytoma or paraganglioma. Physical examination was unremarkable including heart rate and blood pressure (24-hour blood pressure monitoring showing an overall average of 124/86 mmHg, with a range of 117/77 to 126/88 mmHg). Adrenal hormone work-up showed elevated plasma normetadrenalin [1.2 nmol/l (reference range < 0.71)] and plasma metadrenalin [5.62 nmol/l (reference range < 0.36)]. A repeat test showed a persistent elevation of both plasma normetadrenalin and metadrenalin at 1.52 nmol/l and 6.52 nmol/l, respectively. Other tests including full blood count, renal, liver and bone profiles, urinalysis, urine culture and sensitivity, FSH, LH, testosterone, post-dexamethasone suppression test cortisol (26 nmol/l), serum aldosterone (143 pg/ml), active renin (5.6 pg/ml), aldosterone:renin ratio (25.54), DHEAS (8.96 µmol/l) and delta androstenedione (4.89 nmol/l) were within normal limits. CT adrenals with contrast demonstrated a left adrenal rounded 3 cm mass with Hounsfield unit 43/84/60 and absolute washout calculation 60% and relative washout 28%, which is not consistent with adenoma. Echocardiogram showed no significant abnormality thus out-ruling catecholamine associated cardiomyopathy and an MIBG scan was also indicative of a solitary left sided pheochromocytoma. Following a course of alpha blockade with doxazocin, the patient underwent laparoscopic resection of the left adrenal mass and it was confirmed to be pheochromocytoma histologically. At post-surgery the patient remained well and repeat plasma metanephrine levels were within normal limits and required no long-term medications. Genetic tests results concluded no genetic abnormality was detected.
Conclusion
Our case demonstrated that a patient may not have classical symptoms of pheochromocytoma but could have significantly elevated plasma metanephrine levels. Our case also highlights the importance of an urgent assessment of adrenal masses in people <40 years of age as recommended by European Society of Endocrinology clinical practice guideline on adrenal incidentalomas.

Hidden insulinoma overlapped with pregnancy – a challenge for the clinician
Ioana Madalina Cristian[1], Bianca Andreea Balint[1], Catalina Petrescu[1] & Adina Mazilu[1]
Department of Endocrinology – Carol Davila Central Military University Emergency Hospital Bucharest, Romania.

Introduction
Insulinomas are the most common cause of hypoglycemia due to endogenous hyperinsulinism. Almost all insulinomas are benign, and long-term recovery with complete disappearance of preoperative symptoms can be expected after complete resection.
Case report
A 33-year-old woman, who developed gestational diabetes during her second pregnancy, which persisted post-partum, stopped insulin due to recurrent severe hypoglycemia, but which persisted even after stopping insulin, which is why she presented in our department where the suspicion of insulinoma was raised because plasma glucose was 27 mg/dl, concomitant to a high insulinemia of 50.1 µIU/ml. The imaging investigations were normal. Nuclear imaging investigations were also normal. In dynamics, plasma glucose values remained low (13 mg/dl) and insulinemia increased (169.8 µIU/ml), which motivates the initiation of somatostatin analog (SSA). However, the hypoglycemic status was maintained, so the dose of SSA was increased. Although there was no clear imaging localization following the high suspicion of insulinoma it was decided to perform distal pancreatectomy. Post-operative, the patient's condition was good, so the somatostatin analog was stopped. At 8 months follow-up after the surgery, the patient had a normal plasma glucose level and a normal insulinemia level but later hypoglycemic episodes appeared again, which was why the administration of the SSA was restarted but the patient voluntarily stopped the treatment. At the next follow-up, the pregnant patient at that time presented with increasing insulinemia, thus deciding to continue the treatment with SSA with the patient's consent, although there are relative contraindications for administration during pregnancy. The patient was monitored throughout the pregnancy, hypoglycemia prophylaxis was performed but the fetus was small for gestational age (SGA) according to ultrasound evaluations. Due to an obstetrical complication, premature induction of labor was performed at 28 weeks of pregnancy. Post-partum, the patient's status was reevaluated, the imaging and nuclear investigations results showing no pathological images. During the last visit it was decided to increase the frequency of administration of the SSA.
Conclusion
The SGA new-born can be explained both by the mother's persistent hypoglycemic status and by the administration of the SSA which has been proven to lead to intrauterine growth restriction. With a continuous persistence of hypoglycemia despite the distal pancreatectomy, although without imaging evidence of the localization of the insulinoma, the final step of treatment would be cephalic pancreatectomy, a difficult surgery, with multiple complications and with the need for post-operative replacement of the pancreatic exocrine and endocrine function.

Acromegaly and papillary thyroid carcinoma: Incidental association or causal link?

Khaoula Gorgi, Lamya Echchad, Loubna Guissi, Kaoutar Rifai, Hinde Iraqi & Mohamed El Hassan Gharbi
Ibn Sina University Hospital, Endocrinology, Rabat, Morocco

Introduction
Acromegaly is an unusual endocrinopathy due to hypersecretion of growth hormone (GH) and concomitant rise of IGF-1. It is associated with premature of mortality caused by cardiovascular, respiratory and metabolic diseases, as well as increased risk of developing boh benign and malignant tumours. We report the case of a patient with acromegaly associated with papillary thyroid microcarcinoma (PTC).
CASE
A 50-years -old male patient, followed for acromegaly for 2 years, underwent subtotal transphenoidal surgery of the pituitary macroadenoma with surgical failure as shown on the follow-up hypothalamic–pituitary MRI. As part of the workup, a cervical ultrasound was performed, which showed a multiheteronodular goiter for which he underwent a total thyroidectomy. The anatomopathological examination was in favor of a papillary thyroid microcarcinoma.
Discussion ans conclusion
The coexistence of acromegaly and thyroid cancer is rare. The recrudescence of these two tumors can be explained by the fact that both GH and IGF-1 have mitogenic and anti-apoptotic properties. In addition, as both normal and malignant thyroid cells express IGF-1 receptors, an autocrine role for IGF-1 has been demonstrated in human thyroid cancer cell line. The risk of developing thyroid nodules increases with the age of the disease, hence the interest of regular surveillance because of the risk of malignancy.

Different phenotype of familial RET mutation in 2 patients: Medullary thyroid carcinoma and Adrenal Paraganglioma

Laura Naglabeala[1], Alexandra Milicescu[1], Simona Galoiu[1,2], Elena Braha[3], Andrei Muresan[3], Dumitru Ioachim[3], Mircea Ghemigian[3] & Catalina Poiana[1,2]
[1]C. I. Parhon National Institute of Endocrinology, Department of Pituitary and Neuroendocrine Disorders, Bucharest, Romania; [2]Carol Davila" University of Medicine and Pharmacy, Bucharest, Romania; [3]C. I. Parhon National Institute of Endocrinology, Bucharest, Romania

Introduction
RET proto-oncogene is situated on chromosome 10 and encodes a tyrosine kinase receptor. A germline mutation of RET leads to the appearance of MEN 2 syndrome or familial medullary thyroid carcinoma (MTC). One of the most common germline mutation occurs in codon 634. Pheochromocytoma penetrance for codon 634 mutation was demonstrated to increase with age up to 88% by age 77 years.
Aim
To present two familial cases of RET mutation illustrating the different phenotypes that can arise.
Case 1: 44 years old woman who came in our clinic with bilateral hypoechoic thyroid nodules, elevated calcitonin and a slightly raised parathyroid hormone (PTH) with no symptoms. In our center hormonal assessment reflected: calcitonin = 861 pg/ml (n = 1–11), CEA = 76.09 ng/ml. Blood testing for pheochromocytoma and hyperparathyroidism were within the normal range. Fine needle biopsy was performed and the suspicion of MTC (Bethesda V) was confirmed. RET gene analysis showed heterozygous mutation Cys634Trp in exon 11 of RET gene. The patient underwent total thyroidectomy with bilateral jugulocarotid lymphadenectomy, right upper parathyroidectomy and the diagnosis of MEN 2A was confirmed. We did genetic family screening by evaluating her son (negative for RET mutation) and her father, whose case is detailed below.
Case 2: 73 years old man, with grade II hypertension and chronic gastritis, presented with dizziness, nausea and 5 kg weight loss over 3 months. Computed tomography examination showed right adrenal 16×12 mm nodular formation and a cystic formation of 30×22 mm in the left adrenal gland. Subsequent endocrine evaluation revealed high plasma metanephrines in two consecutive measurements: 237 pg/ml, respectively 291 pg/ml (n = 0–100), high cromoganin A, slightly high plasma normetanephrines and a non-suppressed cortisol level after 1 mg of overnight dexametazone. Results of blood testing for hyperparathyroidism and MTC were within the normal range. After performing RET gene analysis, same mutation was confirmed, which guided us to classify the patient into Cluster 2 Adrenal Paraganglioma. The patient underwent preoperatory preparation with doxazosin for laparoscopic right suprarenalectomy.
Conclusion
Screening first-degree relatives for RET mutation is highly recommended because it helps diagnosing adrenal paraganglioma even at average values of hypertension, as well as advanced ages.

The occurrence of adrenocorticotropic hormone-independant Cushing's syndrome in a woman with the history of medullary thyroid carcinoma: a case report

Hayfa Farid[1], Ghada Saad[1,2], Taieb Ach[1,2], El Fekih Hamza[1,2], Asma Ben Abdelkarim[1,2], Yosra Hasni[1,2], Maaroufi Ameml[1,2], Maha Kacem[1,2], Chadli Molka[1,2] & Koussay Ach[1,2]
[1]Hospital Farhat Hached, Endocrinology-Diabetology Department, Sousse, Tunisia; [2]Ibn El Jazzar Medical Faculty of Sousse, Sousse, Tunisia

Background
Medullary thyroid carcinoma (MTC) is a rare neuroendocine tumor that that may be associated with paraneoplastic ACTH-dependent cushing syndrome. There are few case reports on the coexistence of medullary thyroid carcinoma and adrenal adenoma with ACTH-independent Cushing syndrome.
Case presentation
We report the case of a 42-year-old woman, with no family history of endocrine malignancy or endocrine disorders. She underwent total thyroidectomy for MTC. During follow-up, she presented with high blood pressure, hypokalemia, diabetes, and osteoporosis. These symptoms led to the suspicion of Cushing's syndrome. The investigations indeed showed an excessive production of cortisol. contrary to what was expected, Cushing's syndrome is of adrenal origin. Abdominal CT scan showed adrenal adenoma.
Conclusions
We present a rare case of a patient with MTC and Cushing's syndrome. The co-occurrence of two endocrine tumors with different origins is rare. To date, no known genetic syndrome can account for this combination of neoplastic thyroid and adrenal pathologies, future research may prove differently.

Weight loss in diabetics of 2 unbalanced revealing neoplasia

Sofia Ouhessaine, Nassim Essabah Haraj, Siham El Aziz & Asma Chadli
Ibn Rochd University Hospital of Casablanca, Morocco Neurosciences and Mental Health Laboratory Faculty of Medicine and Pharmacy – University Hassan II – Casablanca, Endocrinology, Diabetology, Nutrition and Metabolic Diseases Department, Casablanca, Morocco

Introduction
The incidence of cancer has increased in case of diabetes, as well as the metabolic abnormalities observed during diabetes could have a critical role on carcinogen, nevertheless one should not deny the implication of common factors to diabetes and cancer (obesity, smoking, advanced age, etc).
Study objectives
Describe the biological and morphological screening methods for neoplasia in the event of weight loss concomitant with chronic glycemic imbalance.
Materials and methods
Retrospective descriptive study conducted at the endocrinology and metabolic diseases department of Casablanca, including 186 patients hospitalized for chronic glycemic imbalance with weight loss between 2018 and 2022.
Results
A total of 186 patients were included, reporting an average weight loss of 7.6 kg provided a weight loss assessment including an assay of tumor markers (CA19.9, ACE, CA15.3, CA125, PSA) and morphological minimal (thoracic X-ray and pelvic ultrasound), a specific morphological assessment was carried out in the event of an anomaly (echo-mammography, abdominal cervicothoracic computed tomography) or even a cervical–vaginal smear. The average age was 58.3 years with a female predominance, HBA1C averaged 11.7%, obesity was found in 69.2%, sedentary lifestyle in 91%, smoking in 39.6%, and alcoholism in 18.5%. Among them, 16 patients presented neoplasia including 7 pancreatic neoplasia, 5 mammary, 2 cervical–vaginal, 2 pulmonary and 1 case of esophageal neoplasia.

Conclusion
A chronic diabetic imbalance could suggest a neoplastic cause. Early screening for these neoplasia's is important and should include a stratification model with clinical–biological criteria, and specific imaging.

Recurrent adrenocortical carcinoma: a case report

Ben Salem Maram, Manel Jemel, Asma Ben Salem, Marwa Chiboub, Hajer Kandara & Ines Kammoun
National Institute of Nutrition, Department of Endocrinology, Tunis, Tunisia

Background
Adrenocortical carcinoma is a rare malignancy with a poor prognosis. Local recurrence is affected by the pathologic features (tumor staging and mitotic index) and the complete surgical resection. Treatment of a recurrent adrenocortical carcinoma can be a real challenge.
Case description
We report a case of 47-year-old man who was operated for an adrenal tumor with bone metastases. Left adrenalectomy and splenectomy were performed and histology confirmed the diagnosis of adrenocortical carcinoma. Five cycles of chemotherapy (Cisplatin and bisphophonate) were given. The patient presented an adrenal deficiency and a 10 mg glucocorticoid replacement therapy was prescribed. Seven years later, he presented dyspnea and fatigue with no other clinical or biological abnormalities. CT scan showed a left adrenal tumor of 40× 30 mm and a suspected voluminous lymph node of a 90×63 mm with invasion of the left pulmonary artery and multiple suspected pulmonary lesions. Cortisol failed to suppress after low dose and high dose on Dexamethasone suppression test. Surgery was not possible and the patient continued to deteriorate despite chemotherapy and was subsequently referred to palliative care.
Discussion
Due to the rarity of the adrenocortical carcinoma, the understanding and experience of management modalities is limited. New treatment options may be available in the coming years to improve outcome. Early identification of tumor is the key to improve the prognosis of the disease.

EP656

Primary sinonasal neuroendocrine carcinoma invading the orbit

Chtioui Sara, Zahra Ismail, Sana Rafi, El Mghari Tabib Ghizlane & Nawal El Ansari
Mohammed VI University Hospital Center, Department of Endocrinology, Diabetes, Metabolic Diseases and Nutrition, Marrakech, Morocco

Introduction
Sinonasal neuroendocrine carcinoma SNECs are a rare group of neoplasms that account for only 5% of all sinonasal malignancies. SNECs are categorized by their differentiation grade into well-, moderately- and poorly differentiated.
Case report
We describe a classical case of SNEC with secondary orbital involvement in a 34-year-old male patient presented of the occurrence of a right epistaxis. First of all, the patient is smoking. The beginning of the symptomatology goes back to 2 months before with right nasal obstruction of progressive onset, associated with bloody rhinorrhea and right chronic eye watering. The patient didn't present neurological signs nor cervical lymph nods. Otherwise, ophthalmologic examination found normal visual acuity and ocular mobility on both sides. Sinonasal computed tomography (CT) found a right nasal process enhanced after injection of contrast product 46×30×37 mm invading the orbit. The immunohistochemical study of the tumor biopsy found that the pan cytokeratin and CK7 and the neuroendocrine marker Chromogranin A, synaptophysin and CD56 are positive, with a proliferation index Ki67 of 60%. The multidisciplinary decision taken was treatment by chemotherapy before surgery.
Discussion
Most patients present at advanced stages due to the lack of significant symptoms. Advanced tumors may invade the skull, orbit or brain. Ophthalmic manifestations include exophthalmos, reduced vision and restriction in ocular motility. Ectopic hormone secretion has been described in a handful of cases. Staging is of limited value in predicting prognosis and recent literature clearly highlights the importance of histological diagnosis, particularly differentiation grade, in determining the prognosis and predicting treatment response.
There are no clear treatment and the management include surgery with radiotherapy with/without chemotherapy; chemoradiotherapy; or radiotherapy or chemotherapy alone.

Digestive endocrine tumors: better understanding for better treatment

Mustapha Asfour, Antonio Nfad, Yassine Errahali, Sanae Chakdoufi, Jade Issouani & Ahmed Anas Guerboub
Rabat, Endocrinology Diabetology Nutrition, Rabat, Morocco

Introduction
Digestive neuroendocrine tumors (DNETs) represent a heterogeneous group of tumors. This heterogeneity is manifested by the variable localization of these tumors but also by a great clinical and biological diversity. Thus, they occupy an increasingly important place in digestive oncology.
NETs are very rare and represent about 1% of all digestive tumors, due to their slow evolution. The majority of them develop in the digestive tract (67.5%) (from the esophagus to the anus); the pancreas, the liver and the gallbladder are more exceptionally affected.
We report the observation of a patient with a type 1 neuroendocrine tumor to illustrate the interest of properly typing this type of tumor in order to administer an adequate treatment.
Observation
49 year old patient with antecedents: Biermer's anemia under treatment
Who has chronic intense epigastric pain that is resistant to analgesic treatment and for which endoscopic exploration has demonstrated: Milimetric sessile polyps in the fundus with suspected ECLomas and a histological and immunohistochemical appearance of a well differentiated DNET of grade 2+ Chronic antral gastritis.
The clinical examination was unremarkable.
A workup that could frame TNED as a possible type 1 multiple endocrine neoplasia was requested:
On the biological level:
Gastrinemia 17×N.
Chromogranin A elevated at 172 ng/ml (N: 108 ng/ml).
Insulin, C-peptide, hypophysiogam and Ph-Ca were normal at normal rate.
On the morphological level:
CT scan and Hypothalamic–pitiutary MRI without any particularities
An Otrescan for metastases was requested but did not reveal any other pathological sites
→We conclude to a neuroendocrine tumor type 1
The treatment consisted of clinical surveillance with iterative endoscopic tumorectomy every 6 months.
Conclusion
In the vast majority of cases, differentiating neuroendocrine tumors does not pose a real problem. A few simple rules can help to avoid any diagnostic doubts. The challenge is not to overtreat benign tumors (type 1) and induce surgical morbidity and mortality, or undertreat malignant tumors (type 3).

Clear cell renal carcinoma synchronous with various endocrine pathologies

Andreea Raluca Petria[1], Diana-Georgiana Lazar[1], Sabina Elena Oros[1,2], Dumitru Ioachim[1], Teodor Ionut Constantin[1] & Daniel Grigorie[1,2]
[1]C.I. Parhon National Institute of Endocrinology, Bucureşti, Romania; [2]Carol Davila University of Medicine and Pharmacy, Bucureşti, Romania

Introduction
Clear cell renal carcinoma (ccRCC) is a subtype of renal cell carcinoma, the most frequent one (80%) and usually affecting only one kidney. It is twice as common in men than women between 50 to 70 years old. It can be associated with some genetic conditions that predispose patients to ccRCC, like Von Hipple-Lindau disease. Some clinical observations and molecular studies raised the hypothesis that RCC is a hormone−dependent tumor.
Case reports
We present three cases of ccRCC associated with various endocrine patterns.
Our first case is a 45-year-old man, with a family history of papillary thyroid carcinoma and ccRCC, left nephrectomy for ccRCC and nontoxic multinodular goiter. One year after nephrectomy, he underwent total thyroidectomy (confirmed

histopathological to be a papillary thyroid carcinoma). The second case is a 46-year-old woman who underwent a partial right nephrectomy and right adrenalectomy. The histopathological exam revealed ccRCC and adrenal metastasis of ccRCC. MRI scan showed left longissimus thoracic muscle nodule and left adrenal nodule suggesting metastasis, while having a normal adrenal function. The patient was referred to initiate immunotherapy, therapy that can lead to thyroid disfunction. Our third case is a 52-year-old woman, known with lupus, without documented lupic nephritis, and left nephrectomy for ccRCC. One year after nephrectomy, the patient contracted left shoulder pain, which led to the diagnosis of left humeral osteolytic metastasis, so she started Sunitinib treatment (4 weeks on, 2 weeks off). Six months later, she developed sever hypothyroidism (TSH = 320 × μUI/ml) and began replacement therapy. All our cases are peculair. Age at diagnosis was lower than the known mean age (64 years). Men are predisposed to develop first thyroid cancer (opposite to our case), then kidney cancer, with a distance between the two cancer diagnoses of 5.2 years. Bilateral adrenal metastases are rare (< 0.5%), particularly in case of melanoma, thyroid, hepatocellular and bladder cancer, not in ccRCC. Hypothyroidism is a side effect of Sunitinib (TKI), in patient with underlying autoimune thyroid condition, or through the inhibition of VEGFR and/or PDGFR.. During the treatment with Sunitinib, the patient may need a higher dose of levothyroxine than during the treatment break.

Conclusion

The risk of developing another primary tumor is three times higher in patients with RCC versus other oncology patients. The gold standard in localized RCC is nephrectomy and local lymphadenectomy. In case of metastatic RCC, some of the treatment options are TKI (sunitinib e.g.) and immunotherapy.

Are sugar substitutes potential endocrine disruptors?

Krisztian Sepp[1], Molnár Zsolt[2], Hausinger Peter[3], Mozes Miklos[1], Marianna Radács[2], Zsuzsanna Valkusz[1] & Márta Gálfi[2]
[1]University of Szeged, Hungary, Endocrine Unit of Department of Internal Medicine, Albert Szent-Györgyi Clinical Center, Szeged, Hungary; [2]University of Szeged, Hungary, Institute of Applied Health Sciences and Environmental Education, Juhász Gyula Faculty of Education, Szeged, Hungary; [3]University of Szeged, Hungary, Invasive Cardiology Department, Department of Internal Medicine, Albert Szent-Györgyi Clinical Center, Szeged, Hungary

Keywords: sugar substitute agent exposures, nutritional biology, neuroendocrine system, oxytocin

Human homeostasis is maintained by the complex functioning of the psycho-neuroendocrine-immune system. If a disturbance is generated in this neuroendocrine system for any reason, it can trigger pathogenic processes. One of the factors disturbing homeostasis today may be changes in dietary habits, e.g. through the use of undue sweeteners (e.g. stevia, xylitol etc.). These substances may alter neuroendocrine regulation if they affect natural metabolic processes. *In the present work we aim* to follow the changes in oxytocin (OT) relase induced by certain sugar substituting agents. Continuing our research on this topic, where we have already explored the effects induced in AVP ablation. *In our work*, we treated Wistar (♂) rats *in vivo* with gastrointestinally sweetening agents (aspartame, stevia, saccharin, xylitol) while monitoring their toxicity parameters. At the end of the treatments, *in vitro* neurohypophysis monolayer cell culture models (NH) were prepared (enzymatic /trypsin, collagenase, dyspase enzymes/ and mechanical /d = 80 μm neylon-blutex filter/ dissociation; DMEM + 10% FCS + 10U/ml Pen + Strep culture medium). These were used to study OT regulation after viability, specific-, aspecific function control. We measured the basal OT release of NH wells from confluent cultures formed after in vivo treatment and also determined OT release in vitro in the presence of additional aspartame, stevia, saccharin, xylitol (1 mg/100 mL culture medium). Our results were developed using RIA, ELISA, and Lowry methods. ANOVA was used for statistical analysis. *We found that* after *in vivo* treatment, each sweetener modulated the basal OT secretion of NH cultures in a downward direction, which was followed by a stronger decrease in OT secretion after *in vitro* treatments at the contact cell level. When these data are compared with the AVP release results, it can be seen that OT secretion is more sensitive to the applied sugar substitutes than AVP. The experiments seem to confirm an endocrine modulating effect, which justifies further studies (supported by EFOP-3.6.1-16-2016-00008, EFOP3.4.3-16-2016-00014; TAMOP-4.2.4.A/2-11/1-2012-0001).

Systematic evidence mapping of thyroid hormone patterns after exposure to endocrine disrupting chemicals in adult rodents

Asma Baig[1], Isabel Forner-Piquer[2] & Andreas Kortenkamp[2]
[1]Centre for Pollution Research and Policy, Department of Life Sciences, College of Health, Medicine and Life Sciences, Brunel University London, London, UK; [2]Centre for Pollution Research and Policy, Department of Life Sciences,, College of Health, Medicine and Life Sciences, Brunel University London, London, UK

Certain endocrine disrupting chemicals (EDCs) are known to disrupt the thyroid hormone system. Thyroid hormone (TH) levels are physiologically regulated by the hypothalamic–pituitary–thyroid (HPT) axis, a tight feedback loop, whereby low levels of T4 stimulate an upregulation of TSH, and conversely if T4 levels are raised. Low levels of T4 (with chronic upregulation of TSH) can lead to thyroid hyperplasia – an outcome that is recognised by regulatory groups for substances of concern to human health. In pregnant women, even acute exposure resulting in low T4 can lead to cognitive deficits in the foetus. While most chemicals disrupt the TH system by lowering T4 levels, some chemicals lower T4 but without a concomitant increase in TSH or may lower TSH as well. We were interested to investigate the different TH patterns seen after exposure to various EDCs, towards an understanding of the different mechanisms of action (MoA), we therefore conducted an extensive systematic evidence mapping exercise. We used the PECO method and included published studies that measured T4/T3 and TSH in adult rodents aged ≧ 6 weeks at the life stage of dosing. All chemical classes were included, with their exposure by gavage. Results were collated for T4/T3 and TSH measurements. We found that chemicals were mainly able to decrease T4 together with the expected increase in TSH, suggesting that the feedback loop is unaffected; although chronically unregulated levels of thyroid hormones have adverse health effects. However, some chemicals are able to decrease T4, but also decrease TSH or cause no change in TSH, thereby disrupting the feedback loop and causing apparent central hypothyroidism. EDCs can act on different molecular targets within the TH system such as transporters, enzymes and receptors in different parts of the TH system, including acting on hepatic enzymes to expedite the excretion of THs via the liver. The mechanisms by which various chemicals disrupt the TH system have not yet been fully identified for different chemical classes. Current regulatory tests for market placement of chemicals require T4 measurement, with the assumption that TSH is raised. We find that this is not the case for many chemicals and therefore the complexity of EDC MoA needs to be considered in the testing strategy in order to identify chemicals that are potentially damaging to human health.

Endocrine complications in patients of beta thalassemia major

Nadia Khessairi[1], Anis Grassa[1], Nour Meziou[2], Mehdi Mrad[2], Sonia Mahjoub[3], Afef Bahlous[2] & Melika Chihaoui[1]
[1]Rabta Hospital, Endocrinology, Tunis, Tunisia; [2]Pastor Institute, Biochemistry, Tunis, Tunisia; [3]Rabta Hospital, Haematology, Tunis, Tunisia

Introduction

Endocrine complications are common in beta thalassemia major (BTM) patients receiving blood transfusions. Chelation therapy has a role in preventing such complications. However, patients may have difficulties adhering to chelation therapy. We aimed in this study to determine the endocrine complications in BTM patients.

Methods

This was a descriptive study with cross-sectional data collection over a 6 month period from February 2022 to July 2022, including 43 patients with BTM follow up at Haematology department of Rabta Hospital. The patients underwent a clinical examination and a fasting blood sample was collected for biological measurements.

Results

The mean age was 27 ± 4.78 years. The median duration of erythrocyte transfusions was 25.9 ± 4.75 years. The patients were transfused at a rate of 2 transfusions per week in 65% of cases. Mean ferritin level was 1542.2 ± 594.7 μg/l. Ferritinemia greater than 1000 μg/l was observed in 32 patients (74%). One endocrine complication was found in 35 patients (81%), two endocrine complications was found in 13 patients (30%) and an association of three endocrine complications was found in 3 patients (7%). Fifteen patients developed hypothyroidism (35%). The mean age of patients with hypothyroidism was statistically higher than those with euthyroidism ($P = 0.023$). Diabetes mellitus was found in 14 patients (33%) and prediabetes in 8 patients (19%). BTM patients with prediabetes had statistically higher mean level of ferritinemia ($P < 0.01$). Two

patients developed hypoparathyroidism (5%) and nineteen developed hypogonadism (44%). Patients with hypogonadism had statistically higher mean level of ferritinemia ($P=0.049$). Finally, no cases of adrenal insufficiency were found.
Conclusion
The detection of endocrine and metabolic complications is essential during the follow-up of BTM patients. A monitoring of clinical and biological parameters makes it possible to detect early and sub-clinical abnormalities. Thus, patients will have an early and targeted management.

Early Dinner instead of Late Night reduce the risk of endocrine as well as genetic disruption

Qulsoom Naz[1], Kausar Usman Siddiqui[1], Narsingh Verma[2], B Anjum[3] & Abbas Ali Mahdi[4]
[1]King George's Medical University, Medicine, Lucknow, India; [2]King George's Medical University, Physiology, Lucknow, India; [3]King George's Medical University, Biochemistry, Lucknow, India; [4]King George's Medical University, Biochemistry, Lucknow, India

Background
Our bodies function optimally when we align our eating & sleeping patterns with our circadian rhythms, the innate 24-hour cycles that tell our bodies when to wake up, when to eat and when to fall asleep. Chronically disrupting this rhythm by eating late night meals & sleep could be a recipe for Hypertension, CVD, and metabolic trouble.
Aim and objective
The aim of this study is to investigate whether there was a relationship between morningness(MC) (110n) intermediate(IC) (100n) & eveningness chronotype(EC) (35n) in T2DM.
Methods
A total of 245 subjects' age 18 to 60 years were recruited in Clinical OPD of General Medicine, KGMU. We have tested FBG & PP level, lipid profile HbA1c, Insulin, Leptin and Cortisol level, 48 h ABPM.
Result
When we compared these 3 groups, Significant Different parameters found in FBG ($P=0.01$) Postprandial ($P=0.03$) HbA1c ($P=0.001$) TG ($P=0.0001$), Total Cholesterol ($P=0.01$) & VLDL ($P=0.005$). It also shows the complete inversion of the cortisol level (0.003). Insulin, IL-1 beta & IL-6 also show significant change in late night eating T2DM Patients. Systolic/Diastolic readings of ABPM shows significant change between MC and IC (0.005) but not b/w EC & IC (0.007). And for reliability of sleep by actigraphy shows MC (6:15 $\pm$ 1:35) & EC (8:18 $\pm$ 1:23) take complete sleep but IC total sleep hours (5:10 $\pm$ 1:05) are very less. Disruption of Rev Erb (0.003) & Ror α (0.001) gene expression is also a risk factor for Cardio metabolic Diseases in T2DM patients.
Conclusion
Intermediate & Eveningness type are more likely to have late night eaters & they are associated with greater risk of Metabolic Disorders like Dyslipidemia, T2DM & CVD as well as disruption in circadian expression.

Hospital General de Agudos Cosme Argerich, Ciudad de Buenos Aires, Argentina; [5]Sector Endocrinología, División Laboratorio. Hospital General de Agudos Carlos G Durand., Ciudad de Buenos Aires, Argentina; [6]Laboratorio Hospital General de Agudos Cosme Argerich., Ciudad de Buenos Aires; [7]Sector Endocrinología, División Laboratorio. Hospital General de Agudos Carlos G Durand, Ciudad de Buenos Aires, Argentina; [8]Catedra de Metodología para la Investigación Psicológica I, Facultad de Psicología, Universidad de Buenos Aires, Ciudad de Buenos Aires, Argentina; [9]Catedra de Química Analítica Instrumental, Facultad de Farmacia y Bioquímica, Universidad de Buenos Aires, Ciudad de Buenos Aires, Argentina

In Wuhan China in December 2019, cases of severe atypical viral pneumonia emerged, and the World Health Organization declared COVID-19 a pandemic. In this critical context, health workers were on the front lines, directly participating in the evaluation, diagnosis, and treatment of patients with COVID-19. The objective of our work was to evaluate stress and burnout in health workers and to measure hair cortisol levels as a stress biomarker during the second wave.
Materials and methods
496 health workers were included from Cosme Argerich Hospital ($n=190$), "José de San Martín" Hospital de Clínicas ($n=156$) and Carlos G Durand Hospital ($n=150$). Sociodemographic data of the included individuals was gathered, completing the following psychometric tools: perceived stress, social support, burnout scale, anxiety scale. Hair samples were obtained from posterior vertex between July and October 2021. Hair cortisol was measured following the procedure developed in our laboratory with an automated chemiluminescent method (Immulite 2000).
Results
Table 1 shows the associations found in the studied population. 11% ($n=54$) presented Burnout (High Emotional Exhaustion, low Personal Achievement and high Depersonalization). It was observed that the two Acute Care Hospitals (Argerich and Durand) presented a similar Burnout percentage (13%, $n=25$; 12%, $n=18$, respectively), whereas it was lower in the University Hospital (7%, $n=11$). When we performed a binary logistic regression, we found that Perceived Stress, Anxiety and age were associated with Burnout ($P=0.024$, OR: 1.258 [IC1.030–1.536]; $P=0.025$ OR: 0.894 [IC0.810–0.986]; $P=0.001$ OR: 0.954 [IC0.926–0.981], respectively). Considering individuals with hair cortisol levels above median, a significant association was observed between hair cortisol and age, hours worked, Emotional Exhaustion and Depersonalization ($r=-0.236$, $P<0.0001$; $r=0.204$, $P=0.006$; $r=0.185$, $P=0.006$; $r=0.172$, $P=0.010$).
Conclusion: In this work conducted during the second wave of COVID-19 pandemic, it was observed that Burnout was associated with low social support, high personal exhaustion and younger age. Burnout percentage found during the second wave in Hospital de Clinicas was significantly lower than the one obtained in July 2020. Health workers are especially exposed to stress and burnout, being a

vulnerable population to psychological distress. Therefore, strategies should be implemented to assess this psychological emergency.

Table 1 Statistical Associations

Variable	Anxiety	Burnout		
		Emotional Exhaustion	Personal Achievement	Depersonalization
Hair Cortisol	NS	$r=0.129$, $P=0.005$	NS	NS

Psychosocial profile of transgender population attended in a gender identity unit

Esteban Sánchez Toscano, Irene Zayas Aguilar, Isabel Mateo Gavira, Laura Larrán Escandón & María de la Vega Trujillo López
Hospital Universitario Puerta del Mar, Endocrinology and Nutrition Department, Cádiz, Spain

Introduction
Transgender people are a diverse population affected by a variety of negative health indicators. Studies report, among other conditions, a high prevalence of mental health problems and substance abuse. However, there are still health issues that have been poorly analyzed and long-term longitudinal follow-up studies are scarce.
Objective
The aim of this study is to deep into the demographic characteristics and the psychosocial profile of transgender people attended at the Gender Identity Unit of Hospital Puerta del Mar (Cadiz), as a provincial reference unit.
Materials and methods
This is a descriptive cross-sectional study with data collected during the first visit to the psychology consultation between January of 2019 and December of 2020. 21% of transgender people treated in our unit requested an assessment by a clinical psychologist. The endocrinologist is responsible for making the referral to the psychologist if necessary. Demographic variables and other parameters of the psychosocial sphere are analyzed.
Results
Of the 124 people included in this study, 53% were transwomen and 47% transmen. The mean age was 20.54 ± 6.85 years. Regarding the level of studies, 3.4% had primary studies, 45.7% secondary studies, 27.6% higher studies and 23.3% vocational training. Family support was recognized by 85.5% of the population and 37% had a partner. 46.2% declared bullying in the social field. Gender incongruence began in childhood in 59.1%. Gender affirming hormones have been started in the 31.2% of people analyzed. Reasons for consultation were: anxious-depressive symptoms in 22% of the cases, doubts about gender affirming hormones in 14.4%, family non-acceptance in 6.8%, psychological support in 33.3%, gender dysphoria in 5.3%, various requeriments 6.1% and others in 11.4%. The attitudes most frequently taken on the first visit were: psychoeducation in 31.8% of the cases, family therapy in 5.3% and support in 51.5%.
Conclusions
In our setting, transgender people who request a follow-up in a clinical psychology consultation are mainly young people, with a history of gender incongruence since childhood and a frequent history of bullying. The reasons for the assitance demand are mainly the accompaniment in the gender reassignment process and the management of anxious-depressive symptoms.

Methods for assessment of the mitochondrial toxicity by toxicant with murine kidney stem cell

Eui-Bae Jeung, KangMin Kim & YongIn Kim
Chungbuk National University, Laboratory of Veterinary Biochemistry and Molecular Biology, College of Veterinary Medicine, Cheongju-si, Chungcheongbuk-do, South Korea

Mitochondria play an important role in generating energy, and they are essential to cell survival. Mitochondria have varieties of functions, such as regulating intracellular calcium concentration and signal transduction, controlling hormone synthesis, inflammatory responses, and free radicals. In particular this research is interested in the mitochondria in kidney tubular cell. Since mitochondria in tubular cells play an important role in supplying energy, removal of waste and reabsorption of nutrients in the blood, control of blood pressure, and maintenance of homeostasis. Mitochondrial damage may occur by drugs or related chemicals for the treatment of various diseases. Therefore, it may be related to mitochondrial dysfunction. Following experiment was conducted to investigate the relation between kidney and mitochondrial dysfunction. First, five drugs known to be toxic chemicals to mitochondria were selected. After treatment with mouse kidney stem cells, the specific concentration of cell viability (IC50) was selected for each chemicals. The results of valproic acid, a representative mitochondria toxicant, treated on the cell, confirmed that the expression of SOD2 increased according to the increasing concentration of valproic acid. Result of performing an analysis using MitoSOX red staining to confirm the relationship between mitochondrial toxicity and mitochondrial reactive oxygen species (mtROS), it was found that the level of mtROS according to the concentration of a valproic acid was relatively increased.

Syndromic disorders with short stature

Dounia Zerrouki[1,1], Rami Imane[1], Imane Ziani[1], Siham Rouf[1,2] & Hanane Latrech[1,2]
[1]Faculty of Medicine and Pharmacy, Mohamed First University Oujda/ Mohamed VI University Hospital Center, Endocrinology, Diabetology and Nutrition Department, Oujda, Morocco; [2]Laboratory of Epidemiology, Clinical Research and Public Health, Faculty of Medicine and Pharmacy of Oujda, Mohammed the First University, Oujda, Morocco

Keywords: short stature, Noonan syndrome, Prader-Willi syndrome, Silver-Russell syndrome, genetic syndromes
Introduction
Short stature is one of the major components of dysmorphic syndromes. Growth failure may be due to a wide variety of mechanisms, either related to the growth hormone (GH)/insulin-like growth factor axis or to underlying unknown pathologies. At present, GH therapy is used in most syndromic disorders, although long-term studies evaluating this treatment are insufficient and some controversies exist with regard to GH dose, optimal age to begin therapy and adverse effects.
Objective
To study etiological, genetic and diagnosis aspects of children with dysmorphic short stature.
Methods
Retrospective study including 60 children and adolescents with syndromic disorders with short stature admitted in the Department of Endocrinology diabetology and nutrition. The related anthropometrics and laboratory examinations were assessed in all participants.
Results and discussion
We report 60 children and adolescents with short stature aged 14 ± 3.3 years, including 34 boys and 26 girls, were analysed in this study. The mean weight standard deviation score (SDS) and height SDS were -2.67 ± 1.28 and -4.06 ± 1.51 respectively. The majority of the children (56.9%) were prepubescent. The mean difference in bone age from chronological age was 25 months ± 9. A propranolol–glucagon test was evaluated in 48.3% of patients. The causes of syndromic short stature in our study are represented mostly by: malformation of the pituitary gland in 26.7% and Turner syndrome in 11.7%, followed by MOC (8.3%), prader wili syndrome (6.7%), Noonan's syndrome in 3.3%, 3M syndrome in 8.3%, waardenburg syndrome in 3.3%, russell-silver syndrome in 3.4%, DMC in 3.3%., and lastly 3A syndrom in 1.7%, Meier-Gorlin syndrome in 1.7%, as well as Eliis van Creveld syndrome. The genetic evaluation is still ongoing in 19.9% of the cases.
Conclusions
Genetic disorders are among major causes of short stature in children. Genetic testing is mandatory, in dysmorphic short stature. Patients should be referred to tertiary care centers for an individualized management.

A bibliometric and qualitative analysis of the top 2500 most cited PCOS articles: Analysing global disparities in PCOS research and collaborations

Maiar Elhariry[1], Punith Kempegowda[2,3] & Kashish Malhotra[4]
[1]University of Birmingham Medical School, College of Medical and Dental Sciences, Birmingham, UK; [2]Institute of Metabolism and Systems Research, College of Medical and Dental Sciences, Birmingham, UK; [3]Queen Elizabeth Hospital Birmingham, UK; [4]Dayanand Medical College & Hospital, Punjab, India

Introduction
Polycystic ovary syndrome (PCOS) is a complex condition with multi-systemic implications that can greatly impact patients' lives. To understand and deliver the varied needs of people with PCOS, a substantial onus lies on PCOS researchers to objectively study patient data and formulate evidence-based recommendations. Equitable research is crucial to ensure fair representation of people of various ethnicities and stratify population-specific analysis to have generalisable findings in policy papers and scientific research globally. The aim of this study is to quantify and study the variation and collaboration across geography in top 2500 most-cited PCOS peer-reviewed articles.
Methods
We screened all publications for the search query "Polycystic Ovary Syndrome" in the title or abstract to extract the top 2500 publications with the highest number of total citations using the software Dimensions®. We identified the authors and organisation/ hospital of practice of authors through their listed affiliations. Countries of practice were further classified into high-income, lower-middle income, upper-middle income, or low-income countries(LIC) based on the 2022 World bank report. Vos Viewer® was used to analyse bibliometrics and analyse total link strength between various categories. Network visualisation was done to analyse co-authorship between researchers' countries of practice. Similarly, overlay visualisation was used to study collaborations over time. Mann Whitney U-test was done to study the total link strength in co-authorships in HICs and LMICs with $P < 0.05$ considered as statistically significant.
Results
The authors of the top 2500 of 28 901 most cited articles for PCOS with 396 040 citations(59.5% of the total citations) were from 62 countries(40 HICs, 15 UMICs, and 7 LMICs). The United States had the highest number of total publications(847) and citations(155 590) followed by UK(324 publications with 54 451) and Australia(186 publications with 37 042). Only 3/54 African countries and no low-income countries were identified as the researchers' country of practice. For PCOS research, HICs had higher link strength than LMICs($P = 0.007$). We found only 3 clusters with a total 448 links between countries in the network visualisation with a total link strength of 1310. In overlay visualisation, collaborations during the last decade were noticed between some HICs and MICs including Lebanon, Egypt, India, Sri Lanka, and China.
Conclusion
Our study shows the limited global representation of MICs and LICs in the most impactful PCOS research by total citations. This highlights the need for more extensive partnerships and networks, particularly with researchers from LMICs to increase the representation of PCOS research globally.

Pituitary apoplexy triggered by COVID-19?

Iolanda Brindusa Nicolae[1] & Carmen Gabriela Barbu[1,2]
[1]Elias Emergency University Hospital, Endocrinology, Bucharest, Romania; [2]Carol Davila University of Medicine and Pharmacy, Endocrinology, Bucharest, Romania

Introduction
Pituitary apoplexy is a rare and potentially life-threatening disorder defined by hemorrhage or infarction of the pituitary gland. Occasionally, it may be the first manifestation of an underlying adenoma.
Case report
We present a case of a 70-year-old male, who was admitted in our clinic for an incidentally discovered pituitary macroadenoma accompanied by severe left hemicrania, otalgia and left eyelid ptosis.
Medical history
Two weeks ago, the patient was hospitalized for SARS-COV2 infection, with a moderate form of pneumonia and was administered anticoagulation and glucocorticoid therapy, antipyretics, rehydration fluids, no intubation needed.
During that stay, he suddenly developed a vertebrobasilar syndrome, which prompted an imagistic evaluation, revealing a pituitary macroadenoma with optochiasmatic and cavernous sinus compression, with no signs of acute bleeding or intracerebral lesions, thus excluding a stroke/brain hemorrhage.
Admission to endocrine clinic
Clinical examination showed pale skin, multiple post-anticoagulation hematomas, a remitting left eyelid ptosis, unstable gait, narrowed visual field, no polyuria or polydipsia.
Biological assessment identified microcytic hypochromic anemia, normal platelet count, inflammatory syndrome, elevated D-dimer level, low iron level.
Endocrine evaluation revealed pituitary insufficiency(adrenocorticotropic, tireotropic and gonadal) with a bilateral narrowing of the peripheral visual field.
The pituitary contrast MRI revealed a macroadenoma(21/17/20 mm)within a precocious subacute state hemorrhage with optochiasmatic and cavernous sinus compression. Since the patient was hemodynamically stable, conscious and further evaluations didn't show signs of worsening, we opted for conservative management and corticotherapy. Patient was discharged with improved evolution, and under hormonal therapy.
Second endocrine admission
After two weeks, he was readmitted urgently for severe headache and right eyelid ptosis. We initiated glucocorticoid therapy in anti-inflammatory doses, with remission of clinical symptoms. The second MRI showed a shrinking macroadenoma(18/17/17 mm) with no rebound hemorrhage. During this stay, patient accused mild discomfort in his left iliac region, rapidly progressing to severe pain, with abdominal muscle defense, inflammatory syndrome and increased markers of sepsis. He was sent for exploratory surgery and diagnosed with an abscessed hematoma of the left iliopsoas muscle compartment. The patient was released with a positive outcome and reevaluated regularly.
At 3 months, MRI showed a much smaller adenoma(18/7/15 mm), with withdrawn hemorrhage.
Conclusions
As awareness of COVID-19-associated coagulopathy increases, thrombotic manifestations are implicated in mortality. This case report unveils a rare and never cited before, association between two life-threatening pathologies, that could both be linked to anticoagulation therapy and/or prothrombotic status.

Carney complex as a rare reason of acromegaly in adulthood

Margarita Perepelova, Elena Przhiyalkovskaya, Larisa Dzeranova, Ekaterina Pigarova & Anna Kolodkina
Endocrinology Research Centre, Moscow, Russia

Carney complex is a rare hereditary syndrome with an autosomal dominant inheritance pattern that manifests itself with a set of specific symptoms. Case presentation. 32-year-old woman was admitted to the endocrinological hospital with an active stage of acromegaly. From the anamnesis it is known that at the age of 11, the height was 172 cm. The diagnosis of acromegaly was established at the age of 28 years: IGF-1 673.8 ng/ml (78–311), pituitary gland with para(d)-sellar spread (11×13×9 mm). She did not receive prescribed somatostatin analogs. At the present examination at the age of 32 years: acromegalic clinical features, no skin leisures, weight 71.6 kg, height 173.5 cm, IGF-1 – 475.8 ng/ml, pituitary adenoma was the same size. The examination also revealed endogenous ACTH-independent hypercortisolism: an increase in salivary cortisol (evening) – 11.86 nmol/l (0.5–9.65) and free cortisol in daily urine – 1485.8 nmol/day (100–379), a decrease in ACTH – 1.2 pg/ml (7.2–63.3), according to MSCT – a picture of nodular hyperplasia of both adrenal glands. At the age of 25, she was observed for euthyroid multinodular goiter, at the onset, TAB – Bethesda II was performed, during the present examination, an increase in the node size the left lobe to 15× 16×33 mm was noted, with TAB Bethesda IV.
At the age of 27, resection of the left mammary gland was performed due to fibrocystic mastopathy and intraductal papilloma. At the age of 29 years, echocardiography showed a left atrial myxoma, which was surgically removed with histological confirmation of this type of tumor. Given the young age of the patient and the onset of the disease, the presence of multiple neoplasia, heart myxoma in anamnesis and in mother, a genetic study was carried out: in the *PRKAR1A* gene (NM_212472.2) in the 8th exon, a previously undescribed variant was found (HG38, chr17:68527885delAA, c.755_756del) in the heterozygous state, leading to a deletion of two nucleotides and a shift in the reading frame of p.K252Sfs*17 with a coverage depth of 210×. The variant does not appear in the gnomAD population frequency database. The variant most likely results in the loss of function of the corresponding copy of the gene.

The patient was successfully operated on pituitary adenoma. Of thyroid tumor and Cushing's syndrome, the patient refused. The study of the variability of the components of this syndrome should help various specialists diagnose a rare hereditary pathology.

Medical complications of craniopharyngioma management in a uk tertiary pituitary centre

Stamatios Tzanninis[1], Mohammed Jamsheed[1], Ardalan Zolnourian[2], Alicja Knysak[1], Jonathan Hempenstall[2], Nijaguna Mathad[2], Jana Bujanova[1] & Ma'en Al-Mrayat[1]
[1]University Hospital Southampton NHS Foundation Trust, Endocrinology and Diabetes, Southampton, UK; [2]University Hospital Southampton NHS Foundation Trust, Wessex Neurological Centre, Southampton, UK

Background
Craniopharyngioma (CP) is a rare sellar or suprasellar epithelial tumour with a prevalence of approximately 2 per million and it occurs either in childhood between the ages of 5 and 14 years or in adulthood between the ages of 50 and 74 years. Histologically, CPs are divided into adamantinomatous, more prevalent in children, and papillary, more prevalent in adults. They are usually benign, but rare cases of malignant CPs have been reported. Clinical presentation is usually with symptoms of hypothalamic involvement such as weight gain, disturbance of circadian rhythm, disorders of temperature or thirst regulation, deficiencies of pituitary hormones, visual disturbances, or hydrocephalus. Neurosurgical resection is the treatment of choice but may need to be followed by radiotherapy in case of incomplete resection or tumour recurrence.
Aims
To assess the prevalence of post-operative medical complications in patients with CP in our institution and compare the findings with similar published series of patients from other centres.
Methods
We reviewed the documentation, correspondence, and biochemical records of 82 patients with CP who operated on between 2002 and 2022 at the University Hospital Southampton NHS Foundation Trust, UK. The patients had undergone either open or endoscopic resection of their CPs. Evaluated post-surgical outcomes included growth hormone deficiency, secondary hypothyroidism, hypocortisolism, hypogonadism, arginine vasopressin (AVP) deficiency, hypopituitarism (> 1 hormonal deficiency were present), hypothalamic damage and cerebrospinal fluid (CSF) leak.
Results
In our cohort, 16% of patients (13/82) had a hormonal deficiency at presentation. 62% of patients (51/82) developed new-onset hypocortisolism post-surgery (the commonest hormonal deficiency observed), followed by secondary hypothyroidism in 48% of patients (39/82; one case of late-onset secondary hypothyroidism due to pituitary radiotherapy). AVP deficiency was noted in 39% of patients (32/82), secondary hypogonadism in 32% of patients (26/82) and growth hormone deficiency in 24% of patients (20/82). 59% (48/82) had more than one hormonal deficiency i.e., hypopituitarism and 15% (12/82) had hypothalamic dysfunction manifesting as obesity, sleep-wake disturbance or delayed puberty. 45% (37/82) required adjuvant radiotherapy and in 18% of patients (15/82) the tumour recurred. The commonest surgical complication was CSF leak in about 10% of patients (8/82).
Conclusion
Post-operative hormonal deficiencies are very common in patients undergoing neurosurgical intervention for CPs and it is often a direct unavoidable consequence of surgery in patients without endocrine anomalies at their initial presentation. The findings in our cohort of 82 patients are consistent with similar published series in the literature.

Early Left Ventricular Diastolic Dysfunction in Females with Chronic Hyperprolactinemia: a Doppler Echocardiographic Study

Alberto Maria Marra[1], Michele Arcopinto[1], Roberta D'Assante[1], Valeria Valente[1], Renata Simona Auriemma[2], Giulia Crisci[1], Federica Giardino[1], Rosa Pirchio[2], Rosario Pivonello[2], Eduardo Bossone[3], Annamaria Colao[2] & Antonio Cittadini[1]
[1]University of Naples "Federico II", Department of Translational Medical Sciences, Naples, Italy; [2]University of Naples "Federico II", Endocrinology Unit, Department of Clinical Medicine and Surgery, Naples, Italy; [3]University of Naples "Federico II", Department of Public Health, Naples, Italy

Despite the myocardial prolactin (PRL) binding activity and the known effect to enhance contractility in the isolated rat heart, little information is available concerning the cardiovascular consequences of hyperprolactinemia in humans. To elucidate the effects of chronic hyperprolactinemia on cardiac structure and function, twenty-four patients with isolated PRL-secreting adenoma and twenty-four controls underwent a complete mono- and two-dimensional Doppler echocardiography. Blood pressure and heart rate were similar in the two groups, and no significant differences were observed as to left ventricular (LV) geometry between patients and controls. Resting LV systolic function was normal in patients with hyperprolactinemia, as shown by similar values of fractional shortening and cardiac output. Conversely, hyperprolactinemic patients exhibited a slight impairment of LV diastolic filling, as demonstrated by the prolongation of the isovolumetric relaxation time and the increase of the atrial filling wave of mitral Doppler velocimetry (58 ± 13 vs 47 ± 8 cm s^{-1}, $P < 0.05$) with a subgroup of females (16%) having a clear diastolic dysfunction, and a worse exercise capacity (6 min walking test 452 ± 70 vs 524 ± 56; $P < 0.05$). In conclusion, hyperprolactinemia in humans may be associated with slight impairment of diastolic function, with an overt diastolic dysfunction in a subgroup of females which correlated with poorer exercise performance, in the absence of significant abnormalities of LV structure and systolic function.

Table 1 Echocardiographic parameters and physical performance in controls and hyperprolactinemic subjects.

	Hyperprolactinemia $n=24$	Control $n=24$
Aortic root (mm)	30 ± 3	28 ± 3
Left atrium volume index (ml/m^2)	27 ± 7*	22 ± 6

Hyponatraemia post endoscopic pituitary surgery: A tertiary centre experience of a large cohort

Alicja Knysak[1], Nijaguna Mathad[1], Jonathan Hempenstall[1], Jana Bujanova[2] & Ma'en Al-Mrayat[2]
[1]University Hospital Southampton, Wessex Neurological Centre, Southampton, UK; [2]University Hospital Southampton, Diabetes and Endocrinology, Southampton, UK

Post-pituitary surgery hyponatraemia (HN, sodium < 135 mmol/l) is relatively common and may result in prolonged hospitalisation. Herein we report a retrospective analysis of our experience in a tertiary institute. We conducted a retrospective case note review of **318** patients (M 54%, F 46%, mean age 58 years) 65.7% non-functioning adenoma (NFA), 10% somatotropinoma, 5% prolactinoma, 11% corticotropinoma (half were clinically silent), 8% craniopharyngioma, and 0.3% FSHoma, who underwent endoscopic transphenoidal surgery between 2019 and 2022. Of those 28 patients (19F, 9M) developed post-surgery HN (9% of total), of whom 54% were above 70 years of age, 61% with NFA and 18% with corticotropinoma. Of those with

HN, 39% developed it within 1–3 days of surgery and 61% between 5 and 10 days. The majority had no evidence of prior hormone deficiency (61%), while 36% had pre-operative HN. The severity of HN as follows: mild (130–135 mmol/l) 7%, moderate (125–129 mmol/l) 61% and severe (<125 mmol/l)32%. The majority (68%) were on a pre-operative medication that can cause low sodium including: diuretics, ACE inhibitors, angiotensin receptor antagonists, proton pump inhibitors and antidepressants. Only 9 of 318 total patients undergoing pituitary surgery (2.9%) required readmission due to HN and that is 32% of hyponatraemia cases, most of whom had pre-operative HN or on medication that can caused it, with 54% having HN resolved within 3 days, and 32% within 5–7 days. The management of post-operative HN consisted of 43% fluid restriction (FR) alone, 32% FR and oral sodium tablets, 18% FR and medication review, 15% 1.8% sodium infusion and remaining had a combination of interventions. Our HN incidence is lower than some of the published large cohorts, mostly mild-moderate and not requiring hospital readmission. We have identified several predictive risk factors for development of post-surgery HN: pre-operative sodium, medications, advanced age and female gender, and thus proactive risk mitigation may reduce its occurrence and readmission rate.

Tolvaptan in the management of severe hyponatremia associated with acute intermittent porphyria

Carlos García Gómez, Laura Armengod, Ainhoa Abad, Belén García Izquierdo, Jorge Guzmán Sanz, Miguel Rubio Ramos, Vanesa Capristán Díaz, Natalia Díez Fernández & Nuria Palacios
Puerta de Hierro Majadahonda University Hospital, Endocrinology and Nutrition, Majadahonda, Spain

Background
Acute intermittent porphyria (AIP) is an inherited autosomal dominant disorder characterized by hepatic deficiency of hydroxymethylbilane synthase (HMBS) /porphobilinogen deaminase (PBGD), the third enzyme of the heme synthesis pathway. Hyponatremia is one of the main presenting symptoms and it is thought to be related to an inadequate secretion of ADH (SIADH). Since AIP is an uncommon disease, there is little information about how AIP related hyponatremia responds to standard treatment.
Case presentation
We report the case of a 51−year−old woman who got admitted to the emergency room for acute abdominal pain and dizziness. Physical examination and laboratory tests showed a severe euvolemic hyponatremia with serum sodium (SNa) 119 mEq/l, urine osmolarity 933 mOsm/l and urine Na 149 mEq/l, all of them compatible with SIADH. A sodium chloride 3% infusion at 0.5 ml/kg/h was started. SNa rose to 121 mEq/l after 24 h. In the following days SNa stabilized at 121–122 mEq/l despite water intake restriction, and tolvaptan was started. Following our standard treatment protocol for SIADH related hiponatremia, we started with a tolvaptan dose of 7.5 mg. SNa increased to 122 mEq/l at 24 h and tolvaptan was increased to 15 mg/day on the second day. Without further dose increment, SNa progressively reached normal values within five days. As the patient complained of abdominal pain, AIP was suspected and a Hoesch test confirmed the diagnosis. Treatment with hemin was started, which improved the patient 's clinical signs and normalized the δ-aminolaevulinic acid (ALA) and porphobilinogen (PBG). SNa further increased to 142 mEq/l and tolvaptan was progressively decreased and finally discontinued, with SNa manteined in normal range thereafter.
Discussion and conclusion
As treatment of acute porphyria attacks is mainly based on intravenous administration of glucose 10% and/or human hemin, previous correction of hyponatremia is of paramount importance to avoid further decrease of SNa caused by large amounts of glucose solutions. In our case, the time frame for response to tolvaptan and the dose needed to achieve eunatremia were similar to those for SIADH-associated hyponatremia from a different origin. Thus, tolvaptan is an effective option to guarantee a desired serum sodium increase during acute porphyria attack to safely permit handling high volumes of glucose solutions. Standard protocols for treatment of SIADH related hyponatremia with tolvaptan can be applied to AIP; however, the treatment will only be maintained for the duration of the acute condition.

Metabolic and surgical outcomes of adult patients with craniopharyngiomapatients undergoing extended transsphenoidal surgery (ETS) at a referral center

Ana Piñar Gutiérrez[1], Elena Dios[1], Eva Venegas-Moreno[1], Pablo Remon[1], Bothayna Oulad Ahmed[1], Ariel Kaen[1], Eugenio Cárdenas[1], Elena Fajardo[1], David Cano Gonzales[1] & Alfonso Soto-Moreno[1]
Virgen del Rocío University Hospital, Sevilla, Spain

Objectives
To describe the metabolic and surgical outcomes of adult patients with craniopharyngioma undergoing extended transsphenoidal surgery (ETS). Secondary: to compare surgical outcomes with patients undergoing conventional transcranial surgery (CTS).
Methods
Retrospective observational study. Adult patients with craniopharyngiomas undergoing ETS between 2015 and 2020 were included. Descriptive analysis was performed by obtaining median and quartiles for quantitative variables and frequency for qualitative variables. For the comparison between groups, a matched cohort of patients with craniopharyngioma who underwent CTS was used and a Fisher test was performed for qualitative variables.
Results
$n=16$. Male = 7(43.8%); age = 52.5(37.7–66) years. Follow-up time = 44.5(30–63) months. BMI pre-surgery = 26.01(22.72–28.51)kg/m2. The BMI increase at first year after surgery was 18.14%(7.2–24.26%). Obesity was present in 56.5% at first year post-surgery, although 77.7% were grade I (WHO classification). During follow-up, 25% developed type 2 diabetes and dyslipidaemia.
Conclusions
The most frequent metabolic complication after ETS in patients presenting with craniopharyngioma was obesity, present in 56% of patients in our study. Surgical complications were very frequent (93.8% and 92.8% one month and one year after surgery) due to the high rate of diabetes insipidus (98.8% and 85.7%) and hypopituitarism (87.5% and 78.5%). These data are consistent with the scientific literature and lower than with CTS. ETS compared to CTS reduces adipsia, seizures and psychiatric and surgical complications at first month and hydrocephalus, need for antiepileptic treatment and psychiatric complications at first year after surgery.

Table 1 Post-surgical complications at one month and one year post-ETS.

	First month post-ETS ($n=16$)	First year post-ETS ($n=14$)
Complications after surgery	15(93.8%)	13(92.8%)
Diabetes insipidus	15(93.8%)	12(85.7%)
Adipsia	0(0%)	1(7.1%)
Panhypopituitarism	14(87.5%)	11(78.5%)
Hypothyroidism	15(93.8%)	13(92.8%)
Adrenal insufficiency	17(87.5%)	12(85.7%)
Hydrocephalus	11(32.4%)	1(7.1%)
Seizures/anti-epileptic treatment	1(6.3%)	1(7.1%)
Cerebrospinal fluid fistula	1(6.3%)	0(0%)
Central nervous system infection	3(18.8%)	0(0%)
Visual disturbances	9(56.3%)	7(50%)
Psychiatric disorders	1(6.3%)	1(7.1%)
Neurological disorders	3(18.8%)	4(28.5%)

Table 2 Surgical complications in which significant or near-significant differences were obtained between patients undergoing ETS vs CTS.

		ETS	CTS	*P*
At first month	Adipsia	0(0%)	7(20.6%)	0.05
	Seizures	1(6.3%)	11(32.4%)	0.03
	Psychiatric disorders	1(6.3%)	12(35.3%)	0.021
	Neurological disorders	3(18.8%)	7(50%)	0.023
At first year	Anti-epileptic treatment	1(7.1%)	11(39.2%)	0.03
	Psychiatric disorders	1(7.1%)	12(42.8%)	0.018
	Hydrocephalus	1(7.1%)	9(32.1%)	0.075

Early postoperative growth hormone measurement as a predictor of surgical remission of acromegaly

Ivana Kraljevic[1,2], Diana Kovač[3], Mirsala Solak[1], Tanja Skoric Polovina[1], Karin Zibar Tomšić[1], Annemarie Balasko[1], Tina Dusek[1,2] & Darko Kastelan[1,2]
[1]University Hospital Center Zagreb, Dpt od Endocrinology, Zagreb, Croatia; [2]The University of Zagreb, School of Medicine, Zagreb, Croatia; [3]County Emergency Medicine Institute, Dubrovnik, Croatia

Purpose
To evaluate the value of early postoperative growth hormone (GH) as a predictor of surgical remission of acromegaly.

Methods
We conducted a retrospective search through our database of patients who underwent transsphenoidal surgery for GH-secreting pituitary adenoma from 2011 to June 2022. Only patients who underwent the first pituitary surgery and had GH measurements on the fifth postoperative day were included. The surgical remission was defined as GH nadir <0.4 μg/l during an oral glucose tolerance test (OGTT) and normal insulin growth factor-1 (IGF-1) on the first follow-up three months after the surgery.
Results
We included 65 patients in the analysis with median FU of 31.5(3–155) months. Surgical remission was achieved in 44 patients (67.7%). Patients who achieved remission had significantly lower early postoperative GH levels (0.65 (0.06–8.92) vs. 3.61 (0.25–24.64), $P<0.001$). ROC analysis revealed a significant value of early postoperative GH on the prediction of surgical remission (AUC 0.832, $P<0.0001$), and the cut of GH ≤ 1.57 μg/l had a sensitivity of 90.9% and a specificity of 71.4%, respectively. No patients with an early postoperative GH ≤ 0.23 μg/l developed a relapse of acromegaly during the FU.
Conclusion
The early postoperative growth hormone measurement could be a reliable predictor of surgical and long-term remission of acromegaly.

Prevalence and clinical characteristics of hyponatremia following pituitary surgery

Mikulas Kosak[1], David Netuka[2], Vaclav Masopust[2], Martin Majovsky[2], Jan Jiskra[3] & Jana Jezkova[3]
[1]Central Military University Hospital, Department of Internal Medicine, Prague, Czech Republic; [2]Central Military University Hospital, Department of Neurosurgery and Neurooncology, Prague, Czech Republic; [3]General University Hospital, 3rd Department of Medicine, Prague, Czech Republic

Introduction
Hyponatremia is one of the possible complications of pituitary surgery. Mild, asymptomatic hyponatremia can be managed with fluid restriction and oral supplementation, however more profound hyponatremia, especially when symptomatic, can be a reason for hospital readmission and often needs to be treated with saline infusion in ICU.
Aims
To estimate prevalence of hyponatremia and provide clinical characteristics in the cohort of patients who underwent surgery for tumour in sellar region at our centre.
Method
Single centre retrospective analysis of cohort of patients undergoing pituitary surgery in the past 30 months. Data of patients who had surgery for pituitary adenoma or other sellar tumor were analysed retrospectively. Those who developed hyponatremia in the period of 30 days following surgery were selected for further analysis. Preoperative radiologic features, patterns of sodium level changes, and endocrinological characteristics were noted.
Results
In the selected period, 313 pituitary surgeries have been performed at our centre. 23 cases of hyponatremia were identified of which 16 were women. Average age was 49 years (27–75 y). Pituitary adenoma was histologically confirmed in 15 cases of which 13 were macroadenoma. Four were hormonally active (one prolactinoma and three GH secreting adenoma). Other types of tumours involved 4 cystic lesions a 3 meningiomas. Suprasellar extension was present in 14 cases and parasellar extension in 12 cases. Six patients had early postoperative complication (four cases of CSF leakage and two haemorrhagic complications). Four patients developed early postoperative polyuria but in only one case diabetes insipidus reappeared after recovery from hyponatremia however it lasted only temporarily and the treatment with desmopressin was withdrawn subsequently.
In most of the cases hyponatremia was diagnosed on day 7 (39%, 9 cases, range 3–10 day). The lowest sodium on presentation was 118.9 mmol/l and during the treatment period the sodium nadir level observed was 113 mmol/l. Hyponatremia was symptomatic in 10 patients. Seven patients presented with neurological symptoms (seizures, vertigo, headache or confusion), three patients had gastrointestinal symptoms (nausea, vomiting). Thirteen patients were treated with 3% saline infusion while in the remaining cases treatment with oral salt tablets and fluid restriction was sufficient. Only two patients were treated as outpatient while the rest were readmitted and 9 of them were treated in the ICU. Only two patient developed diabetes insipidus after recovery from hyponatremia.
Conclusion
Hyponatremia was present in 7.3% cases while in only 2.8% hyponatremia was clinically and biochemically severe requiring admission to ICU.

Endocrine side effects of immune-checkpoint inhibitors in patients with malignant melanoma

Annamaria Erdei[1], Enikő Ménes[2] & Gabriella Emri[3]
[1]Faculty of Medicine, University of Debrecen, Divison of Endocrinology, Department of Internal Medicine, Debrecen, Hungary; [2]Faculty of Medicine, University of Debrecen, Debrecen, Hungary; [3]Faculty of Medicine, University of Debrecen, Department of Dermatology, Debrecen, Hungary

Immune-checkpoint inhibitors have become important elements of oncology therapy in recent years. These monoclonal antibodies block immune-checkpoints, unleashing T cells to fight cancer. However, immune-checkpoints also play an important role in the prevention of autoimmune processes and immune-checkpoint inhibitor therapy can also trigger autoimmune adverse effects, termed immune-related adverse events. Endocrinopathies are among the most common immune-related side effects.
Objectives and methods:
We analysed data of 221 patients (131 males, 90 females, age 61.4 ± 13.3 years) retrospectively, who received immune-checkpoint inhibitor therapy for malignant melanoma at the Department of Dermatology since 2015 and we investigated endocrine side effects in these patients. Based on the obtained data, our aim was to develop a diagnostic guideline that can help to recognize endocrine side effects that develop during immune-checkpoint inhibitor therapy as soon as possible and to treat them appropriately.
Results:
Endocrine side effects occurred in 69 cases (31.2% of the patients). 58% of these patients were men, 42% were women and the average age was 61.4 ± 12.8 years. In 25% of the patients, the side effect appeared within one month after starting treatment, and in 89.1% within one year. 83.8% of endocrine side effects affected the thyroid gland, 16.2% isolated the pituitary gland, and 7.4% had side effects in both the thyroid and pituitary gland. We detected central hypadrenia in all patients diagnosed with hypophysitis. 36.2% of patients needed treatment due to endocrinopathy; discontinuation of immune-checkpoint inhibitor therapy due to an endocrine side effect was not necessary in any case.
Conclusions:
Endocrine side effects occurred in almost 1/3 of the patients receiving immune checkpoint inhibitor therapy. Based on the results of our study, endocrinopathies occur in a similar proportion in men and women, which means a difference compared to the female dominance observed typically in autoimmune thyroid diseases and autoimmune hypophysitis. Endocrine side effects occurred in 25% of cases after one month of immune-checkpoint therapy, this result highlight the need for screening in time in order to achieve timely diagnosis and administer appropriate treatment. It is particularly important to recognize hypophysitis, which can cause a life-threatening crisis in the case of untreated central hypadrenia.

Epidemiologic and clinical characteristics of acromegaly in Russian hypothalamic and pituitary tumor registry (OGGO)

Alexander Lutsenko, Olga Vikulova, Zhanna Belaya, Elena Przhiyalkovskaya, Ekaterina Pigarova, Larisa Dzeranova, Liudmila Rozhinskaya, Galina Melnichenko & Natalia Mokrysheva
Endocrinology Research Centre, Moscow, Russia

Background
Pituitary disease registries are major instruments of epidemiological and clinical data collection used worldwide.
Objective
To assess the epidemiological and clinical characteristics of acromegaly in Russia according to Russian hypothalamic and pituitary tumor registry
Material and methods
Database of the Russian hypothalamic and pituitary tumor registry, which includes data from 84 regions of the country, was used for the study. Date of analysis – 01-Sep-2022.
Results
Currently there are 5054 patients with acromegaly in the registry. Prevalence per 100 000 inhabitants is highest in Kirov region (9.82), Karelia republic (9.48) and Vladimirskaya region (7.11). Annual incidence per 1 mil was 0.6 cases in 2021. Male to female ratio 1425(28.2%):3629(71.8%), median age 46.2 years [33.1;52.7], age at

diagnosis 46.2 years [33.1;52.7]. During the last visit, remission was recorded in 1671 patients (42.7%). Pituitary tumor size was available in 2131 patients: macroadenomas in majority of cases (1562 patients, 73.3%). Median IGF1 levels in patients with active disease was 378.0 ng/ml [245.9;620.0], basal GH 4.0 ng/ml [1.6;12.0]. Most prevalent complications were hypertension (47.8%), nodular goiter (31.6%), carbohydrate metabolism disorders (26.5%), obstructive sleep apnea (14.4%) and menstrual irregularity (12.1%). Interestingly, prevalence of joint diseases and colon polyps was quite low – 6.3% and 0.24%, respectively. Among all treated patients, 42.5% underwent neurosurgery, 13.9% – pituitary radiotherapy. Medical therapy, either monotherapy and combination, is registered in 42.3% of patients ($n=2140$): octreotide (75.3%), lanreotide (18.6%), pegvisomant (2.6%), cabergoline (18.7%) and bromocriptine (3.9%).Overall number of registered deaths in patients with acromegaly was 370 cases: 20 due to pituitary adenoma, 73 cardiovascular causes, 36 malignancies, 64 other causes and in 137 the cause was not specified.
Conclusions
Russian Hypothalamic and Pituitary Tumor Registry is a viable instrument for the assessment of epidemiological and clinical data, reflecting the implications of treatment strategies in real life practice. Median age of diagnosis in our study is similar to the literature data, however, other studies do not report female predominance, as seen in our cohort. Complication rates are mostly similar, however, extremely low prevalence of colon neoplasms and joint diseases shows that more effort should be put in the screening of these comorbidities. Remission rates and availability of neurosurgery are also lower than overall literature data, which shows the need for optimization in treatment strategies, as well as increase in data quality and registration.

Clinical features and long-term follow-up of patients with Nelson syndrome: a case series presentation

Alexander Lutsenko, Diana Trukhina, Zhanna Belaya, Elena Przhiyalkovskaya, Larisa Dzeranova, Ekaterina Pigarova & Liudmila Rozhinskaya
Endocrinology Research Centre, Moscow, Russia

Background
Nelson syndrome is a rare complication of Cushing disease (CD), which occurs either in patients with very aggressive CD or as a result of misdiagnosis. Clinical characterization of patients with Nelson syndrome could provide important insights in management of the disorder.
Methods
We analyzed medical records of patients with CD between 2015 and 2021 to identify those who developed Nelson syndrome.
Results
Nine patients developed Nelson syndrome: 2 males and 7 females. Median age of CD onset 27.0 years [20.8;29;8]. Prior to adrenalectomy, 3 patients presented with macroadenomas, 5 – microadenomas, in 1 patient adenoma was not visualized. Seven patients received CD treatment before adrenalectomy: 5 patients underwent multiple transsphenoid neurosurgeries and radiation therapy, 2 were treated only surgically. Mean duration of CS before adrenalectomy was 62 months [48;89]. Mean duration between adrenalectomy and confirmation of Nelson syndrome was 25.5 months [18.5;36.3]. All nine patients developed Nelson syndrome: all had elevated morning ACTH levels – 1176 pg/ml [434;1713], pituitary tumor regrowth or visualization was seen in 6 patients, 4 patients presented with darkened skin tone, 3 – with severe headaches. Median follow-up duration after Nelson diagnosis was 28 months [17;75]. All patients received glucocorticoid replacement therapy – median dose 35 mg/day [25;35]. Three patients received medical therapy, either with cabergoline, long-acting octreotide or lanreotide. Combination of neurosurgery an pituitary radiation was used to treat 3 patients, 2 patients underwent only surgery and 2 received only radiation therapy. At last follow-up visit, 7 patients had pituitary adenoma remnant (5 macro-, 2 microadenoma): without further progression in 6 cases, 1 patient with tumor progression was referred for pituitary irradiation. In 2 patients no signs of regrowth was found on pituitary MRI. Median ACTH during last follow-up was 715.5 pg/ml [453.4;1173].
Conclusion
Nelson syndrome is a severe complication of CD which requires a strict long-term follow-up and all the treatment options to increase the chances of stabilization. In our cohort, combination of treatment modalities led to stabilization of tumor growth in 8 cases, however, ACT remained elevated in all patients. Further reports on this complication could help to identify optimal management strategies and improve the outcomes for Nelson syndrome.

Prediction of the receptor phenotype of somatotrophic tumors and the effectiveness of the use of the first-generation somatostatin receptor ligands (fg-SRLs) in the long-term treatment of acromegaly

Evgeny Pronin[1], Mikhail Antsiferov[1,2], Tatiana Alekseeva[1], Anastasia Lapshina[3] & Vyacheslav Pronin[1,2]
[1]Endocrinological dispensary, Moscow Health Department, Moscow, Russia; [2]Russian Medical Academy of Continuing Professional Education, Ministry of Health of Russia, Moscow, Russia; [3]National Medical Research Center for Endocrinology, Ministry of Health of Russia, Moscow, Russia

The control of acromegaly with drug therapy (DT) by fg-SRLs is achieved only in 40–50% of cases, due to the heterogeneous composition of somatotrophic tumors. In order to optimize DT stratification of clinical and immunophenotypic biomarkers which make it possible to predict the long-term effectiveness of fg-SRLs at early stages is required.
The aim of the work was to assess the informativeness of pharmacotherapeutic testing (% of decrease of IGF-1 level after 3 and 6 months of treatment) for the prognosis of the receptor phenotype of a somatotrophic tumor and the rationality of DT by fg-SRLs.
Materials and methods
The comparative study included 33 and 47 patients with densely and sparsely granulated somatotroph tumors (DGST&SGST) who received postsurgical DT by fg-SRLs. Prolonged forms of lanreotide and octreotide were used. The duration of DT was 21.5 ± 21.8 months. The adequacy of DT was assessed by the level of IGF-1 index (IGF-1/ULN) ≤ 1. The control points were the indicators of IGF-1 before DT, after 3,6,12 months of treatment and at the last visit.
Results
The percentage of decrease of IGF-1 level after 3&6 months of fg-SRLs treatment was correlated with the expression of the SSTR2 ($r=0.44$; $r=0.36$), as well as the difference and the ratio between the SSTR2&SSTR5 [$r=0.46$; $r=0.46$&$r=0.41$; $r=0.43$;($P<0.05$)]. The final value of IGF-1 index in patients with DGST&SGST was 0.95 ± 0.27 vs. 1.4 ± 0.64, ($P=0.0002$). The magnitude of the decrease of IGF-1 level in the groups of patients with DGST and SGST after 3&6 months was 54.8 ± 19.6 vs. 28.4 ± 23.7% and 58.4 ± 18.0 vs. 31.6 ± 24.5%, respectively ($P=0.0002$). The presence of an inverse correlation between the percentage of decrease of IGF-1 level after 3&6 months of fg-SRLs treatment and the final value of IGF-1 index was revealed [$r=-0.59$; $r=-0.72$;($P<0.001$)]. In the ROC analysis, the AUC was 0.841&0.853. The decrease of IGF-1 level after 3&6 months by 46 and 49% of the baseline level was the cut-off point of effective DT. The sensitivity of these markers was 63&75%, the specificity was 79&80%, respectively. With a decrease of IGF-1 level after 3&6 months, over or under 50%, the final IGF-1 index was 0.9 ± 0.2 vs. 1.49 ± 0.62($P=0.000$).
Conclusions
1.The magnitude of the decrease of IGF-1 level after 3&6 months of fg-SRLs treatment reflects the severity of the expression of the SSTR2,as well as the intact postreceptor mechanisms in tumor cells.
2.The results of pharmacotherapeutic testing can be used as an additional predictor of the effectiveness of fg-SRLs long-term treatment.

Evaluation of the ACTH-CLU index for the differential diagnosis of ACTH-dependent Cushing's syndrome

Belén García Izquierdo[1], Laura Rodríguez Delgado[2], Marta Araujo Castro[3], Ainhoa Abad Lopez[1], Carlos García Gómez[1], Miguel Rubio Ramos[1], Jorge Guzmán Sanz[1], Natalia Díez Fernández[1], Vanessa Capristán Díaz[1] & Nuria Palacios[1]
[1]Hospital Universitario Puerta de Hierro Majadahonda, Endocrinology and Nutrition, Madrid, Spain; [2]Universidad Autónoma de Madrid, 6th year

student of Medicine and Surgery, Madrid, Spain; [3]Hospital Universitario Ramón y Cajal, Endocrinology and Nutrition, Madrid, Spain

Introduction
Differentiation between Cushing's disease (CD) and ectopic Cushing's syndrome (ECS) remains a diagnostic challenge. Currently available tests lack sufficient sensitivity and specificity or are invasive and technically difficult. Recently, an ACTH-UFC index has been proposed to differentiate the two forms of ACTH dependent Cushing's syndrome (CS) (Ding, 2021). This work aimed to confirm the diagnostic utility of the ACTH-UFC index to differentiate CD from ECS.
Methods
Retrospective analysis of patients with ACTH-dependent CS seen at the Endocrinology Departments of Puerta de Hierro and Ramón y Cajal Hospitals between 1983 and 2021. The tests' diagnostic performance was evaluated by ROC curves. Gold standard for CD or ECS diagnosis was based on positive staining for ACTH in a tumor sample, remission of CS after tumor excision or inferior petrosal sinus sampling.
Results
80 patients were included (56 female, median age 43 years). 66 were diagnosed with CD (82.5%) and 14 with ECS (17.5%). Median plasma cortisol was 24 μg/dl at 0800 h, 21 μg/dl at 23 h, and 16 μg/dl after suppression with 1 mg dexamethasone, with no significant difference between both groups. Median UFC was 250 μg/day (887 μg/day in the ECS group Vs 221 μg/day in the CD group; $P<0.001$) and median plasma ACTH was 50 pg/ml (88 pg/ml Vs 48 pg/ml; $P=0.014$). The area under the ROC curve (AUC) for the ACTH-UFC index in predicting CD among ACTH-dependent CS was 0.852, lower than the 0.977 in the original study. The optimal cut-off value for the ACTH-UFC index was 1.0 (sensitivity of 68% and specificity of 93% to identify CD). In multivariate analysis, UFC showed an independent association with the diagnosis, with values >250 μg/day increasing the probability of ECS by 16.2 times ($P=0.01$). ACTH levels did not show this association. Accordingly AUC from isolated UFC was similar to that of the ACTH-UFC index (0.828). The exclusion from the analysis of cases with clinical evidence of ECS nullified the diagnostic utility of the ACTH-UFC index (AUC=0.652) and the isolated UFC (AUC=0.567). Nevertheless, diagnosing CD with an ACTH-UFC index ≤ 1 and ECS with an index $\geqq 28$, could save 63% of cases from additional testing, with a 98% certainty of correctly diagnosis.
Conclusions
ACTH-UFC index showed a worse diagnostic performance than referred and not superior to isolated UFC. In cases with greater diagnostic difficulty, neither of these tests were useful. However ACTH-UFC index could save more than 60% of cases from additional testing.

Neuroendocrine regulation of fluid and electrolyte metabolism in patients after transnasal adenomectomy: can oxytocin be a potential hormonal prognostic marker of hyponatremia?

Khava Fargieva, Nino Katamadze, Oksana Ivashenko, Vilen Azizyan, Andrey Grigoriev, Arkadiy Sergeev, Elena Przhiyalkovskaya, Ekaterina Pigarova & Larisa Dzeranova
Endocrinology Research Centre, Moscow, Russia

Introduction
According to recent studies, fluid and electrolyte disturbances complicate the course of transnasal adenomectomy for pituitary adenomas in 13–30% of cases and are associated with a high risk of neurological complications and increased mortality. Neuropeptides discovered in recent decades (apelin, copeptin, oxytocin, brain natriuretic peptide) in many studies demonstrate their significant effect on the regulation of water-electrolyte metabolism, which makes them potentially important hormonal markers of its complications.
Aim
To study a neuroendocrine regulation of water and electrolyte metabolism in patients after transnasal adenomectomy and in cases of the development of hyponatremia.
Materials and methods
The study included the results of dynamic control of sodium and neuropeptides in 22 patients who underwent pituitary adenoma removal (inactive pituitary adenoma – 8 patients, acromegaly – 8 patients, Cushing's disease – 6 patients, 6 men and 16 women, median age 52 years [Q25 39; Q75 62]), 10 of whom developed hyponatremia (group 1) with a median serum sodium of 125 mmol/l, and 12 had no water–electrolyte disorders (group 2). In all patients, Na was determined in blood serum, as well as by ELISA apelin 12, copeptin, oxytocin and proBNP in plasma 24 h before surgery, 12–24 h, 3, 5 and 7–8 days after surgery.
Results
The analysis showed significant changes in oxytocin levels without significant changes in concentrations of other neuropeptides in hyponatremia. Spearman correlation analysis of simultaneous concentrations of oxytocin and sodium in the blood showed the presence of an association between the parameters in the postoperative period, which were manifested by the appearance of a positive correlation on day 3, and a negative correlation on days 5 and 7–8. When comparing oxytocin levels in the groups of hyponatremia and the absence of water–electrolyte disorders, statistically significant differences were revealed. The median concentration of this hormone in the hyponatremia group on day 7–8 was 2.1 times higher with hyponatremia – 6781 vs 3.199 ng/ml for the hyponatremia group and control, respectively ($P=0.002$ for the Mann–Whitney U-test)
Conclusions
Transnasal adenomectomy is the cause of severe hyponatremia in 7–18% of cases, in the pathogenesis of which, apparently, copeptin and oxytocin play a leading role, and the secretion of which has the character of inadequately elevated levels with the loss of a negative feedback with the concentration of sodium in the blood. At the same time, oxytocin has the potential to be a hormonal marker of this life-threatening complication.

Weight gain in adult patients with suprasellar craniopharyngioma with varying degrees of hypothalamic involvement before and after the surgery

Irina Klochkova, Lyudmila Astafieva, Pavel Kalinin, Maxim Kutin, Dmitry Fomichev, Alexsey Shkarubo, Oleg Sharipov, Yulia Sidneva & Aleksandr Konovalov
Burdenko Neurosurgical Institute, Moscow, Russia

Suprasellar craniopharyngiomas (CF) are characterised by a high incidence of involvement of the third ventricle, which determines the risk of hypothalamic obesity (HO). There are no unified diagnostic criteria for HO and its effective treatment. The assessment of pre- and postoperative hypothalamic damage is necessary for the choice of surgical strategy and early therapeutic intervention.
Objective
To estimate the incidence and extent of weight gain in adult patients with CF depending on the degree of hypothalamic involvement.
Methods
58 patients older than 18 years (30 women, 28 men), the median age 42 (range 29–54). All patients were operated, the degree of hypothalamic involvement was assessed on the basis of preoperative MRI and intraoperative data. The criterion for HO was a weight gain of 10 kg or more over a period of 6 months. Body weight was assessed before and after 3,6,12 months after surgery. Body mass index >25.0 for overweight (OW) and >30.0 for obesity (OB). By localizing tumor patients were divided into 2 groups: 1 – at "pituitary stalk" without penetration into the third ventricular cavity (24), 2 – combined "the pituitary stalk" and ventricular (34).
Results
In group 1: before the surgery OW in 25% cases (6), OB in 25% (6), weight gain was observed in 12% cases (3), the m?dian 5 kg (4–5). Total removal in 79% cases (19), of which in 12 patient the tumor was adhering to the third ventricle floor. After the surgery: OW in 25% cases (6), OB in 45%(11), HO developed in 30%(7), weight gain the m?dian 22 kg (15–27). In group 2: before the surgery OW in 32% cases (11), OB in 41%(14), HO in 29%(7), weight gain the m?dian 16 kg (14–18). Total removal in 61% cases (21). After the surgery: OW in 26% cases (9), OB in 64% (22), HO in 38%(13), weight gain m?dian 15 kg (12–25), of which only 2 had preoperative weight gain >10 kg. In both groups weight gain after surgery was observed within the first 6 months.
Conclusion
Preoperative HO was observed only among patients in 2 group, which in combination with MRI data can be regarded as an indication of hypothalamic involvement. Damage to the hypothalamus, due to tumor invasion or surgical treatment, causes weight gain of the same degree. After surgery, patients with a tumor with hypothalamic involvement but without pre-operative weight gain are at risk for HO.

Inferior petrosal sinus sampling and stimulation with CRH: 18 years of experience in a tertiary hospital

Alejandra Maricel Rivas Montenegro[1], Roberto Añez[1], Laura Gonzalez Fernandez[1], Diego Munoz[2], Alberto García Piorno[1], Isabel Losada Gata[1], Mónica Gómez-Gordo Hernanz[1], Gloria Collado González[1], Juan Carlos Percovich[1], Olga González Albarrán[1] & Rogelio García Centeno[1]
[1]Gregorio Marañón Hospital, Endocrinology and Nutrition, Madrid, Spain; [2]Rey Juan Carlos Hospital, Endocrinology and Nutrition, Móstoles, Spain

Background
Inferior petrosal sinus sampling (IPSS) is indicated in the diagnosis of adrenocorticotropic hormone (ACTH)-dependent Cushing's syndrome (CS), especially when the results of the initial diagnostic tests are discordant.
Objective
To describe the patients who underwent this invasive functional test in a tertiary hospital.
Methods
This was an observational study of a retrospective cohort of patients with ACTH-dependent CS and IPSS between 2004 and 2022. We determined their epidemiological, hormonal, radiological and functional characteristics, and evaluated their diagnostic capacity and optimal cut-off points to differentiate between Cushing's disease (CD) and ectopic Cushing's syndrome (ECS).
Results
31 patients were evaluated. It was observed an ACTH secretion of a pituitary origin in 80% of cases and an ectopic origin in 20%. Patients with CD were more frequent female (64%) and those with ECS were mostly male (83.3%). There were no differences between age of diagnosis. Plasma cortisol, urinary free cortisol, and ACTH levels were higher in patients with ECS. Most IPSS were done before going to a definitive surgical treatment, so only 12.9% IPSS were done after surgery, meaning that persistence or recurrence of hypercortisolism was detected during follow-up. Regarding radiological findings, patients with IPSS gradient ACTH C/P compatible with CD (>2 basal or >3 after CRH stimulation) had a visible adenoma in 40% of cases, with a median size of 4 (2.5–5.0) mm. On the other hand, patients with a IPSS gradient of ECS had 33% cases of MRI positive, with a median adenoma size of 7 (7.0–7.0) mm.
Conclusion
ACTH-dependent CS can be a difficult entity to diagnose for clinicians. Clinical, biochemical and radiological characteristics of patients provide an approach to etiologic diagnosis but not in all cases. IPSS with CRH stimulation is a test with a high diagnostic accuracy and it is particularly recommended in patients with negative MRI or with adenoma smaller than 6–10 mm.

ADH-deficiency (central diabetes insipidus) registry in Russia: current results

Alexander Lutsenko[1], Ekaterina Pigarova[1], Larisa Dzeranova[1], Olga Vikulova[1], Zhanna Belaya[1], Liudmila Rozhinskaya[1], Natalia Mokrysheva[1] & The Consortium CDI[2]
[1]Endocrinology Research Centre, Moscow, Russia; [2]Endocrinologists, Participating Regions, Russia

Introduction
ADH-deficiency (central diabetes insipidus, ADH-D) is a rare disease, and data on worldwide and country-specific prevalence rates are scarce. ADH-D registries could provide valuable information on epidemiology, etiological distribution, treatment requirements and potentially serve as a guide for management decisions in clinical practice.
Objectives
To assess the epidemiological data on ADH-D in Russian Registry for Central Diabetes Insipidus (RCDI)
Materials and methods
Database of the Russian Registry for Central Diabetes Insipidus, which includes data from 42 regions. Date of analysis – 10-Sep-2022.
Results
Since previously reported data in 2018, the number of patients has increased from 2004 to 2971 patients with different etiologies of ADH-D. Highest prevalence is seen in Moscow region – 5.4 cases per 100 000 population. Male to female ratio: 1253(42.2%): 1718(57.8%), mean age at diagnosis 32.6 years. Among the identified etiologies the most common were postoperative (16%), pathology of development of hypothalamic–pituitary region (9.3%), head trauma (6.6%), tumors (5.4%) and hereditary forms of ADH-D (4.3%). Rare forms of ADH-D with less than 4% overall were neuroinfection, Langergans cell hystiocytosis, sarcoidosis, Sheehan syndrome, DIDMOAD syndrome and hypophysitis. Idiopathic ADH-D was registered in 42% of patients. Data on current therapy was available in 2657 patients. Most of the patients receive oral desmopressin ($n=1470$, 55.3%), followed by sublingual ($n=911$, 34.3%) and intranasal ($n=276$, 10.4%) forms.
Conclusions
Russian Registry for Central Diabetes Insipidus is a promising instrument for the assessment of epidemiology and treatment modalities in a rare endocrine disorder. Further efforts are made to include all the regions of the country and improve the data quality.

The predictive value of IGF-1 in a cohort of children with growth hormone deficient and sufficient short stature

Anton Ana Maria[1], Ioana Cristina Georgescu[1], Alina Tudorache[1], Gheorghe Elena Teodora[1], Carmen Gabriela Barbu[1,2] & Alice Albu[1,2]
[1]Elias Emergency University Hospital, Endocrinology, Bucureşti, Romania; [2]Carol Davila University of Medicine and Pharmacy, 2nd Clinical Department, Bucureşti, Romania

Introduction
Insulin-like growth factor 1 (IGF-1) is an established serum marker for both diagnosis of growth hormone (GH) deficiency and for monitoring treatment with Somatropin, whether it is recommended for the classic GH-insufficient short stature cases or for other GH-sufficient disorders.
Aim
To evaluate whether serum level of IGF-1 at diagnosis has a predictive value for the response to somatropin treatment during the 2 years of treatment in children with both GH-deficient and GH-sufficient short stature.
Materials and methods
We performed a retrospective study which included 192 children treated with somatropin for at least 2 years with variate causes of short stature (mean age 8.02 ± 3.63, 71 boys, 121 girls). Patients were divided in GH-deficient and GH-sufficient based on peak GH value during stimulation tests with a cut off value of 7 ng/ml. Standard deviation score (SDS) was calculated for height and IGF-1 at diagnosis.
Results
SDS height gain at 2 years of treatment was positively correlated with SDS height gain at 6 months (r 0.549, $P<0.0001$) and 1 year (r 0.719, $P<0.0001$). SDS height gain at 2 years was negatively associated with male gender (beta -0.273, P 0.029) and baseline IGF-1 SDS (beta -0.249, P 0.001), after adjustment for age and diagnosis. When IGF-1 was introduced in the regression model as quartiles, the superior quartile was negatively associated with gain in height at 2 years (beta -0.361, P 0.043). SDS height gain at 6 months (beta 0.991, $P<0.0001$) and 1 year (beta 1.034, $P<0.0001$) of treatment were independently associated with SDS height gain at 2 years after adjustment for confounders.
Conclusion
Short children with highest IGF-1 SDS at diagnosis might have lower response to somatropin administration irrespective of GH reserve. However, the early response to somatropin administration independently predict the 2 year response to treatment, being a possible tool for guiding the therapeutic decision.

Clinical experience of single tertiary center in managing patients with paraganglioma

Valentina Elezovic Kovacevic, Sanja Ognjanovic, Bojana Popovic, Dusan Ilic, Bojana Ilic, Milica Opalic, Lena Radic & Djuro P. Macut
Clinic for Endocrinology, Diabetes and Metabolic Diseases, Clinical Center of Serbia, Belgrade, Serbia, Department for Endocrine Tumors and Hereditary Cancer Syndromes, Belgrade, Serbia

Paragangliomas (PGLs) and pheochromocytomas (PCCs) are rare neuroendocrine tumors that arise from chromaffin cells of the adrenal medulla and the

sympathetic/parasympathetic neural ganglia, respectively. We retrospectively analyzed 82 patients (43 female and 38 males) predominantly with PGLs who were hospitalized between January 2002 and December 2022. Twenty one patients were lost to follow up. The median age at diagnosis was 47 years (11–75) and the mean tumor size was 52.5 mm (26–170 mm). PGLs in our group were mostly distributed in abdomen (57%), head and neck (24.5%), rarely in spine (8.2%) and chest (3.2%). Four of our patients had coexistence of PCC. Hereditary form of disease was present in 19.5% of patients. The most common mutation was in SDHB gene (10/16), hereafter in VHL gene (3/16); 2 patients had mutation in SDHD gene and one in SDHC. Multiple PGLs at diagnosis were identified in 8 patients. Hormonally secreting tumors were present in 32% and 51% of patients had hypertension. Patients were treated mostly with surgery (86%) and tumor embolization (11.6%) in case of head and neck PGLs. At 30 patients, the median proliferation index Ki67 was 2.25% (0.1–25%). Median PASS score was 5 (1–14). Relapse of disease was present in 17% of patients with mean time to relapse 26 month (0–168). Metastatic disease was present in 18.8% of patients at the time of diagnosis and 6 patients had acquired metastasis. Mean time between initial and malignancy diagnosis was 28 months (range 0–300). These patients were treated mostly with PRRT (6/17), chemotherapy (4/17) and sutent (3/17). Median overall survival (OS) was 339 months (95%CI 305–373) with 10-year OS 93%.

We presented clinical characteristics, genetic profile, treatment options and survival of patients with PGLs, our experience as single tertiary center.

EP690

The role of peptide receptor radionuclide therapy in a case series of bronchial and gastroentero-pancreatic neuroendocrine tumors with secondary determinations

Stanca Oana Stefania, Cristina Stancu & Corin Badiu
National Institute of Endocrinology C.I.Parhon, Thyroid Disorders II, Bucharest, Romania

Introduction

Neuroendocrine tumors (NET) represent a heterogeneous group of tumors with different locations, whose management is based on the pathology, immunohistochemical, genetic and molecular profile.

Materials and method

We followed 8 patients with NET between 2014 and 2022 registered at the "C.I. Parhon" National Institute of Endocrinology, Bucharest, who benefited from peptide receptor radionuclide therapy (PRRT). Among them, 75% were male with the average age at diagnosis 43.37 ± 7.15 years. According to the WHO 2019 classification, 1 case presented a well-differentiated tumor grade G1, 5 cases G2, 1 case associated 2 tumors with grade G1 + G2 and 1 case pancreatic mixed neuroendocrine–nonneuroendocrine neoplasms (MiNEN).

Results

The primary localization was in 6 cases pancreatic, one bronchial and pancreatic, one ileo-cecal. All patients presented secondary determinations at diagnosis, 50% hepatic, 42% lymphnodal and 8% vertebral. Sporadic forms were in 6/8 cases and 2/8 cases presented MEN1 syndrome, in one case having confirmed the heterozygous deletion of the MEN1 gene (c.928-33_963del). At diagnosis, carcinoid syndrome was present in 6/8 cases and the average of chromogranin values in 5/8 cases being 1236.4 ± 881.2 ng/ml. In 3 patients, the presence of somatostatin receptors was evaluated: SSTR2 positive, moderate expression in 2/3, respectively strong expression in 1/3, and SSTR5 negative in 1/3, positive with weak expression in 1/3 and moderate expression in 1/3 cases. Six cases presented progressive disease before the initiation of PRRT treatment and the average interval from diagnosis to PRRT was 16.62 ± 14.27 months. The patients performed between 2 and 6 cycles with an average of 3.37 cycles, the radionuclides used was: (177)Lu-DOTATOC (average cumulative dose(ACD) = 16.5 GBq), (90)Y-DOTATOC (ACD = 10.57 GBq) and (225) Ac-DOTATOC (ACD = 20.5 MBq). The treatment associated with PRRT was: somatostatin analogs (87.5%), surgery (75%), chemotherapy (25%), chemoembolization (12.5%). PRRT was never used as the first line of treatment. Regarding the evolution of the disease according to the RECIST1.1 criteria determined over a period of 6 months after the end of the treatment, 50% presented a partial response, 37.5% stable disease, respectively 12.5% (1 case) progressive disease, the case being represented by the tumor MiNEN, where the death also occurred. Neuroendocrine tumor marker Cromogranine A decreased from the average of 1236.4 ± 881.2 ng/ml before PRRT, at 200.2 ± 188.4 ng/ml, at approximately 4.8 months after the last PRRT session.

Conclusions

PRRT shows benefits in the case of well-differentiated neuroendocrine tumors grade G1-G2, with bronchial or gastroenteropancreatic localization, and remains controversial in the case of poorly differentiated tumors, respectively MiNEN.

A systematic review of pituitary apoplexy and Takotsubo cardiomyopathy

Javad Mahdavi & Touraj Valeh
Arak University of Medical Sciences, Students Research Committee, Arak, Iran

Introduction

Pituitary apoplexy is defined as a clinical syndrome resulting from sudden hemorrhage or infarction of the pituitary gland, mostly within a pituitary micro/macroadenoma. One of the rare diseases that has been reported following pituitary apoplexy is Takotsubo cardiomyopathy (TC). TC, also known as stress cardiomyopathy, is a transient left ventricular dysfunction in the absence of coronary artery disease that is usually associated with psychological and physiological stressors. The purpose of this study was to systematically review the papers describing patients with TC and pituitary apoplexy.

Methods

This study is a systematic review that followed the Preferred Reporting Items for Systematic Reviews and Meta-Analyses (PRISMA) guidelines. PubMed, Web of Science, Scopus, ScienceDirect, and Google Scholar were searched up to 2022 using the following keywords: "pituitary apoplexy", "pituitary hemorrhage", "pituitary infarction", "Takotsubo cardiomyopathy", "Takotsubo syndrome", "stress cardiomyopathy", and "broken heart syndrome". English studies reporting TC in patients with pituitary apoplexy were included without any age, gender, and nationality restrictions.

Results

A total of 6 studies describing 6 cases, including 2 (33%) males and 4 (67%) females, were included. The age range of the patients was from 62 to 85 years with an average of 74 years. In past medical history, atrial fibrillation, complete heart block, hypertension, mild cognitive impairment, diabetes insipidus, nausea, and vomiting were reported. The most common signs and symptoms included altered level of consciousness (6 patients, 100%), headache (5 patients, 83%), nausea/vomiting (4 patients, 67%), hypotension, tachycardia, fever (each one: 3 patients, 50%), and neuro-ophthalmic diseases (2 patients, 33%). The electrocardiogram revealed T wave inversion in limb and/or precordial leads in all patients. Echocardiography showed left ventricular ballooning, apex akinesia, and left ventricular ejection fraction reduction with the lowest level of 20%. In laboratory data, ACTH/cortisol insufficiency (6 patients, 100%), abnormal thyroid function test (5 patients, 83%), low testosterone (3 patients, 50%), and elevated troponin were reported. All patients had pituitary adenoma, of which 4 (67%) were treated conservatively and 2 (33%) with transsphenoidal surgery.

Conclusions

It seems that TC can be a rare complication of pituitary apoplexy. The exact mechanism is not understood, but it may be related to endocrinological abnormalities including ACTH, cortisol, and thyroid hormones insufficiency. So, in case of suspicion of TC associated with pituitary apoplexy, it is recommended to perform more appropriate paraclinical measures such as troponin test, electrocardiography, and echocardiography to prevent misdiagnosis and mismanagement.

Macrohormones ("incidental hormones") – a diagnostic challenge in endocrinology: macro-ACTH

Peter Vanuga, Helena Urbánková, Ivana Ságová, Michal Kulich, Peter Huba & Anton Vanuga
National Institute of Endocrinology and Diabetology, Lubochňa, Endocrinology Dpt, Lubochňa, Slovakia

Background
If the laboratory results are not compatible with the patient's clinical symptoms, the presence of possible test interference should be considered. Despite the excellent quality of immunoassays, it is currently estimated that they may be susceptible to several types of interference that may lead to patient misdiagnosis.
Case report
In our case report we present a 71-year-old woman with confirmation of macro-adrenocorticotropic hormone (macro-ACTH). A magnetic resonance imaging (MR) scan revealed macroadenoma of the pituitary gland (size 16×12×14 mm). Laboratory tests revealed repeatedly high plasmatic levels of adrenocorticotropic hormone (without clinical manifestation of hypercortisolism or hypocortisolism), normal plasma cortisol levels with circulating variation and normal 24 – urine free cortisol. Plasmatic levels of another pituitary hormones were normal. A 2 mg and 8 mg dexamethasone blockade were performed with adequate cortisol suppression. Short synacthen test excluded adrenal insufficiency. Due to the suspicion of the presence of interference, we performed precipitation with polyethylene glycol (PEG-precipitation), which confirmed the high probability of the presence of macro-ACTH.
Conclusion
Although the presence of macrohormones is rare, some cases appear in clinical practice, which must be resolved through differential diagnosis. Systematic search for these interferences in clinical practice is not recommended, but an active approach to interference detection can prevent patient misdiagnosis. In our patient, despite the confirmed diagnosis of macro-ACTH, the transsphenoidal resection was performed. Histopathologic and immunohistochemical findings revealed non-functioning pituitary adenoma.

New point mutation in the KAL 2 gene

Reyes Ravé Garcia, Eduardo Torrecillas del Castillo, Pablo Rodríguez deVera Gómez, Maria Asunción Martínez Brocca & Tomás Martín Hernández
University Hospital Virgen Macarena, Endocrinology and Nutrition, Seville, Spain

Although we know the gene alterations associated with KAL 2, at present we still do not know certain mutations of the fibroblast factor receptor 1 gene (FGFR gene) that even show complete penetrance of the syndrome. Kallman syndrome is a genetic disease of embryonic development characterized by the association of hypogonadotropic hypogonadism due to GnRH hormone deficiency because of agenesis or hypoplasia of the olfactory sulci. Three subtypes have been described; the classic or KAL1 linked to the X chromosome. The autosomal dominant form, KAL2, with the associated gene FGFR located at 8p11.2-p11.1, and the Kallman syndrome type 3 (KAL3). In this context, we present the case of a 14-year-old male patient who came to our clinic due to hypogonadism to affiliate. His personal history includes normal pregnancy, congenital right cryptorchidism diagnosed at 3 years of age, and anosmia from second childhood. In the directed anamnesis, no family history of interest with the diagnosis was found. At the time of the examination, he presented axilarchy. G1P sexual development, classified as grade II on the Tanner scale. Testicular volume of 1/2cc located in the inguinal canal. A Kallman-like Syndrome was suspected as the probable cause of the condition, and testicular ultrasound and cranial MRI were requested to complete the study. The testicular ultrasound described small-sized testicles for his age located in the most proximal part of the scrotal sac, impressing the horizontalized right testicle. In the cranial MRI, as pathological findings, an absence of the olfactory bulb and signs of hypoplasia of the olfactory grooves were observed, as well as a decreased adenohypophyseal gland in size. The analytical study with hormonal profile showed values of hypogonadism with decreased values of gonadal-stimulating hormones: FSH 0.3, LH 0.3, estradiol 5. Rest of hormonal profile was normal. A genetic study was requested to confirm the suspected diagnosis of Kallman Syndrome, being detected as a heterozygous carrier of c.983T>C (p.L3285) in the FGFR1 gene, which is associated with Kallman Syndrome type 2. The karyotype study did not show abnormalities. After genetic confirmation, treatment with intramuscular testosterone and evaluation of evolution in successive reviews was decided. With this case we confirm a new identifiable genetic finding for Kallman Syndrome type 2, this being the first report of said mutation related to idiopathic hypogonadotropic hypogonadism. The fact that the patient has no family history makes us think of a probable spontaneous mutation with complete syndrome penetrance.

DOI: 10.1530/endoabs.90.EP693

Thyrotropin-secreting pituitary tumor: a rare entity

Pedro Jimenez Torrecilla[1], Paloma González Lázaro[1], Antonio Moreno Tirado[1], Maria Zhao Montero Benítez[1], Amparo Lomas Meneses[1], Florentino Del Val Zaballos[1] & Cristina Contreras Pascual[2]
[1]Hospital General La Mancha Centro, Endocrinologìa y Nutrición, Alcázar de San Juan, Spain; [2]Hospital Santa Barbara, Soria, Spain

TSH-secreting pituitary adenomas are a rare cause of hyperthyroidism. The diagnosis should be considered in all hyperthyroid patients, especially those with a diffuse goiter and no extrathyroidal manifestations of Graves' disease. Most TSH-secreting adenomas secrete only TSH. Most patients have the typical symptoms and signs ofhyperthyroidism (eg, palpitations, tremor, heat intolerance), but a few patients have mild or even no hyperthyroid symptoms. Other clinical features include a diffusegoiter, visual field deficits, headache, and, in women, menstrual disturbances and galactorrhea. Thyroid function tests shows normal or high serum TSHconcentrations and high serum total and free thyroxine (T4) and triiodothyronine (T3)concentrations. Approximately 50 to 85 percent of patients with TSH-secreting pituitaryadenomas (particularly macroadenomas) have a high serum concentration of the alphasubunit of glycoprotein hormones. The differential diagnosis should be done with assay interference and resistence to thyroid hormone. The initial treatment of a TSH-secreting pituitary adenoma is medical therapy (withsomatostatin analogs) to restore euthyroidism prior to surgery. Once euthyroid,transsphenoidal resection of the tumor is the most appropriate definitive therapy forpatients with TSH-secreting pituitary adenomas. Here I present the case of a 43-year-old woman, referred by her Primary Care physician due to an incidental analytical finding of hyperprolactinemia. The patient was clinically asymptomatic, without symptoms derived from pituitary hyper or hypofunction, nor compression symptoms. The initial study revealed a 12 mm pituitary adenoma on MRI. The pituitary function study revealed slightly elevated T4 levels, with TSH in the normal range and an elevated alpha subunit. There was doubt between a non-functioning or a TSH-producing adenoma. Therefore, a new determination of thyroid hormones was obtained in another laboratory, with the same result; thyroid autoimmunity, which was negative, and a genetic study was subsequently performed, which ruled out resistance to thyroid hormones. The patient did not tolerate the TRH test. After one year of treatment with somatostatin analogues, TSH and T4 levels have been normalized, as well as the tumor has shrunk. Clinically, the patient remains asymptomatic, visual campimetry is normal, and she has not noticed adverse effects derived from medical treatment. In this case we see the difficulty of diagnosis, given the infrequency of the entity and the absence of florid symptoms, as well as the efficacy of treatment with somatostatin analogues, both in terms of normalization of thyroid function and reduction of tumor size.

Anti PD1 induced hypophysitis: a different nosological entity?

Rihab Laamouri[1,2], Wagner Clothilde[1] & Racolta Naculina[1]
[1]Civil Hospital of Colmar, Endocrinology Department, Colmar, France; [2]Faculty of Medicine of Strasbourg, Strasbourg, France

Introduction
The indications for anti-PD1 agents have expanded considerably in recent years, particularly for the treatment of melanoma, lung cancer and kidney cancer.
Hypophysitis is a rare complication of anti-PD1 agents (< 1%) often with an atypical presentation, characterized by a later onset and a less symptomatic presentation.
Case report
A 60-year-old woman was diagnosed with a clear cell renal carcinoma, treated with left nephrectomy in 2018. Two years later, peritoneal, ovarian and hepatic secondary lesions of the cancer have been identified. Checkpoint inhibitors immunotherapy was initiated using NIVOLUMAB (anti-PD1) and IPILIMUMAB (anti-CTLA4). Pre-therapeutic thyroid and pituitary workup did not reveal any abnormality. Between the 2nd and 3rd cure the patient developed a

thyroiditis with initial hyperthyroidism followed by hypothyroidism. Anti-TSH receptor and anti-thyroperoxydase antibodies were negative. Replacement therapy with LEVOTHYROXINE was introduced. IPILIMUMAB was interrupted and NIVILUMAB was majorated by the oncologist. Unfortunately, no systematic monitoring of the pituitary hormone workup was completed between the different treatment cures. During the following months, the patient complained of severe fatigue and nausea with a tendency to lose weight but with otherwise a normal clinical examination. Hormonal assessment confirmed an isolated corticotropic insufficiency with extremely low cortisol level and undetectable ACTH. The rest of the pituitary hormones were in the normal range, with elevated FSH in relation with menopause and normal prolactin. Pituitary MRI showed no abnormalities. HYDROCORTISONE substitutive treatment rapidly resumed all symptoms.

Conclusion

Hypophysitis induced by anti-PD1 seems to be a different nosological entity. Corticotropic insufficiency is often isolated and the symptoms are not very pronounced, apart from fatigue and weight loss which can be attributed to the cancer and/or the treatment regimen used. Through this case, we want to emphasize the importance of hormonal screening before initiating immunotherapy but also regularly during the treatment in order not to miss the diagnosis of a potentially life-threatening pathology.

EP696

Clinical case of reverse hearing loss in a patient with acromegaly and pituitary macroadenoma

Margarita Perepelova[1], Larisa Dzeranova[1], Aleksandra Shutova[1], Lyudmila Lepeshkina[2], Ekaterina Pigarova[1], Vilen Azizyan[1], Pavel Akopyan[1] & Elena Przhiyalkovskaya[1]
[1]Endocrinology Research Centre, Moscow, Russia; [2]Peoples' Friendship University of Russia, Moscow, Russia

Background

Acromegaly is an orphan neuroendocrine disease characterized by a variety of complications. Due to slow symptom progression acromegalic patients often are involved in growth hormone complications correction for a long time instead of search for main cause of these multiple disorders. A view on conductive hearing loss in acromegaly in literature is contradictory. The low incidence of hearing in acromegaly, compared with other complications, is presumably due to the topographic and anatomical location of the pituitary tumor.

Case presentation.

Female patient, 29 years old, was hospitalized in an endocrinological hospital in 2022 with suspected active stage of acromegaly and pituitary adenoma measuring 57×35×32 mm with endo-supra-infra-ante-latero(D+S) sellar growth, chiasm compression (greater on the left), with tumor expansion into in the main sinus and cells of the ethmoid labyrinth, as well as in the cavernous sinuses, more in the left. According to the hormonal study, IGF-1 was 645.2 ng/ml (normal to 311) and growth hormone more than 80 ng/ml (up to 6.9) , which confirmed the hormonal activity of the adenoma. The patient complained of a significant hearing loss and was consulted by an otolaryngologist. Based on the conducted audiometry, chronic bilateral sensorineural hearing loss III degree on the right and I degree on the left, as well as a bilateral increase in the perception thresholds of the III degree on the right and I degree on the left, was diagnosed. Because of transnasal transsphenoidal adenomectomy was performed. According to the results of immunohistochemical study – sparsely granulated somatotropinoma. After surgical treatment, the patient noted an improvement in hearing, repeated audiometry confirmed the positive dynamics of auditory function – a diagnosis of minimal bilateral chronic conductive hearing loss of the 1st degree was established. Such dynamics confirmed the genesis of hearing impairment as a result of hypertrophy of the temporal bone, due to hyperproduction of growth hormone, with subsequent damage to the auditory analyzer of the inner ear.

Conclusions

This clinical case shows the presence of conductive hearing loss in acromegaly and its reversibility after surgical treatment. Allied physicians should be aware of the variety of symptoms and complications of acromegaly, pay attention not only to the main reason for contacting a specialist, but also to the appearance of the patient, accompanying complaints.

Prolactinoma's resistance: diagnostic and treatment perspectives via pharmacokinetic and metabolomic characteristics

Aleksandra Shutova[1], Larisa Dzeranova[1], Ekaterina Pigarova[1], Liliya Usoltseva[1], Natalia Fedorova[1] & Vitalii Ioutsi[1]
National Medical Research Center for Endocrinology, Neuroendocrinology, Moscow, Russia

Introduction

Prolactinomas are the most common type of pituitary adenomas(40% of them) , representing a significant cause of infertility and hypogonadism. About 20% of patients with prolactinomas don't respond satisfactory(i.e. resistant) even to high dose dopamine agonist(DA) treatment(>3.5–4.5 mg/week). Worth noticing that there are no clear signs to anticipate this resistance but to stepwise increase the dose of DA. In addition, the etiology of resistance – subject of lively discussions.

Aim

The aim of our study was to assess metabolism and absorption of cabergoline in patients with DA-resistant prolactinomas.

Materials and methods

In patients($n=7$) with resistant prolactinomas (no normalization of PRL, no menses with max tolerated dose of cabergoline more than 3.5 mg a week) and 7 patients with normal effect of the drug we conducted a specific pharmacokinetic test: 1) cabergoline was preliminary withdrawn 4 days before the test; 2) at 0900 the blood was taken before and 30-, 60-, 90-, 120-minutes, 4 h, 8 h, 24 hours after taking the cabergoline in a fixed doze of 0.5 mg. The concentration of cabergoline substance in the serum was measured using high-performance liquid chromatography–mass spectrometry method(LC–MS/MS).

Results

We found significant differences in serum cabergoline concentration specific to patients with DA-resistant prolactinomas. It is shown that cabergoline concentration curve in patients with resistance to treatment doesn't represent expected pharmacokinetic peaks(the growth rate less than +1–50%). The pharmacokinetic curve of 1 resistant patient represented the peak at 30 min point(the growth rate +175%) with subsequent decline to baseline levels. The cabergoline concentration curve of drug-sensitive patient is characterized by an already significant baseline concentration that becomes progressively higher reaching an outstanding peak(the growth rate +112%) at the end of the test period. Differences in cabergoline concentration persist between two groups of patients over time, reaching a maximum by the 120th and 240th minutes. The values of these time points can be used as cut-off for differentiation the etiologies of drug resistance in prolactinomas.

Conclusion

Our pilot results show that the patients with DA-resistant prolactinomas may have a defect(absorption or metabolic abnormalities) in forming an adequate blood concentrations of the drug as well as genetic or receptors alterations. Understanding the underlying mechanisms will allow us to reveal treatment's resistance at the early diagnostic stage and develop personalized treatment strategy. In vivo pharmacokinetic and metabolomic characteristics of cabergoline can identify a number of causes of resistance to therapy, which has major clinical applications.

Are neurosteroids related to anxiety and quality of life in cases with acromegaly?

Sebnem Burhan[1], Yalçın Hacıoğlu[2], Yeliz Polat[3], Hilmi Furkan Arslan[4], Özlem Balcı Ekmekçi[5], Mutlu Niyazoğlu[1] & Esra Şüheda Hatipoğlu[1]
[1]Istanbul Basaksehir Cam and Sakura City Hospital, Endocrinology and Metabolic Diseases, Istanbul, Turkey; [2]Ministry of Health's Istanbul Education and Research Hospital, Family Medicine, Istanbul, Turkey; [3]Ministry of Health's Istanbul Education and Research Hospital, Psychology, Istanbul, Turkey; [4]Ministry of Health's Istanbul Education and Research Hospital, Biochemistry, Istanbul, Turkey; [5]Cerrahpasa University Cerrahpasa Medical Faculty, Biochemistry, Istanbul, Turkey

Background

Anxiety level is higher in the samples consisting of people diagnosed with pituitary adenoma, including patients with acromegaly, compared to the normal population. A higher level of anxiety indicates a lower Quality of Life (QoL) in acromegaly. This study aimed to evaluate and discuss the possible relationship between anxiety and NS in people with acromegaly.

Method
This cross-sectional comparative study included an acromegaly group (AG, $n=33$) and cases group without acromegaly (CG, $n=30$). People with a history of stroke with a current or past diagnosis of any psychiatric disorder or on steroid therapy were excluded. The data were collected with a Demographic Data Form, Beck Anxiety Inventory (BAI), Short Form (SF-36), SF-36 has subscales as general health, physical functioning, role limitations due to physical health, energy/fatigue, emotional well-being, social functioning, and pain. Also, levels of allopregnanolone (AP), pregnenolone (PRG), 24S-hydroxycholesterol (24OHC), dehydro-epiandrosterone (DHEA), dehydroepiandrosterone sulfate (DHEAS) and androsterone (ADT) as neurosteroids (NS) are measured in this study.
Results
There were statistically significant differences between the AG and the CG for BAI, general health, physical functioning, role limitations due to physical health, energy/fatigue, social functioning, and pain by the Mann–Whitney U test ($P < 0.001$, $P < 0.001$, $P < 0.001$, $P < 0.001$, $P < 0.001$, $P = 0.017$, $P < 0.001$, $P < 0.001$). There was a statistically significant difference between the acromegaly and the control groups for DHEA (Median of AG:6.37, Median of CG:9.48) and 24OHC (Median of AG:8.70, Median of CG:44.25) by the Mann–Whitney U test ($P = 0.007$, $P = 0.002$). There are relationships between emotional well-being and 24OHC, between energy/fatigue and DHEA, and between energy/fatigue and DHEAS ($r = 0.39$, $P = 0.044$; $r = 0.465$, $P = 0.014$; $r = 0.443$, $P = 0.021$) in AG. There are relationships between BAI and general health, energy/fatigue, emotional well-being, social functioning ($r = 0.455$, $P = 0.008$; $r = 0.442$, $P = 0.01$; $r = 0.412$, $P = 0.017$; $r = 0.456$, $P = 0.008$) in AG.
Conclusion
Variation may occur in levels of anxiety and QoL in acromegaly. Levels of neurosteroids may contribute to it for people with acromegaly. Further research, about functions of neurosteroids may contribute to identifying possible pathophysiological processes.

Pathologic characteristics of somatotroph pituitary tumors – an observational single-center study

Agnieszka Tomasik[1], Maria Stelmachowska-Banaś[1], Maria Maksymowicz[2], Izabella Czajka-Oraniec[1], Raczkiewicz Dorota[3] & Wojciech Zgliczyński[1]
[1]Centre of Postgraduate Medical Education, Department of Endocrinology, Warsaw, Poland; [2]Maria Sklodowska-Curie National Research Institute of Oncology, Department of Cancer Pathomorphology, Warsaw, Poland; [3]Centre of Postgraduate Medical Education, Department of Medical Statistics, School of Public Health, Warsaw, Poland

Background
The first-line treatment in acromegaly is transsphenoidal adenomectomy of GH-secreting pituitary tumor. Pathologic evaluation of postoperative tissue is an essential part of patient's assessment.
Aim
The aim of this study was to analyse pathologic characteristics of pituitary tumors in patients with acromegaly.
Patients and methods
One hundred twenty patients with acromegaly after at least one pituitary surgery treated in Endocrinology Department in Bielanski Hospital in Warsaw, Poland were included in this retrospective study. The data on demographics, hormonal, imaging and pathologic results were extracted from the Polish Acromegaly Registry. The study focused on comparison between sparsely (SG) and densely granulated (DG) tumors, GH(+), GH(+) PRL(+) and plurihormonal tumors, α-subunit (α-SU)-positive and α-SU-negative tumors and tumors of various Ki-67 index values in terms of above-mentioned characteristics.
Results
SG tumors occurred in 59 patients (55.66%) and DG tumors were diagnosed in 47 patients (44.34%). SG tumors compared to DG tumors were more frequent in women than in men (73.47% vs. 26.53%, $P=0.001$) and in younger patients [median = 39 years (IQR:32–49) vs. 46 years (IQR:38–58), $P=0.011$]. SG tumors were larger than DG tumors [23 (IQR:20–34) mm vs. 13 (IQR:9–20) mm, $P<0.001$].
Sixty-three tumors stained positive only for GH in immunohistochemistry (IHC) evaluation (53.39%), 46 tumors stained positive for GH and PRL (38.98%) and 9 tumors stained positive for at least three anterior pituitary hormones including GH (7.63%). Patients with GH(+)-PRL(+)-tumors presented with higher PRL concentration and more frequent gonadotropin insufficiency ($P=0.004$ and $P=0.022$, respectively).
Forty-nine tumors stained positive for α-SU (41.88%) and 62 tumors stained negative (52.99%). Tumors with α-SU(+) were smaller and were more often DG tumors compared to tumors with α-SU(−) [16.0 mm (IQR: 10–21) vs. 20.0 mm (IQR: 14–31), $P=0.013$ and 75.51% vs. 35.71%, $P<0.001$, respectively]. Tumors with α-SU(+) expanded extrasellarly less often than α-SU(−)-tumors (40.0% vs. 61.02%, $P=0.039$).
Proliferation index Ki-67 < 1% was found in 89 patients (76.72%) and Ki-67 ≧ 3% in 11 patients (9.48%). Patients with higher Ki-67 index were younger at diagnosis of acromegaly ($P<0.001$) and more often diagnosed with genetic syndromes ($P=0.02$), they had higher GH concentration ($P=0.007$), larger tumors ($P=0.006$) and cavernous sinuses invasion more frequently ($P=0.022$).
Conclusions
Pathologic assessment is an important part of acromegaly patients' evaluation. Pathologic characteristics are associated with patient's age, sex, hormonal results, tumor's size and degree of extrasellar expansion.

DOI: 10.1530/endoabs.90.EP699

Outcomes of Surgically treated Pituitary Adenomas in Malta – A Population-Based Study

Jessica Mangion[1,2], Miriam Giordano Imbroll[1,2], Josanne Vassallo[1,2] & Mark Gruppetta[1,2]
[1]University of Malta Medical School, Mater Dei Hospital, Department of Medicine, Malta; [2]Mater Dei Hospital, Neuroendocrine Clinic, Malta

Aim
The sequelae of surgically treated pituitary adenomas (PAs) is an important area of study to help guide management. Our study aims to analyse all PAs, functional and non-functional, which were operated until the end of 2022 in a well-defined population and to identify radiological characteristics that can predict recurrence before operation.
Methods
206 PAs were evaluated along with their clinical, radiological, and histopathological characteristics. The clinical records of operated patients attending the only central national health service hospital in Malta were retrospectively analysed. Detailed clinical and histopathological data were obtained for each patient. The preoperative MR scan of each patient was analysed, and its radiological size, intensity patterns, suprasellar and infrasellar extension, and lateral extension were recorded. Univariate and multivariate analyses were done to establish the association of different variables and which variables can predict recurrence after operation.
Results
107 (51.9%) patients had a non-functional pituitary adenoma (NFPA), 20 (9.7%) had an ACTH-secreting PA, 68 (33%) had a GH-secreting PA, 10 (4.9%) had a prolactinoma and 1 (0.5%) had a TSH-secreting PA. The median age was 49 years (IQR 37–62). During the study period, 41 (19.9%) patients passed away. The subtype of PA was associated with MR T2 intensity patterns ($P = <0.001$). All prolactinomas, the TSH-secreting pituitary adenoma and 92.3% of NFPA were hyperintense while 80% of GH-secreting PA were hypointense. 41.7% of ACTH-secreting PAs were hyperintense, 33.3% were hypointense and 25% were isointense. 30 patients had tumour regrowth post-operatively, after a median of 39.5 months (IQR 19–84). Univariate analysis revealed a statistically significant association between tumour regrowth and the different subtypes of PAs ($P=0.02$), the presence of chiasmal compression ($P = <0.001$), suprasellar extension ($P=0.006$), cavernous sinus invasion ($P=0.001$), and the presence of residual tumour post–operatively ($P = <0.001$). Cavernous sinus invasion remained an independent predictor of regrowth after logistic regression ($P=0.006$; OR 6.5 95% CI 1.7–24.2). MR T2 solid tumour intensity was statistically significantly associated with maximal tumour diameter (P-value <0.001) and tumour volume (P-value < 0.001), with hyperintense tumours being the largest (median 26.9 mm; IQR 19.8–34.2), followed by isointense (median 14.3 mm; IQR 7.3–28.6) and hypointense tumours (median 11 mm; IQR 7.8–15.9). There was no statistically significant association between tumour regrowth and MR solid T2 intensity.
Conclusion
Our study shows that tumour size is strongly associated with baseline MR T2 intensity patterns. However, such patterns were not significantly associated with tumour regrowth occurrence, with other indices having a stronger association.

Surgical treatment of prolactinomas

Farida Nasybullina[1,2], Gulnar Vagapova[3], Bakhtiyar Pashaev[4] & Regina Ashimova[5]
[1]Kazan State Medical Academy – Branch Campus of the Federal State Budgetary Educational Institution of Further Professional Education "Russian Medical Academy of Continuous Professional Education" of the Ministry of Healthcare of the Russia, Endocrinological, Kazan, Russia; [2]Russia, Endocrinological, Kazan, Russia; [3]Kazan State Medical Academy – Branch Campus of the Federal State Budgetary Educational Institution of Further Professional Education "Russian Medical Academy of Continuous Professional Education" of the Ministry of Healthcare of the Russia, Endocrinological; [4]Kazan State Medical University, Kazan, Russia; [5]Kazan State Medical Academy – Branch Campus of the Federal State Budgetary Educational Institution of Further Professional Education "Russian Medical Academy of Continuous Professional Education" of the Ministry of Healthcare of the Russia

It is known that treatment of prolactinomas with dopamine agonists is accompanied by relapses of the disease after discontinuation of the treatment in about 50% of cases and long-term or lifelong medication is required. The aim of the study was to evaluate the effectiveness of surgery in achieving remission or biochemical control of the disease. We prospectively enrolled 32 consecutive patients with prolactinomas who underwent transsphenoidal resection performed by the highly qualified surgeon. We evaluated the invasiveness of prolactinomas on the Knosp grading scale and measured serum prolactin concentrations on the first postoperative day. Routine histological assessment of the Ki-67 proliferation index was performed. The level of PRL was assessed in the early and in the late postoperative periods. Pituitary MRI with contrast enhancement was performed in 3, 6 and 12 months after surgery. Among 32 operated patients 32% achieved complete recovery and met the remission criteria during the entire follow-up period. In all patients who achieved remission, adenomas were noninvasive (Knosp 0, 1) and non-aggressive (Ki-67 $<3\%$). The average level of PRL on the first day after surgery was 295.2 mMEd/l ($P>0.1$). Biochemical control was achieved in 28%. In this group, 44% had noninvasive adenomas (Knosp 0, 1), 56% had invasive adenomas (Knosp 2,3). Ki-67 was $<3\%$ in all removed tumor tissues. The average value of PRL on the first day after surgery was 1244 mMEd/l. A significant reduction in the volume of prolactinomas after surgical resection (more than 80%) made it possible to normalize the level of PRL against the background of lower doses of cabergoline, compared with the doses of the drug taken before surgery. Patients who did not achieve postoperative remission and biochemical control accounted for 40% of the total number of patients. This group consisted of individuals with large (more than 4 cm) and giant (more than 6 cm) invasive tumors (Knosp 3,4). Ki-67 was $\geq 3\%$, which corresponded to a high degree of invasiveness and aggressiveness of the tumor. The average value of PRL on the first day after surgery in this group was 19 348 $\pm$ 7816 mMEd/l All patients had absolute indications for emergency surgery. Transnasal transsphenoidal adenomectomy leads to complete postoperative remission in 32% of cases and in 28% of cases allows to achieve biochemical control of the disease while taking cabergoline. Radiological assessment of prolactinoma invasiveness and early postoperative serum prolactin concentrations are important predictors of early remission after surgery.

Pituitary apoplexy: clinical characteristics and management

Jessica Ares Blanco
HUCA External Consultations, Endocrinology and Nutrition, Oviedo, Spain

Background and aims
Pituitary apoplexy (PA) is a rare clinical syndrome due to pituitary hemorrhage or infarction. It is an emergent and potential life-threatening complication of pituitary adenomas if not managed properly. It is usually characterized by the sudden onset of one or more of the following: severe headache, visual disturbance, nausea/vomiting, and or altered mental status. We aimed to present clinical and biochemical characteristics as well as management of patients presented with pituitary apoplexy at our department.
Methods
In this study, a total of 14 patients presented with pituitary apoplexy between 2012 and 2022. The data of pituitary apoplexy cases were recorded. Resection rates, hormonal results, and clinical presentation of patients with pituitary apoplexy were evaluated.
Results
Over the last 10 years, 14 patients (2 women) were hospitalized for pituitary apoplexy. The median age of patients was 64.57 $\pm$ 16.11 years. Only one patient had a prolactinoma, the rest of them were non-functioning adenomas. Acute and severe headache was the most frequent symptom (100%), followed by visual disturbances 9/14 (64.3%) and diplopia 6/14 (42.9%). At presentation, the majority of patients 10/14 (71,42%) had one or more anteiror pituitary deficiencies. 3 of 14 tumors (21.4%) were causing cavernous sinus invasion. The median maximum diameter of the tumor was 28.2 $\pm$ 9.7 mm. Nine of fourteen patients (64,3%) underwent transsphenoidal surgery due to visual fields deffects or aggressive tumor.
Conclusion
Severe headache and visual disturbances are the commonest symptoms. Transsphenoidal surgery is the most frequent management.

Silent pituitary macroadenomas – clinical behavior and prognosis

Inês Manique[1], Sara Amaral[1], Ana Palha[1], Luísa Cortez[1], Luís Cerqueira[2], Amets Sagarribay[3] & José Silva-Nunes[1]
[1]Centro Hospitalar Universitário de Lisboa Central, Endocrinology, Lisboa, Portugal; [2]Centro Hospitalar Universitário de Lisboa Central, Neuroradiology, Lisboa, Portugal; [3]Centro Hospitalar Universitário Lisboa Central, Neurosurgery, Lisboa, Portugal

Introduction
A third of pituitary adenomas are non-functioning. Classification depends on adenohypophyseal hormones expression and transcription factors.

Table 1 (Abstract EP703). Silent pituitary adenomas characteristics

	Gonadotropinomas								
	FSH/FSH + LH	FSH-/LH-SF1+	ACTH	TSH	PRL	FSH + LH + TSH	FSH + ACTH + PRL	GH + TSH	PRL + GH
Number	44 (67,7%)	5 (7,7%)	6 (9,2%)	2 (3,1%)	1 (1,5%)	4 (6,2%)	1 (1,5%)	1 (1,5%)	1 (1,5%)

Cabergoline	5	2	0	0	1	0	0	0	1
Radiotheraoy	1	0	2	1	0	1	0	0	0

*In a silent corticotropinoma operated 5 times, Ki-67 increased in the successive histopathologic evaluations reaching 25%.

Aim
Characterize silent pituitary macroadenomas cases regarding their clinical data, treatment, histopathology and prognosis.
Methods
We revised clinical process of patients followed in CHULC. Cases with non-access to clinical follow-up registries or exams were excluded.
Results
Sixty-five patients (69.2% male), diagnosed at 53.6±14.3 years-old, followed during 6.6±4.4 years. 58.5% ($n=38$) were diagnosed in the context of tumoral mass effect; 21.5% ($n=14$) hypopituitarism; 9.2% ($n=6$) pituitary apoplexy and 10,8% ($n=7$) as an incidentaloma. 33,8% ($n=22$) had visual fields alterations with bitemporal hemianopsia being the commonest (9%; $n=16$). The characteristics of the different cases are summarized in Table 1 .
Conclusion
As expected, silent gonadotropinomas were the most prevalent and all the hormone negative adenomas expressed SF1. Although most of silent adenomas have a good prognosis, silent corticotropinomas seems to be more challenging to treat. Histopathology is decisive to predict the prognosis.

Pituitary abscess masquerading as meningitis with partial anterior pituitary deficiency

Shyam Seshadri
Queen Elizabeth Hospital, Diabetes and Endocrinology, Kings Lynn, UK

A 34-year-old woman presented with a worsening headache 4 weeks post-partum following emergency caesarean section. She described the headache as the worst that she had experienced, and this was made worse by bending forwards and with associated photophobia. A CT head scan revealed pan sinusitis and a suggestion of a pituitary tumour while lab results showed mild hyponatremia along with low TSH and FT4. An initial working diagnosis of likely meningitis was made, and she commenced on ceftriaxone and acyclovir. A LP was carried out which revealed xanthochromia and raised CSF protein while the CSF cell count revealed 324 cells with 70% lymphocytes and 30%neutrophils. A visual field testing showed no visual deficit. A baseline pituitary hormone profile showed elevated prolactin and normal cortisol and IGF-1 and she continued to become more hyponatraemic with a sodium of 117 mmol/l. The patient was commenced on levothyroxine as it was thought that the hyponatremia was the result of secondary hypothyroidism. An MRI pituitary revealed possible cystic macroadenoma or pituitary abscess. She was discussed at the pituitary MDT and advised to undergo a further MRI pituitary with diffusion weighted imaging as it felt the pituitary lesion was an abscess. She received a intravenous broad spectrum antibiotics while in the hospital though her inflammatory markers continued to remain normal. A repeat LP was carried out which showed the CSF cell count to be only 20 with 95%lymphocytes and the CSF protein had dropped. A workup for other infectious conditions including screening for HIV, TB, Hepatitis B, Hepatitis C and cryptococcus were all negative. The patient developed a recurrence of her headache post discharge with increasing tiredness and fatigue. A short synacthen test now showed central adrenal insufficiency while MRI pituitary suggested a likely pituitary abscess which was now multi septate with further progression to encroach on the optic chiasm with compression. She commenced steroid replacement and underwent a transsphenoidal drainage of the sellar abscess with frank pus noted intra operatively but no organism was isolated. She had an extended course of intravenous antibiotics over 4 weeks due to the nature of the pituitary lesion and had uneventful post operative recovery with improvement in her hyponatremia which had now normalized. This case highlights the rarity of the pituitary abscess and its close mimic to meningitis. The importance of recognising the need for prompt endocrine work up alongside other causes cannot be over emphasised.

Pituitary macroadenoma apoplexy following treatment with pembrolizumab

Stephanie Andrade Lopes[1], Lucie Sciotto-Canel[1], Shahan Momjian[2], Assma Ben Aissa[3], Elise Brocco[4], Ondine Becquart[4], Kristof Egervari[5], Doron Merkler[5], François Jornayvaz[1], Sophie Leboulleux[1] & Maria Mavromati[1]
[1]Hôpitaux Universitaires de Genève (HUG), Endocrinology, Genève, Switzerland; [2]Hôpitaux Universitaires de Genève (HUG), Neurosurgery, Genève, Switzerland; [3]Hôpitaux Universitaires de Genève (HUG), Oncology, Genève, Switzerland; [4]Hôpitaux Universitaires de Genève (HUG), Dermatology, Genève, Switzerland; [5]Hôpitaux Universitaires de Genève (HUG), Pathology, Genève, Switzerland

A 70-year old man was referred to the endocrinology department for the evaluation of a pituitary macroadenoma which was diagnosed during work-up for a malignant melanoma. Pituitary MRI showed a 20×21×25 mm adenoma with supra-sellar extension and no compression of the optic chiasma. Hormonal work-up revealed central hypogonadism and slight hyperprolactinemia due to stalk compression, while pituitary function was otherwise normal. MRI follow-up was scheduled in six months. The patient had surgery for the melanoma, and started immunotherapy with pembrolizumab. After the third dose of pembrolizumab, treatment was complicated by grade 3 polyarthralgia and grade 2 diarrhea and was temporarily stopped. Two-months later, the patient was admitted to the hospital due to violent headaches. MRI revealed apoplexy of the pituitary macroadenoma. Hormonal work-up showed new onset central hypothyroidism and central adrenal insufficiency. The patient was not on anticoagulation. Due to the absence of visual complications, conservative management was initially decided and treatment with glucocorticoids and levothyroxine was started. One week later, the patient came back to the hospital with worsening headache, motivating surgery. Histologic examination showed necrotic fragments of a pituitary neuroendocrine tumor, with SF-1 immunostaining. Possible metastasis of malignant melanoma was excluded. Central hypogonadism, adrenal insufficiency and central hypothyroidism persisted at 3 months-follow-up. Immune check-point inhibitors have radically improved cancer management. However, they are linked to endocrine adverse events related to pituitary, thyroid and adrenal damage. Pituitary complications include hypophysitis or simple anterior pituitary hormonal dysfunction. Pituitary apoplexy is an uncommon, potentially serious complication of pituitary macroadenomas. The pathophysiology is poorly understood, but some risk factors have been identified, such as coagulation disorders, abrupt increase or decrease in blood flow or pituitary stimulation. Here we describe the case of a patient who experienced apoplexy of a pituitary macroadenoma after pembrolizumab treatment. The link between immunotherapy and apoplexy has not been described so far. Only one case of apoplexy has been described in a patient on anti-PD1. With the increase in numbers of patients treated with immunotherapy, more research is needed to assess whether pituitary apoplexy can be caused by immune checkpoint inhibitors and determine whether pituitary surgery should be performed before starting immunotherapy.

Translation into Portuguese and cultural adaptation of the Literacy Independent Cognitive Assessment

Lucas B. Santos[1], Michael Kellner[2], Walter Oliveira[3], André Faro[3], Carla R P Oliveira[1], Vanderlan O Batista[1], Alécia A Oliveira-Santos[3], Iris de Vita Alves de Brito[3], Viviane Almeida[1], Keila R Villar-Gouy[1], Angela Leal[1], Rivia S Amorim[1], Enaldo V Melo[1], Elenilde G Santos[1], Roberto Salvatori[4] & Manuel H. Aguiar-Oliveira[1,5]
[1]Federal University of Sergipe Campus São Cristóvão, Department of Medicine, Aracaju, Brazil; [2]University Hospital Hamburg-Eppendorf, Hamburg, Germany; [3]Federal University of Sergipe Campus São Cristóvão, Psycology, Aracaju, Brazil; [4]The Johns Hopkins University School of Medicine, Baltimore, USA; [5]Federal University of Sergipe Campus São Cristóvão, Aracaju, Brazil

Population aging has become a universal worldwide phenomenon. Developing countries (such as Portuguese-speaking countries, with a high rate of illiteracy) will see the greatest increase in the absolute number of elderly people, and dementia disorders will pose enormous challenges to public health in these countries. Although the decline in GH secretion with age has been associated with deleterious conditions of aging, our understanding is the opposite, that the decline in GH secretion attenuates the harmful consequences of aging (1), as shown in a cohort with a lifelong congenital, and untreated isolated growth hormone deficiency (IGHD), living in Itabaianinha, Brazil, the largest Portuguese-speaking country. These individuals exhibit normal lifespan and extended healthspan, that is, the period of life free of major chronic clinical diseases and disabilities, thus requiring an assessment of cognitive performance in the elderly. The aim of the present study was to translate and adapt a Portuguese version of the Independent Cognitive Literacy assessment (LICA). The study was carried out in five stages. In the first stage, a psychologist and a psychiatrist translated the instrument from English to Portuguese, maintaining the meaning and structure of the original version. This translation was proofread by an English teacher. The second step was the cultural adaptation, carried out in an interdisciplinary way by 15 authors, including a nutritionist who proposed common food terms in the interior of the Brazilian Northeast, generating the second consensus version after some changes of words and images, to become familiar in the local context. The third step involved an evaluation round with two judges (independent psychologists), who approved this version. In the

fourth stage, the instrument was revised by two senior authors, one psychiatrist and one endocrinologist, thus establishing the final Portuguese version of LICA. In the fifth stage, a pre-test was carried out to verify the understanding of the questionnaire, with five illiterates who understood and approved the instrument, which was later applied to 15 elderly people with isolated growth hormone deficiency and 15 local controls, in which we calculated the test score reliability, by Cronbach's alpha coefficient, based on all LICA standardized items, which was 0.76, indicating good instrument reliability. We conclude that the Portuguese version of the LICA is a reliable instrument, available to be used in this IGHD cohort, as well as in the cognitive assessment of any groups in internal medicine or psychology.

Safety and efficacy of once weekly somapacitan versus once daily growth hormone among adults with growth hormone deficiency: A systematic review and meta-analysis

Faith Abigail Co, Micah Fiel Baliclic, Kevin Sese & Rodolfo S Pagcatipunan Jr.
St. Luke's Medical Center - Global City, Taguig, Philippines

Background

Adult growth hormone deficiency (AGHD) has been increasingly observed among patients with traumatic brain injury, stroke, and central nervous system infection, aside from the subgroup of patients with pituitary tumors. When left untreated, these patients have a significantly increased risk to develop cardiovascular morbidity and mortality and impaired psychosocial function. Existing treatment guidelines on AGHD have recommended the use of growth hormone (GH) replacement as the gold standard, of treatment, requiring daily GH injections, which can be burdensome and costly for patients. More recently, however, a novel drug Somapacitan (Novo Nordisk A/S, Denmark), was investigated in a number of small randomized controlled trials as an effective long-acting form of GH replacement therapy. It acts as a reversible albumin-binding GH derivative, thereby increasing its half-life and reducing its clearance from the body. Despite this discovery, on the other hand, there is no existing meta-analysis to create a more robust conclusion regarding its safety and efficacy.

Objective

This metaanalysis aims to evaluate the overall safety and efficacy of weekly somapacitan versus once daily growth hormone in adults with growth hormone deficiency (AGHD). Specific outcomes that were compared between weekly somapacitan and daily GH injections were the incidence of adverse effects, local tolerability, convenience scores of participants, and mean IGF-1 levels.

Methods

A comprehensive search of literature was done through electronic databases (Pubmed, MEDLINE, Cochrane Library) until December 1, 2022. The study included only phase 3 randomized controlled trials (RCTs) which were directed towards the adult population. RevMan 5.4 was utilized to analyze the efficacy and safety of weekly somapacitan versus daily growth hormone replacement.

Results and analysis

Three RCTs were included with a total of 415 participants. The incidence of adverse events including local injection-related reactions with weekly somapacitan as well as their mean IGF-1 levels were comparable to daily growth hormone injections but had better convenience scores, therefore increasing adherence to treatment which results to better quality of life.

Conclusion

Adherence to treatment plays an important role in improving treatment outcomes in patients with AGHD. With that, once weekly somapacitan can be offered as a safe and well-tolerated alternative to daily growth hormone injections among adults with growth hormone deficiency. This pilot meta-analysis was able to show the efficacy and safety of somapacitan versus the current standard, making it a promising treatment option to adults with growth hormone deficiency which can improve treatment compliance from childhood to adulthood.

Giant pituitary adenomas: Clinical and paraclinical features, management, and outcome

Bel Hadj Sliman Chayma, Ibtissem Oueslati, Ameni Terzi, Sabrina Ayari, Meriem Yazidi & Melika Chihaoui
La Rabta University Hospital, Department of Endocrinology, Tunis, Tunisia

Introduction

Giant pituitary adenomas are defined as tumors with largest diameter $\geq$40 mm. They are characterized by high invasiveness causing compression of adjacent structures and hormonal dysfunction. The aim of this study was to determine the clinical and paraclinical features, management, and outcome of giant pituitary adenomas.

Methods

This was a single-center retrospective study including patients with giant pituitary adenoma. Clinical and paraclinical data were collected from the medical records.

Results

Twenty patients (14 men and 6 women) were included in this study. Their mean age at diagnosis was 34.8$\pm$11.9 years. Giant adenoma was revealed by a tumor syndrome in 17 patients and by signs of hypersecretion in two patients. It was incidentally discovered in one patient. The presenting manifestations were headaches (18 cases), visual disturbances (18 cases), hypogonadism (9 cases), signs of corticotrope deficiency (9 cases), and polyuria-polydipsia syndrome (1 case). The diagnosis of macroprolactinoma was established in 18 patients with a median baseline prolactin level of 8495 ng/ml. Two patients had non-secreting pituitary adenoma. Hypopituitarism was diagnosed in 9 patients. The mean adenoma size was 53.3$\pm$9.4 mm (range: 40–77 mm). Optic chiasm compression, cavernous sinus invasion, sphenoid sinus invasion, and hydrocephalus were observed in 14, 15, 11 and 10 patients, respectively. All patients with macroprolactinoma were treated with dopamine agonists (bromocriptine in 6 patients and cabergoline in 12 patients). Transsphenoidal surgery was performed to two patients and two patients required radiotherapy. Full recovery was obtained in only one patient. For the remaining patients, the outcome was marked by a decrease in the adenoma size in six patients.

Conclusion

Giant pituitary adenomas, although not very common, are a therapeutic challenge due to their size, invasiveness, and the fact that they often have extrasellar extensions.

Long-term Clinical Outcomes in Acromegaly

Yaasir Mamoojee[1], Muhammad Hassaan Pervez[2], Andy James[2] & Neville Shery[2]
[1]Royal Victoria Infirmary, Endocrine and diabetes (on behalf of the RVI pituitary MDT and Endocrine group), Newcastle upon Tyne, UK; [2]Royal Victoria Infirmary, Endocrine & Diabetes, Newcastle Upon Tyne, UK

Background

Acromegaly is a rare condition characterised primarily by tumourous production of excess Growth Hormone (GH) from a pituitary adenoma. Clinical management aims at normalising serum IGF1 levels within sex and age-adjusted reference parameters. Treatment options include pituitary surgery, medical therapy with somatostatin analogue (SSA), cabergoline, pegvisomant or radiotherapy. A combination of treatment modalities is common for the majority of patients.

Aims

We retrospectively reviewed the long-term clinical outcomes in our large cohort of patients with acromegaly at the Royal Victoria Infirmary.

Methods

All patients with acromegaly seen in our dedicated weekly pituitary clinic or discussed in our pituitary MDT since 2019 were included. Data extracted: patient demographics, biochemical and radiological findings at diagnosis, treatment modalities, latest IGF1 level during follow-up and duration of follow-up. IGF1 expressed as x sex-and-age-adjusted upper limit of normal. Data expressed as mean, S.D. and percentages.

Results

From 1970 to 2021, 111 patients were diagnosed with acromegaly. F: M is 1:1, with a mean age of 48 ($\pm$16) years and IGF1 level 2.9$\times$ULN ($\pm$1.1) at diagnosis. 85% of patients had a pituitary macroadenoma. The mean duration of follow-up is 13 ($\pm$11.6) years. 75% of patients underwent pituitary surgery, and 24% were treated with medical therapy only. One patient is awaiting surgery. Overall 87/110 (79%) achieved an IGF1 $\leq$1.3$\times$ULN at the latest review. Post-pituitary surgery, 14% of patients achieved normal IGF1 levels, but 23% of patients achieved IGF1 $\leq$1.3$\times$ULN. Further treatment modalities to achieve IGF1 $\leq$1.3$\times$ULN in the surgical cohort included: cabergoline (10%), SSA (32%), a combination of SSA and cabergoline (8%), pegvisomant (4%) and radiotherapy (7%). Overall, satisfactory IGF1 control ($\leq$1.3$\times$ULN) was achieved in 50% of patients on SSA, 26% on cabergoline and 18% after radiotherapy.

Conclusions

The remission rate post-surgery in our cohort of patients with acromegaly, primarily secondary to macroadenomas, is low at 14%. Nevertheless, either alone

or in combination, long-term medical treatment modalities achieved adequate control in 79% of patients.

Serum prolactin levels and correlation to clinical diagnosis: a study of 259 patients with hyperprolactinaemia

Win Lei Yin[1], Carol Evans[2], Sarah Tennant[2] & Andrew Lansdown[1]
[1]University Hospital of Wales, Department of Endocrinology, Cardiff, UK; [2]University Hospital of Wales, Department of Biochemistry, Cardiff, UK

Introduction
Hyperprolactinaemia is a common finding in endocrine practice and can be due to a number of causes. The degree of elevation of prolactin levels may sometimes be helpful in distinguishing between underlying aetiology.
Aim
To determine if hyperprolactinaemia is correlated with clinical diagnosis in a cohort of patients in the endocrine service at a tertiary centre.
Methods
A biochemistry database held at University Hospital of Wales, Cardiff, UK, was used to find patients who had prolactin levels requested by the endocrinology department between June 2019 and February 2022. This list was used to identify patients who had hyperprolactinaemia, as defined by serum prolactin levels of Males >407 mU/l and Females >557 mU/l, on at least two occasions. The initial elevated prolactin was noted and clinical records were examined to determine the clinical diagnosis made.
Results
A total of 1198 cases were identified. Out of these, 320 duplicates were removed, leaving 878 patients. 410/878 patients with hyperprolactinaemia were identified. 89 patients with incomplete data were excluded and 62 who only had a single elevated prolactin level measured were also excluded, leaving 259 patients. This cohort had their initial elevated prolactin levels identified between the years 2003 and 2022. 193 females and 66 males were identified. Mean age: 44 (17–91)y. A total of 10 diagnoses had been made, with mean prolactin levels and ranges as follows, in order of frequency of diagnosis: Microprolactinoma ($n=111$) 1797 (540–12 488)mU/l, macroprolactinoma ($n=40$) 26 776 (1330–160 452)mU/l, non-functioning pituitary adenoma (NFA) ($n=36$) 796 (466–1406)mU/l, Drug-Induced Hyperprolactinaemia (DIH) ($n=22$) 1989 (454–8355)mU/l, polycystic ovary syndrome ($n=15$) 1137 (628–2223)mU/l, idiopathic ($n=15$) 1113 (608–2458)mU/l, acromegaly ($n=8$) 3286 (444–17076)mU/l, stress ($n=6$) 866 (611–1261)mU/l, craniopharyngioma ($n=4$) 891 (595–1228)mU/l and empty sella ($n=2$) 1318 (1208–1427)mU/l. For the more common diagnoses, mean prolactin in microprolactinoma was higher than NFA ($P<0.001$), but there was no difference in mean prolactin in microprolactinoma compared to PCOS ($P=0.15$) or DIH ($P=0.64$). The mean prolactin in macroprolactinoma compared to NFA was statistically significantly higher ($P<0.001$), and also as compared to microprolactinoma ($P<0.001$).
Conclusions
A number of aetiologies result in elevated serum prolactin concentrations. Our data show hyperprolactinemia is more commonly found in females patients. Although there was an overlap in ranges between many of the diagnoses, in macroprolactinoma prolactin levels were no less than 1000 mU/l and in NFAs, no greater than 2000 mU/l. Mean serum prolactins were statistically higher in macro- and microprolactinomas compared to NFAs, and macroprolactinomas compared to microprolactinomas.

EP711

Can early post-operative hypocortisolaemia predict remission after transsphenoidal surgery in Cushing's disease

Irfan Khan, Andy James, Razan Ali Rashid, Claire Nicholson & Yaasir Mamoojee
The Newcastle Upon Tyne Hospitals, Department of Endocrinology, Newcastle upon Tyne, UK

Background
Cushing's disease (CD) is rare, and standard treatment is trans-sphenoidal surgery (TSS). We previously reported a remission rate of 56% in patients undergoing TSS for CD from a microadenoma/normal pituitary on MR in our unit. Early post-operative hypocortisolaemia performs well at predicting durable remission early on. Post-operative day 1 cortisol of <55 nmol/l has a 100% sensitivity and <138 nmol/l 95% sensitivity at predicting remission. Since October 2021 all patients with CD are operated on by a single neurosurgeon in our unit and we have adopted early post-operative cortisol assessment.
Aims
We retrospectively reviewed the performance characteristics of early post-operative serum cortisol assessment in all patients undergoing TSS for Cushing's disease at our centre since October 2021.
Methods
Patients do not receive perioperative steroid cover during TSS for microadenoma or normal pituitary MRI and a 0600 h serum cortisol is checked on day 1 post-surgery before starting steroid replacement therapy. Subsequent hormonal assessment (short synacthen testing – SST) occurs 8–10 weeks post-operatively after steroid weaning and if euadrenalism is proven then dynamic testing for steroid excess is undertaken (dexamethasone suppression testing & 24-hour urinary free cortisol estimation).
Results
Nine patients with pituitary microadenoma and 2 patients with normal pituitary MRI underwent pituitary surgery for CD. F:M is 4:1. Day 1 post-operative serum cortisol level, measured in 10 patients, was <50 nmol/l, 50–150 nmol/l and >151 nmol/l for 6, 2 and 2 patients respectively. 10/11 (90%) patients remain in remission post-surgery. Eight patients failed their post-operative SST. Two out of three patients with normal SST post-operatively had normal steroid dynamics as assessed by dexamethasone suppression testing and 24-hour urinary free cortisol estimation. The one patient with ongoing CD did not have day 1 post-operative serum cortisol measurement.
Conclusions
Remission rate in Cushing's disease in patients with microadenoma or normal pituitary on MRI has improved to 90% in our unit. In our cohort day 1 post-operative serum cortisol level of >150 nmol/l did not predict persistent Cushing's disease as we observed late remission post TSS in 20% of our cohort.

Thyroid fine needle aspiration for the diagnosis of Langerhans Cell Histiocytosis of the suprasellar region

Lucie Sciotto-Canel[1], Stephanie Andrade Lopes[1], Verdiana Caironi[2], Essia Saiji[1], Maria-Isabelle Vargas[1], François R Jornayvaz[1], Shahan Momjian[1], Grégoire Stalder[3], Sophie Leboulleux[1] & Maria Mavromati[1]
[1]Hôpitaux Universitaires de Genève (HUG), Genève, Switzerland; [2]EOC Ente Ospedaliero Cantonale, Bellinzona, Switzerland; [3]Lausanne University Hospital, Lausanne, Switzerland

A 25-year old woman with Hashimoto thyroiditis was referred to the endocrinology department for investigation of a 40 kilogram weight gain, polyuria, polydipsia and secondary amenorrhea. Hormonal work-up showed diabetes insipidus, central hypogonadism, secondary adrenal insufficiency, central hypothyroidism and slight hyperprolactinemia. Pituitary magnetic resonance imaging (MRI) revealed a 15 mm hypothalamic tumor expanding to the infundibulum, associated with pituitary stalk thickening. Serum and cerebrospinal fluid tumor markers were negative and without evidence of infiltrative disease. Extensive whole body imaging was unremarkable except for high uptake of the suprasellar lesion (SUV 11.8) on 18F-fluorodeoxyglucose positron emission tomography and computed tomography (FDG-PET/CT). The patient refused transcranial biopsy for fear of potential complications. Due to mildly increased angiotensin-converting-enzyme and 24-hour urine calcium, neurosarcoidosis was suspected and prednisone was initiated (1 mg/kg) then stopped because of side effects (uncontrolled diabetes and weight gain) and the absence of radiologic improvement. Methotrexate was then prescribed and continued for a year. One year later, FDG-PET revealed high FDG uptake of the thyroid gland (SUV 4.1), which was also present at baseline and attributed to Hashimoto thyroiditis. Thyroid ultrasound showed heterogeneous pattern with slightly increased vascularity. On follow-up, thyroid parenchyma showed marked changes with intense hypoechoic pattern and decreased vascularity. Fine-needle aspiration (FNA) of the thyroid gland was then decided and cytology showed a proliferation of Langerhans cells with deeply grooved nuclei admixed with eosinophils. The Langerhans cells were strongly positive for CD1a by immunocytochemistry. Cladribin treatment was initiated and resulted in a significant decrease in tumor size within 2 months (craniocaudal axis on MRI: 19 mm versus 24 mm at baseline). Histiocytosis includes a group of syndromes characterized by tissue infiltration of histiocytes thought to be derived from dendritic cells or macrophages that may infiltrate various organs, notably the central nervous system. Thyroid involvement has rarely been reported, is more common in adults and is usually related to multi-systemic disease. Ultrasound

shows hypoechoic pattern, heterogeneity and rare calcifications. Thyroid FNA can be useful in establishing the primary diagnosis if no other tissue biopsy can be done and immunohistochemical staining shows positivity for S100, CD1a and langerin. Thyroid ultrasound should thus be performed in all patients with intracranial tumors suggesting LCH, especially in case of increased FDG-avidity of the thyroid parenchyma. FNA could be systematically considered as being part of the differential diagnosis workup in these cases.

Kisspeptin Kindred: Case Report and Literature Review

Kanokporn Sanpawithayakul[1], Sasha Howard[2] & Marta Korbonits[1]
[1]William Harvey Research Institute, Queen Mary University of London, Endocrinology, London, UK; [2]William Harvey Research Institute, Queen Mary University of London, Paediatric Endocrinology, London, UK

Context
Normosmic idiopathic hypogonadotropic hypogonadism (nIHH) is a rare endocrine disease in which patients have isolated gonadotropin releasing hormone (GnRH) deficiency in the context of otherwise normal structure and function of anterior pituitary and hypothalamus with normal olfactory ability.
Objective
To explore the underlying pathogenic defect in patients with delayed puberty.
Patients
We investigated genetic defects in a consanguineous family of Pakistan patients with nIHH. The proband is a male who presented with delayed puberty at the age of 22 years. His younger sister, who was 18 years old at the time of presentation experienced primary amenorrhea. Both of them have a normal sense of smell.
Methods
High-throughput exome sequencing with the NHS Genomic Medicine R148 Hypogonadotropic Hypogonadism gene panel (14 genes) was undertaken. The identified predicted pathogenic variant in *KISS1R* was confirmed by Sanger sequencing.
Results
Hormonal profiles confirmed isolated GnRH deficiency in the proband with undetectable LH and testosterone, and inhibin B 26.7 pg/ml, as well as in his younger sister. A homozygous variant in *KISSR1* was identified, namely a nonsense stopgain (c.827G > A; p.(Trp276Ter)) in both siblings. The variant is not present in the gnomAD database.
Conclusion
We describe a novel homozygous nonsense variant in *KISS1R* resulting in nIHH in one kindred exhibiting delayed or absent pubertal onset.
Keywords: hypogonadism, normosmic, delayed puberty.

A patient with two forms of PA – pituitary adenoma and primary aldosteronism

Htet Htet Aung[1], Amna Zeeshan[1], James Macfarlane[1], Kieren Allison[2], Felicity Kaplan[3], Waiel Bashari[4] & Mark Gurnell[1]
[1]Cambridge University Hospital NHS Trust, Diabetes and Endocrinology, Cambridge, UK; [2]Cambridge University Hospital NHS Trust, Histopathology, Cambridge, UK; [3]East and North Hertfordshire NHS Trust, Diabetes and Endocrinology, Stevenage, UK; [1]Cambridge University Hospital NHS Trust, Diabetes and Endocrinology, Cambridge, UK

Background
Clinically relevant pituitary adenomas (Pit PA) affect approximately 1:1200 of the general population, and may manifest with hormone hypersecretion, hypopituitarism and compression of the visual pathways. Primary aldosteronism (Adr PA) is now recognised to account for 5–14% of all cases of hypertension and is associated with excess morbidity when compared with primary hypertension. Here, we report a patient who was noted to have a history suggestive of Adr PA whilst being investigated for Pit PA.
Case
A 45-year-old man attended his primary care physician with a 6-month history of reduced sexual function. Laboratory investigation demonstrated partial hypogonadotrophic hypogonadism [LH 2.6 U/l (RR 1.5–9.3); FSH 8.8 U/l (RR 1.4–18.1); total testosterone 6.7 nmol/l (RR 7.2–31.3)], with associated mild hyperprolactinaemia [prolactin 719 mU/l (RR 45–375)] and possible partial central hypothyroidism [Free T4 10.3 pmol/l (RR 10.5–21.0); TSH 0.7 mU/l (RR 0.35–5.5)]. Serum cortisol was normal with no evidence of Cushing's syndrome clinically or biochemically (UFC 42 nmol/24 h; LNSC 0.5 and 0.9 nmol/l) Serum calcium was normal. Formal visual field testing with perimetry showed a left temporal defect, and subsequent pituitary MRI revealed a 34 × 26 × 19 mm macroadenoma with suprasellar extension. Whilst being investigated for Pit PA, parallel investigations were initiated for suspected Adr PA based on the patient's history of hypertension (treated with amlodipine) and unprovoked hypokalaemia. Plasma renin concentration (PRC) was low (3 mU/l), which coupled with a plasma aldosterone concentration (PAC) of 790 pmol/l, yielded a markedly raised aldosterone: renin ratio (263.3). Adrenal MRI demonstrated a possible nodule in the body of the left adrenal gland, with thickening of the medial limb; the right adrenal appearances were unremarkable. Subsequent ACTH-stimulated adrenal vein sampling (AVS) indicated a bilateral origin of PA (Ttable 1): The patient was changed to mineralocorticoid receptor antagonist (MRA) therapy with good control of blood pressure and correction of hypokalaemia. At trans-sphenoidal surgery, a macroadenoma was resected, with immunohistochemistry showing positivity for FSH. Transcription factor expression is negative. Genetic screening for a familial syndrome is awaited.
Conclusions
Although, the co-occurrence of Pit PA and Adr PA in our patient may represent a simple coincidence, the possibility that they are linked [either through an underlying genetic predisposition (e.g., MEN1) or a novel pathophysiological pathway (as previously proposed for macroprolactinomas and Adr PA – Williams *et al*., JCEM, 2015)] remains.

	IVC	Left adrenal vein	Right adrenal vein
Aldosterone	1,160	44,200	32,500

Predictive factors of biochemical remission after transsphenoidal surgery in acromegaly

Cherchir Faten, Sabrine Mekni, Sawsen Essayeh, Sahar Abidi, Nadia Mchirgui, Ibtissem Ben Nacef, Imen Rojbi & Karima Khiari
Hospital Charles Nicolle, Endocrinology, Tunis, Tunisia

Introduction
Excessive production of growth hormone (GH) in acromegaly is most commonly caused by a somatotroph pituitary adenoma. The therapeutic arsenal is based on selective transsphenoidal adenomectomy (STA) as a first-line treatment. The aim of our study was to determine predictive factors of postoperative biochemical remission in acromegalic patients.
Methods
We conducted a retrospective study including 18 acromegalic patients followed-up in the endocrinology department of Charles Nicolle hospital, who underwent STA. Clinical, biochemical, and tumor imaging data were extracted from medical records. According to postoperative biochemical investigation patients were subdivided into two groups: remission (normal IGF-1 and GH level < 1 ng/ml, 3 months postoperatively) versus persistence.
Results
There were 10 women and 8 men with a mean age of 42.9 ± 12.9 years. Pituitary imaging showed a macroadenoma in 94% of cases with extrasellar extension in 61% of cases. Postoperative biochemical remission was seen in six patients (33%). Patients who achieved biochemical remission had significantly smaller tumors compared with those who did not attain remission (mean diameter 15.2 versus 25.6 mm; $P = 0.018$). Moreover, locoregional invasion ($P = 0.043$) and the persistence of a tumor remnant ($P < 10\text{-}3$) were significantly associated with a decreased rate of biochemical remission. However, we did not find significant associations between postoperative biochemical remission and these parameters: age, sex, preoperative GH and IGF-1 levels, pituitary hormone deficiencies, visual impairment and the delay between the diagnosis of acromegaly and STA.
Conclusion
STA of somatotroph adenomas remains the only curative treatment in acromegaly. The biochemical remission rate obtained after STA ranges from 32 to 85% of cases. Consistent with literature, our study showed that postoperative biochemical remission rate is lower in case of voluminous adenomas, locoregional invasion and persistence of residual tumor.

Coexistence of acromegaly and Xanthomatous Hypophysitis

Rukiye Dilara Tekin Uzman[1], Sebnem Burhan[1], Fatih Mert Dogukan[2], Burak Kocak[3], Esra Suheda Hatipoglu[1] & Mutlu Niyazoglu[1]
[1]University of Health Sciences, Basaksehir Cam and Sakura City Hospital, Department of Endocrinology, İstanbul, Turkey; [2]University of Health Sciences, Basaksehir Cam and Sakura City Hospital, Department of Pathology, İstanbul, Turkey; [3]University of Health Sciences, Basaksehir Cam and Sakura City Hospital, Department of Radiology, İstanbul, Turkey

Introduction
Hypophysitis is a rare pituitary inflammation due to primary and secondary causes. Xanthomatous hypophysitis is the rarest subtype and described with lipid-laden cystic areas, transparent cytoplasmic and lipid-laden histiocytes and foamy (xanthomatous) histiocytes. Although the etiology of xanthomatous hypophysitis is not clearly known, it has been suggested to develop as a result of autoimmune cause or inflammatory process of infiltration of cyst components from other sellar masses. Clinically, it shows symptoms similar to pituitary adenomas, but no case of hypophysitis accompanied by acromegaly has been reported among the few cases seen in the literature. We present a case with xanthomatous hypophysitis which was diagnosed after re-operation for acromegaly.
Clinical case
A 38-year-old female patient presented with complaints of headache, enlargement of the hands and feet, increase in shoe size, and enlargement of the jaw for 6 months. Physical examination revealed acromegaly, other systemic examination was unremarkable. Laboratory examination revealed IGF1:659 ng/ml (93.1–228) and GH:24.4:4.02 ng/ml (0.126–9.88) Other anterior pituitary hormones were within reference ranges. MRI revealed a 19×13 mm hypointense mass lesion in the right lateral half of the pituitary. Visual field evaluation was normal. The patient was operated with a prediagnosis of acromegaly. The pathology result was compatible with acromegaly. 3rd month follow-up revealed IGF1:554 ng/ml (93.1–228) GH:8.79, ng/ml (0.126–9.88) other anterior pituitary panel was again normal and imaging showed a 12×12 mm residual mass in the right half of the pituitary. After re-operation for the residual tumor the pathology specimen of the second operative pathology was reported as sparsely granular somatotroph adenoma favoring focal recurrence/residue in the adjacent area containing CD 68+ diffuse foci of xanthomatous hypophysitis. Medical treatment for acromegaly was started.
Conclusion
Although the pathogenesis of xanthomatous hypophysitis is unknown, it may develop as a local reaction to hemorrhage, degeneration necrosis and inflammation. Also, it has been previously associated with rathke cleft cysts (lit). However, to our knowledge reoperation for a somatotropinoma has not been defined as a secondary cause. Immunohistochemical staining is supportive to confirm the diagnosis in our case.

Bilateral petrosal sinus sampling – a 15-year experience from a tertiary hospital

Helena Urbano Ferreira[1], Juliana Gonçalves[1], Sandra Belo[1], Gonçalo Alves[2], Maria Luís Silva[2], Davide Carvalho[1] & Paula Freitas[1]
[1]São João Universitary Hospital Center, Department of Endocrinology, Diabetes and Metabolism, Porto, Portugal; [2]São João Universitary Hospital Center, Department of Neuroradiology, Porto, Portugal

Introduction
In patients with ACTH-dependent Cushing Syndrome, differentiating between pituitary and ectopic sources can be challenging. Noninvasive testing can be performed, but bilateral inferior petrosal sinus sampling (BIPSS) remains the gold standard. In the last years however, novel imaging modalities, namely 3T-MRI with 3-dimensional spoiled gradient-echo sequence and 68Ga-tagged CRH combined with positron emission tomography, have been proposed as alternatives.
Aim
To evaluate the accuracy of BIPSS performed in a single tertiary hospital in differentiating between hypophyseal and ectopic causes of ACTH-dependent Cushing syndrome. A secondary aim was to compare BIPSS and traditional non-invasive test results (MRI, high-dose dexamethasone suppression test and CRH stimulation test).
Methods
Forty patients with ACTH-dependent Cushing syndrome underwent BIPSS from 2006 to 2022 in a tertiary hospital. Fourteen patients were excluded due to lack of documented hypercortisolism at the time of BIPSS, lack of a definitive diagnosis, or sample loss (hemolysis). Clinical files were reviewed for patient demographics, biochemical, histological and imaging findings. Cushing's disease was confirmed in case of cure after transsphenoidal surgery or histology indicative of an ACTH positive pituitary adenoma. Similarly, ectopic Cushing syndrome was confirmed in case of cure after surgery or histology indicative of ACTH-positive neuroendocrine tumor (surgery or biopsy).
Results
Twenty-six participants were evaluated (76.92% female, median age 43.31 ± 2.36 years). Cushing's disease was confirmed in 19 patients, and BIPSS was compatible with this diagnosis in 13 patients. Ectopic Cushing syndrome was confirmed in 5 patients, and BIPSS was compatible with this diagnosis in 4 patients. The fifth patient had results suggestive of ectopic Cushing syndrome before CRH stimulation, and Cushing's disease after. BIPSS sensitivity was 71.43%, and specificity was 100.00% and 80.00%, before and after CRH stimulation. Accounting for an estimated prevalence of Cushing's disease of 80% among patients with ACTH-dependent Cushing's syndrome, accuracy was 77.14% and 70.74%, before and after CRH stimulation. MRI ($n=26$) sensitivity was 66.67% and specificity was 60.00%. High dose dexamethasone suppression test ($n=14$) sensitivity was 80.00% and specificity was 25.00%. CRH stimulation test's ($n=8$) sensitivity was 100.0% and specificity was 0.00%.
Conclusion
BIPSS had overall lower sensitivity and higher specificity compared with non-invasive testing. Specificity was higher before CRH stimulation. Novel non-invasive diagnostic tools with higher accuracy in differentiating the cause of ACTH-dependent Cushing syndrome could possibly replace invasive testing in the future.

Radiological characteristics of pituitary adenomas in men

Dhoha Ben Salah, Trigui Souleima, Faten Haj Kacem Akid, Frikha Hamdi, Nadia Charfi, Mouna Mnif, Nabila Mejdoub, Fatma Mnif, Mouna Elleuch & Mohamed Abid
CHU Hedi Chaker, Endocrinology, Sfax, Tunisia

Background and aims
Pituitary adenomas (PA) are small, generally benign tumors found in the pituitary gland.PA in men are rare However, they are characterized by the frequency of invasive and aggressive tumours, which makes their management difficult. The aim of this study is to clarify radiological characteristics of pituitary adenomas in men. Materials and methods: Retrospective descriptive study of 80 adult men with PA, hospitalized in the endocrinology department from 1998 to 2020. It included 35 non-functioning adenomas (NFPA), 27 prolactin adenomas, 15 somatotropic adenomas and 3 corticotropic adenomas.
Results
The mean tumour size was 31.6 mm $\pm$17.2 [5–90 mm] with macroadenomas predominating; 55 cases (68.7%). Prolactinomas had the largest dimensions with a mean height of 46 mm [9–90 mm] compared to 27.8 ± 12 mm [9–56 mm] for NFPA, 27.6 mm $\pm$8.9 [9–56 mm] for somatotropic adenomas and 14.3 mm [5–37 mm] for corticotropic adenomas. Fifteen patients (18.7%) had a giant adenoma of which 13 patients had a prolactinoma. Macroadenomas were predominant in NFPA (88.5%), somatotropic adenomas (73.3%) and corticotropic adenomas (66.6%). Prolactin adenomas and NFPA were predominantly T2 hypersignal (71.1% and 74% respectively). Somatotropic adenomas, on the other hand, were predominantly T2-hyposignal (60%). Suprasellar extension was the most frequent, whatever the type of adenoma (59 cases, 73.7%), i.e. 82.8% of NFPAs, 85.2% of prolactinomas, 33.3% of somatotropic adenomas and 66.6% of corticotropic adenomas. Compression of the optic chiasma was found in 35% of cases and hydrocephalus in 15% of patients. The pituitary stem was compressed in 21.2% of cases. Lateral extension to the cavernous sinuses was found in 42.5% of cases, i.e. 66.6% of corticotropic adenomas, 45.7% of NFPA, 48.1% of prolactinomas and 20% of GH adenomas. Invasion of the sphenoidal sinus was noted in 16.2% of cases, all were giant adenomas. Posterior extension to the brainstem and prepontine cisterns was noted in 3 cases. The post-pituitary gland was pushed back in 2 cases. Finally, extension to the nasal cavity and orbit was noted in 3 cases. Radiological pituitary apoplexy was found in 38.7% of PA. A cystic component was present in 20% of NFPA and 30.7% of giant prolactinomas. Only one PA was abcessed. This was a NFPA.
Conclusion
PA are characterised by the frequency of macroadenomas and by a greater potential for progression. They are more prone to pituitary apoplexy, which causes higher morbidity and mortality.

Polyuria after steroid replacement in a patient with adrenal insufficiency – not always vasopressin deficiency

Kavita Narula[1], Sandhi Nyunt[2], Aditi Sharma[3], Kate Lazarus[2], Agnieszka Falinska[4], David Russell-Jones[4] & Karim Meeran[2]
[1]London North West University Healthcare NHS Trust, UK; [2]Imperial College Healthcare NHS Trust, UK; [3]Barts Health NHS Trust, UK; [4]Royal Surrey County Hospital, UK

A 54-year-old man with a recurrent non-functioning pituitary gonadotroph adenoma previously treated with transphenoidal surgery (TSS) in 2015, presented to Charing Cross hospital for repeat transsphenoidal surgery in May 2022. Since his initial surgery, he remained on Levothyroxine 50 µg once daily only. There was no evidence of adrenal insufficiency (0900 h cortisol 333 nmol/l at day 6 following initial TSS). In February 2022, his electrolytes, FSH, LH, testosterone, prolactin and IGF-1 levels were normal. A repeat Short Synacthen Test (SST) showed normal results (baseline cortisol 94 nmol/l, 30 minutes 404 nmol/l, 60 minutes 451 nmol/l). Routine pre-operative bloods on the day of admission for repeat surgery in May 2022 showed a new hyponatraemia of 125 mmol/l (range 133–145 mmol/l) and an undetectable cortisol (<28 nmol/l). He was given an induction dose of Hydrocortisone pre-operatively, and immediately became polyuric passing over 200 ml per hour, with a total of 6050 ml in 24 h. His operation was postponed and the polyuria settled within 24 h. Repeat bloods the following morning showed a sodium of 133 mmol/l. He was discharged on replacement Prednisolone 4 mg once daily, and a repeat TSS was rearranged. The ACTH deficiency prevented free water clearance, which immediately reversed on treatment with Hydrocortisone. The ACTH deficiency was presumed to be a result of corticotroph suppression by tumour growth against the sella turcica. A subsequent water deprivation test on replacement Prednisolone, to ensure that the glucocorticoid replacement had not uncovered vasopressin deficiency, was entirely normal. He subsequently had TSS in June 2022. A postoperative SST revealed a baseline cortisol of 283 nmol/l, 30 min 517 nmol/l and 60 min 631 nmol/l. His Prednisolone was hence weaned down to 3 mg and then stopped. His TSH also normalized, and the Levothyroxine was stopped. Textbook definitions for syndrome of inappropriate antidiuretic hormone secretion (SIADH) state that patients must have adequate cortisol and thyroxine reserve to make the diagnosis. This case, however, confirms that deficiency of either, can present as SIADH, which resolves when these hormones are replaced. Our case also highlights that corticotrophs are sensitive to the pressure effects of pituitary tumours, but that full recovery can occur following surgical decompression. It is important that patients' hypothalamic–pituitary–adrenal axis are reassessed to avoid unnecessary glucocorticoid replacement.

Increased mortality in COVID-19 patients with admission hyponatremia is associated with sustained hyponatremia, and volemia-inappropriate therapy

Mario Pazos Guerra[1], Jorge Gabriel Ruiz Sánchez[2], Xavier Pérez Candel[1], Celia Lopez Nevado[1], Fernando Hernández Olmeda[1], Patricia Espinosa De Los Monteros[1], Martín Cuesta Hernández[1], Alfonso Calle[1], Javier Sánchez Martín[3] & Isabel Runkle[1]
[1]Hospital Clínico san Carlos, Endocrinology and Nutrition, Madrid, Spain; [2]Fundación Jiménez Díaz, Endocrinology and Nutrition, Madrid, Spain; [3]Hospital Clínico san Carlos, Emergency Department, Madrid, Spain

Introduction
Admission hyponatremia, frequently detected in patients hospitalized for COVID-19, has been associated with increased mortality. However, although SIADH-induced euvolemic hyponatremia is the single most-common cause of hyponatremia in community-acquired pneumonia, repercussions of admission-hyponatremia volemic classification on COVID-19 hospitalizations have yet to be described. We sought to identify factors contributing to mortality and hospital length-of-stay (LOS) in hospitalized patients admitted with hyponatremia, taking volemia into account.
Method
Retrospective study of 247 patients admitted with COVID-19 to a tertiary hospital in Madrid, Spain from March 1st through March 30th, 2020, with a glycemia-corrected serum sodium level (SNa) < 135 mmol/l. SNa, creatinine, urea, glycemia, O2 Saturation were recorded at admission, at day 2nd–3rd of hospitalization, and ensuing days when hyponatremia persisted (>3 days). Volemia was determined according to: maximum height of internal jugular vein pulse (HIYP), and 2 of following: presence/absence of thirst, orthostatic symptoms, blood pressure ≤ 90/60 mmHg, heart rate ≥90 bpm, urinary sodium ≤ 30 mmol/l and/or a rise in serum creatinine (SC) and/or serum urea (SU) accompanying the descent in SNa. In absence of registered HIJP, 3 of the latter criteria were used. Variables studied included demographics, comorbidities, therapy of hyponatremia, LOS and in-hospital mortality rate.
Results
Age: 68 years [56–81]; 99/247 (39.9%) female. Median admission SNa: 133 mmol/l [131–134]. In the majority (188/247:76%), hyponatremia was mild (SNa 131–134 mmol/l). Volemia in 208/247 patients: 119/208 (57.2%) were euvolemic, and 89/208 (42,8%) were hypovolemic. The median LOS was 11 days [6–18], with a mortality rate of 21.5%. LOS was correlated with total hospitalization days with hyponatremia ($r=0.474$, $P<0.001$), and negatively correlated with admission SNa ($r=-0.224$, $P<0.001$). Patients who died had a higher median rate of hospitalization days with hyponatremia (25% vs. 17%, $P=0.007$) than survivors, with a shorter LOS: 7 [4–12] vs. 12 [7–20] days, $P<0.001$. Higher 02 saturation levels were independently associated with reduced mortality (OR: 0.88, 95%CI 0.78 to 0.99), and an oncological history with increased mortality (OR: 13.17, 95%CI 1.79 to 96.84). Neither the degree of hyponatremia, nor volemia were independently associated with mortality. However, initial therapy of hyponatremia was: euvolemic patients inadequately treated at admission with iv isotonic saline showed an increased mortality rate (36.6% vs 20.2% $P=0.02$).

An international, simulated-use study assessing nurses' preferences between two lanreotide syringes (Somatuline Autogel vs Pharmathen) for treatment of neuroendocrine tumours (NETs) and/or acromegaly: PRESTO 3

Diego Ferone[1], Wendy Martin[2], Jessica Williams[3], Aude Houchard[4], Christelle Pommie[4], Antonio Ribeiro-Oliveira[5] & Ashley B Grossman[6]
[1]IRCCS AOU San Martino, Genova, Italy; [2]King's College Hospital, London, UK; [3]Oregon Health and Science University, Portland, USA; [4]IPSEN, Boulogne-Billancourt, France; [5]IPSEN BIOSCIENCE INC., Cambridge, USA; [6]The Neuroendocrine Tumour Unit, London, UK

Introduction/Background
Patients with NETs and acromegaly are commonly treated with somatostatin analogues (SSAs), such as octreotide and lanreotide depot formulations. The Pharmathen syringe is now available in several European countries and the USA for lanreotide depot injection. When using SSAs, confidence in and ease of use with syringes is important for decision-making in long-term therapy.
Aims
PRESTO 3 compared nurses' preference for the Somatuline Autogel syringe versus the Pharmathen syringe after injection-pad testing. Here we report preferences for 11 attributes.
Methods
This international, simulated-use study included oncology/endocrinology nurses (initial planned sample size 92) with ≥1 year experience in managing NETs and/or acromegaly. Each nurse tested both syringes twice in a randomised order, before completing an electronic preference survey. The primary objective was to assess overall preference (%, 95% confidence interval [CI]) for the Somatuline Autogel syringe versus the Pharmathen syringe, assessed using a one-sample exact binomial test. Secondary objectives included ranking importance and rating performance (scored from 1 [not at all] to 5 [very much]; Wilcoxon 2-sided signed-rank test) of attributes for both syringes.
Results
Ninety-four nurses were enrolled: mean age, 41.0 (s.d., 11.5) years; 72.3% in Europe (7 countries) and 27.7% in the USA. The proportion of nurses stating a preference ('strong' or 'slight') for the Somatuline Autogel syringe [86.2% (95% CI 77.5%–92.4%)] was statistically significantly higher than 50% ($P<0.0001$). Ranking of syringe attributes are reported in the Table. Performance rating was statistically significantly higher with Somatuline Autogel than the Pharmathen syringe for 10/11 attributes ($P<0.05$) (Table 1).
Conclusions
This simulated-use study showed that nurses strongly preferred the user experience of the Somatuline Autogel syringe over the Pharmathen syringe. "Ease of use" and "comfortable to handle" were considered the most important

syringe attributes, and performance rating was significantly higher with Somatuline Autogel than the Pharmathen syringe for all but one attribute.

Attributes	Most important, %	Second most important, %	Least important, %
Easy to use	**30.9**	11.7	4.3
Comfortable to handle	20.2	**16.0**	1.1
Convenience of syringe format	8.5	11.7	9.6

Experience with cabergoline in the treatment of an active gonadotropinoma

Irina Klochkova, Lyudmila Astafieva, Alexsey Shkarubo, Yulia Sidneva, Pavel Kalinin, Sergey Urakov, Inna Badmaeva, Natalia Sergeeva & Irina Zorilova
Burdenko Neurosurgical Institute, Moscow, Russia

Gonadotropinomas secreting biologically active hormones, most commonly follicle-stimulating hormone (FSH), are a very rare pathology. The clinical manifestations depend on the gender and age of the patient. Men may observe enlarged testicles and erectile dysfunction. Reports on the results of the drug treatment are sporadic.

Objective

To describe a rare clinical case of an active giant FSH-secreting pituitary tumour in a 62-year-old man with the development of hyperandrogenism and secondary erythrocytosis. Patient Y. 62 years old applied to the neurosurgical centre with complaints of decreased vision. MRI examination revealed a giant tumor of the chiasmal-sellar region (maximum size 63 mm). Ophthalmological examination: decreased visual acuity in the OS- 0.3, OD- 0.9, left-sided hemianopsia. ?ormonal tests: FSH – 30 U/l (1,4-9,6), LH – 8,6 U/l (2,5-11), testosterone – 58 nmol/l (12-27); PRL, TSH, free T4, IGF-1, cortisol levels were within the reference values. The clinical blood test revealed secondary erythrocytosis (Hb – 199 g/l (130–170), erythrocytes – 6.5×10.12/l, Ht – 58% (40–51)), other parameters were unchanged. Urological examination revealed moderate diffuse changes in the prostate gland, testicular volume was within the age norm. The somatic status had no features. The localization and size of the tumour determined a high surgical risk. The patient refused the proposed surgical treatment. Cabergoline therapy was attempted. A normalization of laboratory values was observed on a 1.5 mg weekly basis for 3 months (FSH – 10 U/l; LH – 2,7 U/l, testosterone – 9,5 nmol/l; Hb – 162 g/l (130–170), erythrocytes – 5.3×10.12/l, Ht – 46%. During the following 7 years of follow-up a control MRI of the brain with contrast (the interval of investigation was 3–6 months during the first 3 years, then annually) showed tumor without significant changes in its size. Visual function remained at the same level.

Conclusion

In this case, the increase in sex hormones did not lead to a recognizable clinical syndrome. It should be remembered that endogenous hyperandrogenism may be the cause of erythrocytosis. The lack of progression of neurological symptoms for 7 years and the normalization of laboratory values, as a demonstration of the tumor's "response" to therapy, allowed the patient to continue treatment with cabergoline. Further accumulation of clinical cases can determine the management for patients with active gonadotropinomas.

Cure rates after different therapy lines among patients with growth hormone (GH)-secreting pituitary adenomas

María Dolores Moure, Elizabeth Salinas Ortiz, María Muñoz Del Diego, Elena González Estella, Claudia Sánchez Arauco & Javier Santamaría Sandi
Cruces University Hospital, Endocrinology and Nutrition, Bilbao, Spain

Introduction

Even Though resection via transsphenoidal surgery is the optimal primary treatment for growth hormone (GH) secreting pituitary adenomas, medical therapy must also be considered when biochemical control after surgery is not achieved. The aim of our study was to describe the cure rates of acromegaly patients after different lines of therapy.

Methods

A retrospective study (1971–2022) of 89 patients diagnosed with acromegaly was conducted. Age, sex, radiological characteristics of the pituitary adenoma, hormonal evaluation and response to different therapy lines were the studied. SPSS Statistics software was used for the analysis.

Results

A total of 89 patients were reviewed. The mean age at diagnosis was 51 ± 10.2 years, 57.3% were females. The mean maximal tumor diameter was 1.7 ± 0.65 cm, and up to 67.1% were macroadenoma. The MRI described cavernous sinus invasion in 19% of microadenoma and in 48% of macroadenoma. A total of 17 (19.8%) patients showed hyper-intense adenoma on T2- weighted MRI sequences, 13 (15.1%) are described as hypo-intense whereas 39(45.3%) appear to be isointense. Chiasmatic involvement was observed in 24 (28.9%). Basal insulin-like growth factor type 1 (IGF-1) above the upper limit of normal (ULN) and growth hormone (GH) levels after an oral glucose load (OGTT) (mean ± s.d.) were 678 ± 265 and 8.5 (1.5–20.7) ng/ml, respectively. Out of 89, 78 patients (80.9%) underwent surgery as primary treatment, the remaining cases required first-line medical treatment due to a rejection of surgical treatment or non-suitability because of high surgical risk. The histopathology report described proliferative marker Ki-67 $\leq$ 3% in 45 patients (Ki >3% in 10 patients). After surgical intervention, 74 patients continued in active followed up. Forty-seven of them (63.5%) were in disease remission (GH nadir on OGTT <0.4 ng/dl). Second line therapy was used for the 27 patients with persistent disease activity despite surgical resection. Five of them were treated with dopaminergic agonist another 16 with somatostatin receptors ligands (SRL), 2 with pegvisomant and the remaining 4 cases required a combination of SRL and cabergoline. A total of 24 patients (93%) showed IGF1 levels in normal range (5, 15, 2 and 2 for each therapy respectively).

Conclusion

Surgical intervention as the first line of treatment for patients with acromegaly achieves high cure rates. In those cases in which the disease is not cured, the available pharmacological treatments allow us to achieve disease control in practically all patients.

Case report of a patient with partial antidiuretic hormone deficiency (central diabetes insipidus)

Nino Katamadze, Aleksandra Shutova, Khava Fargieva, Ekaterina Pigarova & Larisa Dzeranova
Endocrinology Research Center, Moscow, Russia

Introduction

Diabetes insipidus (DI) is a rare condition characterized by excretion of large amounts of dilute urine and increased thirst due to deficiency or renal resistance of antidiuretic hormone (ADH). DI is often difficult to diagnose reliably and accurately, especially in patients with partial DI.

Aim

The aim of our case report is to present the patient with partial diabetes insipidus and to report the results of water deprivation and hypertonic saline stimulation tests.

Material and methods

18-year-old female patient was admitted to the hospital with chief complaints of increased thirst and urinary frequency after transnasal adenomectomy.

Results

In accordance with the results of water deprivation and hypertonic saline stimulation tests partial ADH-deficiency was diagnosed in our patient due to maximum urine osmolality of less than 539 mOsm/kg and 504 mOsm/kg, plasma osmolality 292 mOsm/kg and 311 mOsm/kg, maximum plasma sodium was 144,4 mmol/l and 143 mmol/l, respectively, and no change in urine osmolality after administration of 0.1 mg desmopressin sublingually.

Conclusion
Postoperative diabetes insipidus is often transient, which occurs as our data show in the gradual restoration of ADH secretion through the clinic of partial diabetes insipidus (ADH deficiency).

Coexistence of PRL-secreting adenoma and germ cell tumor in 14-year-old adolescent

Alexey Kalinin[1], Natalia Strebkova[1], Igor Chugunov[1], Galina Kolesnikova[1], Olga Bezlepkina[1], Olga Zheludkova[2] & Valentina Peterkova[1]
[1]The National Medical Research Center for Endocrinology, Moscow, Russia; [2]Scientific and Practical Center for Specialized Medical Care for Children named after V.F. Voyno-Yasenetsky, Moscow, Russia

Coexistence of different types of brain tumors is a very rare condition. We present a clinical case of PRL-secreting adenoma and germ cell tumor coexistence in 14-year-old adolescent. The patient was admitted to our Center with complaints of headache with nausea episodes, left-sided ptosis. Visual acuity was: visus OD = 1.0; visus OS = 0.6 Cyl -0.5 ax 70 = 1.0. Neuroimaging revealed supra-para(D,S)sellar mass 39 × 32 × 21 mm. Laboratory data revealed hypothyroidism, hypocortisolism and low prolactin level (43 mU/l). After 100-fold serum dilution (in order to exclude hook effect) prolactin level was 14 000 mU/l (*n* 60–510). Prolactinoma has been diagnosed and therapy with cabergoline (0.75 mg/week), hydrocortisone and levothyroxine was started. Two months after hospitalization visual acuity worsening has been noted and readmission was carried out. During second hospitalization, prolactin level became 4500 mU/l (after 100-fold serum dilution), MRI neuroimages showed a pronounced increase in the size of the neoplasm 78 × 52 × 48 mm. Levels of tumor markers were determined: hCG was < 2.39 mIU/ml (*n* 0–2.39), AFP was > 1000 IU/ml (*n* 0–5.5). Based on laboratory and instrumental data coexistence of PRL-secreting adenoma and AFP-secreting germ cell tumor was diagnosed. The patient was transferred to oncology department for immediate start of chemotherapy.

Joint disease in patients with acromegaly

Margarita Perepelova, Elena Przhiyalkovskaya, Natalya Tarbaeva, Larisa Dzeranova, Ekaterina Pigarova & Liliya Kovalevich
Endocrinology Research Centre, Moscow, Russia

Background
Acromegaly is a neuroendocrine disease that occurs with slowly progressive symptoms, which leads to delayed diagnosis and the development of complications. Arthropathy is one of such complications, which is accompanied by severe pain and significantly worsens the quality of life. The main attention of researchers is devoted to the pathology of the hip, knee and hand joints. At the same time, the study of the shoulder, acromioclavicular, costovertebral joints in acromegaly has not been carried out in detail.
Purpose
The objective of the study is to study damage of the shoulder, acromioclavicular, costovertebral joints in patients with acromegaly.
Materials and methods
The study included 31 patients (15 men and 16 women) with active acromegaly and 25 patients (12 men and 13 women) of the control group without acromegaly. Both groups had no trauma or rheumathoid disoders. The median age was 43.74 in patients with acromegaly and 46.64 in the control group. The duration of acromegaly at retrospective assessment ranged from 1 to 32 years, activity was confirmed by the results of the level of IGF-1 (median 577.98 ng/ml).
Results
In patients with acromegaly, arthrosis of the costovertebral joints was diagnosed 87% and did not depend on age and gender, in contrast to the control group, where the pathology of the costovertebral joints was detected in 64% of patients and there is a clear correlation with age. Arthrosis of the acromioclavicular joints was detected in patients with acromegaly in 32% of cases; these changes did not have a clear pattern with age characteristics and gender. In the control group, 16% over 55 years of age had pathology of the acromioclavicular joints, regardless of gender, and 8% of men under 55 years of age. In 54.8% of patients with acromegaly, arthrosis of the shoulder joints was found equally in women and men, and the defeat of these joints in the control group was registered only in 20% exclusively in males.
Conclusions
In patients with acromegaly, arthrosis of the acromioclavicular, costovertebral and shoulder joints is observed more often than in patients without this neuroendocrine pathology and does not depend on gender. The high frequency of joint damage in patients with acromegaly requires special attention to diagnosis, as it is an important component of quality of life.

Prolactin-secreting pituitary adenoma: Clinical, radiological features and predictors of response to dopamine agonists

Martina Romanisio[1], Alice Ferrero[1], Tommaso Daffara[1], Sara Catenazzi[1], Rosa Pitino[1], Beatrice Cavigiolo[1], Marco Zavattaro[1], Paolo Marzullo[1], Marina Caputo[1,2], Flavia Prodam[1,2] & Gianluca Aimaretti[1]
[1]Endocrinology, Department of Translational Medicine, Novara, Italy; [2]Department of Health Sciences, Novara, Italy

Aim
Prolactinomas are the most frequent pituitary adenomas. Clear predictors of response to dopamine agonists (DA) are still discussed. The purpose of the study was to evaluate the clinical, radiological and hormonal characteristics of PRL-secreting pituitary adenomas, and to evaluate morphological changes over time and predictors of response to DA.
Patients and Methods
Patients affected by PRL-secreting adenoma undergoing DA therapy in follow-up in a tertiary care center (2000–2021) were retrospectively evaluated. Demographic (sex, age at diagnosis), clinical (BMI, cabergoline dose, surgery, symptoms at diagnosis), hormonal (PRL, pituitary function, hormone replacement therapy) and radiological parameters at diagnosis and during follow-up (major diameter, cranio-caudal, antero-posterior and latero-lateral diameters, adenoma volume, cavernous sinus invasion, optic chiasm compression, delta of adenoma diameter change) were collected. Subjects with ≥20% reduction in volume or major diameter were defined as responders. High-responders were those with ≥50% reduction.
Results
Sixty-two patients (median age 37 years, IQR 26.5–45.3) were included; most of the patients were female (62.9%), who had also more frequently microadenoma (82.6%, $P < 0.0001$). The median dose of cabergoline was 1.0 mg/week (0.5–1.4 mg/week). Forty-eight subjects (77.4%) were responders, 35 of whom (56.5%) were high responders. Response to therapy did not differ between sex or micro/macro lesions. Male patients and macroprolactinomas had higher early response rates (6–12 months) during follow-up ($P < 0.05$). An early (6-month) reduction in adenoma volume predicted a long-term shrinkage. Age, basal prolactin and cortisol levels were independent predictors of radiological outcomes.
Conclusions
Adenoma shrinkage and decrease in PRL levels can be useful predictors in the long-term workup management of prolactin-secreting lesions. They should be validated to drive early surgical intervention.

Features of pituitary macroadenomas with one size less than 10 mm

Yulya Krivosheeva & Irena Ilovayskaya
Moscow Regional Research and Clinical Institute (MONIKI), Neuroendocrinology, Moscow, Russia

There are clinical recommendations to conduct a hormonal investigation in all cases of pituitary tumors > 6 mm in size that seems to be uncertain.

The objective

To reveal features of pituitary macroadenomas with at least one size less than 10 mm

The materials and methods

We have analyzed medical records of 380 newly diagnosed patients with pituitary macroadenomas before any treatment: 162 non-functioning adenomas (NFAs), 74 prolactinomas, 144 somatotropinomas. Median patients' age was 56 [47; 63] y.o., 30 [25; 44] y.o. and 48.5 [35; 58] y.o., accordingly.

The results

The prevalence of macroadenomas with one size less than 10 mm were: 8/162 (4.9%) NFAs, 10/74 (13.5%) prolactinomas and 14/144 (9.7%) somatotropinomas. All patients were female except 2 men with somatotropinoma. The first complaints of patients with NFAs were headache – 6/8, in prolactinomas were menstrual disorders – 8/10 and in somatotropinomas were headache – 6/14, appearance changes – 4/14. The "first referred" specialists were: NFAs – neurologist (6/8); prolactinomas – gynecologist (8/10), somatotropinomas – therapist (10/14). Age at diagnosis was: NFAs 39.5 [27.8; 60.5] y.o., prolactinomas 25 [19.5; 27.5] y.o., somatotropinomas 52 [21; 67] y.o. ($P=0.009$). Compared to the general group of patients with relevant hormonal activity, patients with NFAs and prolactinomas were younger, and patients with somatotropinomas were older. Pituitary tumour volumes were: NFAs 470.3 [191; 807] mm^3, prolactinomas 384 [294; 564.4] mm^3, somatotropinomas 594 [355; 756] mm^3 ($P>0.05$). The pituitary macroadenomas were endosellar in 12/32 cases (4/8 NFAs, 5/10 prolactinomas and 3/14 somatotropinomas). Other different growth directions were suprasellar (3/8), laterosellar (3/10) and suprasellar (5/14), accordingly. Hypopituitarism (as secondary hypothyroidism) was diagnosed in 2/14 patients with somatotropinomas. Another 6 patients (4 – prolactinomas, 2 – somatotropinomas) had hypogonadism due to hyperprolactinemia.

The conclusions

Despite the small number of observations, we could describe some features of such pituitary "mini"-macroadenomas with one size less than 10 mm: mainly found in women; mainly found in prolactinomas and somatotropinomas; patients with NFAs and prolactinomas were younger and patients with somatotropinomas – older that general group of patients; in majority of cases had extrasellar extension. However, hypopituitarism was rare in such cases.

Medical treatment of acromegaly is currently performed through a trial-error manner using somatostatin receptor ligands (SRLs) as first-line drugs. Average SRLs response is seen in 50% of cases; subsequent drugs are indicated following clinical judgement. Some biomarkers either before or after surgical failure have been reported to predict SRLs response, including intensity in T2 weighted MRI, short acute octreotide test (sAOT), and different molecules such as SST2 and E-cadherin. We report the preliminary data of the ACROFAST study, a prospective trial based on the assignation of medical treatment according to SRLs response biomarkers compared to a control group.

Methods and subjects

Prospective clinical academic trial in which 21 university hospitals participated. Two protocols were compared in which the outcomes were time to control and percentage of subjects controlled at 6 and 12 months of treatment: A) a sequential protocol in which SRLs were started at mild doses (octreotide 20 mg and lanreotide 90 mg) for all patients and B) a personalized protocol in which SRLs were given as monotherapy (B1), in combination with pegvisomant (B2) or were replaced for pegvisomant as monotherapy (B3) according T2 MRI signal and sAOT in presurgical cases and the E-cadherin immunoexpression in tumor tissue in case of active disease after surgical treatment. B1 option included patients in which T2 MRI showed an hypointense signal, a GH at 2 h <2.7 ng/ml in the sAOT or had a full + immunostaining for E-cadherin. B3 option included cases in which MRI presented an hyperintense signal and sAOT GH decrease $<50\%$ over basal and in postsurgical failures, those – for E-cadherin; B2 were considered partial responders, in which sAOT showed a GH value at 2 h >2.7 ng/ml and $>$ 50% over basal together with an hypointense T2 MRI image, and in postsurgical intermediate positivity for E-cadherine.

Results

By December 2022, 73 patients have been recruited and 53 were evaluable, 27 in the personalized arm and 30 in the control sequential group. More patients in the personalized protocol 19/27 (70%) had achieved hormonal control compared to those in the sequential group – 14/30 (43%), $P<0.03$)- as well as in a shorter period of time: 263 days -8.8 months- vs 360 days -12 months- ($P<0.009$) for partial and resistant cases.

Conclusion

Personalized medicine is feasible by using a relatively simple protocol and allows a higher number of patients under control in less time since treatment initiation.

Management of necrolytic migratory erythema with lanreotide a patient diagnosed with pancreatic glucagonoma: A rare case report

Ege Ulusoydan[1], Banu Ertürk[2], Mustafa Gökhan Gedikoglu[3], Suayip Yalcın[4] & Süleyman Nahit Şendur[2]
[1]Hacettepe University, Internal Medicine, Ankara, Turkey; [2]Hacettepe University, Endocrinology and Metabolism, Ankara, Turkey; [3]Hacettepe University, Pathology, Ankara, Turkey; [4]Hacettepe University, Oncology, Ankara, Turkey

Introduction

Glucagonomas are rare neuroendocrine tumours (NET). Glucagonoma syndrome is often misdiagnosed as other skin lesions by clinicians due to typical clinical sign of necrolytic migratory erythema (NME). In this article, we report a metastatic glucagonoma case diagnosed at adult age with distinct features of the disease.

Observations

We present a case of a 28-year-old female patient. The initial rash appeared in early 2019 and was mostly on lower extremities by the ankles, which were red

patches with irregular borders, intact and ruptured vesicles, and crust formation. The patient was prescribed several topical glucocorticoids and antimicrobials, but the rash was persistent and spread over her proximal lower extremities, back, chest, face and thus became generalized. By this 15 month interval the patient also developed symptoms of weight loss of 10 kg, nausea-vomiting, night sweats and abdominal-back pain. A skin biopsy was performed in 2020 and necrolytic migratory erythema was diagnosed. The patient then admitted to investigate glucagonoma. Admission laboratory measurements demonstrated no hyperglycemia but elevated blood glucagon levels (>700 ng/ml). Initial screening demonstrated a distal pancreatic lesion and overspread metastatic liver involvement. A liver biopsy was performed and the diagnosis of glucagonoma was established. The patient was initiated lanreotide 90 mg q28d and the dose was uptitrated to 120 mg q28d after 1 year. In this time interval generalized skin rash disappeared completely, and other symptoms improved. Then, she had recieved six doses of peptide receptor radionuclide therapy. Control imaging demonstrated that partial metabolic response. And, she underwent distal pancreatectomy and liver metastasectomy. Pathology report demonstated metastatic glucagonoma. Treatment of lanreotide 120 mg per/28 day was continued postoperatively. Imaging after 3 months showed multiple metastatic lesions over the liver. A chemotherapy regimen of capecitabine, temozolomide and bevacizumab was initiated. She is still receiving treatment and is in good performance condition.

Discussion

Clinicians should consider glucagonoma diagnosis based on the typical initial symptoms. An early diagnosis is critical for a better prognosis. Treatment options include somatostatin analogs, peptide receptor radioligand therapy, cytotoxic chemotherapy and surgery. In patients with unresectable metastatic cancers, a multidisciplinary approach is effective.

Pituitary metastasis in neuroendocrine neoplasms, lesson learned from cases reports

Shawg Ganawa[1], Waqas Ilyas[2], Shadman Irshad[3], Adeel Hamad[3], Omar Pathmanaban[3], Dusan Milanovic[4], Rovel Colaco[4], Fiona Blackhall[5], Juan Valle[5], Jan Hoong Ho[1] & Safwaan Adam[1]
[1]The Christie NHS Foundation Trust, Endocrinology, Manchester, UK; [2]The Christie NHS Foundation Trust, Manchester, UK; [3]Salford Royal, Salford UK; [4]The Christie NHS Foundation Trust, Clinical Oncology, Manchester, UK; [5]The Christie NHS Foundation Trust, Medical Oncology, Manchester, UK

Introduction

Pituitary metastases (PM) are an uncommon manifestation of Neuroendocrine neoplasms (NENs) and are rarely reported. We report two cases of PM with different clinical lessons.

Case 1

A 37-year-old female underwent surgical resection for a high grade poorly differentiated neuroendocrine carcinoma of the cervix (Ki67 90%). Serial follow-up surveillance assessments revealed disease progression (local, liver, lung, and bone) for which she underwent different oncological therapies including chemo-, immuno- and radiotherapy. However, 4 years from initial diagnosis, she presented with frontal headaches and peripheral visual disturbance. MRI brain imaging revealed a 3 cm lesion within the pituitary Sella with suprasellar extension suggestive of pituitary metastasis. Treatment with dexamethasone led to symptomatic relief. Biochemistry was suggestive of secondary hypothyroidism (TSH 0.1 mU/l [0.55–4.78]; free T4 10 pmol/l [10–22]) and hypogonadotrophic hypogonadism (LH <1 mu/l; FSH 3 mU/l; oestradiol <70 pmol/l). Her pituitary lesion showed a marked reduction in size with the addition of carboplatin/paclitaxel (from 3 cm to 0.8 cm). Due to tumour size reduction and patient wishes, surgery was withheld. She was subsequently treated with external beam radiotherapy.

Case 2

A 64-year-old female diagnosed with a T2a N2 M0 lung NEN for which she underwent primary surgical resection (histology: well-differentiated grade 3 NEN [Ki67=25%]) with satisfactory postoperative cross-sectional and functional imaging. Within 12 months surveillance imaging showed bone metastases and she was commenced on lanreotide, Denosumab and external beam radiotherapy. Three months later she presented with headaches and visual disturbance; MRI brain showed 0.7 cm hypointense lesion on the pituitary gland. She was biochemically eupituitary and suspected to have an incidental pituitary adenoma. Surveillance imaging (4 months later) showed progressive increase in the size of the pituitary lesion (11 mm). Clinical symptoms and pituitary function tests revealed panhypopituitarism and DI (cortisol 84 nmol/l, ACTH <5 ng/l, TSH <0.02 mU/l, free T4 11.6 pmol/l, FSH 1 IU/l, LH 1 IU/l, serum osmolality 296 mOsm/kg [275–295], urine osmolality 87 mOsm/kg [>100], sodium 147 mmol/l [133–146], IGF-1 22 ng/ml [39–165]). She was treated with hydrocortisone, levothyroxine, and desmopressin. She underwent debulking surgery after multidisciplinary team discussion and post-operative histology was in keeping with a metastatic lung NEN. She is receiving postoperative radiotherapy.

Discussion

Pituitary metastases are rare but important in NENs and should be considered in patients with headaches, visual disturbances or features of hypopituitarism. The multimodal treatment for PM requires multidisciplinary input with individualized options being offered to the patient.

Endogenous hyperinsulinemic hypoglycemia: A retrospective analysis of 10 cases

Wafa Belabed, Fatma Mnif, Abdel Mouhaymen Missaoui, Mouna Elleuch, Nadia Charfi, Nabila Mejdoub, Mouna Mnif & Mohamed Abid
Hedi Chaker University Hospital, Department of Endocrinology and Diabetology, Sfax, Tunisia

Background and aim

Non-diabetic hypoglycemia is a rare entity that regroups several pathologies. Its exact diagnosis is mostly challenging. Endogenous hyperinsulinism is a curable cause that should be thoroughly screened. The objective of our study was to analyze the ethipathological aspects of hypoglycemia by endogenous hyperinsulinism.

Patients and methods

We conducted a retrospective study at the Endocrinology department of Hedi Chaker University Hospital, Sfax, Tunisia. We involved 10 patients investigated for endogenous hyperinsulinemic hypoglycemia, whose clinical, biochemical, and imaging peculiarities were collected from medical charts.

Results

Ten patients, 6 men and 4 women, with a mean age of 43 years (range 17–68 years) were included. The diagnosis of organic hypoglycemia was established based on Whipple's triad associating neuroglycopenic signs in all cases, a concomitant mean venous glycemia of 1.8 mmol/l (extremes: 1.2–2.8) with an improvement after glucose intake. Biological investigation results were consistent with an endogenous hyperinsulinemic hypoglycemia (a hypoglycemia concomitant to an insulinemia ≥3 mUI/l (average 19 mUI/l) and a C-peptide level ≥0.6 ng/ml (average 3 ng/ml). Topographic exploration had objectified a pancreatic lesion in 9 patients. All these patients underwent pancreatic surgery. The pancreatic lesion was histopathologically confirmed to be a well-differentiated neuroendocrine tumor in all cases. No pancreatic lesion was identified in one patient. This was a non-syndromic congenital hyperinsulinism most likely secondary to an ATP-sensitive potassium (KATP) channel defect.

Discussion

Non-diabetic hypoglycemia is a rare entity whose main etiology in adults is insulinoma. Congenital forms of hyperinsulinemic hypoglycemia can be transient or persistent, mild or severe. These conditions are present at birth and most become apparent in early infancy.

The Strongest Clinical Tool is the Patient's Voice

Margaret McBride[1,2]
[1]Lancaster University, School of Health Sciences, Bailrigg, UK; [2]Lancaster, School of Health Sciences, Lancaster, UK

Introduction

As a Cushing syndrome (CS), patient myself and healthcare researcher I recognise that the patient's voice is the strongest weapon in a clinician's toolbox. Conducting a Doctor of Philosophy (PhD), study on a condition you have been diagnosed with was a journey of discoveries. My CS took almost 7 years to diagnose having been referred to a myriad of physicians prior to my definitive diagnosis. This was the driving force behind my desire to find out if other patients had similar experiences. This paper concentrates on a section of the disease-specific health-related quality of life (HRQoL), questionnaire specifically designed for my PhD study.

Method
Qualitative analysis was performed on open questions which were based on the members' perceived changes in their social and personal lives and any further information which they experienced, negative or positive as a consequence of their Cushing's illness. Thematic analysis of the textural content given in the answers was used to ascertain patterns (*themes*). Using the frequency results for the reasons given for a change, the emerging responses were coded in hieratical order to categorize the data. This process enabled the analysis of the common themes which emerged from the members responses. The frequency (%), of responses were displayed in Graphs and reported in themes. In addition, members were asked if they were satisfied with their clinician's ability to diagnose their CS.
Result
Eighty-six members of the Pituitary Foundation participated. *81%* found that their social lives had changed and *95.7%* their personal lives had also changed creating not only a physical but an emotional impact. The main reasons were their lack of sexual desire, body changes, anxiety, depression, mood swings, personality changes, exhaustion, fatigue, and suicidal ideation. Members felt that many physicians have little time to listen. This was reflected in *61.6%* who relied on their support groups and helplines to share their experiences and seek advice. Feelings of frustration, dismay were experienced by *43.3%*, expressing that their appointments were, "rushed," with very little information, advice and what to expect regarding the long-term effects. Families were often not invited to their consultations, and this led to a lack of understanding by their families.
Conclusion
Clinicians should apply listening skills as a master key in their toolbox leading to speedier diagnosis and treatment assisting them to not only focus on the disease but adopt a patient-centred approach to treat patients as an individual with unmet needs.

Predictive clinical factors of stature gain in congenital growth hormone deficiency treated patients

Faten Haj Kacem Akid, Wafa Belabed, Abdel Mouhaymen Missaoui, Wajdi Safi, Mouna Elleuch, Fatma Mnif, Dhoha Ben Salah, Nabila Mejdoub, Mouna Mnif & Mohamed Abid
Hedi Chaker University Hospital, Department of Endocrinology and Diabetology, Sfax, Tunisia

Background and aim
The management of Congenital Growth hormone deficiency (CGHD) is based on hormonal substitution with recombinant GH. The stature prognosis may be affected by several clinical, genetic, and therapeutic factors. This study aims to assess the predictive clinical factors of stature gain in CGHD-treated patients.
Patients and Methods
We conducted a retrospective study (1991–2019) at the Endocrinology department of Hedi Chaker University Hospital, Sfax, Tunisia. We involved 87 patients diagnosed with CGHD, whose clinical, biochemical, and imaging peculiarities were collected from medical charts.
Results
The mean age at diagnosis was 14 years, with a male predominance (59%). The most frequent reason for consultation was short stature (75%). The median height was 131 cm. The bone age was behind the chronological age in all cases. The average bone age delay was 48 months. GH substitution was indicated in 60% of cases. The stature gain was significantly associated with the severity of the growth retardation, combined hypopituitarism, pituitary hypoplasia, and pituitary stalk abnormalities as shown in Table 1. The female gender was strongly predictive of reaching the target adult height (Table 2).
Discussion
To optimize stature prognosis in CGHD patients, all studies have tried to find factors that predict good responders to GH treatment. Multivariate analysis in the KIGS study established a strong correlation between parental target height and growth rate in the first year of treatment and stature gain. According to the French registry, younger age at the initiation of treatment, delayed bone age, and severity of DGH were positive predictive factors for stature gain, which is in line with our results.

Table 1: Predictive clinical factors of stature gain in CGHD-treated patients

Studied factors		Mean stature gain (s.d.)	*P*-value
CGHD	**Isolated**	1.1±1	**0.009**
	Combined	1.8±1.4	
CGHD	**Total**	1.4±1.3	0.773

Morphological pituitary abnormalities in patients with congenital Growth Hormone deficiency

Faten Haj Kacem Akid, Abdel Mouhaymen Missaoui, Wafa Belabed, Wajdi Safi, Nadia Charfi, Fatma Mnif, Dhoha Ben Salah, Nabila Mejdoub, Mouna Mnif & Mohamed Abid
Hedi Chaker University Hospital, Department of Endocrinology and Diabetology, Sfax, Tunisia

Background and aim
Disorders of the development of the pituitary gland could result in some forms of Congenital Growth hormone deficiency (CGHD). This study aims to assess the morphological abnormalities of the pituitary gland in patients with CGHD.
Patients and Methods
We conducted a retrospective study (1991–2019) at the Endocrinology department of Hedi Chaker University Hospital, Sfax, Tunisia. We involved 87 patients diagnosed with CGHD, whose clinical, biochemical, and imaging peculiarities were collected from medical charts.
Results
The mean age was 14 years, with a male predominance (59%). Seventy-five percent of patients were referred for short stature. We noted a delayed diagnosis in 65% of cases. The median height was 131 cm. Severe growth delay was noticed in 38.6% of cases. The average delay of bone age was 48 months. Eighty percent of CGHD patients combined hypopituitarism. A positive correlation was established between the precocious onset of the pituitary dysfunction and the presence of pituitary hypoplasia ($P=0.009$), as well as with the severity of growth retardation ($P=0.016$) and the number of affected axes ($P=0.02$). The latter correlation was significant when three or more pituitary axes were involved, which also remained significant for pituitary stalk anomalies. Posterior pituitary ectopy was inversely correlated with the age of discovery of hypopituitarism ($P=0.001$) but not with neonatal distress ($P=0.28$).
Discussion
The hypoplastic pituitary is the most common morphological abnormality in patients with CGHD since GH-secreting cells represent the largest cell population in the pituitary gland. In our cohort, 49.4% of CGHD cases had pituitary hypoplasia. Similar findings were reported in literature where hypoplasia was noted in 59% to 61% of patients. Pituitary stalk abnormalities expose the affected patient to a 3.28-fold increased risk of progression to combined forms of hypopituitarism.

Table 1: Predictive clinical factors of pituitary abnormalities in patients with CGHD

Studied factors	Normal pituitary	Pituitary Hypoplasia	*P*-value
Age at diagnosis (years)	14	11	**0.009**
Severe statural retardation	61%	84%	**0.016**
Number of hypopituitarisms	2.3	3.1	**0.02**
Severity of GHD	46%	54%	0.16

Table 2: Morphological pituitary abnormalities and the number of hormonal dysfunctions in patients with CGHD

Hormonal dysfunctions	Normal pituitary	Pituitary hypoplasia	Pituitary stalk abnormality
Isolated CGHD	64%	35%	11%
2 axes	68%	31%	18%
3 axes	50%	50%	27%
4 axes	33%	66%	60%
5 axes	11%	88%	66%
***P*-value**	**0.037**	**0.037**	**0.001**

Predicting the risk of developing cerebrospinal fluid fistula in patients with prolactinoma

Diana Cuconu[1], Alexandra Marin[1] & Corin Badiu[1,2]
[1]National Institute of Endocrinology, Thyroid Related Disorders, Bucharest, Romania; [2]"C.Davila" University of Medicine and Pharmacy, Endocrinology, Bucharest, Romania

Introduction
Prolactin secreting pituitary adenoma represents the most common functioning pituitary neoplasm with a clinical picture that includes amenorrhea, galactorrhea and infertility. Tumor size may vary from microadenomas amendable to medical therapy with dopamine agonists to macroadenomas with difficult management. Complications are usually related to tumor size and most frequently include hypogonadism alone or associated with other pituitary deficiencies, visual field defects, headache and cranial neuropathies. Cerebrospinal fluid fistula represents a rare but severe finding that can complicate the evolution of prolactinomas.
Materials and methods
We report three cases of prolactinomas complicated with cerebrospinal fluid leak either spontaneously or during the course of treatment. The patients were all males, with age between 22 and 66 years and high tumor volume and prolactin values at diagnosis. The first patient presented with bitemporal hemianopia with an 86/77/64 mm sellar mass invasive into the suprasellar region and both sphenoid sinuses and a prolactin value at diagnosis of 11 432 ng/ml. He developed cerebrospinal fluid fistula after 9 months of treatment with cabergoline, at the attempt of increasing the dose from 3 mg/week to 4.5 mg/week. The second patient was diagnosed with pituitary macroadenoma on cerebral CT starting from clinical features that included headache, visual field defects and hypogonadism and performed transfrontal adenomectomy as first line therapy. His postoperative course was complicated by transient diabetes insipidus, hypopituitarism and cerebrospinal fluid leak that required surgical repair. Diagnosis of prolactinoma was established at the postoperative evaluation due to high levels of prolactin of 10 635 ng/ml and received treatment with dopamine agonists. The third patient presented with spontaneous rhinoliquorrhea and an invasive pituitary tumor of 67/45/44 mm. He performed transsphenoidal debulking of pituitary adenoma and surgical repair of the sellar floor. Postoperative, diagnosis of prolactinoma was made, with a prolactin value of 18 638 ng/ml and treatment with cabergoline was initiated.
Discussion
Cerebrospinal fluid fistula is a life-threatening condition associated with a high risk of developing meningitis, intracranial abscess and pneumocephalus. Postulated mechanisms are invasive pituitary macroadenomas with bone destruction in the sellar floor. Tumor shrinkage induced by medical or surgical treatment uncovers the bone defects leading to cerebrospinal fluid rhinoliquorrhea. Surgical repair via a transphenoidal approach is mandatory and long term follow-up is usually needed.

Pituitary macroadenoma, incidental finding after soccer match

Cristina Serrano Valles, Higinio Ortega Sanchez, Cristina Contreras Pascual & Karol Almendra Alvarado Rosas
Complejo Hospitalario de Soria, Endocrinología y Nutrición, Soria, Spain

Introduction
Thyrotropin-secreting pituitary tumors (TSH-omas) are a rare disorder and an infrequent cause of hyperthyroidism. The prevalence in the general population being 1 to 2 cases per million. However, recents studies have demonstrated an increase of TSH-omas over time. The increased number of cases principally results from the ultrasensitive TSH immunometric assays and from improved general practioner endocrinologist awaress. There is an inappropriate secretion of TSH due to autonomous and refractory to the negative feedback of thyroid hormones. In about 30% of patients with pituitary adenomas, hypersecretion of other pituitary hormones can be detected. The most frequent associations are the hypersecretion of GH and/or PRL.
Clinical case
A 28-year-old woman attended the emergency room by left hemicranial headache after accidental head injury in a soccer match. Pituitary MRI found a pituitary macroadenoma (18.5×25×31.5 mm). There are no symptoms of amenorrhea or galactorrhea. She also didn't complain of symptoms of tachycardia, tremor or weight loss. She didn't refer changes in shoe or ring size. On examination, there is no goiter or other stigmata of endocrine dysfunction. Laboratory evaluations showed central hyperthyroidism (FT3 6.85 pg/ml, FT4 1.98 ng/dl, TSH 6.66 mU/l), circulating free alpha-GSU elevation (> 9 mUi/l), insulin-like growth factor elevation (IGF-1 237 ng/ml) and hyperprolactinemia (PRL pool 64.97 ng/ml). TRH stimulation test was performed and TSH and alpha-GSU levels didn't increase after TRH injection. GH nadir concentrations after 75 mg oral glucose tolerance test (OGTT) was ≥1 µg/l. Therefore, hypersecretion of thyrotropin and GH was confirmed. Hyperprolactinemia was attributed to pituitary stalk compression. The patient was prescribed the somatostatin analogues (somatuline autogel 60 mg every 28 days). After 1 month of treatment, IFGF-1 level decreased to 180 ng/ml and normalitation thyroid function (FT3 2.48 pg/ml, FT4 0.97 ng/dl, TSH 2.48 mU/l). Somatuline autogel dose was titrated up to 120 mg every 60 days. After 3 months of treatment, tumor size has been reduced (18×19×16 mm). A transnasal adenoidectomy was performed with restoration of euthyroidism and normalization of IGF1 and PRL levels. Preserved pituitary function after surgery resection. The pathological anatomy showed positive cells for synaptophysin, CAM 5.2 TSH and GH.
Conclusions
TSH-omas are rare pituitary tumors but the use of ultrasensitive immunoassay methods and the increase in imaging tests allow early diagnosis. Treatment with somatostatin analogues may be useful to reduce hyperthyroid signs and symptoms, as well as the adenoma size.

Homocysteine levels in acromegaly patients: comparison of active disease with remission

Seher Tanrikulu[1], Zeynep Ece Demirbas[2] & Mehmet Emre Elci[2]
[1]Acıbadem Ataşehir Hospital, Istanbul, Turkey; [2]Dr. Siyami Ersek Thoracic And Cardiovascular Surgery Education Research Hospital, Istanbul, Turkey

Objective
Acromegaly is associated with increased cardiovascular mortality. Hyperhomocysteinemia has been associated with cardiovascular disease, lower-extremity peripheral arterial disease and heart failure. Data on the prevalence of hyperhomocysteinemia and peripheral arterial disease in patients with acromegaly is still limited. The aim of this study was to compare serum homocysteine levels between acromegaly patients with active disease and remission, and to evaluate presence of peripheral arterial disease.
Material and Method
A single-center, cross-sectional study was conducted in patients with acromegaly. Patients were compared with respect to their serum homocysteine levels, clinical and metabolic parameters, and ankle brachial index (ABI). Patients who had folate, vitamin B6, or vitamin B12 deficiency; chronic kidney disease; using drugs that change homocysteine levels were not included in the study.
Results
A total of 31 patients (19 female/12 male), diagnosed with acromegaly were recruited for this study. Patients were divided into two groups: active disease (group 1, $n=18$) and remission (group 2, $n=13$). Fasting blood glucose level were higher in group 1 than group 2 (111 ± 22.3 vs. $93\pm10,9$ mg/dl, respectively, $P=0.01$). Only one patient had low ABI whose homocysteine level was normal. ABI were similar between the active disease and remission groups. Homocysteine levels were high in 12 (37.5%) patients (6 in group 1 and 6 in group 2) and body mass index was higher in pateints with elevated homocysteine levels (29.6 ± 3.8 vs. 26.8 ± 3.7, $P=0.04$). Although ABI were not correlated with homocystein levels, especially systolic blood pressure in both posterior tibial arteries were low ($P=0,048$).
Conclusion
This study revealed that high homocysteine levels are associated with increased body mass index. Since acromegaly patients more prone to risk of cardiovascular disease, it is important to examine all possible risk factors in these patients.

Pituicytoma – case report of an extremely rare and little-studied primary tumour of the adult neurohypophysis

Muhammad Taqi[1], Shahzad Akbar[2], Shah Rukh Malik[2] & Shiva Mongolu[2]
[1]Hull Royal Infirmary, Endocrinology and Diabetes, Hull, UK; [2]Hull Royal Infirmary, Kingston upon Hull, UK

The pituicytomas are extremely rare and little-studied primary tumours of the adult neurohypophysis. These are low-grade (World Health Organization [WHO] grade 1), indolent gliomas which present as a sellar mass, which is usually mistaken for a pituitary adenoma, and has no known hormonal secretory function. A 63 years old retired paediatrician was referred to the neurology clinic with the

history of constant severe headache ongoing for a few weeks. It involved the whole of the head and was associated with dizziness. There were no postural symptoms and no history of vomiting or nausea or any signs of raised ICP. His past medical history included hypertension, cataract and glaucoma. An urgent MRI head, requested by Neurology, revealed a pituitary lesion which was not fully characterised. He subsequently had a pituitary MRI which showed left sided pituitary adenoma of 7×8×8 mm size with areas of previous haemorrhage. He was urgently seen in Endocrinology clinic and the blood test for anterior pituitary profile were normal. MRIs at the intervals of 6 months and then 18 months showed a slow growth in the tumour size to 15×11 mm with the compression on the right optic chiasm. Formal visual field test showed normal field of vision in the right eye and a stable defect in the left eye. This case was discussed in pituitary MDT and it was thought to be likely craniopharyngioma at that point. Transsphenoidal surgery was offered due to enlarging lesion and constant headache. Surgery was aimed at significant debulking and it went well without any complications. Histology report confirmed pituicytoma. Patient remained very well and his symptoms of headache resolved with an improvement in his vision and visual field. His pituitary function remained normal. Patient was interested to explore the options of radiosurgery or radiotherapy for the remnant part of the cytoma. His case was discussed in the pituitary MDT at another centre which admitted that there was paucity in experience with a rare tumour like pituicytoma and advised to continue conservative approach and to consider repeat surgery or SRS if the growth recurs. It has been a very interesting case for Endocrinology, Neurosurgery, Radiology and Oncology teams who have been involved in his care. Patient, being a doctor himself, had a very good understanding of his condition and was aware of the rare nature of the tumour. We continue to follow him up in our Endocrine clinic.

Vitamin D status and cardiovascular risk in a cohort of acromegalic patients

Iustin-Daniel Toma[1,2], Raluca Trifanescu[1,2], Maria-Alexandra Mohora[2], Ionela Baciu[1,2], Nicoleta Baculescu[1,2], Iulia Florentina Burcea[1,2], Cristina Capatina[1,2], Roxana Dusceac[2], Găloiu Simona Andreea[1,2], Dan Alexandru Niculescu[1,2], Ileana Nitu[3], Serban Radian[1,2] & Catalina Poiana[1,2]
[1]Carol Davila University of Medicine and Pharmacy, Endocrinology, Bucharest, Romania; [2]C. I. Parhon National Institute of Endocrinology, Pituitary and Neuroendocrine Disorders, Bucharest, Romania; [3]C. I. Parhon National Institute of Endocrinology, Cardiology, Bucharest, Romania

Background
Vitamin D deficiency is the most common nutritional deficiency, estimated to affect almost one billion people worldwide. Multiple factors influence 25(OH)D levels: nutrition, sunlight exposure, outdoor physical activity, skin color. Patients with active acromegaly (AA) have lower 25(OH)D levels compared with healthy population and are at a higher risk to develop vitamin D deficiency. Also, some studies have suggested a possible protective role of vitamin D on the cardiovascular system.
Aim
To assess the impact of vitamin D deficiency on cardiovascular disease risk (CVD) in patients with acromegaly from Romania, a country situated in northern hemisphere at latitudes greater than 40°N.
Methods
Retrospective study by analyzing the files of patients with confirmed acromegaly who underwent treatment in a tertiary endocrine center. 134 patients (91F/43M) were included. IGF1, GH, 25(OH)VitaminD were measured by chemiluminescence either at diagnosis of acromegaly or throughout the follow-up. Total, LDL ad HDL cholesterol, triglycerides, serum glucose, HbA1c, blood pressure were also measured and the acromegaly activity was assessed according to the newest guidelines. The ACM patients were divided into three subgroups: active acromegaly (AA), controlled acromegaly (CA) and cured acromegaly. The cardiovascular disease (CVD) risk has been assessed at the moment of vitamin D dosage using European's Society of Cardiology (ESC) CVD risk tool.
Results
Globally, 95 patients had AA, 30 patients-CA, 3 patients were cured, whilst for 6 patients there was not enough information to quantify their acromegaly status. Mean age at vitamin D dosage was 51.3±12.4 years. AA patients had more frequently normal total cholesterol and triglycerides values if their 25(OH)D was over 20 ng/ml ($P=0.008$ respectively $P=0.05$; chi-sq). AA women also had more frequently normal cholesterol values if their 25(OH)D levels were > 20 ng/ml ($P=0.01$; chi-sq). No differences were found between vitamin D and lipid profile in the other 2 subgroups, regardless of gender. However, after excluding diabetic acromegalic patients, when calculating the personal risk profile for each AA patient ($N=53$, F+M) using ESC CVD Risk tool and classifying them into low, moderate and severe risk according to age, subjects with 25(OH)D < 20 ng/ml levels had more frequent a moderate and severe 10-year CVD episode risk ($P=0.03$; chi-sq).
Conclusion
Patients with active acromegaly may benefit from dosing the 25(OH)D levels and, if needed, prescribing supplementation may help. Therefore, further prospective studies evaluating the impact of vitamin D levels on CVD risk are necessary to confirm these findings definitively.

Hyponatremia apparently due to carbamazepine as the initial presentation of panhypopituitarism in a patient with a non-functioning pituitary tumour

Andreea Vladan[1], Cristina Iancu[2], Serban Radian[1,2] & Catalina Poiana[1,2]
[1]C. Davila University of Medicine and Pharmacy, Bucharest, Romania, Dept of Endocrinology, Bucharest, Romania; [2]C.I. Parhon National Institute of Endocrinology, Department of Pituitary and Neuroendocrine Diseases, Bucharest, Romania

Introduction
Hyponatremia, defined as a serum sodium concentration below 135 mEq/l, has a heterogeneous etiology, the main endocrine causes includind the syndrome of inappropiate antidiuresis (SIAD), adrenal insufficiency and severe hypothyroidism.
Materials and methods
Clinical, hormonal and imaging evaluation
Aim
To present a case of hyponatremia leading to the diagnosis of a large pituitary tumor
Case presentation
A 61 year-old male with a history of grandmal epilepsy treated with carbamazepine 600 mg/day, arterial hypertension, type 2 diabetes mellitus on oral antidiabetic drugs, obesity and dyslipidemia, presented initially to the ER for fatigue, nausea and emesis. Three weeks prior to presentation, he had undergone a laparoscopic intervention for an inguinal hernia. Physical examination revealed hypotension (BP=90/70 mmHg). Serum biochemistry revealed severe hyponatremia (107 mEq/l), hypochloremia and hypokalemia (2.5 mEq/l). Causes of pseudohyponatremia (hyperglycemia, hyperlipemia and hyperproteinemia) were ruled out. A cerebral CT scan demonstrated a pituitary tumor (2.1/2.7/3.1 cm) invading the right cavernous sinus. Biochemical tests of pituitary function demonstrated hypogonadotrophic hypogonadism and possible hypocortisolemia (5.8 µg/dl at 1300 h). Immediate administration of 3% NaCl and replacement of carbamazepine (a known SIAD cause) with levetiracetam led to gradual improvement. Ten days after initial presentation, the patient was admitted to our department for complete endocrine workup. On admission, clinical status was unremarkable, except for a right eye temporal visual field defect. Laboratory tests demonstrated panhypopituitarism and normoprolactinemia. His general status improved upon glucocorticoid replacement therapy followed by thyroid replacement. Ophtalmological examination showed optic chiasm syndrome, with right eye temporal hemianopia and left eye temporal and inferior quadrantanopia. The pituitary MDT recommended a pituitary MRI and neurosurgical evaluation, which are pending.
Conclusions
Our case illustrates the incidental discovery of a pituitary tumour and hypopituitarism in a pacient who already had a plausible cause of SIAD. Awareness of various causes of hyponatremia and attention to clinical detail are critical for detecting the complete etiology, which determines appropriate treatment in hyponatremia.

Survey on caregivers' experiences and perspectives on children's daily growth hormone treatment

Pia Korhonen[1], Jarno Ruotsalainen[2], Mari Pölkki[2], Tuire Prami[2], Mia Siven[3] & Juha Turunen[1]

[1]Pfizer Oy, Helsinki, Finland; [2]Oriola, Espoo, Finland; [3]University of Helsinki, Helsinki, Finland

Background and objective
Human recombinant growth hormone (hrGH/GH) is an injectable medication used commonly for growth hormone deficiency (GHD) and other health conditions that reduce growth and adult height. Daily GH injections can burden families and result in poor adherence. This study was conducted to investigate caregivers' experiences, attitudes and preferences regarding pediatric GH treatment. At the time of data collection, the long-acting GH products were not available on the market.
Methods
This survey to the caregivers of under-aged patients using GH was conducted in 50 community pharmacies across Finland between June 2021 and April 2022. Caregivers were identified in pharmacies when purchasing GH. They were asked to complete an anonymous semi-structured electronic questionnaire on a tablet computer.
Results
Total of 78 caregivers responded to the survey. Mean age of the children on GH treatment was 10.1 years (range 2–17 years). Two thirds (65.4%) of them were boys. Most common indications for GH treatment were GHD (67.9%) and small for gestational age without catch-up growth (10.3%). Two thirds (67.9%) of children had been using GH for 3 years or longer, and one third (32.1%) for 2 years or less. All caregivers were very satisfied (70.5%) or quite satisfied (29.5%) with the GH treatment. However, three out of four caregivers (74.4%) reported at least one challenge related to the GH treatment. The most common challenges were administration by injection (35.9%), cold storage requirement (35.9%), high price (16.7%) and child's unwillingness to take GH (10.3%). Caregivers were asked to describe in their own words an as good and well functioning GH treatment they can think of. Open answers were categorized and quantified. Most frequently mentioned attributes were less frequent dosing interval (25.6%), storage in room temperature (24.4%) and easy-to use dosing device (23.1%). Also good response (11.5%), different administration route, such as cream or tablet (9.0%) and few adverse effects (7.7%) were mentioned.
Conclusions
All caregivers were satisfied with the GH treatment. However, nearly 75% of the responders identified treatment-related challenges. The most frequently reported challenge was the mode of administration (injection). When describing optimal GH treatment, the wish for a less frequent dosing interval was the most often mentioned. Data from this survey can provide support in selecting the optimal type of GH treatment for paediatric and adolescent patients.

Introduction
Non-alcoholic fatty liver disease (NAFLD) is a systemic, metabolic condition associated with increased morbidity and mortality. Defined by an increase in hepatic lipid content (HCL), NAFLD develops in consequence of lipid oversupply and/or a diminished disposal of hepatic lipids. The latter may include an impaired export of triglycerides (TG) via the secretion of very-low density lipoprotein1 (VLDL1) particles, an important mechanism of the liver to protect itself from steatosis. Growth hormone (GH) is known for its beneficial effects on body composition and increases lean body mass by favouring overall lipid consumption. Furthermore, studies in acromegalic patients suggest excessive GH secretion to decrease HCL. Although current data are conflicting, GH might mediate the reduction of HCL by fostering the export of TG rich VLDL1 particles.
Aim and methods
We aimed to determine the impact of exogenous GH treatment on hepatic TG export, hypothesizing an increase of VLDL1-TG secretion after short-term GH excess. Therefore, using an intralipid infusion protocol, VLDL1-TG secretion was assessed in five healthy, male volunteers (age 26.8±4.7 years; BMI 23.8±3.8 kg/m^2) at baseline and after one week of GH treatment with daily injections of 2 mg Genotropin®. Parameters are given as mean ±standard deviation and paired *t*-test was used for analysis.
Results
After one week of GH treatment, secretion of VLDL1-TG increased in four of five cases, depicted by a mean increase of 10.5% (687.8±289.2 vs. 813.2±518.8 mg/h, $P=0.294$). Marked increases in serum IGF-1 (231.2±22.3 vs. 480.4±101.8 ng/ml, $P=0.009$), insulin (8.3±3.1 vs. 16±3.6 µIU/ml, $P=0.021$), and C-peptide (1.8±0.3 vs. 2.5±0.7 ng/ml, $P=0.088$) indicated a sufficient impact of GH dosage.
Future perspective
This preliminary analysis shows a trend towards increased VLDL1-TG secretion in response to short-term subcutaneous GH treatment in humans. Further investigation of GH-mediated hepatic TG export might pave the way for novel therapeutic strategies in the treatment of NAFLD.

Patient-centric design of the lonapegsomatropin auto-injector for pediatric growth hormone deficiency

Michael Lau[1], Paul Erik Fabricius[2], Josephine Jensen[3], Nils Berg Madsen[3] & Henrik Egesborg[3]
[1]Nemera Insight Chicago LLC, Chicago, USA; [2]Phillips-Medisize A/S, Struer, Denmark; [3]Ascendis Pharma A/S, Hellerup, Denmark

Background
Lonapegsomatropin (SKYTROFA™; TransCon hGH), an FDA and EMA approved once-weekly prodrug of somatropin for pediatric growth hormone deficiency (pGHD), uses TransCon® technology to transiently link an inert carrier to a parent drug to achieve sustained release. Daily growth hormone injection, standard treatment for pGHD for decades, may be associated with challenges including needle anxiety and low adherence. The lonapegsomatropin Auto-Injector, winner of two innovation awards for drug delivery and patient-centric design, was developed through user testing and feedback to complement weekly lonapegsomatropin and minimize challenges in reconstitution and injection. Key design features of the Auto-Injector include a hidden needle, empty-all cartridge design, and icons to indicate and guide completion of all steps.
Aim
The lonapegsomatropin Auto-Injector was evaluated under simulated use conditions as outlined in FDA guidance: "human factors and usability engineering processes are performed to maximize the likelihood that new medical devices will be safe and effective for the intended users, uses and use environments… without serious use errors or problems."
Methods
Usability of the lonapegsomatropin Auto-Injector was evaluated in trained and untrained patients (pGHD or other chronic conditions requiring injection,) caregivers, and health care providers (HCPs) responsible for giving injections or training patients/caregivers. Auto-Injector, cartridges, packaging, instructions for use (IFU), quick reference guide, helpline, and training video were available for self-exploration. Participants were evaluated on device use, charging, and comprehension of IFU.
Results
All participants, (120 children and caregivers, 60 injection-naïve, and 15 HCPs) were able to complete an injection successfully with the lonapegsomatropin Auto-Injector. Usability issues observed for injection tasks for all participants were low and comparable to typical observations in usability studies: patients (3.2%), caregivers (2.4%), and HCPs (2.8%). All participants reported they could follow the instructions as written and 98% of participants felt they could use the device as intended on their own or with supervision (patients only).
Conclusions
The patient-centric design of the award-winning lonapegsomatropin Auto-injector leads to successful, confident usage in which participants can follow the instructions to deliver an injection as intended. Together with once-weekly lonapegsomatropin, the lonapegsomatropin Auto-Injector may overcome challenges in treatment of pGHD such as needle anxiety and difficulties with

injection, with the potential to improve adherence which has been shown to impact outcomes in real-world use.

Tumor mimicking ampullary carcinoma in a patient with acromegaly

Molka Ben Bnina, Sabbagh Ghada, Hamza Elfekih, Ghada Saad, Barkallah Fatma, Yosra Hasni & Molka Chadli Chaieb
Farhat-Hached University Hospital, Endocrinology-Diabetology Department, Sousse, Tunisia

Introduction
Acromegaly is the set of clinical manifestations induced by chronic exposure to an endogenous excess of growth hormone (GH). Most often, acromegaly is related to GH production by a pituitary adenoma. It may be associated with neuroendocrine tumors of the pancreas as part of multiple endocrine neoplasia type 1 (MEN1). Herein, we described a tumor mimicking a carcinoma of the Ampulla of Vater in a patient with acromegaly.
Observation
A 54-year-old patient has an over 13-year history of acromegaly secondary to a pituitary macroadenoma of 21 mm with lateral extension to the left cavernous sinus. His acromegaly was complicated by diabetes mellitus, hypertension, colonic diverticulosis, and an EU-TIRADS III thyroid nodule. The patient underwent a transsphenoidal surgery that was complicated by transient central diabetes insipidus and a corticotropin deficiency. IGF-1 levels remained elevated postoperatively although the absence of residual tumor. Hence, monthly octreotide injections were prescribed complicated by a vesicular lithiasis operated 5 years ago. During follow up, the patient presented one year ago epigastralgia associated with jaundice, elevated liver enzymes and cholestasis. An abdominal MRI revealed ampullary carcinoma that was ruled out later histologically after pancreaticoduodenectomy.
Discussion
Acromegaly is a chronic, progressive and systemic disease that requires long-term treatment and follow up. Its association with a carcinoma of the Ampulla of Vater, which is a tumor with a poor prognosis, was not reported in the literature, contrary to the neuroendocrine tumors of the pancreas. A biopsy of the inflammatory tumor in our patient would prevent a major surgery.

Immune landscape of peripheral blood mononuclear cells in patients with Cushing's syndrome and mild autonomous cortisol secretion

Ariane Bäuerle[1], Hanna F Nowotny[1], Natalie Doll[1], Stephanie Zopp[1], Elisabeth Nowak[1], Frederick Vogel[1], Adrian Gottschlich[2], Thomas Marchant Seiter[1], Nicole Reisch[1], Simon Rothenfußer[2], Kroiss Matthias[1], Leah Braun[1] & Martin Reincke[1]
[1]University Hospital LMU Munich, Department of Internal Medicine IV, Munich, Germany; [2]University Hospital LMU Munich, Division of Clinical Pharmacology, Medicine IV, Munich, Germany

Background
Endogenous Cushing's syndrome (CS) is associated with increased susceptibility to infections and mortality. Previously reported effects of hypercortisolism on immune function include a reduced CD4+/CD8+ ratio with a shift towards IL4+T helper cells (Th2), suppressed NK-cell cytotoxic activity as well as a low-grade inflammatory profile.
Aim
This cross-sectional single center study aims to compare immune phenotype in patients with overt CS, mild autonomous cortisol secretion (MACS), CS on long-term adrenostatic treatment (> 5 months, LAT) and healthy controls.
Methods
T- and NK-cell subsets from peripheral blood mononuclear cells (PBMCs) isolated by density gradient centrifugation were analyzed using multicolor flow cytometry in 20 overt CS, 15 MACS, 15 LAT patients and 63 age and sex matched healthy controls.
Results
We found a significant reduction of CD4+/CD8+ ratio in patients with overt CS (median 1.7, IQR 0.65) and LAT (median 1.61, IQR 0.89), compared to healthy controls (median 3.18, IQR 2.43), with a significant shift towards Th2 differentiation. In contrast, there was no significant reduction of CD4+/CD8+ ratio in MACS (median 2.47, IQR 1.4), while the shift towards Th2 differentiation was still significantly present. FoxP3+ regulatory T cells (Tregs) and the overall NK-cell count were significantly reduced in patients with overt CS, LAT and MACS ($P<0.0001$), compared to healthy controls, with upregulated CD56dimCD16bright NK-cells and CD107a expression. Patients with overt CS presented with a significant reduction of activating ($P=0.0028$) and inhibitory ($P=0.0161$) NK-cell receptors. Patients on LAT and patients with MACS were found to have reduced NKp46 expression ($P<0.0001$) with no significant change in inhibitory NK-cell receptors, overall outweighing the presence of activating NK-cell receptors.
Conclusion
Altered CD4+/CD8+ ratios in patients with overt CS and LAT suggest a higher susceptibility to opportunistic and viral infections. The suppression of Tregs implies a chronic inflammatory state in all patient subgroups. Upregulation of cytotoxic NK-cell subsets may be a compensatory mechanism to suppression of activating NK-cell receptors. Changes in immunophenotype found in patients with MACS indicate less pronounced alterations compared to overt CS. Immunophenotype of patients with CS appears to be unchanged by LAT.

Clival prolactinoma: A case report

Meriem Adel, Marwa Chiboub, Ben Salem Maram, Chayma Besrour, Hajer Kandara, Manel Jemel & Ines Kammoun
Nutrition, Endocrinology, Tunis, Tunisia

Introduction
Ectopic pituitary adenomas (EPAs) are extremely rare intracranial tumors. Since 1909, few cases has been reported in the literature. We report a case of clivus prolactinoma.
Case report
A 52-year-old women with a history of infertility, presented one year ago at the emergency with headaches and a sudden decreased visual acuity. The pituitary MRI revealed an arachnoidocele, pituitary adenoma of the left cavernous lodge measuring 20×18×17 mm, with ectopic development in the clivus. Pituitary workup showed a hyperprolactinemia at 225 ng/ml, a cortisol level 60 min after synacthen at 517.3 nmol/l, but a peripheral hypothyroidism with a high TSH level at 9.6 µUI/ml and a low FT4 level at 12.2 pmol/l normal range (12–22). The evolution was marked by a spontaneous resolution of hedaches and total visual recovery. Thus, a medical treatement was decided.The patient has recieved dopamin agonists with prolactin normalisation but persistance of the same tumor's size.
Conclusion
Clival tumors represent 1% of intracranial neoplasms. EPAs are thought to originate from remnants of the embryological migratory path of the pituitary gland.In the literature review, the most diagnostic presentation of clival adenomas are headache. Focal neurological deficits can be seen in case of the compression of adjacent structures. Clival adenomas are functional in 75% of cases, prolactin-secretion is the most frequent. Pharmacotherapy is the first line treatment but the results are discordants.

A case of Turner syndrome associated with growth hormone deficiency

Cristina Serban[1], Nicoleta Baculescu[1,2] & Catalina Poiana[2,3]
[1]Department of Pituitary and Neuroendocrine Disorders, C.I.Parhon National Institute of Endocrinology, Bucharest, Romania; [2]Department of Endocrinology, Carol Davila University of Medicine and Pharmacy, Bucharest, Romania; [1]Department of Pituitary and Neuroendocrine

Disorders, C.I.Parhon National Institute of Endocrinology, Bucharest, Romania

Background
Turner syndrome (TS) is an important cause of short stature, however, there are a few reported cases of concomitant occurrence of TS and growth hormone deficiency (GHD).
Case report
We report a 23-year-old female with concominat TS and GHD, also presenting partial FSH/LH deficiency and primary myxedema. The patient had iniatially been evaluated at the age of 15 for short stature and primary amenorrhea when she was diagnosed with Turner syndrome (45 X karyotype) and primary hypothyroidism, but didn't comply with treatment and follow-up recommendations. At clinical examination she was 130 cm (−5.4 SDS) and 47 kg in weight with proportionate dwarfism, dysmorphic facial features, webbed neck, brachydactyly, broad chest with wide-spaced nipples, genu valgum, flat feet, secondary sexual characters rated B2, P1 according to Tanner's classification. Bone age was 9.5 years. Biochemical tests revealed: FSH = 22.36 UI/l (n = 3.85–8.78), LH = 1.69 UI/l (n = 2.12–10.89), Estradiol = 18.36 pg/ml (n = 22.4–115); IGF-1 = 88.42 ng/ml (n = 103–326); PRL = 28.7 ng/ml (n = 3–26.72); freeT4 < 5.15 pmol/l (n = 9–19), TSH > 100 uUI/ml, ATPO > 1000 UI/ml. Other hormone levels were within normal ranges. The serum ionogram, glucose, hepatic and renal function were also normal. Abdominal CT scan excluded renal anomalies. Echocardiogram was normal. The patient received Levothyroxine 75 µg/day with progressive normalization of thyroid hormone profile. During the next 3 months, PRL level normalized, but FSH (22.45 U/l) and LH (7.19 U/l) values indicated persistence of partial gonadotropin deficiency. Considering the severe short stature, we evaluated GH response in ITT, with peak GH after insulin induced hypoglycemia of 0.31 ng/ml demonstrating GH deficiency. Sella MRI showed adenohypophysis of normal size, convex cranially and inhomogeneous basally on the left side by the presence of a microadenoma of 6.5/4/7 mm. We considered the bone age of 9.5 years and unfused epiphyseal plates demonstrating growth potential and the rhGH therapy was initiated, at a dose of 30 µg/kg per day given by subcutaneous injection. The initiation of estrogen replacement therapy was postponed in function of the patient's growth velocity. In a 3 month follow-up she grew 1.8 cm in height.
Conclusions
We presented a patient with Turner syndrome with severe short stature by concomitant GH deficiency; in this case with a non-functioning pituitary microadenoma, we can not exclude the hyperplasia of the TSH-producing cells associated with a long time untreated primary myxedema as a supplementary cause of GH deficiency. We will perform the long-term follow-up with close monitoring of rhGH therapy.

Sheehan syndrome revealed by acute adrenal insufficiency 3 months after the delivery

Rihab Laamouri[1,2], Agnès Smagala[1] & Racolta Niculina[1]
[1]Civil Hospital of Colmar, Endocrinology Department, Colmar, France; [2]Faculty of Medicine of Strasbourg, Strasbourg, France

Introduction
Sheehan syndrome (SS) is a hemorrhagic necrosis of the pituitary gland responsible of anterior pituitary insufficiency. It occurs in a context of cerebral hypo flow due to a rapid blood pressure drop and/or acute hemorrhagia. We report a case of SS revealed by acute corticotropic insufficiency.
Case report
A sunday morning 34 years-old woman consulted the emergency department for of a fatigue and diarrhea. She reported a 7 kg weight-loss in the late 2 months associated with a lack of appetit. Her blood pressure 96/56 mmHg. Biologic assessment showed a natremia at the low range and a normal kaliemia. Hypoglycemia at 0.38 g/l was objectified. An acute adrenal insufficiency was suspected. Intravenous hydrocortisone and glucosed fluid infusion immediately after cortisol blood sample. The hormonal assesment confirmed a corticotrope insufficiency with a low level of both plasma cortisol 113 nmol/l (<138) and ACTH <0.2 nmol/l. Bacterial infection by Aeromonas punctata was confirmed. Oral antibiotic treatment using Ciprofloxacine 500 mg twice a day stoped diarrheas. Three months before, the patient reported an hemorrhagic delivery, a lack of lactation and persistance of amenorrhea. Other typical symptomes were also found: lack of pubic and axillairy pilosity and vaginal dryness. In this clinical context the diagnostic of SS was retained. A screening of other pituitary dysfunction showed, a thyreotrope insufficiency (low fT4 and fT3 with low normal TSH level), a low FSH and LH levels and low prolactinemia. IGF1 level was normal. After 48 h glucocorticoid substituition the patient presented a polyuric poludipsic (PUPD) syndrome. The fluid restriction test was rapidly stopped because of hypernatremia at 150 mmol/l. The treatment by desmopressin 90 µg/d was initiated with resolution of the PUPD syndrome and natremia normalisation. Pituitary MRI showed a sequelae-like changes involving the entire pituitary gland but respecting its stem. Post hypophyse was reduced to punctiform hyposignal T1. The diagnosis of central insipidus diabetes was confirmed.
Comments and conclusions
SS is due to a necrosis of the pituitary gland in the context of reduced brain output. Sometimes the diagnosis of this rare syndrome may be delayed notably when the first typical symptômes (lack of lactation, post-partum amenorrhea, lack of pubis hairs in the waxed women) are not spontanously reported by the patient. Acute adrenal gland insufficiency and even diabetes insipidus may occur lately with a severe clinical presentation in the course of common minor illness like bacterial diarrhea.

Every post op hyponatremia is not a SIADH; missed case of hypopituitarism after TBI

Fatima Azad & Darryl Meeking
Portsmouth Hospitals University NHS Trust, Endocrinology, Portsmouth, UK

Introduction
The incidence of hospitalised and fatal traumatic brain injury(TBI) is 235/100 000 with an average mortality rate of 15/100 000. A meta-analysis from 19 studies showed a prevalence of hypopituitarism after TBI of 27.5%.
Case report
We report case of 72-year-old man, who suffered traumatic brain injury in October 2021, sustaining multiple skull fractures, with traumatic subarachnoid haemorrhage and subsequent pneumocephalus. He underwent burr-hole surgery with an extended stay on the neurosurgery ITU. After returning to ward, he started vomiting,became tachypnoeic,hypotensive and suffered a PEA cardiac arrest.ROSC was achieved and he was taken to ICU. During ITU stay he required adrenaline boluses followed by noradrenaline infusion to maintain his blood pressure. He was given stress dose of steroids during his subsequent ITU stay. He developed hyponatraemia that was attributed to SIADH, cortisol was not checked on admission. He was stepped down from ITU to ward and was noted to have postural hypotension and continuing hyponatraemia. He received a long acting steroid injection in knee for pseudogout and was manged with intravenous fluid and slow sodium tablets. He was discharged in February 2022 but developed ongoing symptoms-persistent tiredness and weight loss. His symptoms worsened in April 2022 when he presented to his GP with dizzy spells and was found to have postural hypotension and ongoing hyponatraemia. He was prescribed slow sodium tablets and fludrocortisone. He had a syncopal episode while on holiday and was admitted to hospital. He had hyponatraemia and was confused on admission. He subsequently underwent short Synacthen test and was diagnosed as having secondary adrenal insufficiency.He was then commenced on replacement hydrocortisone.A full pituitary hormone profile was completed. This showed evidence of secondary hypothyroidism and secondary hypogonadism. He was subsequently started on Levothyroxine and testosterone replacement, MRI pituitary showed partial pituitary damage with residual intact normal tissue.
Discussion
Pituitary dysfunction after TBI is a common complication. Postulated mechanisms of pathophysiology include primary injury caused by direct trauma and secondary involvement due to illness, hypotension and infarction. Unrecognised hypocotisolism related to pituitary dysfunction after TBI can be life threatening. In our patient, while he was inpatient had a long-acting steroid injection and stress-doses of steroid that may have temporarily protected him from symptoms of secondary adrenal insufficiency. His low sodium during admission was attributed to SIADH but secondary adrenal insufficiency should always be suspected in patients of TBI having hyponatraemia or/and hypotension.

Response to quinagolide of a pituitary prolactin macroadenoma

Rahal Amel[1,2]
[1]Medecines, Endocrinology, Algiers, Algeria; [2]Hopital Bologhine Ibn Ziri, Endocrinology, Algiers, Algeria.

Introduction
The treatment of prolactin adenomas is medical based on the use of dopaminergic agonists but the presence of an underlying valvulopathy makes the treatment by cabergoline delicate.
Clinical case
We report the case of a 60 year old female patient, operated on for aortic valve disease, with moderate mitral leakage. On the occasion of a decrease in visual acuity; a prolactin macro adenoma is diagnosed In agreement with the cardiologist; we opt for a treatment with quinagolide at progressive dose leading to a decrease of prolactin with especially an improvement of the visual disorders
Conclusion
The presence of valvulopathy in patients with prolactin macroadenoma may hinder the practitioner in his therapeutic choice; although it is considered less effective than cabergoline, quinagolide has allowed the decompression of the visual pathways and remains an alternative in valvulopathic patients at risk.

Double functional pituitary adenomas causing acromegaly and subclinical Cushing disease

Salma Salhi, Ibtissem Oueslati, Sarra Ziouche, Fatma Hammami, Meriem Yazidi & Melika Chihaoui
La Rabta University Hospital, Department of Endocrinology, Tunis, Tunisia.

Introduction
Double Pituitary adenomas with growth hormone (GH) and adrenocorticotropic hormone (ACTH) secretion are very rare. They are responsible for acromegaly with hypercortisolism. Subclinical corticotropic adenomas are exceptional. Herein, we report the case of a patient with double functional pituitary adenomas causing acromegaly and subclinical Cushing's disease.
Observation
A 45-year-old woman was referred to our department for suspected acromegaly. Her past medical history included well-controlled diabetes mellitus treated with oral antidiabetic drugs and hypertension. On physical examination, she had a body weight of 65 kg, a body mass index of 26.7 kg/m^2, a blood pressure of 130/80 mmHg, a heart rate of 72 beats/min, enlarged hands and feet, a large prominent forehead, thickened lips, increased interdental spacing, and prognathism. No signs of hypercortisolism were found. Biological investigations showed an elevated insulin-like growth factor-1 (IGF-1) level at 555 ng/ml (normal range: 81–267), a GH nadir after 75 g oral glucose tolerance test at 2 ng/ml, a morning cortisol level at 158 ng/ml, an ACTH level at 64 pg/ml, a TSH level at 2.26 mIU/l (nr: 0.35–4.94), and a FT4 level at 12.8 pmol/l (nr: 10.6–19.4). Cortisol after the dexamethasone 4 mg suppression test was 86 ng/ml. The diagnosis of acromegaly associated with Cushing's disease was established. Pituitary magnetic resonance imaging (MRI) showed a pituitary macroadenoma with no clear limits, with heterogeneous signals before and after Gadolinium injection. The patient underwent transsphenoidal tumor resection. The pathological examination revealed two separate pituitary adenomas showing different histological, immunohistochemical, and ultrastructural features. The positivity to ACTH and GH was 100% and 80%, respectively.
Conclusion
This case emphasizes the necessity of an evaluation of all the pituitary axes in case of adenoma in order not to miss a double hormonal secretion or more even in the absence of suggestive clinical signs.

Isolated hypopituitarism as the first manifestation of neurosarcoidosis

Lina Ghram[1], Ibtissem Oueslati[1], Meriem Yazidi[1], Salma Salhi[1], Fatma Boussema[2] & Melika Chihaoui[1]
[1]La Rabta University Hospital, Department of Endocrinology, Tunis, Tunisia; [2]Habib Thameur University Hospital, Department of Internal Medicine, Tunis, Tunisia.

Introduction
Sarcoidosis may affect the central and peripheral nervous systems in 5–16% of patients. In most cases, such involvement occurs within a multi-systemic disease. Neurological involvement is rare but a potentially life-threatening form of sarcoidosis. The endocrine manifestations of neurosarcoidosis include hypothalamic dysfunction, diabetes insipidus, hypopituitarism, and amenorrhea–galactorrhea syndrome. Herein, we report the case of a patient with hypopituitarism secondary to neurosarcoidosis with no other manifestations of the disease.
Observation
A 35-year-old man was admitted for severe hyponatremia. His past medical history was unremarkable. The diagnosis of acute hypopituitarism with ACTH and TSH deficiencies was established. The patient was put on hydrocortisone and then levothyroxine. Initial pituitary magnetic resonance imaging (MRI) revealed a thickened pituitary stalk, an ectopic posterior lobe, and an intrasellar process. The second MRI performed 18 days later, showed pituitary necrosis and a partially empty sella with optic chiasm ptosis. Biological tests were normal (total calcium level, protein electrophoresis, serum angiotensin-converting enzyme (ACE) level). Tuberculin skin test showed tuberculin anergy. Direct staining and culture do not demonstrate the presence of mycobacteria in urine and sputum. Chest-x-ray and cervical-thoracic-abdominal-pelvic computed tomography scan were normal. Bronchoalveolar lavage and salivary gland biopsy were normal. Immunological investigations revealed the presence of atypical ANCA, normal IgG4 levels, and negative AAN. Cerebrospinal fluid examination showed an increased ACE level. The diagnosis of neurosarcoidosis was established and the patient was treated with high-dose oral corticosteroids.
Conclusion
Our case represents an unusual form of neurosarcoidosis. It should then be considered as part of the etiological diagnosis in patients with hypopituitarism especially when infiltrative lesions of the infundibulum, hypothalamus, or pituitary gland are identified.

EP755

Cushing's disease with empty sella turcica: A problematic situation

Boutheina Mohamed Ali, Moctar Mohamed, Mariem Cheikh, Kaoutar Rifai, Iraqi Hinde & Mohamedelhassan Gharbi
Ibn Sina Hospital, Endocrinology, Rabat, Morocco.

Introduction
Cushing's disease is characterized by an endogenous hypercortisolism related to a pituitary adenoma, its association with an empty sella turcica is exceptionally rare.
Case report
A 55 year old diabetic patient with hypertension was admitted for investigation of Cushing's syndrome. Clinical examination found facial and truncal obesity with facial erythrosis, capillary fragility with multiple ecchymoses, proximal amyotrophy of the limbs. Biologically, urinary free cortisol was 5 times the normal range, midnight cortisol was elevated to 180 ng/ml and Adrenocorticotropic Hormone (ACTH) was 91 pg/ml confirming the ACTH-dependent nature of Cushing's syndrome, the high-dose dexamethasone suppression test was positive. Magnetic resonance imaging revealed an intra sellar arachnoidocele with no detectable adenoma. The diagnosis of cushing's disease was retained and the patient was put on ketoconazole 400 mg/d.
Discussion
Imaging-negative cushing's disease is not uncommon, the association with an empty sella turcica is a major challenge and could be explained by the apoplexy of a pituitary adenoma. Catheterization of the petrous sinuses remains the gold standard for topographic diagnosis. Transsphenoidal surgery is the first-line treatment but is not without risks. Medical treatment allows control of hypercortisolism in case of failure of surgery or while waiting for the appearance of an adenoma on imaging.

Intrasellar ectopic salivary gland rests related with Rathke's cleft cyst

Sebnem Burhan[1], Dilara Uzman[1], Buruç Erkan[2,3], Burak Koçak[4], Fatih Mert Doğukan[3], Mutlu Niyazoğlu[1] & Esra Şüheda Hatipoğlu[1]

[1]Basaksehir Cam and Sakura City Hospital, Endocrinology and Metabolic Diseases, Turkey; [2]Neurosurgery, Basaksehir Cam and Sakura City Hospital, Neurosurgery, Turkey; [3]Basaksehir Cam and Sakura City Hospital, Neurosurgery, Turkey; [4]Basaksehir Cam and Sakura City Hospital, Radiology, Turkey; [5]Basaksehir Cam and Sakura City Hospital, Pathology, Turkey.

Introductıon
Rathke's cleft cysts (RCCs) are benign lesions originating from the epithelial remnants of Rathke's pouch with a peak incidence at 30–50 years of age. It is detected at a rate of 13–33% in several autopsy series. RCC is usually asymptomatic and diagnosed incidentally. In symptomatic cases, common symptoms are headache, visual disturbance, and symptoms related to hypopituitarism.
Case
A 28-year-old male patient presented a three-year history of headaches, severe weakness, impotence, and decreased libido. The patient had no polyuria or polydipsia. Physical examination was unremarkable. Laboratory data revealed panhypopituitarism. TSH: 0.01 mIU/ml (0.27–4.2 mIU/ml), T4: 0.5 ng/dl (0.93–1.70 ng/dl), kortizol: 2, ACTH:13 pg/ml (7.2–63.3 pg/ml), FSH: 1 mIU/ml (1.1–12.4 mIU/ml), LH:1.1 mIU/ml (1.7–8.6 mIU/ml), total testosterone: <0.025 ng/ml (2.8–8) Prolactin: 2.72 ng/ml (4–15 ng/ml). MRI showed a cystic tumor in the sellar region, with a largest diameter of 11 mm. Replacement treatment with levothyroxine, hydrocortisone, and testosterone was initiated, and surgery was recommended because of panhypopituitarism. He underwent transsphenoidal surgery. His pathology is Rathke cleft cyst, and focal nonproliferative salivary gland glandular structures adjacent to these areas are observed.
Discussion
Pituitary development begins in the 3rd and 4th weeks of the fetal period. The anterior lobe (adenohypophysis) is derived from oral ectoderm and is epithelial in origin, whereas the posterior lobe (neurohypophysis) derives from the neural ectoderm. Rathke's cleft cysts originate from epithelial cells of the developing Rathke's pouch. It can be explained by the migration of seromucous glands located in the primitive oral cavity into the Rathke pouch. Salivary gland (SG) tissue may occur in different sites. Intrasellar ectopic SG rests are typically localized close to the neurohypophysis or in the pars intermedia, often communicating with the Rathke's cleft, and maybe incidentally found at autopsy. Only a small group of people is noticeable because of mass effects and endocrine dysfunction, particularly hyperprolactinemia, as the current literature is limited to case reports.

A dwarfism revealing a Pituitary stalk interruption syndrome (PSIS) at the age of 36 years

Talbi Dounia, Ikram Amira, Manal Azriouil, Kaoutar Rifai, Iraqi Hinde & Mohamedelhassan Gharbi
Chu Ibn Sina, Endocrinology, Rabat, Morocco.

Introduction
Pituitary stalk interruption syndrome (PSIS) is a distinct developmental defect characterized by a thin or absent pituitary stalk, hypoplasia of the adenohypophysis, and ectopic location of the neurohypophysis.
Case report
A 36 years old male patient, full term born by vaginal delivery, with birth asphyxia. Birth weight was 2800 g, length was 51 cm, and no other postnatal events were noticed. Psychomotor milestones were achieved normally. his height remained at -4, -5 S.D. till this thirties. The clinical examination finds particular facial features with central adiposity. MRI hypothalamo hypophysia was performed showing ectopic posterior pituitary located adjacent to the optic chiasm, absent pituitary stalk, and severe anterior pituitary hypoplasia associated to type 1 chiari malformation. Hormonologic assessment showed an hypopituitarism.The patient was put on L-thyroxine, hyrocortisone and testosterone treatment.
Discussion
PSIS is manifested as isolated or combined pituitary hormone deficiencies (CPHDs) with variable timing in the onset of symptoms. The precise etiology of PSIS still remains elusive or incompletely confirmed in most cases. Adverse perinatal events, including breech delivery and hypoxia, were initially proposed as the underlying mechanism affecting the hypothalamic–pituitary axis. Nevertheless, recent findings have uncovered a wide variety of PSIS-associated molecular defects in genes involved in pituitary development. Severe and life-threatening symptomatology is observed in a subset of patients with complete pituitary hormone deficiency during the neonatal period. Nevertheless, most patients are referred later for growth retardation. Prompt and appropriate hormone substitution therapy constitutes the cornerstone of treatment.
Conclusion
PSIS is a developmental defect easily diagnosed by MRI, his diagnosis is often delayed, which often result in a gradual occurrence of multiple pituitary hormones deficiencies, requiring careful follow up of affected patients.

Pituitary apoplexy in cabergoline-resistant macroprolactinoma

Ozlem Kanburoglu Meletli, Cigdem Birinci, M. Cuneyt Bilginer, Hulya Coskun, Irfan Nuhoglu, Ozge Ucuncu & Mustafa Kocak
Karadeniz Technical University Faculty of Medicine, Department of Endocrinology and Metabolism, Trabzon, Turkey

Introduction
Pituitary apoplexy is a life-threatening clinical syndrome that develops as a result of bleeding or infarction in a pituitary adenoma. Here, we aimed to present a case of cabergoline-resistant macroprolactinoma who developed pituitary apoplexy.
Case Report
A 40-year-old male patient presented to neurology 2 years ago with severe headache. Brain magnetic resonance imaging (MRI) revealed a $15.5\times18\times21$ mm macroadenoma in the pituitary gland that did not compress the optic chiasm. Visual field examination was normal. He had loss of libido and erectile dysfunction. Endocrinological evaluation (Table 1) showed hyperprolactinemia and hypogonadism. With the diagnosis of macroprolactinoma, cabergoline 0.5 mg/week was started and it was planned to increase the dose gradually. He was informed about the side effects of cabergoline and the findings of pituitary apoplexy. After 3 months of treatment, the adenoma size was the same, but his complaints decreased, prolactin and testosterone were normal. Thereupon, the dose of cabergoline was increased to 3 mg/week. In the pituitary MRI performed at the end of 1 year, it was observed that the size of the adenoma remained constant, but the clinical and laboratory well-being continued. Adenoma-reducing transsphenoidal surgery was recommended for cabergoline-resistant macroprolactinoma. However, the patient did not accept surgical treatment. Six months later, he presented with severe headache, nausea, vomiting, weakness and blurred vision. Prolactin, cortisol, and testosterone levels were low (Table 1). Pituitary MRI revealed an increase in size of the adenoma and compression on the optic chiasm. Pituitary apoplexy and hypopituitarism were considered. No underlying predisposing factor was detected except for cabergoline use. Steroid replacement was started, adenoma resection was performed by transsphenoidal surgery and histologically confirmed as lactotroph adenoma. Visual field examination was normal in the postoperative follow-up, but hypopituitarism persisted.
Conclusion
Pituitary apoplexy due to the use of dopamine agonists in macroprolactinoma is a rare complication. Because of the high mortality and morbidity rate of pituitary apoplexy, it should be known that patients with macroprolactinoma should be followed closely while using dopamine agonists. It should be kept in mind that when pituitary apoplexy occurs, timely surgical decompression should be the best treatment option for patients.

Table 1: Laboratory findings

Parameter		Result	Reference Range
	First diagnosis	18th month	
Prolactin (μg/l)	>200	<0,25	2,64–13,13
Diluted prolactin (μg/l)	3652		2,64–13,13
Follicle Stimulating Hormone (IU/l)	2,21	3,38	1,27–19,26
Luteinizing Hormone (IU/l)	1,39	0,97	1,24–8,62
Total Testosterone (μg/l)	0,97	<0,1	1,98–6,79
Cortisol (μg/dl)	14,3	1,91	
Adrenocorticotrophic Hormone (ng/l)	27,9	18,4	<46

Endocrinopathy behind the facemask – follow up

Sandhi Nyunt[1], Aditi Sharma[1], Kavita Narula[1], Catherine Mitchell[2], Nigel Mendoza[3], Yong Yong Ling[2], Emma Hatfield[1], Karim Meeran[1] & Niamh Martin[1]

[1]Imperial College Healthcare NHS Trust, Endocrinology and Diabetes, London, UK; [2]The Hillingdon Hospitals NHS Foundation Trust, Endocrinology and Diabetes, UK; [3]Imperial College Healthcare NHS Trust, Neurosurgery, London, UK.

A 44-year-old gentleman presented to the Emergency Department with a 2-week history of fever and rigors. Past medical history was unremarkable other than an earlier diagnosis of hypertension. He was noted to have new onset atrial fibrillation with rapid ventricular response; a diagnosis of hypertrophic obstructive cardiomyopathy (HOCM) was made on echocardiography. In addition, a vegetation was identified on the mitral valve. Treatment for infective endocarditis (*Streptococcus oralis*) was initiated and he was subsequently transferred to a specialist centre for mechanical mitral valve replacement surgery. Warfarin was commenced post operatively with target INR of 3.5–4.5. During the admission, a history of chronic headaches was investigated. MRI pituitary revealed a 3.8×1.9 cm macroadenoma with suprasellar extension and invasion of the right cavernous sinus. He was further evaluated in the outpatient endocrine clinic. On removal of his facemask, examination revealed typical acromegalic features with supraorbital ridge prominence, significant underbite and macroglossia. Visual fields were normal to confrontation testing. Pituitary function showed: IGF-1 140.3 nmol/l (range 8.5–31.0), 0900 h cortisol 352 nmol/l (range 200–750), prolactin 1119 mU/l (range 60–300), TSH 1.98 mU/l (range 0.34–5.60), FSH < 0.U/l (range 1.7–8.0), testosterone 8.7 (range 10.0–30.0). Acromegaly was confirmed with an oral glucose tolerance test. The patient was subsequently discussed in Pituitary MDT and commenced on monthly Lanreotide injections to induce tumor size reduction while awaiting pituitary surgery. His IGF-1 remained high despite monthly Lanreotide and therefore Cabergoline was added for further medical management whilst planning his surgery, since this required close collaboration with his cardiothoracic team regarding his cardiac function and prosthetic valve in addition to extensive discussions with Haematology regarding plans for safe peri-operative anticogulation. He underwent successful transphenoidal pituitary surgery; subsequent MRI imaging revealed a good surgical resection with histology confirming a sparsely granulated somatotroph pituitary adenoma (Ki67 1%). Despite a good surgical outcome, his post-operative course was complicated by repeated episodes of epistaxis requiring regular input from Haematology and ENT teams. Anticogulation was cautiously continued due to the high risk of mechanical valve related thrombosis. Control of epistaxis was eventually achieved following a return to theatre for ligation of the sphenopalatine artery. He was discharged once INR was within the therapeutic target range. This case highlights the requirement for early diagnosis and treatment to prevent further complications as well as the need for individualisation of complex treatment decisions through the involvement of multiple specialties within multi-disciplinary team working patterns.

Recurrence of ACTH dependent Cushing's syndrome after pregnancy: Clinical case

Malika Kozhemzharova[1] & Anna Bazarova[2]
[1]Astana Medical University, The Department of Internal Medicine with courses in gastroenterology, endocrinology and pulmonology, Astana, Kazakhstan; [2]Astana Medical University, The Department of Internal Medicine with courses in nephrology, hematology, allergology and immunology, Astana, Kazakhstan.

Introduction
Pituitary ACTH-dependent Cushing's syndrome (CS) is a condition characterized by an overproduction of cortisol due to pituitary adenoma which infers high morbidity and mortality. Transsphenoidal surgery (TSS) is the first-line therapy of an ACTH-secreting pituitary adenoma. But, even after surgical resection of the adenoma, up to 50% of cases may develop a recurrence of the disease.
Case presentation
A woman, 32 year-old, developed recurrent Cushing's disease after 6 years remission following TSS for a pituitary microadenoma. The first clinical symptoms appeared at the age of 26 after the pregnancy and birth (cycle disorder, obesity, weight gain by 15 kg, depression). According to medical history: mean 24-hour UFC was 652 719 ng/24 h, Serum cortisol was not suppressed after low-dose dexamethasone suppression testing (191 ng/ml), but was suppressed (28.3 ng/ml) during high-dose dexamethasone testing, Cortisol stimulation after CRF 225 ng/ml basally, maximum 284 ng/ml, ACTH 56.2 pg/ml, after CRF 112 pg/ml, respectively. These results suggested ACTH-dependent CS, underwent TSS. Histopathologic examination confirmed the diagnosis of pituitary adenoma with positive ACTH immunostaining. In the postoperative period there was clinical and laboratory remission, symptoms regressed, weight decreased. She got pregnant in a 2 and 5 years after the surgery, which ended with term deliveries, without complications. A year later, in the postpartum period, clinical signs of hypercortisolism accompanied moon face, and buffalo hump without purple striae, increased weight gain of 10 kg, headaches, and depression. Clinical examination revealed central obesity, moon face, body mass index (BMI) 29.7 kg/m^2, BP 150/90 mm Hg. A laboratory analysis showed: morning serum cortisol was 530 nmol/l (normal: 171–536 nmol/l), late-night salivary cortisol (LNSC) – 23.1 nmol/l (ref less than 7.56 nmol/l); plasma ACTH was 73.01 pg/ml (normal: 7.2–63.30 pg/ml). Persistent hypercortisolism continued for 7 years. MRI pituitary: no signs of adenoma, but recurrence of ACTH-dependent Cushing's syndrome was confirmed by CRH stimulation test, inferior petrosal sinus sampling (IPSS) and transnasal adenomectomy was performed. Histopathological examination – micro-adenoma with positive ACTH immunostaining. In the postoperative period no signs of Cushing.
Conclusion
In this case, pregnancy was a factor of debut and a recurrence of ACTH dependent Cushing's syndrome.

Delayed onset of pasireotide-induced hyperglycemia: Report of two cases

Sylvère Störmann, Katharina Schilbach, Felix Amereller, Júnia Ribeiro de Oliveira Longo Schweizer & Jochen Schopohl
LMU Klinikum, Medizinische Klinik und Poliklinik IV, München, Germany.

Introduction
Pasireotide is a potent somatostatin analogue (SSA) and used in therapy-refractory acromegaly, commonly after failure of treatment with first-generation SSA. However, it may induce severe hyperglycemia, which usually occurs rapidly after initiation of therapy and in general gradually improves over time. We here present two cases of young male patients who developed severe pasireotide-induced hyperglycemia after several years of treatment.
Case 1
The patient was diagnosed with gigantism due to a growth hormone secreting pituitary macroadenoma at the age of 17 and received pituitary surgery one month after diagnosis. Due to residual tumor tissue the patient received medical treatment with a dopamine agonist and then octreotide. However, only partial biochemical control has been achieved. Additional Gamma-Knife radiosurgery 3 years after diagnosis did not result in biochemical control within the following years. Ultimately, the patient was started on pasireotide subcutaneously in a clinical trial 8 years after diagnosis and reached biochemical control within months. After two years therapy was switched to pasireotide LAR. Glycemic status remained stable during the first 3 years of pasireotide therapy, but then HbA1c and fasting plasma-glucose (FPG) levels quickly increased and we initiated antidiabetic treatment. Pasireotide was continued. Currently, he is on a combination therapy with metformin, sitagliptin, and repaglinide with acceptable glycemic status while maintaining biochemical remission.
Case 2
The diagnosis of acromegaly was established in a 27-year-old male presenting with acral enlargement, paresthesia of both hands, thickening of fingers, prognathism, and progressive asthenia. Transsphenoidal resection of a pituitary macroadenoma ensued quickly, but IGF-I levels remained equally elevated during the months following surgery. He was treated with lanreotide, almost achieving biochemical control but with persistent clinical signs of active disease. The patient was then started on pasireotide subcutaneously in a clinical trial achieving IGF-I levels below the upper limit of normal. After two years the treatment was switched to pasireotide LAR. Afterwards FPG steadily increased and after two further years antidiabetic treatment became necessary. After two more years FPG and HbA1c continued to rise. As the patient refused more intensive antidiabetic treatment pasireotide had to be stopped. Glycemic status returned to normal thereafter.
Conclusion
We present two cases of patients with acromegaly who developed severe hyperglycemia only after several years of pasireotide treatment. Therefore, long-term monitoring of glucose control is necessary in the follow-up of pasireotide treatment.

Challenges in the management of prolactinomas: A case of partial resistance to high-dose cabergoline in a young male with an invasive giant prolactinoma

Larisa-Nicoleta Chetan[1], Andreea Vladan[2], Dan Hortopan[3], Ionut Gobej[4], Serban Radian[1,2] & Catalina Poiana[1,2]

[1]C.I. Parhon National Institute of Endocrinology, Department of Pituitary and Neuroendocrine Diseases, Bucharest, Romania; [2]C. Davila University of Medicine and Pharmacy, Bucharest, Romania, Department of Endocrinology, Bucharest, Romania; [3]Gral Medical, Department of Imaging, Bucharest, Romania; [4]Neurohope, Department of Neurosurgery, Bucharest, Romania.

Background
Giant prolactinomas are rare pituitary tumours larger than >40 mm in diameter, representing 2–3% of prolactin secreting tumours. Management is challenging especially in male patients, due to resistance to dopamine agonists (DA).
Methods
Clinical, hormonal and imaging evaluation and follow-up
Aim
To describe a case of partially resistant giant prolactinoma in a young male patient
Case report
A 17-years old adolescent with a 2 years history of progressive loss of vision and visual field defects (right eye blindness and left eye temporal hemianopia) presented following MRI identification of a 30×28×45 mm sellar mass, extending suprasellary, into the left cavernous sinus, compressing the left temporal cerebral lobe. Examination revealed left oculomotor palsy, delayed puberty (Tanner stage III), without other signs of hypopituitarism. Laboratory workup demonstrated severe hyperprolactinemia (6739.8 ng/ml), normal IGF1 and thyrotroph and gonadotrop insufficiency. Family history was negative for MEN1 and FIPA and hyperparathyroidism screening was negative. Our MDT considered surgery for rapid visual pathways decompression, but a 2 week course of cabergoline lead to significant improvement of vision and visual fields, obviating the need for surgery. Continued cabergoline in escalating doses produced a steady reduction of prolactinemia and further visual improvement and a great reduction in tumour size. The evolution was complicated by an episode of pituitary apoplexy and transient hypocortisolism, managed conservatively. Gradual testosterone replacement led to induction of puberty, accompanied by a plateauing of prolactinemia to 33.5 ng/ml, despite escalation of cabergoline to 8 mg/week. Prolactinemia showe no response to added anastrozole, and then began rising slowly. Tumour control was maintained. Initial and follow-up echocardiograms were unremarkable.
Conclusion
Our case illustrates partial biochemical resistance to high-dose DA, despite excellent tumour response. Anastrozole did not improve the biochemical response. We are closely monitoring the patient, who continues to have an excellent clinical status.

EP763

A rare case of Cushing syndrome ectopic-ACTH

Sanaa Bammou, Neima Hassan, Sana Rafi, Ghizlane El Mghari & Nawal El Ansari
Mohamed VI University Hospital Center, Department of Endocrinology, Diabetology, Metabolic Diseases Nutrition, Marrakesh, Morocco.

Introduction
Malignant tumors, nevertheless, have been associated with extremely high circulating ACTH and cortisol levels, and short duration of symptoms of Cushing syndrome (CS) besides atypical clinical phenotype, when compared with pituitary-dependent Cushing. Identification of the source of ACTH can be challenging, as sometimes the primary lesion is not identified even after prolonged and repeated follow-up
Case report
A 33-year-old woman with a history of insulin-induced diabetes admitted to our department for suspicion of ACTH-dependent Cushing's syndrome held in front of: a Cushing's syndrome clinic, biological Cushing's syndrome, CLU: 2894 µg/24 h, minute braking: negative, cortisolemia 32.1 µg/dl, ACTH: 232 ng/l, CT scan of the adrenal glands in favor of moderate adrenal hyperplasia. MRI Pituiray without anomaly, strong negative braking. an Octreoscan objectified the presence of two thyroid nodules of hypodense generation moderately fixing the radiotracer, measuring respectively 1.9×1.2 cm on the right and 1.5×1.1 cm on the left. The focus intensely fixes the retrotracheal radiotracer and the right paravertebral retrotracer. tumor markers are negative. the patient was operated on for anopathy: thyroid nodular dystrophy, reactive lymphadenitis, a review of the anopathy with iminohistochemistry is requested results in progress. the patient comes to our training 1 month post-operative, the patient reports a regular cycle return, the clinical examination shows a disappearance of purple stretch marks and bruises. Control octreoscan shows the absence of signs in favor of a neuroendocrine tumor at the pleuro-pulmonary, digestive or thyroid level.
Discussion
Most primary endocrine tumors responsible for Ectopic ACTH syndrome (EAS) are located in the chest. Among all ACTH-secreting thoracic tumors, the most common, in a modern endocrine patient recruitment, are welldifferentiated NETs located in the bronchi (formerly called 'carcinoids') and these account for 20% to 40% of all cases of EAS in recent series. They can recur, especially after initial resection without systematic lymphadenectomy. 'Tumorlets' or diffuse idiopathic pulmonary neuroendocrine cell hyperplasia, a precursor to carcinoid tumors and tumorlets, represent a particular bronchial NET type, being small These are mainly located in the chest and can mimic lung metastases. Thymic NETs are also an important cause of EAS due to thoracic tumors accounting for 5% to 10% of EATs, depending on the series.
Conclusion
ACTH-dependent Cushing syndrome due to ectopic ACTH production most of times is difficult to manage. The identification of the source of ACTH may take many years until final diagnosis.

EP764

A very rare case of familial glucagonoma with renin co-secretion and hypokalemia in MEN1 multiple neoplasia

Ramona Poalelungi[1], Mihai Daniel[1] & Corin Badiu[1,2]
[1]C.I Parhon, Endocrinology, Bucharest, Romania; [2]"C. Davila" University of Medicine and Pharmacy, Bucharest, Romania.

Introduction
A glucagonoma is a rare neuroendocrine tumor that originates almost exclusively in the pancreas and probably accounts for 1% of all neuroendocrine tumors. MEN1[1] is characterized by the development of primary hyperparathyroidism (PHPT), pancreatic neuroendocrine tumors and pituitary adenomas.
Methods
We present the case of a 39-year-old female, with history of type 2 diabetes mellitus and hypokalemia[2] who presented to the "C.I Parhon" National Institute of Endocrinology with repeated low potassium levels in the last year. Endocrine tests showed secondary hyperaldosteronism (renin 341.8 pg/ml, aldosterone 371 pg/ml), primary normocalcemic hyperparathyroidism (PTH 584 pg/ml) and hyperprolactinemia (69.63 ng/ml). The serum potassium level was low (1.9–2.7 mEq/l), totally asymptomatic. Abdominal MRI revealed a pancreatic corporeal-caudal tumor (40/10 mm) with an appearance compatible with a neuroendocrine tumor, with secondary lymph node, liver determinations and bilateral adrenal tumors. Fine needle aspiration from the pancreatic tumor revealed atypical cells for a neuroendocrine tumor proliferation. Neuroendocrine tumor markers: Cromogranin A 1700 ng/ml, glucagon 1329 ng/l. Pituitary MRI: left pituitary adenoma 1.03/1.05 cm. Normal pituitary function. Radionuclide Technetium 99m SESTAMIBI scan was positive for left inferior parathyroid.
Results
Corporal-caudal splenopancreatectomy en bloc with partial left adrenalectomy and enucleoresection of cephalopancreatic exopthytic tumor was performed. The pathology and IHC examination certifies well-differentiated neuroendocrine tumor G1 pT3 pN1 pM1a and AE1-AE3 positive chromogranin and synaptophysin in the tumor, negative CD56 and Ki67 < 1%.Microwave ablation of liver tumor segment VII. Lanreotid autogel was started. Despite sustained increased PTH values, the calcium level was normal during the follow up for 4 years.
Conclusions
The renin co-secretion from a glucagonoma is a very rare combination, with only few cases reported in literature. The hypokaliemia is severe and may be corrected after tumor debulking and systemic therapy of metastatic disease, but the prognosis is poor. Another rare occurrence is normocalcemic primary hyperparathyroidism in MEN 1 syndrome.
Keywords: glucagonoma, hypokalemia, MEN 1, secondary hyperaldosteronism.

'Needless needles': Can GH injections be prevented by treatment of deep vitamin D deficiency?

Kirsten Davidse[1,2], Judith van Eck[3], Erica van den Akker[3], Aart-Jan van der Lely[1] & Laura de Graaff[1,2]

[1]Erasmus University Medical Center, Department of Internal Medicine, Division of Endocrinology, Rotterdam, Netherlands; [2]Erasmus University Medical Center, Department of Internal Medicine, Center for Rare Genetic Syndromes, Rotterdam, Netherlands; [3]Erasmus University Medical Center – Sophia Children's Hospital, Department of Paediatric Endocrinology, Rotterdam, Netherlands.

Introduction
Growth hormone (GH) is not only important for growth during childhood. Also, for (young) adults, growth hormone is important for bone mass, muscle strength and metabolism. GH deficiency (GHD) is a condition that can cause a broad range of adult health issues, if left untreated. Therefore on one hand, it is important to confirm and treat GHD after transfer to adult care. On the other hand, the personal and financial burden of *unnecessary* growth hormone injections should be avoided. For this reason, adolescents with childhood onset GHD should be retested after reaching adult height.
Case presentation
We present a case of a 19-year-old non-obese Caucasian male who, due to isolated GHD, was treated with GH during childhood (needle-free system). After reaching adult height, GH treatment was stopped and the patient was re-tested for GHD after a washout period. GH peak after stimulation with GHRH-arginine was 5.5 µg/l, which is considered persistent GHD. When the paediatric endocrinologist wanted to restart GH, patient refused, as he had a fear of needles and the needle-free GH was no longer available. Therefore the shared decision was made that restarting GH would be evaluated after transfer to adult endocrinology. At the first appointment at the adult outpatient clinic it was noted that, apart from low serum IGF-1 levels, 25-OH vitamin D level was extremely low (<10 nmol/l). Knowing that the promoter of the *GH1* gene contains a vitamin D-responsive element, it was hypothesized that the low vitamin D levels might have contributed to low IGF-1 levels. After six months of vitamin D replacement and near-normalisation of 25-OH vitamin D (49 nmol/l, ref. 50–120 nmol/l), IGF-1 level had almost normalised (18.6 nmol/l, ref 19–66 nmol/l). Although GHRH arginine test will be repeated to definitively rule out GHD, it was remarkable that IGF-1 levels clearly increased after treatment of severe vitamin D deficiency. Especially in this patient with needle-fear, this could avoid a lot of stress.
Conclusion
In our patient with childhood onset GHD, IGF-1 levels nearly normalised after treatment of his severe vitamin D deficiency. Especially as fear of needles is common during the transition phase (20–50% in adolescents and 20–30% in young adults), it is worth reassessing IGF-1 levels after vitamin D supplementation, to avoid needless GH injections.

Gaps in the long term post-treatment follow-up of pituitary tumors

Paras Imran[1], Tasnim Ahsan[2] & Heer Dilawar[3]
[1]Jinnah Postgraduate Medical Center (JPMC), Medicine, Karachi, Pakistan; [2]Jinnah Postgraduate Medical Center (JPMC), Medicine and Endocrine, Karachi, Pakistan; [3]Medicell Clinic, Karachi, Pakistan.

Objective
To study the spectrum of Pituitary tumours, their presentation, treatment and compliance with follow-up.
Methods
A mixed retrospective and prospective study was conducted at the Medicell Institute of Diabetes, Endocrinology and Metabolism (MIDEM) and Jinnah Postgraduate Medical Centre (JPMC) Karachi,Pakistan. All cases of pituitary tumours, were prospectively followed. Data regarding age, gender, duration of disease, symptoms, mode of treatment administered and compliance with the follow-up instructions was retrieved.
Results
A total of 173 patients were enrolled with a mean age of 36.4 ± 10.6 years. Female predominance was seen in our study 97 (56.1%). Of the 136 married patients, subfertility was seen in 48 (36.3%). Headache was observed in 164 (94.8%) of patients. Prolactinoma was the lead tumour comprising of 76 cases (43.9%), followed by non-secretory tumours 47 (27.2%), and acromegaly 43 (24.9%). Other rare disorders including Cushing's disease, craniopharyngioma and gonadotropinoma were also seen. Cabergoline was prescribed in 136 (78.6%) cases. Transsphenoidal surgery (TSS) was done in 74 (42.8%) of patients. Out of 97 female patients, 38 (39.2%) had persistent amenorrhea post-treatment, while this data was not available for 40 (41.2%) of these women, who were lost to follow-up. The difference between mean prolactin levels prior and after the treatment (1390.048 ± 2646.986 versus 116.360 ± 163.369) were found to be statistically significant $P<0.001$). Similarly, IGF-1 levels were significantly improved post treatment indicating tumour stability. Moreover, the level of mean FT4 post-treatment was 1.64, reflecting adequate replacement.
Conclusion
Majority of the patients had improvement post-treatment in pituitary tumour symptoms, including vision, headache and sexual function. Failure to attend for follow-up for tumour stability, control of excess hormone, and pituitary hormone replacement was seen in a large number of patients in this study. This requires careful consideration of different strategies to ensure better long term care in pituitary tumours.

Autosomal dominant familial neurohypophyseal diabetes insipidus in three generations

Sanaa Bammou, Hind Ouakrim, Sana Rafi, Ghizlane El Mghari & Nawal El Ansari
Mohamed VI University Hospital Center, Department of Endocrinology, Diabetology, Metabolic Diseases Nutrition, Marrakesh, Morocco.

Introduction
Familial neurohypophysial diabetes insipidus (FNDI), an autosomal dominant disorder, comes in many forms that are differentiated by the inheritance pattern and the underlying genetic lesion. The disease is caused by mutations in the vasopressin-neurophysin 2-copeptin protein (AVP-NPII), in wolframin (WFS1) or in proprotein convertase subtilisin/kexin type 1 (PCSK1) genes.
Materials and methods
In this study, we report a case of familial neurohypophyseal DI in three generations; followed in unit of the endocrinology, diabetology, metabolic diseases and nutrition department of the Mohammed VI University Hospital of Marrakesh.
Results
This was a 45-year-old patient who had been suffering from polyuro-polydipsia syndrome since the age of 12, with daily urine volumes ranging from 8.0 to 15.0 l, but had not seen a doctor. The patient was born without complications and had normal puberty. In the family history, three other members of the patient's family have also had polypolypolydispic syndrome since adolescence, covering three generations, including the patient's mother, her younger sister and daughter. A water restriction test was performed but the patient did not tolerate it. We completed with the minirin test with a good clinical response: urine concentrated with a volume of 500 ml, and urinary osmolarity at H4 of 276.13 (Fig. 2). As presented in (Fig. 3), cranial MRI revealed a hypersignal region in the posterior pituitary lobe. Serum cortisol, thyroid function, and estrogen were all in the normal range The growth hormone (GH), insulin-like growth factor (IGF)-1 levels and the genetic testing were not performed due to limited financial resources. After treatment with oral desmopressin 60 µg two times daily was started, the symptoms of polydipsia and polyuria were satisfactorily controlled. She currently drinks about 1.5 l of water per day and she has a urine volume of 1.5 l per day. Her sister's daily water/diuresis intake is 3.0 l/2.0 l, due to the effects of the medication.
Discussion
The mutations involved in familial neurophyphyseal DI include small deletions, as well as missense and nonsense mutations that affect the signal peptide, the AVP moiety, or the AVP carrier protein, NPII.
Conclusion
Familial neurohypophyseal ID is a rare hereditary disease that has a negative impact on the patient's quality of life. The majority of cases are inherited in an autosomal dominant pattern, which is why screening and appropriate management are necessary.

Pituitary spindle cell oncocytoma presented as pituitary apoplexy, case study

Bessaid Khadidja, Mouna Mezoued & Malha Azzouz
Bologhine Ibn Ziri, El Hammamet, Algeria.

Introduction
Spindle cell oncocytoma (SCO) of the pituitary gland is a rare thyroid transcription factor 1 (TTF-1)-positive pituitary neoplasm.

Observation
We report the case of a 42-year-old man, with a personal history of type 2 diabetes, consulting for intense headaches and vomiting. The visual field shows an amputation of the left temporal hemifield and the MRI shows a pituitary adenoma with suprasellar development, initially measuring 22×28×37 mm, taking contrast heterogeneously and presence of hemorrhagic areas. The biological assessment objectified a normal level of prolactin and a triple deficit corticotrope, thyrotrope and gonadotrope. The diagnosis of pituitary apoplexy was retained. The patient received high-dose corticosteroid therapy. 20 days later, MRI showed a reduction in tumor volume measuring 22×17×21 mm with normalization of the visual field. The patient was put on 2 mg per week of cabergoline with regular monitoring. Two years later the MRI showed an increase in tumor volume 18×26×16.6 with bitemporal hemianopsia. The patient underwent transphenoidal surgery. The pathology concludes to a spindle cell oncocytoma of the hypophysis. Two months later, the visual field has not improved. The MRI shows an increase in the size of the lesion measuring 18×26×24 mm.
Discussion
SCO was first described by Roncaroli *et al*. in 2002, subsequently less than 100 cases have been described in the literature. Clinically, biologically and morphologically SCOs are indistinguishable from other sellar tumors. The usual presentation is that of an intracranial tumor syndrome associated with pan hypopituitarism. However, a recent data showed that frequent endocrine-related symptoms, hypervascular signs, and anterosuperior displacement of the gland support preoperative diagnosis of SCO. The tumor is classified in the WHO classification of tumors of the central nervous system from 2007 as grade I. It consists of spindle cells with eosinophilic, finely granular, mitochondria-rich cytoplasm, shows immunoreactivity to TTF-1, and lacks expression of chromogranin and pituitary hormones. Global tumor resection (GTR) seems to have better long-term tumor control, whereas the fibrous, hypervascular, and adhesive nature of SCO makes it difficult to achieve GTR. In patients with non-GTR, radiotherapy may help decrease tumor progression. In our case, we opted for revision surgery followed by radiotherapy.

MRI assessment of typical pituitary gland size and shape: Age and gender associated changes

Anand Shankar[1], B B Bharti[2], Ajay Kumar Sinha & Subhash Kumar[4]
[1]Shankar Diabetes Care Centre, Diabetes, Patna, India; [2]Ford Hospital, Medicine, Patna, India; [3]Nalanda Medical College Hospital, Medicine, Patna, India; [4]Diabetes and Obesity Care Center, Diabetes, Patna, India.

Background
For a thorough evaluation of the pituitary gland, it is important to understand its typical structure, including the physiological differences in size and form across age groups in both males and females.
Objectives
To use magnetic resonance images to examine the size, shape, and average normal volume of the normal pituitary gland at various age groups in both genders (MRI).
Material and methods
200 individuals who underwent brain MRIs in the department were included in the retrospective analysis, with 161 men and 39 women, ages ranging from one year to 50 years. Patients with endocrine or pituitary disorders weren't allowed to participate in the study. MRI scanner was used to capture every MRI image. ANOVA and Chi-square tests were used to determine the relationship between mean volume and age. A P-value < 0.04 was regarded as significant.
Results
Female patients in each age group had pituitary glands that were on average more than male patients in the same age group. In the age range of 1–11 years, the average pituitary volume was 5.2 ± 1.3 mm. The average pituitary volume was measured at 6.2 ± 1.7 mm in the age groups of 20 to 31 years, 30–41 years, and 40–51 years. The most typical form was flat, which was seen in 45% of persons across all age groups and both genders, followed by convex in 31.1% and concave in 22.7%. Males had a mean pituitary volume of 209 ± 0.71 mm^3 while females had a mean pituitary volume of 199 ± 0.5 mm^3 in the age range of 1 to 11 years. The average pituitary volume in people between the ages of 11 and 20 was 341 ± 126 mm^3 in men and 281 ± 122 mm^3 in women. The mean pituitary volume in people aged 20–31 was 431 ± 115 mm^3 in men and 441 ± 181 mm^3 in women. Males had a mean pituitary volume of 381 ± 141 mm^3 and females had a mean pituitary volume of $441 \pm 110 \pm 115$ mm^3 in the 30- to 41-year age range. The average pituitary volume in those aged 41–50 was 421 ± 115 mm^3 in women and 401 ± 158 mm^3 in men.
Conclusion
To compare the abnormal growth in size, knowledge of physiological variation in the pituitary gland's size and form is required. Pituitary glands that are borderline abnormal in size and shape should have a dynamic contrast MRI examination performed to further assess them.

Re-evaluation of MRI in the follow-up of acromegaly – a path towards long-term remission?

Shahriar Atai[1,2], Martin Knudtzon Andersen[3,4], Jens Bollerslev[1,2], Daniel Dahlberg[5], Markus Wiedmann[5], Geir Andre Ringstad[3] & Ansgar Heck[1,2]
[1]Oslo Universitetssykehus HF, Rikshospitalet, Endocrinology, Oslo, Norway; [2]University of Oslo, Faculty of Medicine, Oslo, Norway; [3]Oslo Universitetssykehus HF, Rikshospitalet, Radiology, Oslo, Norway; [4]Diakonhjemmet Hospital, Radiology, Oslo, Norway; [5]Oslo Universitetssykehus HF, Rikshospitalet, Neurosurgery, Oslo, Norway.

Introduction
Remission by complete surgical tumour removal is not achieved in all patients with acromegaly and a subset of patients remain on long-term pharmacological treatment. Repeated surgery or targeted radiation therapy can be considered in patients with residual or recurrent tumour. Identification of residual or recurrent tumour available for surgical treatment can be challenging, and underreporting may lead to a loss in treatment opportunity. The aim of the present study was therefore to identify pituitary tumour remnants by systematic re-assessment of MRIs in pharmacologically treated patients with acromegaly.
Methods
Adult patients diagnosed and managed at a tertiary care centre 2005–2021 and presently on pharmacological treatment for acromegaly were included. Main outcome: Number and proportion of patients with a visible tumour, no visible tumour or a possible finding on MRI. A trained clinician (SA) and radiologist (MK) separately classified the latest routine MRI in a standardized manner, also taking into consideration baseline and all follow-up MRIs. In case of discrepant classification, consensus was achieved together with an experienced neuroradiologist (GR). Routine MRI reports were compared with the consensus classification.
Results
The study cohort consisted of 78 patients, of which 35 were women. Visible tumours and possible findings were seen in 31 (40%) and 36 (46%) patients, respectively. In 11 (14%) patients no visible tumours were seen. No visible tumours were reported in 23 (29%) patients in the routine MRI report, while we identified visible tumours in 2 (9%) and possible findings in 12 (52%) of the same 23 patients. Discrepancies between the routine reports and consensus classification were found in 31 (40%) patients.
Conclusion
Our study found visible tumours or possible findings in the majority of the patients. Identification of tumour remnants in patients with secretory activity is important as they may be candidates for redo surgery or targeted radiotherapy. Better imaging protocols or more advanced imaging may further contribute to tumour identification in uncertain findings.

A rare case of macro-ACTH in patient with adrenal incidentaloma

Piotr Przybycień[1], Danuta Gasior-Perczak[1,2], Anna Słuszniak[1], Wojciech Placha[3] & Aldona Kowalska[1,2]
[1]Holycross Cancer Centre, Endocrinology, Kielce, Poland; [2]Jan Kochanowski University, Collegium Medicum, Kielce, Poland; [3]Jagiellonian University, Medical Biochemistry, Kraków, Poland.

Introduction
Adrenocorticotropic hormone (ACTH) is a tropic hormone produced by the anterior pituitary that stimulates the adrenal glands to release cortisol. The ACTH measurement is often used to diagnose the pituitary and/or adrenal disorders, mainly Cushing's disease, Cushing's syndrome, Addison's disease and hypopituitarism. Therefore, the assessment of plasma ACTH concentration is a crucial step in the differential diagnosis of hypothalamic–pituitary–adrenal axis dysfunction. The purpose of our study was to present a case of patient with unexpectedly high concentration of ACTH

Case details
A 63-year-old Caucasian man was referred to our clinic for hormonal diagnostics due to a tumor in the left adrenal gland found in an abdominal CT scan, which showed an 11×10 mm mass with attenuation of approximately 20 HU (Hounsfield unit) in the left adrenal gland. Contrast-enhanced magnetic resonance imaging showed an 11×13 mm tumor without features of a lipid-rich adrenal adenoma. Plasma ACTH levels were highly elevated with normal cortisol levels using chemiluminescent immunoassay (Immulite 2000Xpi). The 24-hour ACTH and cortisol secretion profiles in the serum of the patients were respectively 602.00 [pg/ml] and 19.10 [μg/dl] at 0800 h, and 539.00 [pg/ml] and 3.12 [μg/dl] at 1000 h. Cushing's disease (due to an ACTH-secreting pituitary tumor) was ruled out by a low-dose dexamethasone suppression test, and Addison's disease (adrenal insufficiency) was ruled out by a normal Synacthenem short test. No pathological changes were found on MR imaging of the pituitary. In addition, polyethylene glycol 25% (PEG) precipitation and serial dilutions were applied to the serum. After PEG precipitation, ACTH decreased from 331 to 18.92 [pg/ml] (recovery: 5.72%). Endocrine diagnostics showed no hormonal activity of the adenoma in the left adrenal gland.
Conclusion
Macro-ACTH should be suspected when elevated ACTH levels are not consistent with clinical picture. Consideration of alternative testing methods, including PEG precipitation testing and clinical assessment, are of paramount importance in making the correct diagnosis. Strict cooperation between the physician and the laboratory is important in the approach to such cases.

Characteristics of pituitary insufficiency in acromegaly: report on 28 cases

Sahar Abidi, Sabrine Mekni, Sawssen Esseyah, Faten Cherchir, Nadia Mchuirgui, Imene Rojbi, Ibtissem Ben Nacef & Karima Khiari
Charles Nicolles Hospital, Endocrinology Department, Tunis, Tunisia.

Introduction
Acromegaly is a rare condition secondary to the hypersecretion of GH, often by a pituitary adenoma, which can lead to hypopituitarism of varying degrees. Our study aimed to analyze the characteristics of pituitary insufficiency during acromegaly and to search for its predictive factors.
Methods
Retrospective study carried out in the endocrinology department of Charles Nicolles Hospital. We recorded 28 patients with acromegaly over a period of 30 years.
Results
The study included 17 women and 11 men. The mean age at diagnosis of acromegaly was 45.9±13.9 years. Acromegaly was due to a pituitary adenoma in all cases (4 microadenomas and 24 macroadenomas). The average size of the adenomas was 20.4±9 mm. The hormonal assessment showed gonadotropic insufficiency, corticotropic insufficiency, and thyroid insufficiency in 67, 41, and 19% of cases. Thyroid insufficiency was present in 4 women and 1 man. The average size of the adenoma in the affected subjects was 24.8 mm. Gonadotropic insufficiency was present in 10 women and 8 men. The mean size of adenoma in these patients was 23.9±7, 8 mm with a statistically significant difference compared to the unaffected subjects 13, 8±8, 2 mm ($P=0.008$). GH nadir under OGTT ($P=0.03$) and tumor size ($P<10\text{-}3$) were significantly higher in patients with corticotropic insufficiency. A positive correlation was found between the number of affected axes with the value of GH nadir under HGPO75 ($r=0.611$; $P=0.001$) and the size of the adenoma ($r=0.744$; $P<10\text{-}3$). The number of affected axes was significantly higher in patients with aggressive adenoma ($P=0.031$). Age, gender and diagnostic delay did not significantly interfere with the number of pituitary deficient
Conclusion
We concluded that Tumor size, aggressive adenoma and GH nadir are a predictive factors of pituitary insufficiency.

Metabolic profile during Sheehan's syndrome

Imane Boubagura, Sana Rafi, Ghizlane El Mghari & Nawal El Ansari
University Hospital of Marrakech, Marrakech, Morocco, Department of Endocrinology, Diabetology and Metabolic Diseases, University Hospital of Marrakech, Marrakech, Morocco.

Introduction
– Sheehan syndrome (SS), or postpartum pituitary necrosis, is a rare but potentially serious complication of postpartum.
– SS remains an important cause of hypopituitarism in Morocco.
– The aim of this study is to evaluate the metabolic profile of patients with SS.
Materials and methods
– This is a retrospective descriptive study conducted in the endocrinology department, spread over a period of 12 years, between the year 2010 and 2022, The data were collected on a data sheet based on the analysis of medical records (paper and computer) and telephone calls if information was missing.
Results
– We collected 28 patients followed for Sheehan's syndrome during the study period from 2010 to 2022, The average age was 47±7 years with extremes ranging from 35 to 81 years, All patients explored had a thyroid insufficiency, Corticotropic insufficiency was found in 27 patients, Prolactinemia was low in 20 patients with a mean level of 2.6±1.65 ng/ml, 23 patients had a disturbed gonadotropic balance, The somatotropic axis was not explored in our patients, None of the patients had diabetes insipidus. The average BMI of the patients was 28 kg/m^2±4.89, and the average waist circumference was 95.7±4.34 cm, HTA in 3 patients, Five patients had a blood glucose level < 0.8 g/l. The rest of the patients had correct blood glucose levels. One case of diabetes mellitus revealed during the follow up, Hypercholesterolemia was found in 13 patients (46.42%). All patients had a pituitary MRI which revealed: an empty sella turcica in 15 patients, 1 case of anteropituitary hypotrophy.
Discussion
– The results of our study agree with those of the literature and show an overexposure to metabolic syndrome in patients with SS.
– This metabolic syndrome is related to the associated anteropituitary deficits:
– GH deficiency is associated with: Dyslipidemia, Obesity and body composition changes, and hypertension. Thyrotropic deficiency is associated with: HTA, An increase in total cholesterol, LDL, and triglyceridemia. The impact on HDL is more controversial.
– Gonadotropic deficiency is associated with: Change in body fat distribution from gynoid to android, Dyslipidemia, Disorder of carbohydrate metabolism, and HTA.
Conclusion
– Reduction of morbi-mortality associated with Sheehan syndrome relies on prevention and early diagnosis especially in our setting.
– GH deficiency seems to be at the center of the metabolic abnormalities observed in patients with hypopituitarism.

The role of artificial intelligence algorithm in predicting the prognosis in prolactinomas

Zehra Kara, Cem Sulu, Ahmet Numan Demir & Pinar Kadioglu
University of Istanbul-Cerrahpasa, Cerrahpasa Medical Faculty, Endocrinology, Metabolism and Diabetes, İstanbul, Turkey.

Objective
To test the utility of the artificial learning algorithms using magnetic resonance (MR) images of the pituitary gland in predicting the prognosis of prolactinoma.
Methods
This single-center, retrospective study was conducted in the Pituitary Center of a tertiary care university hospital. A total of 224 images derived from 38 patients with treatment-refractory prolactinoma, 23 patients with prolactinoma remission and 51 healthy individuals were used. Pituitary MRI protocols are of three sequences: T1-weighted imaging (T1WI), contrast-enhanced T1WI (CE-T1), and T2-weighted imaging (T2WI). A machine learning algorithm that includes image filtering and classification. Data were classified with support vector machine.
Results
No difference was found between the refractory and the remission groups in terms of age, sex, education, the baseline prolactin level and radiological features. Images were classified with a support vector machine; area under curve (AUC), accuracy rate, sensitivity and specificity of 0.90 (95% confidence interval, 0.679–1), 91.6%, 91.7%, 88.3%, respectively.
Conclusion
These results indicate that a new image of unknown nature can be correctly identified with the specified percentages.

Quality of life in acromegaly

Zvezdana Jemuovic[1], Marina Nikolic Djurovic[1,2], Sandra Pekic Djurdjevic[1,2], Dragana Miljic[1,2], Marko Stojanovic[1,2], Ana Petakov[1], Aleksandra Jovanovic[1], Danica Grujicic[2,3], Toplica Milojevic[3], Mihailo Milicevic[2,3], Aleksandar Stanimirovic[3], Emilija Manojlovic Gacic[2,4], Ivana Cekic[1] & Milan Petakov[1,2]
[1]Clinic for Endocrinology, Diabetes and Diseases of Metabolism, University Clinical Center, Department of Neuroendocrinology, Belgrade, Serbia; [2]Faculty of Medicine, University of Belgrade, Belgrade, Serbia; [3]Clinic for Neurosurgery, University Clinical Center of Serbia, Belgrade, Serbia; [4]Institute of Pathology, Belgrade, Serbia.

Introduction
Acromegaly is a rare chronic disease characterized by systemic comorbidity. As a chronic disease, which in most cases requires long-term treatment, it is often accompanied by musculoskeletal, metabolic, and cardiovascular diseases, as well as headaches, anxiety, and depression, which leads to impaired quality of life.
Aim
Assessment of quality of life in patients with acromegaly compared to healthy controls.
Materials and methods
In the study participated 18 patients with active acromegaly (51.7±11.7 years, 38.9% men, 61.1% women) compared to 18 healthy individuals of similar age (48.9±11.5 years, 16.7% men, 83.3% women). Growth hormone in oral glucose tolerance test were determined as well as levels of IGF1. All participants filled out the SF36 quality of life questionnaire. Arithmetic mean±SD. and Mann–Withney test were used for statistical processing.
Results
We have shown that in the group of patients with acromegaly, IGF1 was elevated 2.53±1.1 times than ULN. 33.3% of patients had hypopituitarism. Examining 8 aspects of health within the SF36 questionnaire, the results showed that subjects with acromegaly had lower average values for each aspect, as well as the total score, compared to the control group, however statistics showed significant difference only in terms of general health (55.22±15.5 vs 75.00±13.3, $P<0.001$). There was statistically significant difference between the males and females in dimension A /physical functioning/ in favour of the males, which showed higher values (74.57±19.9 vs 55.00±22.0, $P<0.001$), in dimension B /mental health/ (73.71±15.5 vs 55.36±21.1, $P=0.004$), as well as in the total SF36 score (76.57±17.5 vs 56.64±21.5, $P<0.001$).
Conclusions
This is a pilot study in which it was found that patients with acromegaly had lower average results on SF36 questionnaire. Their perception of the general state of health was significantly impaired compared to the control group, which suggests poor quality of life. Further studies are needed to include larger acromegaly population as well as other assessment tests, in order to obtain relevant results and to gain complete insight into the quality of life of these patients.

Features of neuroendocrine, hormonal and ophthalmic complications of giant pituitary adenomas depending on the volume and growth of the tumor (data from a prospective study)

Yulduz Urmanova[1], Malika Mirtukhtaeva[2] & Feruza Khodgaeva[1]
[1]Tashkent Pediatric Medical Institute, Department of Endocrinology, Tashkent, Uzbekistan; [2]Republican Specialized Scientific Practical Medical Center of Endocrinology of Public Health Ministry named by acad. Ya.Kh. Turakulov, Department of Neuroendocrinology, Tashkent, Uzbekistan.

Aim
To study features of neuroendocrine, hormonal and ophthalmic complications of giant pituitary adenomas depending on the volume and growth of the tumor (data from a prospective study).
Material and methods
Us for the period from 2020 to 2022. 151 patients with macro- and giant NFPA were prospectively examined. According to the size of pituitary adenomas, patients of prospective (151 patients) observation were divided into 2 groups: group 1 – patients with macro NFPA – 55 persons, group 2 – patients with giant NFPA – 96 persons. The patients were subjected to a complete examination: biochemical, hormonal, immunocytochemical, ophthalmic neuroimaging (MRI of the pituitary gland). Some of investigations have been repeated in various time. MRI showed that in half of the cases pituitary adenomas were observed with a total growth variant – 104 cases (69.0%), as well as with endo- and suprasellar growth – 25 (16.5%)
Results
The most common complaint in patients with pituitary adenomas were: headaches – 122 patients (80.7%), bitemporal hemianopsia – 128 (84.7%) secondary amenorrhea – 51 patients out of 66 women (77.2%), decreased vision – 95 (62.8%), etc. It was found that in the 2nd group of patients, panhypopituitarism was most common – in 78 out of 96 patients (81.2%), postoperative panhypopituitarism occurred in 43 out of 96 patients (44.9%), while in group 1, panhypopituitarism was up to no operation was observed. Bitemporal hemianopsia was also observed with greater frequency in patients of group 2 – 93 cases (97%). In addition, secondary amenorrhea was also more common in patients of group 2 – 37 (38.5%). The most significant decrease in the average values of basal levels of tropic plasma hormones – STH, LH, FSH, ACTH – was recorded in patients of group 2. In addition, it was in these patients that the levels of cortisol and IGF-1 were also significantly reduced, while in patients of group 1, IGF-1 was on average within the normal range.
Conclusions
In general, patients had a decrease in the average values of tropic pituitary hormones, but most significantly and often in patients with giant pituitary adenomas. In patients with giant pituitary adenomas, first of all, there is a decrease in the level of growth hormone, FSH, LH (45%). The most pronounced neuroendocrine and ophthalmic disorders occurred in group 2 patients with giant pituitary adenomas.

DOI: 10.1530/endoabs.90.EP776

EP777

Differential diagnosis of the progressing pituitary lesion in a pregnant woman

Irena Ilovayskaya[1], Daria Mikhaylova[1], Yulia Krivosheeva[1] & Irina Komerdus[2]
[1]Moscow Regional Research and Clinical Institute (MONIKI), Neuroendocrinology, Moscow, Russia; [2]Moscow Regional Research and Clinical Institute (MONIKI), Therapeutic endocrinology, Moscow, Russia.

A 31-year-old female patient without previous history of pituitary diseases, at 16 weeks of 4th spontaneous pregnancy complained about severe headache; diplopia and right ptosis developed shortly, nausea and vomiting appeared. Brain MRI showed the mass lesion 30×19×14 mm (frontal×vertical×sagittal) with supralaterosellar extension, deforming and displacing optic chiasm; signs of pansinusitis, pathological contents of the right mastoid cells, vascular malformation in the right temporal lobe. Hormonal investigation showed low concentrations of TSH, free T4, free?3, cortisol and ACTH so hypopituitarism was diagnosed, and appropriate replacement therapy started. According to clinical symptoms, patient required higher doses of glucocorticosteroids to stop signs of adrenal insufficiency. She also received the antibiotic therapy and repeated surgical interventions due to purulent pansinusitis and secondary meningoencephalitis with the formation of an abscess of the left frontal lobe. However, the condition worsened despite the cavities and abscess sanitation: headaches persisted, a progressive decrease in vision (bilateral amaurosis) and bilateral ptosis were observed. Also poliuria up to 6–9 l/daily without hypernatremia or a decrease in the specific gravity of urine were revealed. An antidiuresis and hyponatremia 124 mmol/l were detected on the background of single-dose desmopressin 30 μg. Hyponatremia was self-recovered, however, low-normal values of sodium (130–135 mmol/l), potassium (3.6–4.3 mmol/l) and glucose (3.5–4.1 mmol/l) remained in dynamics. The MRI control every 2 weeks showed the rapid unexpectable growth of pituitary lesion with both cavernous sinus invasion: 47×21×18 mm – 60×24×21 mm (frontal×vertical×sagittal×). The diagnosis of pituitary adenoma was doubtful, the presence of hypophysitis or other sellar mass's etiology were assumed and pituitary biopsy was performed to clarify the diagnosis. The extranodal T/NK cell nasal lymphoma was diagnosed according to histological and immunohistochemical studies (Ki-67 up to 90%). Cesarean section was performed at 23 weeks of gestation for life indications to start chemotherapy. This clinical observation shows the difficulties of differential diagnosis of rare extranodal T/NK-cell lymphoma of the nasal type with CNS and pituitary lesion in a pregnant women with hypopituitarism and optic nerve atrophy. Such rude progression of pituitary lesion with predominant increase of frontal size is not characteristic for pituitary tumors and/or hypophysitis so rare and malignant disorders should be suspected.

Induction of secondary sexual characteristics with gonadotropins in an adult male with Kallman syndrome

José Vicente Gil Boix[1], Guillermo Serra Soler[1], Javier Bodoque Cubas[2], Meritxell Viñes Raczkowski[1], Alicia Sanmartín Sánchez[1], Andreu Campos Peris[1], Mercedes Noval Font[1], Santiago Tofé Povedano[1] & Iñaki Argüelles Jiménez[1]
[1]Hospital Universitari Son Espases, Endocrinology and Nutrition, Palma, Spain; [2]Hospital Virgen de la Cinta, Endocrinology and Nutrition, Palma, Spain.

Introduction
Hypogonadotropic hypogonadism is the cause of sexual deficiency, sometimes difficult to differentiate from constitutional growth delay (CGD).
Clinical case
A 19-year-old male consulting endocrinology for delayed puberty. Pointed to, at 13 years of age, as having had CGD. His medical report include a viral meningitis at 8 years of age and anosmia since 3 years of age. He expressed lack of sexual desire and concern about the size of his genitals. On physical examination, his weight was 64 kg, height 175 cm and his Tanner stage was II (A2P2G2). Suspecting Kallman syndrome (KS), due to delayed puberty and anosmia, the following tests were requested: bone age, which was 16 years old; bone mineral densitometry that diagnosed osteoporosis (*Z*-score −3.6 in the spine and −3.1 total femur); Pituitary MRI showing agenesis of bands and olfactory bulbs. Blood tests showed a normal pituitary hormonal profile, except for hypogonadotropic hypogonadism, low Inhibin-B and elevated Anti-Mullerian Hormone. A genetic study showed a mutation in the FGR1 gene (c.560G>A / p.Arg187His) associated with hypogonadism with or without anosmia, of autosomal dominant inheritance. His mother had the same mutation. With the diagnosis of KS, the different therapeutic options for the induction of secondary sexual characteristics were discussed: testosterone analogues or use of gonadotropins, opting for the second to also achieve gonad development. HCG 1000UI twice a week and rFSH 75UI 3 times a week were started, without side effects. After 8 months of treatment, rFSH was increased to 150UI. The clinical and analytical evolution was adequate, presenting a Tanner IV stage at 13 months and his first seminogram reported hypospermia. (Table 1)

Table 1

	Basal	3 months	7 months	13 months
FSH (mUI/ml)	0,7	1,1	2,8	4,6
LH (mUI/ml)	0,22	<0,12	<0,12	<0,12
Testosterone (ng/ml)	0,13	6,7	8,8	8,6
17-beta-estradiol (pg/ml)	<24	66	58	59
Inhibin-B (pg/ml)	58	74	71	90
Anti-Mullerian (ng/ml)	67,6	21,3	–	5,57
Testicles (cc)	3–4	5–6	6–7	12

Conclusions
Importance of early diagnosis and treatment of hypogonadotrophic hypogonadism in KS to perform adequate pubertal induction, achieve sexual and bone maturity, and avoid emotional and social problems. Gonadotropin therapy is an effective alternative to testosterone analogues for achieving induction of secondary sexual characteristics, testicular development and fertility.

Mental health issues of patients with acromegaly: A systematic review

Merve Murat[1], Selda Celik[2] & Elvan Emine Ata[1]
[1]University of Health Sciences, Hamidiye Faculty of Nursing, Psychiatric Nursing Department, Istanbul, Turkey; [2]University of Health Sciences, Hamidiye Faculty of Nursing, Internal Medicine Nursing Department, Istanbul, Turkey.

Background
Acromegaly which is caused by excessive growth hormone is a rare chronicle endocrine disorder. Because it is a rare disorder, limited data are available on the impact and consequences of acromegaly on the mental health of patients, but the investigations are growing over time.
Aim
It aims to summarize the evidence identifying the mental health issues of patients with acromegaly.
Methods
MEDLINE (PubMed), Web of Science, and CINAHL databases were searched to retrieve potential studies from January 2000 to December 2022. Two reviewers independently screened abstracts, following specific eligibility criteria.
Findings
According to the studies, the main mental health issue was decreasing the quality of life of the patients. Other mental health issues were having depressive symptoms and mood swings, feeling of burden, impairments in body-self-perception, disruption in interpersonal relations, decrease in sleep quality, and social withdrawal anxiety.
Conclusion
Overall, the findings of this review suggest that there are many different mental health issues among patients with acromegaly which emphasize holistic health care. Also, the number of psychological interventional randomized controlled studies should be increased.

Keywords: acromegaly, mental health, quality of life

Gelastic seizures caused by pituitary stalk interruption syndrome: Case report

Hadami Ben Yamna, Bchir Najla, Salma Abadlia, Annam Benchhida, Chedia Zouaoui & Haroun Ouertani
The Principal Military Hospital of Instruction of Tunis, Department of Endocrinology, Tunis, Tunisia.

Introduction
Gelastic seizures have been typically described with hypothalamic hamartomas and precocious puberty. Invasive EEG recordings have shown that gelastic seizures originated from the hypothalamic hamartomas, however recent findings

have shown that they might also arise from other central lesions, like tumors, malformations of cortical development, postinfectious foci and other hypotalamic or pituitary abnormalities. In this case, we describe a patient with gelastic seizures and a short stature, in whom pituitary stalk interruption syndrome was discovered.
Case presentation
We report the case of a 13-year-old patient, who presented with slowed growth and short stature. Parents described brief laughter attacks, apparently unmotivated, that was perceived as strange behavior by his family. Physical examination showed a height of 142 cm which was below the second percentile for chronological age, and weight was 50 kg which was normal for age. Bone age was at 12 years. EEG showed some rare focal frontal lobe discharges. Laboratory findings revealed hypopituitarism with a thyroid-stimulating hormone level of 2.7 mIU/l and free thyroxine at 7.8 pmol/l (normal range 11 to 18 pmol/l). Cortisol level was 196 and 188 nmol/l after ACTH stimulation test. The rest of the biological investigation was normal. The patient underwent Insulin-induced hypoglycemia test and Glucagon stimulation test. Both tests confirmed the diagnosis of growth hormone deficiency since the maximal level of GH was 0.65 mI/l. Combined pituitary hormone deficiency was therefore held. Imaging of the sellar region was conducted, showing the typical triad of pituitary stalk interruption syndrome with interrupted pituitary stalk, hypoplasia of the anterior pituitary and ectopic posterior pituitary. Patient was treated with lamotrigin, risperidone, hydrocortisone and levothyroxin, and received growth hormone replacement therapy with good statural evolution. Puberty was induced at the age of 19 with good response.
Conclusion
These findings suggest that gelastic seizures can be generated in the hypothalamus or in its neighboring regions. Patients who suffer from these seizures should be screened for central endocrine abnormalities including precocious puberty and hypopituitarism.

Macroprolactinoma in a patient with Schizophrenia: which illness should be treated first?

Bel Hadj Sliman Chayma, Bchir Najla, Baltagi Myriam, Annam Benchhida, Dorra Dorraelguiche, Zouaoui Chadia & Haroun Ouertani
Military Hospital of Tunis, Endocrinology, Tunis, Tunisia.

Introduction
Prolactinomas are the most common of functional pituitary tumors. Dopamine agonists are the first line treatment of prolactinomas but have antagonistic effect with antipsychotics (dopamine receptor blockers) used in schizophrenia. The association between these two illnesses is a medical challenge, as the treatment of one disease can exacerbate the symptoms of the other one.
Clinical case
We report the case of a 72-year old man, newly diagnosed with schizophrenia (in March 2022) on the basis of positive symptoms. After two months of daily treatment (dopamine receptor blockers) the patient presented frequent headache. The MRI revealed a pituitary macroadenoma ($20 \times 15 \times 18$ mm) with cavernous sinus invasion without displacement of the optic chiasma. Hormonal evaluation revealed elevated serum prolactin levels at 4237.29 mUI/l. The other pituitary hormones were normal. The patient was initially treated with 1.5 mg/week of Cabergoline. Two months later, serum prolactin levels were reduced down to 1250 mUI/l. However, the patient developed episodes of visual hallucinations: zoophilia. The decision was to adjust his antipsychotic treatment by adding haloperidol and to reduce the dose of cabergoline down to 0.5 mg/week. The following month was marked by the increase in serum prolactin levels up to 1500 mUI/l with no progression of the macroadenoma showed on MRI and with stabilization of schizophrenia positive symptoms.
Conclusion
Treating a patient with both schizophrenia and macroprolactinoma is a balance between both entities: symptoms and treatment's side effects. We should monitor the treatment doses to avoid their side effects and exacerbation of chronic diseases.

Prolactinoma in women

Asmae Salhi[1], Anouar Jamal[1], Hanae Bakmizi[1], Hanae Rachedi[1], Siham Rouf[2] & Hanane Latrech[2]
[1]Endocrinology-Diabetology and Nutrition Department, University Hospital Center Mohammed-VI, Oujda, Morocco; [2]Department of Endocrinology, Diabetology and Nutrition, Laboratory of Epidemiology, Clinical Research and Public Health, Faculty of Medicine and Pharmacy, Mohamed I University, Oujda, Morocco.

Introduction
Prolactinoma is the most common type of pituitary adenoma, but it still presents difficulties in management especially in women who present some particularities hence the interest of our study.[1]
Material and method
This is a retrospective, descriptive study including 14 patients, hospitalized in the Endocrinology-Diabetology-Nutrition Department at CHU-Mohammed-VI-Oujda, between 2016–2022. The statistical analysis was performed by SPSS version 21 software.
Results
The mean age of the patients was 35.9 ± 13.2 years, of which 55.5% were in the menopausal period. The mode of revelation was mainly presented by a tumor syndrome in 57.1% of cases, isolated signs of hyperprolactinemia in 42.9%, while infertility was observed in 35.7%. Galactorrhea was present in 64.3% of women, cycle disorders in 78.6%, and decreased libido in 28.6%. The mean prolactin level was 353.4 ng/ml, associated with a gonadotropic deficit in 64.3%. Morphologically, macroprolactinomas predominated with 57.1% of cases. All patients benefited from medical treatment with dopaminergic agonists, and surgery in 21% of cases, which allowed recovery of gonadotropic function in 85% of cases, and the achievement of pregnancy in 28.5% of cases.
Discussion-conclusion
Dopaminergic agonists remain the effective first-line treatment for prolactinomas, allowing both the restoration of gonadal function and the achievement of pregnancy, which remains however of delicate management requiring a codified management[2].

Radiological features of non-functioning pituitary adenomas in the Tunisian population

Abdel Mouhaymen Missaoui, Nabila Rekik Majdoub, Siddiqa Soomauroo, Faten Haj Kacem Akid, Dhoha Ben Salah, Fatma Mnif, Nadia Charfi, Mouna Mnif, Mouna Elleuch & Mohamed Abid
Hedi Chaker University Hospital, Department of Endocrinology, Sfax, Tunisia.

Objective
To describe the radiological features of non-functioning pituitary adenomas (NFPA) at diagnosis.
Patients and methods
A retrospective descriptive study of 35 patients followed for NFPA between 2000 and 2022. A pituitary magnetic resonance imaging (MRI) scan was performed in all patients.
Results
The mean age was 52.1 ± 11.4 years with a male predominance (61.3%). Pituitary tumor syndrome was the main reason for consultation (77.4%). Visual impairments were observed in 80.6% of cases. It was frequently a macroadenoma in 90%, and a microadenoma in 10%. The majority of tumors were between 1 and 2 cm in size (46.7%). In 10% of the cases, the NFPAs were larger than 4 cm in diameter. Radiological analysis revealed hemorrhagic lesions in 25% of cases, and rarely a necrotic aspect (19.2%). Optic structures were invaded in 41.4%. Sphenoidal sinus infiltration was observed in 32.1%. In two-thirds of the cases, the cavernous sinus was invaded, indicating a locally advanced tumor status. The NFPA showed an aspect encompassing the internal carotid artery partially ($< 180°$) in 53.3% and massively ($> 180°$) in 13.3% of cases.
Discussion
The most common radiological findings at the time of diagnosis of NFPA are those of a locally aggressive sellar tumor invading the noble visual and vascular structures. This locoregional aggressiveness poses a therapeutic challenge, particularly for surgical resection, which is often incomplete. The tumor residue is a major prognostic factor that requires clinical, ophthalmological, and radiological monitoring, sometimes with adjuvant treatment (radiotherapy, surgical revision).

Cushing's disease with negative imaging: What diagnostic and therapeutic approach?

Sadi Maya[1], Mouna Mezoued[2], Bessaid Khadidja[1] & Malha Azzouz[1]
[1]Bologhine Hospital, Endocrinology, Alger, Algeria; [2]Bologhine Hospital, Alger, Algeria.

Introduction
Cushing's disease with negative hypothalamic–pituitary imaging is not a rare situation,since it is found in 1/3 of cases. This is a situation that complicates the etiological and therapeutic approach of the pathology, questioning the practitioner as to the effectiveness of pituitary surgery in this case.
Objective of the study
The aim of our study was to compare the results of pituitary surgery in the groups of patients with and without visualization of the adenoma on imaging and the contribution of petrous sinus catheterization in the latter.
Patients and methods
This is a retrospective study including 69 patients with Cushing's disease, over a period from January 1999 to August 2022, admitted to the endocrinology department of EPH Bologhine. Patients with exogenous Cushing's syndrome, ACTH-dependent Cushing's syndrome of paraneoplastic origin, and pseudo-Cushing's were excluded from the study. The statistical test used in this study is the T-student with P-value < 0.05 considered significant.
Results
Our series delivered 69 patients (55 women and 14 men) with Cushing's disease. 13 patients had a normal hypothalamic–pituitary MRI, ie 18.84% of cases, and 7 of them had undergone petrous sinus catheterization (53.84%). In 85.71% of cases, i.e. in 6 patients, catheterization revealed a centro-peripheral gradient, with lateralization of secretion in 57.14% of our patients (75% on the right and 25% on the left). Transsphenoidal surgery was the preferred approach in 6 of these patients (46.15%) with clinical and biological remission of Cushing's syndrome in 38% of cases in the group with normal hypothalamic–pituitary MRI, compared to 35.71% in patients with adenoma visualized on imaging (P-value = 0.046). Patients who did not obtain surgery were either lost to follow-up (6 patients) or died (1 case)
Conclusion
The etiological diagnosis of ACTH-dependent hypercorticism is not always easy. It turns out that in a third of the cases, the imaging techniques, as advanced as they are, do not make it possible to highlight the microadenoma in question. This is where catheterization of the petrous sinuses should provide the topographical diagnosis of Cushing's syndrome. In first intention, surgery via the transsphenoidal approach should be preferred. However, drug treatments remain important in the event of failure of surgery or while waiting for the appearance of a pituitary image.

Acromegaly and metabolic comorbidities – a retrospective study

Teodor Dumitras[1], Simona Gabriela Duta[1], Ruxandra Calapod[1], Alexandra Bancu[1], Irina Nistor[1], Anca Sirbu[1,2], Sorina Martin[1,2], Carmen Barbu[1,2] & Simona Fica[1,2]
[1]Elias University Emergency Hospital, Bucharest, Romania, Endocrinology; [2]"Carol Davila" University of Medicine and Pharmacy, Bucharest, Romania.

Introduction
Acromegaly is a rare endocrine disease characterised by excess GH produced by a pituitary adenoma. It is associated with several complications and comorbidities. Metabolic alterations such as diabetes and dyslipidemia are quite frequent described in these patients.
Materials and methods
This is a retrospective observational cross-sectional study meant to assess the metabolic modifications in a group of acromegaly patients evaluated in our department.
Results
We included 67 patients in our study (38 female and 29 male). The mean age at diagnosis was 46.15 while mean disease duration was 10.42 years with 38 patients having below 10 years of disease activity. 77.6% of our patients presented with macroadenoma at diagnosis. There were 15 patients who refused surgery or had contraindication and 31 patients who did not undergo any type of radiotherapy. 42 patients received treatment at one point in time with a somatostatin analogue, 13 patients with pegvisomant and 26 patients with dopamine agonist. Out of all patients, 20 had no tumoral rest, no medical treatment and no disease activity (random GH $<$ 1 ng/ml, GH OGTT $<$ 0.4 ng/ml or GH/24 h $<$ 1 ng/ml, IGF1 $<$ 1.3$\times$ upper superior limit adjusted for sex and age), 24 were in biochemical remission and 23 still had active disease with partial response. Diabetes was diagnosed in 42 patients (22 female and 20 male) and dyslipidemia in 52 patients (30 female and 22 male). People with more than 10 years of disease activity had higher IGF1/USL in female patients, higher glycemia in male patients and higher triglycerides with lower HDL cholesterol irrespective of sex. Diabetic patients had higher mean value for GH over 24 h and IGF1/USL compared to those without diabetes, irrespective of sex and irrespective of disease status (complete, biochemical or partial response). Female patients with dyslipidemia had higher mean value for GH over 24 h and IGF1/USL. Female patients presented higher IGF1/USL than men in both diabetic and dyslipidemic groups. In both diabetic and dyslipidemic groups, higher values of GH/24 h and IGF1/USL were correlated with higher glycemia ($P > 0.05$) and triglycerides ($P < 0.05$).
Conclusions
Acromegaly is a complex pathology and needs to be treated accordingly. Diabetes and dyslipidemia are important complications which do not need to be overlooked and could be linked to disease activity.

Key words: acromegaly, diabetes, dyslipidemia, retrospective study

De-escalation treatment with pasireotide for aggressive acromegaly: A long-term experience

Sara Menotti, Antonella Giampietro, Sabrina Chiloiro, Alfredo Pontecorvi, Laura De Marinis & Antonio Bianchi
Università Cattolica del Sacro Cuore, Endocrinology, Rome, Italy.

Introduction
Pasireotide long acting release (LAR) is approved for second line treatment of acromegaly. We present 3 patients with aggressive acromegaly treated with a personalized de-escalation approach.
Case 1
A 61-year-old female affected by acromegaly reisistant on first-line SSAs. In 2015 therapy was switched to pasireotide LAR 60 mg every 28 days. After two years, the IGF-I level touched the lower age range and therapy was downscaled to pasireotide LAR 40 mg, and in 2020 to 20 mg. In 2021 and 2022, the IGF-I level remained within the normal age range.
Case 2
A 40-year-old female affected by acromegaly resistant on first line SSAs and pegvisomant, who underwent on 3 different neurosurgeries. In 2011 he was enrolled in a Phase III clinical trial (PAOLA study) and assigned to receive pasireotide LAR (60 mg every 28 days). Due to IGF-I overcontrol and radiological stability, in 2016 therapy was downscaled to pasireotide LAR 40 mg and in 2019 further downscaled to pasireotide LAR 20 mg. During the treatment, the patient developed hyperglycemia treated with metformin 500 mg 3 times daily.
Case 3
A 37-year-old male affected by acromegaly resistant on first line SSAs. In 2011 the patient was enrolled in the PAOLA study assigned to receive pasireotide LAR (60 mg every 28 days). In 2018, therapy was downscaled to pasireotide LAR 40 mg for IGF-I overcontrol and in 2022 to pasireotide 20 mg. He developed hyperglycemia, HbA1c values stayed under 6.5% (48 nmol/l) for 7 years.
Discussion
Initiating therapy with a high dose of pasireotide (60 mg) could allow a greater proportion of patients to achieve acromegaly control, particularly in selected cases of clinically aggressive acromegaly that may respond well to pasireotide (characterized by high IGF-I values at diagnosis, invasion of the cavernous sinuses, partial resistance to first-line SSAs and positive expression of SSTR5). Another benefit of this treatment could be the long-term control of IGF-I levels and its oversuppression that continues even when the dose of pasireotide LAR is reduced. The major risk seems to be hyperglicemia. Nevertheless, GH and IGF-I uncontrolled levels are major players in the glucose metabolism. The main limitation of our observation is the very small sample size of our series, to confirm our observations clinical studies are required.
Conclusion
This de-escalation pasireotide treatment could allow to both achieving control of acromegaly and acceptable metabolic tolerance in selected cases of aggressive acromegaly potentially responsive to pasireotide.

Somatotrpic adenomas: Radiological features at diagnosis in a Tunisian cohort

Faten Haj Kacem Akid, Wafa Belabed, Abdel Mouhaymen Missaoui, Dhoha Ben Salah, Mouna Mnif, Fatma Mnif, Nabila Mejdoub & Mohamed Abid

Hedi Chaker University Hospital, Department of Endocrinology and Diabetology, Sfax, Tunisia.

Background and aim

Acromegaly is mostly due to a somatotropic adenoma. Regarding its insidious nature, this adenoma is often revealed at an invasive stage. This study aims to describe the radiological specificities of somatotropic adenomas at the time of diagnosis

Patients and methods

We conducted a retrospective study at the Endocrinology department of Hedi Chaker University Hospital, Sfax, Tunisia. We involved 29 patients diagnosed with acromegaly, whose clinical, biochemical, and imaging peculiarities were collected from medical charts.

Results

The mean age at diagnosis was 45.8 ± 12.4 years with a male predominance (51.7%). The majority of patients (60%) presented with symptoms evolving 5 years before the diagnosis. The reasons for consultation were dominated by a pituitary tumor syndrome (30%) or acrofacial dysmorphia (16.6%). A hypothalamic–pituitary MRI was performed in all patients. Somatotropic macroadenomas were predominant, noted in 82.8%. The frequency of microadenomas did not exceed 17.2%. The mean tumor size was 23 ± 10.5 mm. The majority of adenomas (44.8%) were between 10 and 20 mm. Two patients had a giant adenoma (46 mm and 50 mm). A T1 hypo-signal or iso-signal was observed in 47.1% and 52.9% of patients, respectively. On T2-weighted sequences, the adenoma appeared as iso-signal in 44.4%, more rarely as hypo- (27.8%) or hyper-signal (27.8%). Pituitary apoplexy was found in 2 cases. The adenoma was invasive in 48.3%. This invasion was at the expense of the cavernous sinus (20.7%), the supra-sellar cisterns (31%) or the sphenoidal sinus (6.9%).

Discussion

Somatotropic adenomas are classically invasive macroadenomas. Their spontaneous signal is variable but a heterogeneous appearance is frequent, particularly clear in T2. Some studies suggest that a hypointense T2 appearance correlates with high secretory activity (densely granulated cells) and is predictive of a better biological response to somatostatin analogues.

EP788

Prolactinoma in men

Dhoha Ben Salah, Trigui Souleima, Frikha Hamdi, Nadia Charfi, Mouna Mnif, Nabila Mejdoub, Fatma Mnif, Faten Haj Kacem Akid & Mohamed Abid
CHU Hedi Chaker, Endocrinology, Sfax, Tunisia

Introduction

Prolactinomas in men are rare but are characterised by their giant and invasive nature. They present with signs of hypogonadism and mass effect. The aim of this study is to clarify the clinical, biological, radiological and therapeutic features of Prolactinomas in men.

Patients and methods

Retrospective descriptive study including 27 adult males with a prolactin pituitary adenoma hospitalized in the endocrinology department of the Hedi Chaker Sfax university hospital over the period from 1998 to 2020.

Results

The average age of diagnosis was 38.6 years with two peaks of incidence: between 20 and 39 years (59.52%) and between 40 and 59 years (25.9%). The most frequent revealing symptom was mass effect (48.1%) Dcreased libido and erectile dysfunction were found in 85.1% and 81.4% of cases respectively. Gynecomastia was found in 8 patients and galactorrhea in only 2 patients. Prolactin levels above 250 ng/ml were present in 24 patients, 7 of whom had prolactin levels above 10 000. The prevalence of pituitary insufficiency was 85.1%. Gonadotropic deficiency was the most frequent (85.1%, $n=23$) followed by corticotropic and thyroid deficiency (37% and 25.92% respectively). The mean tumour size was 46 mm [9–90 mm]. Giant prolactinomas and macroprolactinomas were the most frequent (48.1% and 40.7% respectively). Only 3 patients had a microprolactinoma. Suprasellar extension was found in 85.2% of cases. Invasion of the cavernous sinus was found in 48.1% of cases and invasion of the sphenoidal sinus in 40.7% of cases. A cystic component was found in giant prolactinomas (30.7%, $n=4$).Radiological apoplexy was found in 29.5% of cases. The first-line treatment was medical in almost all patients. Surgical treatment was performed in 5 patients in the case of resistance to medical treatment in 4 patients and as first-line treatment in the case of chiasmatic compression with visual prognosis in one patient. Complete disappearance of the adenoma was observed in only 5 patients and 63.1% of prolactinomas were resistant to treatment.

Conclusion;

Compared to other types of adenoma. Treatment resistance defined as persistence of the adenoma and/or hyperprolactinemia is common in macroadenoma and invasive tumours. Other factors are very young age, male gender, cystic, haemorrhagic and/or necrotic components on initial imaging. This leaves room for new therapeutic alternatives such as pasireotide and temozolomide.

Diagnostic approach and treatment options for a geriatric patient with panhypopituitarism due to pituitary apoplexy

Natia Shonia[1,2], Ketevan Chanturishvili[1,2], Natia Margvelashvili[1,2], Nino Zavrashvili[1,2] & Qetevan Gvazava[1,2]
[1]Tbilisi Institute of Medicine, Endocrinology, Tbilisi, Georgia; [2]David Tvildiani Medical University, Endocrinology, Tbilisi, Georgia.

Pituitary apoplexy (PA) is a rare clinical syndrome related to abrupt hemorrhage and/or infarction of the pituitary gland, usually occurring in patients with preexisting pituitary disease. It is an endocrine emergency requiring rapid diagnosis and appropriate management. Pituitary apoplexy may lead to multiple pituitary hormone deficiencies. Without proper diagnosis and management, these can lead to the occurrence of irreversible complications, most significantly adrenal crisis due to secondary adrenal failure. Secondary adrenal insufficiency is the most common subtype of adrenal insufficiency caused by certain medications and pituitary conditions (pituitary masses, inflammation, hemorrhage or infiltration) and etc. We present a case of 77 y/o male patient who presented in our clinic in June of 2022 with the complaints of fatigue, weakness, voice changes, lethargy and weight loss. His medical history revealed a presence of pituitary macroadenoma diagnosed in 2009, without proper functional status assessment. His medications included levothyroxine 37.5 μg since 03.2022. Patient was hospitalized twice in 2021 due to low blood pressure, nausea, vomiting and syncope but no definitive diagnosis was made. Laboratory work-up confirmed secondary adrenal insufficiency, secondary hypothyroidism and secondary hypogonadism. Patient was referred to radiologist, upon MRI imaging diagnosis of Supra/endosellar neoplasia, with pituitary apoplexy and panhypopituitarism were made. Treatment with hydrocortisone was initiated, levothyroxine was discontinued temporarily and later restarted to avoid adrenal crisis. Patient's clinical condition was significantly improved, he was referred to endocrine surgeon for further assessment. Decision was made to follow-up patient and continue medical treatment. Considering patient's medical history, current clinical status and age, multidisciplinary team approach is recommended to tailor treatment options for individual cases.

Werner syndrome and endocrine involvement: A case report

Nassim Ben Hadj Slama, Ghada Saad, Gorchene Asma, Taieb Ach, Maha Kacem & Koussay Ach
University Hospital of Farhat Hached Sousse, Endocrinology, Tunisia.

Introduction

Werner syndrome is a rare genetic disease affecting the WRN gene, of autosomal recessive inheritance.

Case-presentation

We report the case of a 34-year-old patient who presented with erectile dysfunction and asthenia. His brother underwent surgery for meningioma. He was also diagnosed with hypogonadism, suffered from bilateral cataract and diabetes, and died following acute Leukemia at the age of 35 years. Our patient is from a second-degree consanguineous marriage, he has a low intelligence quotient, a bilateral cataract for which he underwent surgery, a growth retardation secondary to a GH deficiency, peripheral hypothyroidism, and diabetes treated with metformin. On examination, he had a hoarse voice, short stature, facial dysmorphia with triangular bird's head face and spread ears, flat feet, and canities. He had hypopigmented areas on the limbs with scleroderma of the skin without melanoderma. Both testicles were in place with a pubertal stage estimated at G3P3 according to Tanner scale. He did not have gynecomastia or micropenis. Hairiness was rare. On biology, he had an HBA1C at 7.2%, hypertriglyceridemia at 6.47 mmol/l, TSH at 2.7 mUI/l, low baseline cortisol level at 32 ng/ml, ACTH

at 50 pg/ml, FSH at 1.3 mUI/l, LH at 5.3 mUI/l, Testosteronemia was low at 0.7 ng/ml and Prolactinemia at 150 µUI/l. The hypothalamic–pituitary MRI was normal. A genetic study revealed a mutation of the WRN gene confirming Werner syndrome. The patient was treated by substitution therapy with Hydrocotrtisone and Testosterone Enanthate along with with dietary rules and Fenofibrate. During follow-up, the patient was diagnosed with a locally advanced nasopharyngeal carcinoma. The patient died as a result of complications related to radiotherapy.
Discussion
Werner syndrome usually begins in adolescence with a peak at age 30. It is responsible for premature aging and affects almost all functions, especially endocrine ones. The latter is manifested essentially by hypothyroidism, hypopituitarism, and hypogonadism. Hypothyroidism is generally peripheral due to atrophy of the thyroid gland, but central hypothyroidism remains possible. Hypogonadism is essentially a hypergonadotropic hypogonadism due to premature atrophy of the reproductive organs. Hypogonadotropic hypogonadism may be found more rarely, probably in relation with hypopituitarism. Diabetes observed in this syndrome is due to insulin resistance and decreased insulin secretion. The prognosis is linked to the occurrence of early and aggressive cancers.

Pituitary formation according to the results of magnetic resonance imaging studies

Elena Brutskaya-Stempkovskaya[1], Yuliya Dydyshka[1], Siarhei Kavetski[2], Ivan Vasilevich[1] & Artsiom Alperyn[3]
[1]Belarusian State Medical University, Minsk, Belarus; [2]Republican Clinical Hospital of Medical Rehabilitation, Minsk district, Aksakovshchina Village, Belarus; [3]Belarusian State University, Minsk, Belarus.

Objective
The introduction of imaging technologies into routine clinical practice has increased the pituitary incidentalomas cases detection by magnetic resonance imaging (MRI) of the brain. Identification of pituitary formations requires additional hormonal examination and dynamic MRI pituitary examination for differential diagnosis and treatment strategy for patients. An important clinical problem is to determine the malignancy, predictors of potential growth and hormonal activity of pituitary incidentalomas from the results of MRI studies.
Materials and methods
A preview of retrospective study patients with pituitary incidentalomas detected by pituitary MRI examination at Republican clinical hospital of medical rehabilitation in 2021–2022 years is presented. All patients underwent pituitary MRI without gadolinium using at the beginning. In doubtful cases, repeated MRI was performed with gadolinium. Sagittal and coronal scans were examined. A pituitary macroadenoma was diagnosed with a one size of 10 mm or more. Laboratory, clinical and MRI data were analyzed using a neural network. Our neural network architecture consists of two consecutive parts. Detection model presented as a one-stage object detection neural network (Retina Net) to produce bounding boxes of the pituitary. Diagnosis model: ResNet-34 used to predict probabilities of pituitary macro/microadenoma using output of previous neural network (segmented slices). Derived probabilities was combined with hormonal tests via Gradient Boosting on Decision Trees algorithm.
Results
We studied 310 patients with pituitary incidentalomas, average age 40.9 ± 15.91 years. A pituitary macroadenoma was diagnosed in 24 (7.7%) patients, average age 50.8 ± 14.09 years, male:female rate was 1:2 (male – 8 (33.3%), female – 16 (66.7%)). 286 patients with pituitary incidentalomas less 10 mm, average age 36.2 ± 13.55 years. Pituitary macroadenoma was significantly more frequently diagnosed in older patients compared to younger ones ($P < 0.05$). Pituitary incidentalomas less than 10 mm were more frequently diagnosed in young patients ($P < 0.05$).
Conclusion
The results of the study indicate an increased prevalence of pituitary macroadenomas in women and associated with an increase in age. It is necessary to clarify the plan for long-term monitoring of incidentalomas in young people for timely detection of growth.

Pituitary pathology and pregnancy

Belhadi Leila, Bensbaa Salma, Nassim Essabah Haraj, Siham El Aziz & Asma Chadli
University Hospital Center Ibn Rochd, Department of Endocrinology and Metabolic Diseases, Casablanca, Morocco.

Introduction
Pregnancy in patients with pituitary pathology is a rare and delicate situation. However, risks for the mother and the foetus as well as the consequences of pregnancy on the history of pituitary adenoma require close monitoring.
Goals
Illustrate through 5 observations the evolution of pituitary pathology during pregnancy.
Observations
1st patient: 41-year-old followed for somatotropic pituitary macro adenoma for which she was operated on with treatment failure. Pregnancy occurred 2 years post-operatively, with a preconception IGF1 level twice normal; MRI performed at 10 WA showed regression in the size of the adenoma, without visual complications. The delivery was scheduled at 37 WA by cesarean section without complications. The patient breastfed for 20 days and then stopped when the tumor syndrome accentuated.
2nd patient: 29 years old, followed for somatotropic pituitary macro adenoma operated on twice by transsphenoidal approach with treatment failure, then received medical treatment. The pregnancy was uneventful with unassisted home birth without complications. The patient breastfed for 20 months, currently, the child is 30 months old with good psychomotor development.
3rd patient: 37 years old who presented during the second trimester of pregnancy with a Cushing syndrome on pituitary macroadenoma with visual complications. Treatment consisted of complete transsphenoidal resection at 13 weeks. The evolution was marked by the occurrence of a spontaneous abortion at 20 SA.
4th patient: 35 years old followed for Cushing disease operated on with recurrence. The indication for a surgical revision was posed after medical preparation which was stopped in front of the discovery of pregnancy. The revision surgery was planned after delivery. The pregnancy was carried to term without complications. The delivery was vaginal without complications. The patient breastfed for 12 months.
5th patient: 36 years old followed for Cushing disease for 2 years on pituitary microadenoma operated and complicated by corticotropic insufficiency in remission. The pregnancy occurred 3 months later with good clinical evolution. The delivery was vaginal without complications, and the patient did not breastfeed.
Conclusion
Pregnancy is rare in patients with pituitary adenoma. On the other hand, its occurrence most often requires multidisciplinary and close care to prevent maternal and fetal consequences.

EP793

Metabolic complications of acromegaly: About 62 cases

Nana Aichatou Harouna, Nassim Essabah Haraj, Siham El Aziz & Asma Chadli
CHU Ibn Rochd, Endocrinologie- Diabétologie et Maladies Métaboliques, Casablanca, Morocco.

Introduction
Metabolic disorders caused by acromegaly are responsible for three times the morbidity of the general population
Study objectives
To analyze the different metabolic complications in acromegalic patients.
Materiel and methods
This is a retrospective study of 62 cases of acromegaly followed at the Department of Endocrinology and Metabolic Diseases CHU IBN ROCHD from January 2005 to December 2022. The data analysis was done with the Excel software in its 2021 version.
Results
The mean age was 54 years (17–88), Sex Ratio: F/H of: 2.6, the age of the disease at diagnosis averaged 10 years, the mean IFG1 level was 721.53 ng/ml. The average BMI level was 29 kg/m^2. The clinical examination found overweight in 15 patients or 24.19%, and obesity in 28 patients or 45.16%. The metabolic balance objectified carbohydrate metabolism disorders: prediabetes in 14 patients or 22.5% and diabetes in 27% patients or 43.5%. Dyslipidemia was objectified in 35 patients or 56.45% with a mean cholesterol level of 2 g/l, mean triglyceride of 1.7 g/l, mean HDL of 0.43 g/l and mean LDL level of 1.2 g/l. Hyperuricemia in 5 patients or 8% with an average uric acid level of 45 mg/l. All patients with carbohydrate metabolism disorders were put on hygiene-dietary measures, and in 74% on oral antidiabetics (ADO), and 21% on insulin therapy + ADO. Patients with dyslipidemia, were put in addition to hygiene-dietary measures adapted to statins in 65.2%. A marked improvement in the control balances has been achieved.
Conclusion
The systematic screening of metabolic complications in acromegalic patients and their early and adequate management is of major interest in order to prevent morbidity and mortality which results mainly that related to vascular accidents

MAFLD prevalence in a cohort of patients with Cushing's disease

Pablo Remon[1], Ana Piñar Gutiérrez[1], Eva Venegas Moreno[1], Elena Dios-Fuentes[1], David Cano Gonzales[1], Manuel Romero-Gomez[2] & Alfonso Soto-Moreno[1]
[1]Institute of Biomedicine of Seville (IBIS), Virgen del Rocio Hospital/C-SIC/University of Seville, Department od Endocrinology and Nutrition, Seville, Spain; [2]Department of Gastroenterology, Department of Gastro-enterology, Seville, Spain.

Objectives
To describe the prevalence of liver steatosis in a cohort of patients with Cushing's disease.
Methods
Cross-sectional descriptive study. We included 59 patients with Cushing's disease from our cohort of patients who underwent a Fibroscan to analyze the degree of hepatic steatosis (CAP measured in dB/m) and liver fibrosis (fibrosis measured in kPa). Biochemical algorithms of liver steatosis and fibrosis were assessed.
Results
7 (11.9%) men and 52 (88.1%) women. Median age 52 [43–61] years with 9.3 [3.7–18] years of follow-up. 40 (67.8%) cured and 19 (32.2%) non-cured. Median years of hypercortisolism was 2.13 [0.76–5.17] years. 26 (44.1%) showed any pituitary defficiency, 18 (30.5%) ACTH defficiency, 7 (11.9%) sex hormones defficiency and 16 (27.6%) thyroid. Metabolic morbidities were, obesity in 29 (48.3%) patients, type 2 DM 16 (27.6%), HBP 30 (50.8%), dyslipemia 29 (49.2%) and **4 (6.9%) chronic renal disease**. As mayor cardiovascular disease (3, 5.1%) suffered hearth disease and 2 (3.4%) an stroke. Four (6.8%) had chronic renal disease. 55.9% patients showed any degree of MAFLD with a median CAP of 265 [212–288] db/m. Two (3.4%) patients were diagnosed with liver fibrosis (kPa compatible with F3-F4). MAFLD was associated with obesity, time of hypercortisolism, curation, type 2 DM and hypertrigliceridemia.
Conclusions
The prevalence of MAFLD in patients with Cushing's disease is high and higher than described in previous studies. Hepatic steatosis is associated with variables related with the metabolic syndrome and the curation of Cushing' s disease. It is postulated that despite metabolic control, there is an increased risk of hepatic steatosis in uncured patients. A low percentage of liver fibrosis has been observed compared to the degree of fibrosis.

Coexistence of acromegaly and autoimmune disorders: Between hazard and causality – a case series

Mădălina Elena Iftimie[1], Burcea Iulia-Florentina[1,2], Ramona Dobre[1,2], Raluca Trifanescu[1,2], Dan Alexandru Niculescu[1,2], Ionela Baciu[1,2], Serban Radian[1,2], Cristina Capatana[1,2] & Catalina Poiana[1,2]
[1]C.I. Parhon National Institute of Endocrinology, Pituitary and Neuro-endocrine Disorders, Bucharest, Romania; [2]Carol Davila University of Medicine and Pharmacy, Bucharest, Romania.

Introduction
Acromegaly is a rare, chronic endocrinopathy, that results from persistent hypersecretion of growth hormone (GH) and consequently of insulin-like growth factor 1 (IGF1). It is well known that GH excess has multisystemic effects throughout the body, but its interaction with the immune system has only been suggested in the last few decades. This prompted us to explore the frequency of autoimmune disorders in a retrospective acromegaly cohort.
Case description
We present 7 cases of acromegaly occurring in association with autoimmune diseases, other than autoimmune thyroiditis, that have been evaluated in our clinic between 2015 and 2022. Two patients were diagnosed with myasthenia gravis (one of them with concurrent Graves disease), two with vitiligo, one patient had antineutrophil cytoplasmic autoantibodies (ANCA) associated vasculitis, another patient displayed a case of severe rheumatoid arthritis, and one had generalized psoriasis. The mean age at diagnosis was 47.4 years for acromegaly and 47 for autoimmune diseases, with a 6:1 female to male ratio. The most common presenting symptom for acromegaly was headache (57%), whilst autoimmune disease manifestations varied from fatigue and unilateral eyelid twitching to thrombotic events and acute kidney failure. Six patients had pituitary macroadenomas and only one had a microadenoma with a mean IGF1 at diagnosis of 2.9× upper limit of normal. The diagnosis of acromegaly preceded the autoimmune disease confirmation in only three cases, with an estimated duration of 40.3 months; was concomitant with the diagnosis of one myasthenia gravis case and was established during the evolution of vitiligo and rheumatoid arthritis in the other three patients. Six patients (86%) underwent surgery (one of them had two interventions), 4 of which (57%) required additional therapy for biochemical control consisting of somatostatin analogues (SA, $n=3$) or combination therapy with SA and cabergoline ($n=1$). One patient was treatment-naïve. Complete biochemical control was achieved in 5 patients (71%) and 2 out of 3 patients had controlled acromegaly at the time of the autoimmune disease's diagnosis. Complications of acromegaly or autoimmune diseases were identified in 86% of cases.
Conclusion
Despite the increasing evidence of the immunomodulatory actions of the GH/IGF1 axis, the reports on autoimmune diseases in acromegaly patients are sparse. Considering the increasing prevalence of this disorders and the debilitating complications of both acromegaly and autoimmune afflictions, the interaction between GH excess and a dysregulated immune system should be further analysed.

Octreotide and pasireotide LAR in non-functioning pituitary neuro-endocrine tumours treatment

Anna Bogusławska, Łukasz Kluczyński, Magdalena Godlewska, Ewelina Rzepka, Alicja Hubalewska-Dydejczyk & Aleksandra Gilis-Januszewska
Chair and Department of Endocrinology, Jagiellonian University, Medical College, Kraków, Poland.

Somatostatin analogues (SSA) are first/second line treatment in the management of acromegaly and Cushing disease (CD), however, recent data suggest that they can be effective in the management of non-functioning pituitary neuroendocrine tumour (PitNET). We present one clinically silent gonadotroph PitNET treated with octreotide and two silent corticotroph PitNETs treated with pasireotide.
Case 1
A 50-year-old female presented with frontal headache and visual field deficits. In magnetic resonance imaging (MRI) a pituitary mass 30×34×34 mm with suprasellar expansion, compressing third ventricle and optic chiasm, invading sphenoid and cavernous sinus was described. She underwent transsphenoidal surgery (TSS), however, due to residual mass 34×28×37 mm a second TSS was performed. In histopathology gonadotroph PitNET; LH-, FSH +, SF1++, Ki-67<1%, SSTR2A++ was described. In control MRI 32×32×22 mm mass was visualised, patient has been continuously suffering from severe headaches. After multidisciplinary tumour board Octreotide LAR 20 mg/monthly was introduced. After 6 months of treatment, milder headaches and stable pituitary mass were noted.
Case 2
A 33-year-old male was admitted to Emergency Department due to severe headaches (8–9/10 using numbering rating score (NRS)) and vomiting. Sellar tumour (39×33×55 mm) and cerebral edema were found. External ventricular drainage and TSS were performed. Histopathology results showed silent adenoma subtype 1 (densely granulated), Ki67<1%. Three months later, MRI showed progression of PitNET (40×39×30 mm). Subsequently, patient underwent two emergency TSS and stereotactic fractionated radiotherapy. Treatment with temozolomide, pasireotide, cabergoline, radiotherapy was introduced. After 18 months of combined therapy stable disease was observed. Implementation of pasireotide resulted in spectacular decrease of headaches (initially 9–10 to none /10 using NRS).
Case 3
A 31-year-old male presented in our clinic due to headaches and bitemporal hemianopsia. In MRI PitNET was found (22×19×23 mm) and active CD was diagnosed. TSS was performed in 2013. Histopathology results showed corticotroph PitNET with Crook cells. Postoperatively, PitNET progression (17×26×13 mm) was observed with no overt CD. In 2022, due to worsening of headaches and vision loss, second TSS was performed. Histopathologists described corticotroph tumor with Crook cells with ATRX mutation of uncertain significance. Pasireotide implementation is planned. Pharmacotherapy with SSA in the cases of non-functioning PitNETs allows the stabilisation of the disease, decrease the headaches and can be considered as an alternative for the next neurosurgeries, however, further multicentre studies should be carried out.

Pituitary stalk interruption syndrome: A rare and severe cause of hypoglycemia in the newborn

Fatima Akioud[1], Imane Moustaghit[2] & Sana Abourazzak[3]
[1]University Hospital Center Souss Massa, Faculty of Medicine and Pharmacy Gadir Morocco, Endocrinology Diabetology and Nutrition, Agadir, Morocco; [2]Medical School,Souss Massa University Hospital Center, Endocrinology Diabetology and Nutrition, Agadir, Morocco;

[3]University Hospital Center Hassan II University Hospital, Faculty of Medicine and Pharmacy, Sidi Mohamed Ben abdellah University, Pediatric Endocrinology and Diabetology, Fes, Morocco.

Introduction
Pituitary Stalk Interruption syndrome (PSIS) is a congenital anomaly of the pituitary gland responsible for isolated or combined anteropituitary insufficiency. We report a case of Pituitary Stalk Interruption Syndrome (PSI) diagnosed in a newborn with profound hypoglycemia.
Case report
We report the case of a newborn with hypotonia, neonatal jaundice associated to a micropenis and a bilateral cryptorchidia. Because of severe hypoglycemia at 1.80 mmol/l (0.33 g/l), persistent despite infusions of glucose serum and glucagon, a hormonal assessment was requested at 48 h of life revealing corticotropic, thyroid and somatotropic insufficiency in favor of a congenital pituitary deficiency. A hypothalamic–pituitary MRI revealed a complete interruption of the pituitary stalk, an ectopic post pituitary associated with hypoplasia of the corpus callosum without other cerebral anomalies. Immediate hormone replacement therapy with hydrocortisone and Lthyroxine resulted in clinical improvement. Growth hormone treatment was also delivered for metabolic and neurodevelopmental purposes to limit the risk of further hypoglycemic episodes. The gonadotropic axis was explored at 6 weeks of age and revealed congenital hypogonadotropic hypogonadism, which led to the initiation of androgen therapy.
Discussion-conclusion
Complete or incomplete pituitary stalk syndrome is a rare syndrome defined by morphological abnormalities on MRI: small or interrupted pituitary stalk, hypoplastic anteroposterior pituitary and ectopic or absent posterior pituitary. The precise pathophysiology of this syndrome is discussed but the theory of congenital malformation with associated midline malformations is retained. Despite the fact that SITP is a rare disorder, it should be considered as a differential diagnosis in the newborn with severe hypoglycemia.

Pituicytoma in 64 years old man

Eleftheria Barmpa, Ioanna Meleti, Dimitra Pappa, Grigorios Efraimidis & Alexandra Bargiota
University Hospital of Thessaly, Department of Endocrinology and Metabolic Diseases, Larissa, Greece.

Introduction
Pituicytoma is a rare, primary benign, tumor of the sellar and suprasellar regions which is arising from pituicytes of the neurohypophysis and infundibulum and mainly affects middle age adults. We present here such a case
Presentation
A 64-years-old man was referred to our clinic. For further investigation of a sellar lesion with suprasellar extension. The patient underwent investigations due to visual disturbances which he noticed initially 6 months ago and gradually became worse. On opthalmological examination he found to have bitemporal hemianopsia and magnetic resonance imaging (MRI) of the brain and the pituitary revealed a well-circumscribed lesion about $2\times2\times1.8$ cm in size in sellar region with suprasellar extension, compressing the optic chiasm. The lesion was isointense on T1- and T2-weighted images, with heterogeneous enhancement following intravenous administration of Gd-DTPA. Clinical examination and laboratory testing did not reveal any hormonal deficiencies. Trans-sphenoidal surgery was carried out for optic nerve decompression, but full removal of the lesion was not possible due to bleeding during the operation. Histopathological examination revealed tumor cells spindle shaped, with unclear boundary and abundant cytoplasm. The tumor displayed diffuse immunoreastivity for TTF-1, S-100, focally GFAP and vimentin. These findings are typical features of pituicytoma. Following the surgery, the patient developed transient diabetes insipidus and his bitemporal hemianopsia was improved.
Conclusions
Pituicytoma is a rare tumor with less than 200 patients to be reported in the literature. It can be detected either as an incidental finding due to increasing imaging or due to symptomatology related to location and the tumor size. Clinical symptoms can include visual disturbances, headache and hypopituitarism. The diagnosis is based on histopathological examination which reveals the typical morphological and immunohistochemical features of pituicytoma.

Craniopharyngiomas in adult patients: Retrospective, multicentric study in Buenos Aires, Argentina

Susana Mallea-Gil[1], Mariela Glerean[2], Amelia Rogozinski[3], Carolina Ballarino[1], Maria Florencia Battistone[4], Karina Danilowicz[5], Sabrina Diez[6], Patricia Fainstein Day[2], Alejandra Furioso[3], Mirtha Guitelman[7], Debora Katz[4], Monica Loto[8], Marcela Martinez[9], Karina Miragaya[10], Soledad Sosa[5], Patricia Slavinsky[4], Julieta Tkatch[7], Marcelo Vitale[11], Valeria Gonzalez Pernas[4], Valeria Garcia Roel[3] & Jesica Pingel[4]
[1]Hospital Militar Central, Endocrinology, Buenos Aires, Argentina; [2]Hospital Italiano, Endocrinology, Buenos Aires, Argentina; [3]Hospital Ramos Mejia, Buenos Aires, Argentina; [4]Instituto Fleni, Endocrinology, Buenos Aires, Argentina; [5]Hospital de Clínicas, Endocrinology, Buenos Aires, Argentina; [6]Hospital I. Pirovano, Endocrinology, Buenos Aires, Argentina; [7]Hospital Durand, Endocrinology, Buenos Aires, Argentina; [8]Hospital Británico, Endocrinology, Buenos Aires, Argentina; [9]Hospital C. Milstein, Endocrinology, Buenos Aires, Argentina; [10]Sanatorio Güemes, Endocrinology, Buenos Aires, Argentina; [11]Hospital Santa Lucia, Endocrinology, Buenos Aires, Argentina.

Craniopharyngiomas are rare lesions derived from cell remnants of Rathke's pouch, usually localized in the sellar and suprasellar areas.
Objectives
To analyze clinical, endocrine and histological features in a group of patients from Buenos Aires city. To assess efficacy, number of surgeries and complications after surgery or other treatments.
Material and methods
Multicentric, retrospective, transversal study. Adult patients with craniopharyngiomas were included. We assessed clinical, biochemical, MRI features, at diagnosis and after treatments, the follow-up and recurrence of tumors.
Results
Ninety-seven patients, 49 women. Mean age at diagnosis: 41.4 ± 16.04. Symptoms at diagnosis: visual field defects (VFD): 47.4%, headache: 14%, both symptoms: 14%, in this group with mass effect, the VFD reached 61.8%. Other symptoms at diagnosis: incidental findings: 8,2%, diabetes insipidus (DI) 5.2%, and others 11.2% (n:10): 4 hypopituitarism, 2 oligomenorrhea, 2 neurocognitive deficit, 1 behavior disorder, 1 intracranial hypertension. Supraselar extension was present in 88.7%. Endocrine tests showed: hyperprolactinemia 27.8% (Prolactin levels: 61.6 ng/ml (21-156). DI and panhypopituitarism (PHP) were present in 30.5 and 26% respectively; VFD 78.5%: hemianopsia (60.9%): 50/82, quadrantopsia 19% and blindness 10.5% (9/85). Basal BMI was 28.6 ± 7.6. Surgical treatment (95/98): transcranial approach was performed in 71.1%, transsphenoidal approach was used in 25.8%; gross total resection was reached in 46.4%, subtotal 37.1% and partial resection 14.4%. Adamantinomatous type was found in 58.8%, papillary type in 13.4%. In the post-surgical assessment: 71.1% developed (PHP) (p .002) and DI 64.9% (p.002). VFD were 45.4% (40/88): hemianopsia 36.4%, quadrantopsia 9.5% and unilateral or bilateral amaurosis 9% (P 0.002 vs pre surgery). Tumor remnants were observed in 46.8% and recurrence rate was 19.6%. A second surgery was performed in 42.3%. Radiotherapy was indicated in 9.6%. Median time of follow-up was 57 months (4-427). Nine patients died, 4 related to the craniopharyngioma.
Conclusions
In this cohort of adult patients with craniopharyngiomas, VFD was the main symptom. Transcranial approach was the predominant surgery; Adamantinomatous type was the most frequent. In the post-surgical assessment, there was significant improvement in the visual field, but a significant increase in the BMI of patients and in the number of subjects with PHP. A second surgery was performed in 42.3% and 9.6% was treated with radiotherapy. These patients with long-term morbidities need life-long follow-up by a multidisciplinary team

Metastatic insulinoma in MEN1 patient

Barbora Havlinova[1], Jiri Soukup[2], Eva Hovorkova[2] & Jan Cap[3]
[1]University Hospital Hradec Králové and Charles University, Faculty of Medicine in Hradec Králové, Czech Republic, 4th Department of Internal Medicine – Hematology, Hradec Králové, Czech Republic; [2]University Hospital Hradec Králové and Charles University, Faculty of Medicine in Hradec Králové, Czech Republic, The Fingerland department of Pathology, Hradec Králové, Czech Republic; [1]University Hospital Hradec Králové and Charles University, Faculty of Medicine in Hradec Králové, Czech Republic; 4th Department of Internal Medicine – Hematology, Hradec Králové, Czech Republic.

We present a case report of a 56-year-old woman with MEN1 syndrome diagnosed at the age of 28 years. It was completely expressed by the set – insulinoma, prolactinoma and primary hyperparathyroidism. She underwent resection of 2/3 of the pancreas for symptomatic hypoglycaemia in the age of 28 years (1991). After two resections of parathyroid glands hypocalcaemia replacement was necessary. Prolactinoma was transiently treated with dopamine agonists. In the age of 45 years hypoglycaemia symptoms reappeared and a 30 mm recurrence of neuroendocrine tumour in the pancreatic head was detected. After its surgical enucleation (complicated with pancreatic fistula) hypoglycaemia symptoms improved, but did not completely disappeared. On abdominal ultrasound examination, small multiple hyperechogenic foci in the steatotic liver were observed. From the age of 53, the size of the largest lesion in segment VI progressed to 25 mm, then after one year to 30 mm. Clinical complaints included symptoms of hypoglycaemia – weakness, sweating, trembling hands, resolution of symptoms after eating. Whole-body scintigraphy after administration of ^{111}In-pentetreotide (Octreoscan) did not show expression of somatostatin receptors in the liver foci. A biopsy of the lesion in the right lobe of the liver followed in November 2022. The liver histology confirmed metastases of pancreatic insulinoma – NET G1 with the somatostatin receptors 5 (SSTRs-5) positivity (about 90% of cells, 2-3+). Recently, microwave ablation of the largest liver lesion was performed. The clinical manifestations were relieved and glycaemia normalized shortly after microwave liver ablation. In our case, recurrence of liver metastases of malignant insulinoma in the liver occurred 28 years after the diagnosis of MEN1 syndrome. The tumour strongly expressed SSTR-5 on liver metastases, but no SSTR-2 was revealed, which is rare and explains Octreoscan negativity. Thus, further pasireotide therapy was indicated with the aim of antisecretory and antiproliferative effect on neuroendocrine tumour.

Cushing syndrome (CS) is a chronic and debilitating condition with high morbidity and mortality. Development of novel, safe, and effective pharmacologic therapies with improved risk-benefit profiles would enrich treatment options for patients. Relacorilant is a selective glucocorticoid receptor (GR) modulator that competitively antagonizes cortisol activity and, unlike the FDA-approved GR antagonist mifepristone, does not bind to the progesterone receptor. In a phase 2 study in patients with endogenous CS (NCT02804750), relacorilant treatment was associated with clinically meaningful improvements in hypertension and hyperglycemia without undesirable antiprogesterone effects or drug-induced hypokalemia (Pivonello *et al. Front Endocrinol.* 2021;12:662865). GRACE (NCT03697109) and GRADIENT (NCT04308590) are ongoing phase 3 trials of relacorilant in patients with endogenous CS and concurrent hypertension and/or hyperglycemia. This abstract presents the study design of the phase 2/3, single-arm, open-label extension study (NCT03604198; EudraCT 2018-001616-30) evaluating the long-term safety and therapeutic effect of prolonged GR modulation with relacorilant. Study participants must have successfully completed one of the parent studies of relacorilant (NCT02804750, NCT03697109, NCT04308590) and, in the investigator's opinion, may benefit from further treatment. Biochemical entry criteria are consistent with the parent studies. For participants who completed relacorilant treatment >12 weeks before entering the extension study, reconfirmation of hypercortisolism is required. Participants receive daily relacorilant at the last dose received in their parent study unless dose modification is indicated by the investigator's clinical judgment. For participants entering from a placebo-controlled study or if the last dose of relacorilant was >4 weeks before enrollment, the starting dose is 100 mg oral capsule once daily, titrated up to the maximum tolerated dose not to exceed 400 mg. Treatment continues until relacorilant is commercially or otherwise available or until the study is stopped by the sponsor.

Primary endpoints are the incidence of treatment-emergent adverse events and changes from baseline in:

- Clinical laboratory tests
- Physical examinations and vital signs
- 12-lead electrocardiograms
- Pituitary tumor size based on magnetic resonance imaging for participants with Cushing disease

Exploratory endpoints assess the long-term benefit of relacorilant in the treatment of signs and symptoms of endogenous CS, including changes from baseline in the parent study in hemoglobin A1C, impaired glucose tolerance, and blood pressure. Additional exploratory endpoints include changes from baseline in body weight and composition, quality of life, bone remodeling, and other metabolic covariates of interest. This study is currently open for enrollment at centers in Europe, Israel, and North America.

Diagnostic and therapeutic challenges in cyclic Cushing's syndrome: A systematic literature review

Elisabeth Nowak[1], Frederick Vogel[1], Adriana Albani[1], Leah Braun[1], German Rubinstein[1], Stephanie Zopp[1], Katrin Ritzel[1], Felix Beuschlein[1,2], Marily Theodoropoulou[1] & Martin Reincke[1]
[1]Department of Internal Medicine IV, University Hospital, LMU Munich, Munich, Germany; [2]Department of Endocrinology, Diabetology and Clinical Nutrition, University Hospital Zurich (UHZ), Zurich, Switzerland

Background

Cyclic Cushing's syndrome (cCS) is a sub-entity of Cushing's syndrome (CS) associated with diagnostic and therapeutic challenges. It describes a condition, in which phases of clear-cut biochemical hypercortisolism are followed by spontaneous troughs of normal or subnormal cortisol secretion. We conducted the first systematic literature review to identify common features of cCS.

Methods

We searched MEDLINE (via PubMed) for eligible single case reports and case series from inception to October 10th, 2022, using two independent search terms. We compared outcomes to patients with noncyclic CS derived from the literature and to a longitudinally enrolled cohort from LMU hospital Munich as a reference standard.

Findings

In total, 212 cases with cCS were included for further analysis. Pituitary tumor origin accounted for 143 (67%), ectopic for 36 (17%), and adrenal for 23 (11%) cases. 4 (2%) cases were of occult origin, and 6 (3%) cases were unclassified. Clinical signs and symptoms were comparable to non-cyclic CS. In ACTHdependent forms, inferior petrosal sinus sampling had a positive and negative predictive value of 100% when performed during hypercortisolism vs 76% and 29% when performed irrespective of cortisolemic status. Overall, twelve (6%) patients underwent unnecessary surgery due to misdiagnoses. Remission rates were significantly lower and time to remission significantly longer when compared to the population with non-cyclic CS ($P < 0.001$).

Interpretation

We identified a heterogeneous population of patients with cCS with various tumor etiologies. Unpredictable cycle duration and frequency may cause diagnostic challenges resulting in misdiagnoses and missed diagnoses.

Rheumatologic complications of acromegaly

Oumaima Magouri[1], Lamiae Zarraa[1], Ouafae Elmehraoui[1], Siham Rouf[2] & Hanane Latrech[3]
[1]Endocrinology-Diabetology and Nutrition Department Hospital University Center of Mohamed VI, Oujda, Morocco; [2]Endocrinology-Diabetology and Nutrition Department Hospital University center of Mohamed VI, Laboratory of Epidemiology, Clinical Research and Public Health, Faculty of Medicine and Pharmacy, Mohammed First University Oujda, Oujda, Morocco; [3]Endocrinology-Diabetology and Nutrition Department Hospital University Center of Mohamed VI, Laboratory of Epidemiology, Clinical Research and Public Health, Faculty of Medicine and Pharmacy, Mohammed First University Oujda, Oujda, Morocco

Introduction
The osteoarticular complications of acromegaly are among most disabling impacts, and can be explained by two mechanisms, chronic exposure to high levels of GH and IGF1 leading to increased bone turnover, hypertrophy and osteocartilaginous degeneration, as well as the gonadal insufficiency observed during acromegaly may aggravate the situation. The objective of this study is to describe the rheumatological manifestations of acromegaly.
Materials and methods
This is a descriptive study of 25 patients followed up in the endocrinology, diabetology and nutrition department of the Mohammed VI University Hospital center in Oujda. All patients had a complete clinical examination, a phosphocalcic assessment and a bone densitometry.
Results
The mean age was 49.1 ± 14.4 years (24-71) with a sex ratio (M/F) of 1.08. The mean age of the diagnostic disease was 71 years and the mean IGF-1 level was 706.5 ± 257.8 ng/mL. Peripheral articulation manifestations included diffuse arthralgias and acromegalic arthropathy, which were present in 69.6% and 28.6% of the cases respectively. Axial affection was dominated by spinal pain, which was present in 30.4% of cases, accompanied by scoliosis and cervical hyperlordosis in 16% and 48% respectively, and vertebral fractures were found in 13% of cases. Neuromuscular manifestations with carpal tunnel syndrome were reported in only one patient. The evaluation of the phosphocalcic assessment finds vitamin D deficiency in 83% of cases. Bone densitometry showed osteoporosis in 16.7%, osteopenia in 44.4% of patients.
Discussion - Conclusion
The rheumatological complications of acromegaly are the principal causes of functional incapacity, hence the interest in seeking them out early in order to reduce their impact on the functional prognosis. Our results confirm the frequency of these manifestations detected at the time of diagnosis or follow-up of acromegaly, underlining the need for a multidisciplinary approach in order to improve the quality of life of patients.

Correlation Betwen Obesity in Patients with A Diagnosis of Non-Functioning Adenomas and Prolactinomas

Stefany Baquero, Darlyng Quishpe Lopez, Gabriela Freire Salazar, Jorge Luis Salazar Vega, Rossana Ruiz Urbáez & Xavier Villota Acosta
Hospital Eugenio Espejo, Endocrinología, Quito, Ecuador

Background
Obesity is a chronic and complex health problem. Although it is a preventable health risk factor, iís prevalence has grown rapidly in recent years. There are studies that demonstrate the relationship between hyperprolactinemia and obesity. However, it is not well explained and the results are contradictory. The objective of this study was to evaluate the relationship between increased prolactin and Body Mass Index (BMI) in patients with pituitary macroadenomas.
Methods
A retrospective case-control study was carried out by extracting information from medical records of patients with non-functioning macroadenomas and macroprolactinomas, taking into account the difference in prolactin level due to their functionality; excluding other lesions of the sella turcica. The study population was under hormonal supplementation of the affected axis in the case of have it. Descriptive statistics and subsequent odds ratio analysis were performed.
Results
112 patients were included, of which 44 were prolactinomas and 68 non-functioning adenomas, with no significant difference between gender. The current mean age was 44.29 years (SD 15.77), the average BMI 29.59 Kg/m2 (SD 5.11), the mean tumor size was 32.53 mm (10 to 75). Mean prolactin values measured in non-functioning adenomas were 34 ng/mL (2 to 111) and prolactinomas 5800 ng/mL (217 to 47,000). 44.7% of the sample had a BMI greater than 30 kg/m2. In the Odds Ratio analysis we obtained a value of 1.636 (interval 0.774-3.576) indicating that there is no relationship between the amount of prolactin and the risk of developing obesity.
Conclusion
Despite previous evidence demonstrating a relationship between prolactin and obesity risk due to changes in the functionality of adipose tissue, lipid metabolism, insulin resistance and hypothalamic cathepsin and kisspeptin secretion. In this study, relating two populations with similar characteristics in terms of gender, tumor size, and age, we found that the increase in prolactin was not related to having a greater risk of obesity. Taking into account that in our general population 19.93% have obesity (ENSANUT 2018), in our universe 44.7% present this condition. Due to the findings of a higher BMI in the population with the presence of a sellar lesion, we recommend weight approaches in the population group studied, regardless of their functionality.

Secondary amenorrhea revealing pituitary sarcoidosis: a case report and review of the literature

Mennani Fatima Ezzahra, Mballou Camara, Sana Rafi, Ghizlane Elmghari & Nawal EL Ansari
Centre Hospitalo-Universitaire Mohammed Vi Marrakech, Endocrinology, Marrakech, Morocco

Introduction
Hypothalamic-pituitary involvement during sarcoidosis is rare, less than 1%. Granulomatous infiltration can lead to anteropituitary insufficiency, disconnection hyperprolactinemia and diabetes insipidus. We report a case of hypothalamic-pituitary sarcoidosis with review of the literature.
Observation
Patient aged 39 years, she complains of chronic headaches for 10 months without decrease in visual acuity, secondary amenorrhea for 6 months. The clinical examination reveals a bilateral multiporous induced galactorrhea. The hypothalamo-hypophyseal MRI showed a thickening of the pituitary stem. The hormonal assessment revealed a cortisol level of 3.6 mg/dl at 8 o'clock in the morning, prolactin at 64.6 ng/ml, FSH at 0.7 mIU/ml, LH at 0.6 mIU/ml, estradiol: 5ng/l, TSH us at 2.08 uIU/ml, free thyroxine (T4L) at 12.7 pmol/l, corrected calcemia at 89.49 mg/l, the visual field showed no abnormality. The general work-up revealed a pulmonary localization with a stage II sarcoidosis on the thoracic CT scan and a skin involvement confirmed on biopsy: an aspect of epithelioid and gigantocellular granulomatous hypodermitis without caseous necrosis. The patient was put on corticosteroid therapy and hormone replacement therapy with estrogen-progestin
Discussion
Sarcoidosis is a chronic systemic disease of unknown etiology characterized by the presence of epithelioid granuloma without caseous necrosis. Neurosarcoidosis is found in 5-26% of patients with sarcoidosis. Isolated hypothalamic-pituitary involvement is rare, representing 0.5% of sarcoidosis cases and 1% of sella turcica lesions. The endocrine disorders most frequently encountered in neurosarcoidosis are: diabetes insipidus, hyperprolactinemia and to a lesser degree hypogonadism. However, a review of the literature published by Anthony *et al* classified the endocrine disorders in order of frequency: central hypogonadism in 88.8% of cases, central hypothyroidism in 67.4% of cases, diabetes insipidus in 65.2% of cases, low GH levels in 54% of cases, low ACTH levels in 48.8% of cases, hyperprolactinemia in 48.8% of cases. The most common radiological abnormalities in neurosarcoidosis are multiple white matter involvement (43%) and pathological contrast of the meninges (38%), rarely obstructive hydrocephalus or spinal cord involvement. Imaging may be normal in 12% of cases. The treatment is mainly medical with administration of corticosteroids; in case of poor response to corticosteroids, other therapies may be prescribed such as immonosuppressive drugs and immunomodulators; radiotherapy may also be indicated in some refractory cases.
Conclusion
Hypothalamic-pituitary involvement in sarcoidosis is rare with more frequent complications, the diagnosis is often late. It requires a multidisciplinary management.

Analysis of The Modulating Effect of Melatonin on Reproductive Processes and Cognitive Potential Under Conditions of Chronic Inflammation Using The Model of Estrous Cycles of Sexually Mature Female Rats

Aisance Tchang, Lada Naimushina, Yves Lemba & Vladimir Belyakov
Samara National Research University, Biology Faculty, Samara, Russia

Introduction
Reproductive processes are regulated with the participation of the kisspeptinergic neurotransmitter system and the hormonal axis hypothalamus – adenohypophysis – gonads. The action of all regulators of reproductive processes can be disturbed by the development of inflammation and the action of pro-inflammatory cytokines. In this case, cognitive dysfunctions may occur, since sex hormones are involved in the regulation of brain functions. The study analyzed the effect of melatonin on the course of the estrous cycle and cognitive functions of adult female rats under conditions of an experimental model of chronic inflammation (the effect of LPS – lipopolysaccharide *Salmonella typhi*).
Methods
To create chronic inflammation, group A rats received LPS (i.p., 50 μg/kg) daily for 10 days. Group B rats received LPS with melatonin (oral, 0.5 mg/kg) for 10 days. Rats in the control group received sterile water. The phases of the estrous cycle were determined by the ratio of different cell types on stained vaginal smears by light microscopy. The behavior of rats in all experimental groups was tested under the following experimental conditions: open field, elevated plus maze, Barnes' maze, extrapolation escape.
Results
Exposure to LPS in group A led to disruption of the estrous cycle. The duration of diestrus increased by 28% ($P< 0.05$). In vaginal smears, the number of epithelial cells with destruction of organelles significantly decreased, the karyopicnic index decreased by 24% ($P< 0.05$). The action of melatonin reduced the pathological effect of inflammation on the estrous cycle. Group A rats showed a low level of exploratory activity in the open field. In the Barnes maze, group A rats spent more time searching for a safe haven and showed more erroneous responses. In the extrapolation escape test, group A showed an increase in the time to escape from a stressful situation. Rats treated with melatonin maintained higher levels of cognitive ability on various tests.
Conclusions
Melatonin reduces the pathological influence of the used inflammation model on the neuroendocrine mechanisms of regulation of the estrous cycle and cognitive functions. It is likely that the established effects of melatonin may be related to its immunomodulatory and neurotropic properties.

Co-occurrence of premature ovarian insufficiency and Rathke Cleft Cyst: case report

Hadami Ben Yamna, Marwa Chiboub, Emna Naccache, Radhouane Gharbi, Manel Jemel & Ines Kammoun
National Institute of Nutrition and Food Technology, Department of Endocrinology, Tunis, Tunisia

Introduction
Rathke cleft cysts (RCC) are benign cystic lesions of the sellar and suprasellar region, which is believed to arise from the remnants of the Rathke pouch. Symptomatic RCC are rare. Endocrine symptoms are usually caused by compression of the surrounding pituitarygland. It can therefore cause hypopituitarism, but it is rarely associated with primary endocrine dysfunctions. In this case, we report a co-occurrence of premature ovarian insufficiency and RCC.
Case summary
We report the case of a 29-year-old female patient, who first presented with headaches, irregular menses and galactorrhea. Initial investigation showed a hyperprolactinemia with a level of 154 ng/mL without other hormonal abnormalities (TSH:1,27 μUI/ml, fT4: 16,7 pmol/l, cortisol at 428 nmol/l and 603 nmol/l after ACTH stimulation test). Initial hormonal investigation for FSH and LH were at normal levels. Cerebral MRI showed intrasellar cystic low density lesion of 7mm with ring enhancement which evoked a Rathke cleft cyst. She was treated initially with bromocriptine with a well evolution. Interestingly, despite normalization of prolactine levels after two years and disappearance of the galactorrhea, our patient began to have secondary amenorrhea with hot flashes. Hormonal investigation showed hypergonadotropic hypogonadism with high levels of FSH (79,61 mUI/mL) and LH (37,21 mUI/mL). Pelvic ultrasound revealed decrease in both ovaries volume but did not show any other abnormalitites. Genetic testing showed a normal karyotype. The diagnosis of primary ovarian insufficiency was held. The patient received hormone replacement therapy and reported better quality of life.
Conclusion
Rathke cleft cyst occurs mostly in females and may result in a variety of symptoms. Hyperprolactinaemia is the commonest associated endocrine dysfunction, followed by hypopituitarism. This hyperprolactinaemia due to RCC may predispose to autoimmune thyroiditis; however, the association between RCC and primary thyroid disease remains to be clarified.

Infectious manifestations during neuro-gastrointestinal mitochondrial encephalopathy: about 2 patients

Lachiheb Nabil, Bartegi Ines, Bougharriou Ichrak, Ben Hmida Salma, Hadj Kacem Faten[2], Mnif Mouna[2] & Abid Mohamed[2]
[1]Hedi Chaker-Department Of Infectious Deseases, Sfax, Tunisia; [2]Hedi Chaker-Department Of Endocrinology, Sfax, Tunisia

Introduction
Mitochondrial neuro-gastro-intestinal encephalopathy (MNGIE) is a rare autosomal recessive disease caused by a mutation in the TYMP gene.
Patients-methods
Retrospective study including 2 cases (brother and sister) followed for MNGIE confirmed by genetic study at the endocrinology department of Sfax.
Results
-> 1st case: 25-year-old man, follow-up for diabetes, dilated cardiomyopathy, renal lithiasis, MNGIE.
He presented :
- A cerebral abscess treated by surgery, without bacteriological documentation at the age of 19,
- Recurrent severe oral candidiasis due to Candida albicans
- Documented parenteral feeding catheter sepsis due to Staphylococcus lugdunensis
- Sequelae of ocular toxoplasmosis

-> 2nd case: 22-year-old woman followed for functional anterior pituitary insufficiency. She presented with recurrent oral candidiasis due to Candida albicans, died of digestive complications
Discussion
The prevalence of infections during MNGIE is 7.9% but no particular association candidiasis and MNGIE For our patients, the acquired immune deficiencies have been eliminated (negative HIV serology and tuberculosis investigation), the dosage of immunoglobulins could not be carried out
Conclusion
The prognosis of MNGIE is severe and linked to the severity of the digestive attack with the occurrence of infections and the use of permanent parenteral nutrition.

The importance of Prompt Treatment of Ectopic Cushing Syndrome

Inês Meira[1], João Menino[1], Jorge Pedro[1,2,3], Davide Carvalho[1,2,3] & Paula Freitas[1,2,3]
[1]São João Universitary Hospital Center, Department of Endocrinology, Diabetes and Metabolism, Porto, Portugal; [2]Faculdade de Medicina da Universidade do Porto - FMUP, Porto, Portugal; [3]i3S - Instituto de Investigação e Inovação em Saúde da Universidade do Porto, Porto, Portugal

Introduction
Ectopic ACTH production accounts for up to 20 percent of ACTH-dependent Cushing syndrome (CS). Small cell carcinoma and carcinoid of the lung represents half of its cases. These patients lack some of the more obvious clinical features of cortisol excess. Therefore, this can cause a delay in the diagnosis of CS and these patients may be at high risk of life-threatening complications such as infections or thrombosis.
Clinical case
Case of a 70-year-old man, with recent diagnosis of small cell lung cancer was admitted for rapidly progressing hypertension, hypokalemia and severe hyperglycemia. There was no previous medical history of diabetes or hypertension. On physical examination, he did not have typical Cushingoid

features; he presented lower extremity edema and high blood pressure reaching 180/120mmHg. At admission, plasma glucose was 336mg/dl, serum potassium 2.6mmol/l, arterial pH 7.54. Cushing syndrome was suspected, and an endocrine evaluation revealed an ACTH-dependent hypercortisolism: cortisol after an overnight 1-mg dexamethasone suppression test 60.6µg/dL and ACTH 175.5ng/l. CRH stimulation test had a borderline result to differentiate the cause. Treatment with metyrapone was considered immediately and readily requested to the hospital pharmacy committee; however, there was a delay in the provision of the drug. He started emergency treatment with potassium supplementation and spironolactone. In order to use somatostatin analogs to treat the ectopic secretion, a 111-In-octreotide scan was performed, that revealed receptors in the left lung and contralateral pleura. Unfortunately, on the tenth hospital day, before any treatment for hypercortisolism was started, the patient's hospital course was complicated with a nosocomial pneumonia and the patient died.
Conclusion
Patients with ectopic ACTH secretion can be very hard to detect and typically present with a much more rapid progression compared to Cushing disease. Indeed, these patients often represent an endocrine emergency due to the intensity of their hypercortisolism. Worsening hyperglycemia in the presence of hypertension, even without typical Cushing features should prompt further hormonal work-up. To offer the patient the best chance of survival and avoid Cushing's complications such as severe infections, hypercortisolism must be controlled without delay.

Challenges in treatment of carotid paraganglioma : About a case report

Chtioui Sara, Alhyane Meryam, Sana Rafi, El Mghari Ghizlane & El Ansari Nawal
Mohammed VI University Hospital Center, Department of Endocrinology, Diabetes, Metabolic Diseases and Nutrition, Marrakech, Morocco

Introduction
Carotid body tumor is a hypervascular tumor with multiple feeding arteries and unique orientation at the carotid bifurcation. Although resection is a radical therapy for this tumor, complete resection is challenging.
Case report
A 33-year-old female patient consulted with a neck swelling that had persisted for 3 years. On physical examination, a movable and pulsating hard mass was found on the left side of her neck. Computed tomography, magnetic resonance image and angiography all demonstrated a well-circumscribed tumor mass showing high vascularity and located at the bifurcation of the left carotid artery. The tumor involved the left carotid artery measuring 44 × 43X55 mm in size but the patency of the artery was preserved. The urinary catecholamines were negative. Since the tumor was strongly adherent to the carotid arterial wall, the resection was a surgical challenge and achieved due to multidisciplinary approach and cooperation with otolaryngologist and vascular surgeon. Histologically, the tumor was compatible with paraganglioma without signs of malignancy.
Discussion
Cooperation with an otolaryngologist and vascular surgeon during surgery is recommended due to frequent damage to carotid vessels by carotid paragangliomas. Detection of the tumor in the early stages improves surgical treatment outcomes and reduces the number of complications. Regular post-operative check-ups are necessary due to possible occurrences of multiple tumors.
Key-Words: Paraganglioma-Carotid body-Surgery-Risk

DOI: 10.1530/endoabs.90.EP810

EP811

A Rare Case of recurrent Hypoglycaemia

Aisha Aslam & Alex Lewis
Manchester Royal Infirmary, Manchester, United Kingdom

Insulinomas, uncommon neuroendocrine tumours, may produce insulin-induced hypoglycemia. It causes neuroglycopenia and autonomic sympathetic dysfunction. Glucose immediately relieves these sensations. Hypoglycemia without plasma sulfonylurea and increased C-peptide is diagnostic. The tumour must be found before surgery.
Introduction
Hypoglycemia is caused by insulinomas. Insulinoma, the most frequent functional pancreatic tumour, occurs just four times per million. Extra-pancreatic insulinomas are rare. This unusual tumour causes sympathetic and neuroglycopenic symptoms.
Case Presentation
24-year-old boy who presented to endocrine department with recurrent episodes of hypoglycemia. This case was challenging because of the patient's history of anorexia nervosa and substance abuse. He used substances, including marijuana, cocaine, and MDMA, in the past. He had a history of at least six years of recurrent admissions to emergency care with a diminished level of awareness and seizure activity and blood glucose levels below 2.2. His symptoms recovered once his hypoglycemia was treated. Multiple studies were done to determine his symptoms because he was not diabetic. He was tested for liver, kidney, and hormonal dysfunction, such as adrenal insufficiency. In the limited supervised fast demonstrated, glucose was 1.8 mmol/l, insulin 52 pmol/l, C-peptide 795 pmol/l, beta-hydroxybutyrate less than 100 umol/l, and the IGF2:IGF-1 ratio was 2.4. Insulin antibody-negative. Negative sulfonylureas. Radiological screening proceeded. unremarkable pancreas MRI. No pancreatic lesion, especially an arterial-enhancing lesion identified. Gallium-deficient PET/CT showed no insulinoma. Endoscopic ultrasonography and biopsy were inconclusive for endogenous insulinoma.
Management
Continuous glucose monitoring equipment was supplied to check his hypoglycemia. It was difficult to control his hypoglycemia without medicine, so he began taking 150 mg of diazoxide three times a day to avoid further episodes. Further investigations are continuing. A supervised 72-hour fast was performed, which reciprocated the result of the limited fast. We chose selective calcium stimulation to locate the insulinoma. He was advised to cease diazoxide seven days before the test to prevent interference. A catheter was implanted in the right hepatic vein, proximal gastroduodenal, proximal splenic hepatic, and superior mesenteric regions. Post-calcium gluconate insulin and C-peptide levels were elevated, although we could not discern a gradient in any arterial territory to validate localization.
Recommendation
1. Consider continuing medical management, control your diet, and continue to follow up.
2. Consider an exploratory laparotomy to see if any lesion can be identified.
3. Consider partial pancreatectomy, which might be able to help with the frequency of hypoglycemia but might be tricky for iatrogenic diabetes and surgical complications.

Adolescent Acromegaly : About 2 Case Studies

Alida Mireille Uwimana, Nassim Essabah Haraj, Siham El Aziz & Asma Chadli
Hassan II University, Casablanca, Department of Endocrinology and Metabolic Diseases, Casablanca, Morocco

Introduction
Acromegaly is an unusual disease in adolescence. Its diagnosis and management are a challenge in this population. Here we report 2 rare cases of acromegaly in this age group.
Patients and Observations
Observation 1: This is a 17 year old patient admitted for acromegaly on pituitary microadenoma measuring 4*3mm who presents a symptomatology made of an accentuation of the growth rate, thin and long limbs, elongated hands and feet without dysmorphic syndrome and without tumor syndrome. His GH level is 1.8 times normal and IGF1normal. Therapeutically, the patient benefited from a total removal of the tumor.
Observation 2: The patient was 16 years old and had been followed for acromegaly on pituitary macroadenoma since the age of 11 years. The initial symptomatology was an increase in growth rate without dysmorphic signs and without tumor syndrome. His IGF1 level was 2.3 times normal. The patient has already benefited from 3 surgeries of the adenoma with complementary medical treatment.
Conclusion
Adolescent Acromegaly is rare and characterized by large size and rapid progression of symptoms as the main diagnostic criteria. Other clinical signs are less marked than in adults. Surgery is the first-line treatment with importance of long-term follow-up.

Craniopharyngioma masquerading as a suprasellar Rathke cleft cyst in a young patient with a history of Ewing sarcoma: A case report

Calapod Ioana Ruxandra[1], Luminita Cima[1,2], Alexandra Mirica[3,4], Codruta Ulpia Comsa[3], Monica Dragomir[2,5], Sergiu Stoica[6] & Simona Fica[1,2]
[1]Spitalul Universitar de Urgenţă Elias, Bucureşti, Romania; [2]Carol Davila University of Medicine and Pharmacy, Bucureşti, Romania; [3]Parhon

Hospital Bucharest, Bucureşti, Romania; [4]Spitalul Clinic de Urgenţă pentru Copii Grigore Alexandrescu, Bucureşti, Romania; [5]Institutul Oncologic Bucureşti Profesor Doctor Alexandru Trestioreanu, Bucureşti, Romania; [6]Monza Metropolitan Hospital, Bucureşti, Romania

Craniopharyngiomas are rare, benign tumors, typically found in childhood or early adulthood, that can cause a wide range of symptoms such as visual impairment, headaches, nausea and endocrine disturbances. Ewing sarcoma, on the other hand, is a rare and aggressive tumor that arise from primitive neuroectodermal cells and represents about 10% of all pediatric osseous primary tumors. We present the case of a 14-year-old patient who was admitted to our clinic in March 2022 for obesity, secondary amenorrhea and visual impairment. The patient was diagnosed at the age of 11 with Ewing sarcoma of the lumbar spine with left intracanal extension L5-S1. She had received concomitant local radiotherapy (45Gy per 25 fractions) and chemotherapy (8 cycles of Vincristine, Ifosfamide, Doxorubicin, Etoposide) according to Ewing Protocol from 2008. The patient experienced her first menarche 2 months after the first cure of chemotherapy, followed by one additional menstrual cycle at a two-month interval, with secondary amenorrhea since. In July 2020, she experienced a seizure and visual disturbances. Cerebral MRI showed a suprasellar cystic mass measuring 1.6/1.3/1.5cm, causing optic chiasm compression, first diagnosed as a Rathke cleft cyst. The patient began anticonvulsant treatment and continued to receive regular follow-up care. During the patient's first presentation in our clinic, laboratory evaluation revealed elevated follicle-stimulating hormone levels (35.30mIU/ml) with low estradiol levels (13.18 pg/ml) and AMH levels (0.01ng/ml) suggesting primary ovarian failure due to radiotherapy and chemotherapy. Thyroid function was also modified, suggesting hypothyroidism due to autoimmune thyroiditis. Ophthalmologic evaluation revealed right homonymous hemianopia. The 2-year follow-up MRI showed unchanged dimensions of the suprasellar mass, impingement on the optic chiasm. Unfortunately, according to the neurosurgeon the mass was highly suggestive for a craniopharyngioma requiring surgery if the visual impairment intensified. Taking in consideration the fact that our patient had a history of epilepsy, we initiated sex hormone replacement therapy with low doses of estrogens, progestin and levothyroxine. In conclusion, we report a rare association between Ewing sarcoma, an aggressive bone and soft tissue tumor and craniopharyngioma, a benign, intracranial tumor, both requiring complex and challenging management by a multidisciplinary team due to significant long-term morbidities caused by their treatment and the loco-regional tumor growth. A lifetime follow-up is necessary to address multiple endocrine deficits, that may adversely affect fertility, growth or thyroid function, highly influencing the quality of life.

Short stature caused by pituitary stalk interruption syndrome in a type 1 diabetic child: a case report

Hadami Ben Yamna, Bchir Najla, Annam Benchhida, Salma Abadlia, Chedia Zouaoui & Haroun Ouertani
The Principal Military Hospital of Instruction of Tunis, Department of Endocrinology, Tunis, Tunisia

Introduction
Pituitary stalk interruption syndrome is a rare disorder characterized by a specific tirade: an absent or hypoplastic anterior pituitary gland, thin or absent infundibulum, and ectopic posterior pituitary location. This syndrome has been described in association with other somatic abnormalities and recently a polygenic etiology has been suggested. Herein, we report a case of type 1 diabetic patient, explored for short stature, revealing a pituitary stalk interruption syndrome.
Case presentation
We report the case of an 8-year-old patient, with a medical history of type 1 diabetes since the age of two. During his follow up, stature delay has been noticed but initially put on the account of diabetes. At the age of eight, he consulted our endocrinology department. Physical examination showed a height of 110 cm which was below the second percentile for chronological age, and weight was 23 kg which was at the third percentile. Bone age was five years according to the Greulich and Pyle method. Biological analysis revealed an HbA1c level of 7,5%. First line investigation, including complete blood count, creatinine and liver enzyme was normal. Antitissue transglutaminase, anti-endomysium, and anti-gliadin antibodies were negative. The hormonal investigation showed a normal thyroid function test (TSH level of 1.35 mIU/l and free thyroxine of 10.9 pmol/l). The diagnosis of corticotropic insufficiency was confirmed by a low baseline plasma cortisol level (168 nmol/l) unstimulated by Insulin-induced hypoglycemia test and low adrenocorticotropin hormone (ACTH) level. IGF1 levels were 82 ng/mL which was normal for age. The diagnosis of GH deficiency was retained based on no GH response to two stimulation tests: Insulin-induced hypoglycemia and clonidine tests. Pituitary MRI showed the typical triad of pituitary stalk interruption syndrome. The patient was treated with hydrocortisone and recombinant GH replacement therapy with good evolution of stature.
Conclusion
Pituitary stalk interruption syndrome should be kept in mind while investigating a child with short stature, even if patient history suggests other etiologies. The pathophysiology of this syndrome is not yet fully understood, but it has been described in association with several diseases and appears to be polygenic.

Desmopressin or decompensated corticotropic insufficiency: who is the guilty party in profound hyponatremia?

Ali Halouache[1], Ghita Khamel[2], Isouani Jad[1] & Guerboub Ahmed Anas[1]
[1]Hopital Militaire d'Instruction Mohamed V, Endocrinology, Rabat, Morocco; [2]CHU Avicenne, Endocrinology, Rabat, Morocco

Introduction
We report the case of a patient with corticotropic insufficiency associated with diabetes insipidus who presented to the emergency room with profound hyponatremia; a complicated situation, whose solution was hidden in the galenic form of Desmopressin.
Case report
Mrs Y. Amina, 37 years old, has been followed for 10 years for a non Langerhansian histiocytosis of pituitary location, complicated by a corticotropic insufficiency under hydrocortisone, and a diabetes insipidus under inhaled desmopressin, consulted in the emergency room for a confusional syndrome associated with nausea, vomiting and abdominal pain, the assessment carried out in urgency showed a deep hyponatremia at 118 mEq/l. This situation led to the suspicion of a decompensation of corticotropic insufficiency and the patient was put on intravenous hydrocortisone hemi succinate. The evolution was marked by the persistence of hyponatremia and the installation of hypokalemia which worsened progressively, thus signalling a corticosteroid overdose and the theory of a decompensation of corticotropic insufficiency was questioned in favor of another possibility; Desmopressin overdose, a reduction in the dose of this drug was considered, from 2 puffs per day to one puff per day, the natremia thus went to 124 mEq/l, and remained stationary. Our decision was to change the galenic form of the drug, and the patient was put on Desmopressin tablet (1 tablet in the morning and 1 tablet in the evening), the evolution was favorable with correction of the natraemia and disappearance of the symptoms.
Discussion
Used to prevent or control symptoms of central diabetes insipidus, Desmopressin is a synthetic analog of arginine vasopressin. It is more potent and much longer acting than vasopressin. Hyponatremia is a classic complication of desmopressin overdose, usually corrected by dose reduction, but in some cases, individual sensitivity is so great that even small doses can cause overdose effects. It is at this point that it is necessary to think about changing the dosage form, as the bioavailability of desmopressin varies considerably from one dosage form to another, and the fact of changing, in our case from the potent inhaled form to the oral form, has made it possible to reduce the bioavailability of the molecule.
Conclusion
In situations similar to ours, when inhaled desmopressin is at its lowest dose, we suggest changing the galenic form in order to reduce the bioavailability of the drug and thus make the adverse effect beneficial.

A Rare Pituitary Pathology: Patient With Crooke Cell Corticotroph Adenoma

Ekin Yiğit Köroğlu[1], Cevdet Aydin[2], Caglar Keskin[1], Ömer Faruk Türkoğlu[3], Servet Güreşçi[4], Oya Topaloglu[2], Reyhan Ersoy[2] & Bekir Cakir[2]
[1]Ankara City Hospital, Endocrinology and Metabolism, Ankara, Turkey; [2]Ankara Yıldırım Beyazıt University Faculty of Medicine, Endocrinology and Metabolism, Ankara, Turkey; [3]Ankara City Hospital, Neurosurgery, Ankara, Turkey; [4]Ankara City Hospital, Pathology, Ankara, Turkey

However ACTH secreting adenomas are one of the most common functional pituitary tumors, subtypes such as Crooke cell corticotroph adenoma(CCCA) are relatively rare. We present here a patient with CCCA who had severe hypercortisolism mimicking ectopic ACTH syndrome. A 69 years old female

patient admitted to emergency department after a fall. On cranial MRI,'a 3.5x2.5x3cm mass appearance with a sellar-suprasellar location, which is compressing the optic chiasm, expanding the sella to cavernous sinuses' was detected. It was learned that she gained weight in the last year and his blood sugar had been dysregulated. She had a buffalo hump, thin extremities and central obesity. No signs of abdominal wall striae, facial plethora and proximal myopathy were observed. The biochemistry and anterior pituitary hormone examination results are as in Table 1. The result of 1 mg dexamethasone suppression test was 43.56μg/dl. The midnight serum cortisol was found to be 33μg/dl, the midnight salivary cortisol was 2.24μg/dl and 24 hours urinary free cortisol level was 1718,35 mg/24 h. Spironolactone and metyrapone were started due to resistant hypokalemia and overt hypercortisolemia. In the multidisciplinary council; surgery was decided. After transsphenoidal surgery, focal staining with ACTH and thick membranous staining in more than 50% of cells were detected in the operation material. Pathology result was reported as compatible with CCCA. Metyrapone was discontinued in the post-operative period. The patient who developed central hypothyroidism and central diabetes insipidus was started on levothyroxine and desmopressin treatments. Hypercortisolemia could not be evaluated in the post-operative period;because after the surgery, dexamethasone was given to the patient with subdural hematoma secondary to falling, for anti-edema effect. CCCA are rarely seen tumors. They tend to be invasive and clinically aggressive. They may recur after surgery and may show resistance to re-operation or radiotherapy(1). In our case;there was a pituitary mass pressing on the surrounding tissues, severe hypercortisolemia and rapid progression of clinical and laboratory findings mimicking ectopic ACTH syndrome.

Contribution of MRI to the diagnosis of hypophysitis

Siham Benouda, Salma Derbel, Nabila Zeryouh, Siham Rouf & Hanane Latrech
Mohammed-VI University Hospital Center, Endocrinology-Diabetology-Nutrition, Oujda, Morocco

Introduction

Hypophysitis is a rare condition corresponding to a chronic inflammation of the pituitary gland, The clinical and radiological signs are not specific and the pathogenesis remains poorly elucidated. The aim of our work is to report the clinico-radiological aspects of hypophysitis.

Material and Methods

This is a retrospective descriptive study of 09 patients hospitalized in the department of Endocrinology-Diabetology-Nutrition of Mohammed-VI University Hospital Center, Oujda, over a period of 5 years who were diagnosed with hypophysitis. All our patients underwent hypothalamic-pituitary MRI. Data were collected from medical records and analyzed by SPSS-V21 software.

Results

The age of our patients ranged from 16 to 49 years, 6 were female. One patient was in immediate postpartum, 3 other patients were already being followed for autoimmune diseases : a Hashimoto disease, a coeliac disease and a lupus. A COVID-19 infection was found in one patient. Polyuro-polydypsia syndrome was the main revealing sign, associated in one case to clinical signs secondary to mass effect and in another case to signs of hypopituitarism. MRI showed a diffuse enlargement of the pituitary gland in 5 cases, a thickened pituitary stalk in 2 cases, markedly homogeneous contrast enhancement of the pituitary gland in 2 cases. Loss of posterior pituitary bright spot was observed in 3 patients. A lymphocytic autoimmune origin was retained in 6 patients. Infiltration of the gland by a tuberculous granuloma was retained in a single case with a good clinical evolution under treatment.

Discussion-conclusion

Hypophysitis is a rare pathology of the pituitary gland that predominates in young women. It is often manifested by hypopituitarism or visual disorders simulating a pituitary adenoma. MRI allows the diagnosis to be suspected by showing an intra- and extra-sellar mass, symmetrical, taking the contrast in a homogeneous way, which is associated during infundibulo-neurohypophysitis to a thickening of the pituitary stem as well as the loss of the spontaneous bright-spot reflecting the absence of vasopressin storage at this level. Its interest is primordial in the diagnosis and the control of the evolution of lymphocytic and granulomatous hypophysitis.

A Pituitary Neoplasm with an Aggressive Course: Silent Corticotroph Adenoma

Ekin Yiğit Köroğlu, Mehdi Houssein, Belma Tural Balsak, Burak Bahadır[2], Servet Güreşçi[3], Oya Topaloglu[4], Reyhan Ersoy[4] & Bekir Cakir[4]
[1]Ankara City Hospital, Endocrinology and Metabolism, Ankara, Turkey; [2]Ankara City Hospital, Neurosurgery, Ankara, Turkey; [3]Ankara City Hospital, Pathology, Ankara, Turkey; [4]Ankara Yıldırım Beyazıt University Faculty Of Medicine, Endocrinology and Metabolism, Ankara, Turkey

Patient is a 43 years old female without any known additional disease. A pituitary mass was seen in the cranial MRI taken due to the complaint of forgetfulness. Pituitary MRI of the patient revealed a 'large intrasellar mass of 3.2x3x2.3 cm, which expanded the sella and pressed the optic chiasm'. The patient didn't describe any symptoms other than forgetfulness. She didn't have galactorrhea, cushingoid or acromegaloid appearance. Patients laboratuary evaluation can be seen in Table 1. The patient was started on levothyroxine for central hypothyroidism and it was thought that the patient had a non-functional pituitary adenoma. In the follow-up of the patient who underwent transsphenoidal surgery, no hypopituitarism or central diabetes insipidus was detected. In the immunohistochemical and histological examination of the patient's surgical material:'Tumor cells showed diffuse staining with ACTH. GH, PRL, TSH, FSH, LH are negative. The Ki-67 proliferation index was 3-4%.'These findings, patient's pre-operative examinations and clinically situation were evaluated and it was determined that the patient had a 'silent corticotroph adenoma'. The patient had no complaints in the post-operative first month. Her anterior pituitary hormones were observed(Table 2). Due to the tendency of silent corticotroph adenomas to progress aggressively, pituitary MRI control was planned at the post-op 3rd month. Silent corticotroph adenomas constitutes 4.8-6.8% of all pituitary adenomas and 19% of non-functioning pituitary adenomas. It has a highly aggressive and invasive course. It often recurs after treatment and is resistant to treatment. In the studies,0.5 mg DST performed with a cut-off value of 3.0μg/dl in the screening of Cushing's syndrome. That has been shown to have higher sensitivity and specificity than the classical 1 milligram DST. In our case, both screening tests were applied.

Table 1 Biochemistry and pre-operative anterior pituitary hormone examination results.

Glucose	83mg/dl	TSH(0,55-4,78 mU/l)	0,90mU/l
ACTH(<46pg/mL)	17,3μg/dl	**Free T4(0,89-1,76 ng/dl)**	**0,75ng/dl**

Noonan syndrome associated with SOS1 gene mutation with autosomal dominant RASopathy : a case report

Asmae El Hafiani, Manal Azriouil, Lamya Echchad, Kaoutar Rifai, Iraqi Hinde & Mohamedelhassan Gharbi
Ibn Sina University Hospital, Endocrinology, Rabat, Morocco

Introduction
Noonan syndrome (NS) is an autosomal dominant genetic disorder characterized by the combination of facial dysmorphia, short stature and congenital heart disease. The mutation of the PTPN11 gene is present in 50% of cases, recently the mutation of other genes was found, notably KRAS and SOS1. We report the case of a patient followed in our department for NS with a SOS1 gene mutation.
Case report
A 4 years old male patient, referred to our department for failure to thrive (FTT). The diagnosis of NS was made in view of a typical facial dysmorphia, a congenital cardiac disorder with a moderately tight pulmonary valve stenosis, a bicuspid aortic valve and a non-stenosing sub-aortic septal hypertrophy for which the patient was operated, as well as a FTT with a weight and a height between - 2 and - 3 standard deviation (SD). A left cryptorchidism was also found on clinical examination. The genetic study found a pathogenic variant of the SOS1 gene with autosomal dominant RASopathy. For his FTT, the first line workup was normal. IgF1 was normal for the age of the patient. The glucagon test wasn't in favor of growth hormone (GH) insufficiency.
Discussion and conclusion
At present, seven genes have been shown to be associated with NS: PTPN11, SOS1, RAF1, KRAS, NRAS, SHOC2, and CBL. The most common gene associated with NS is PTPN11, which accounts for approximately 50% of all cases. SOS1 missense mutations are the second-most-common cause of NS, accounting for approximately 15% of cases. NS is one of a group of genetic diseases called RASopathies. They are clinically defined as a group of medical genetic syndromes caused by germline mutations in genes that encode components or regulators of the Ras-mitogen-activated protein kinase (MAPK) pathway. These disorders include neurofibromatosis type 1, Noonan syndrome, Noonan syndrome with multiple lentigines, capillary malformation–arteriovenous malformation syndrome, Costello syndrome, cardiofaciocutaneous syndrome, and Legius syndrome. They have in common many symptoms. In our patient, Costello syndrome was also discussed as a diagnosis, but we did not find an abnormality of the HRAS gene.

Delayed diagnosis of idiopathic growth hormone deficiency in children

Abeer Alassaf & Rasha Odeh
University of Jordan, Pediatrics, Jordan

Background
The delay of diagnosis of idiopathic growth hormone deficiency (GHD) in children, would result in delayed management, and would significantly affect final adult height.
Methods
This was a retrospective chart review study for patients seen at the pediatric endocrine clinic at the Jordan University Hospital, over a period of six years. Demographic, clinical, auxological and hormonal characteristics were studied.
Results
There were 87 patients diagnosed with idiopathic GHD, where there were no identified etiology, out of those patients 50 (57.5%) patients were males. Average age at presentation was 9.40 ± 2.90 years and 86.2% were pre-pubertal at presentation. The mean height standard deviation score (SDS) was -2.97 ± 1.02, while mid-parental height SDS was -0.98 ± 0.67. Mean bone age delay was 2.73 ± 0.70 years and insulin growth factoe-1 was 107.0 ± 89.1 ng/ml. There was history of consanguinity in 28 (32.2%) patients, this relatively higher percentage of consanguinity would suggest that there were underlying genetic disorders which were not identified for lack of genetic testing in developing countries.
Conclusion
Diagnosis of idiopathic growth hormone deficiency in children in Jordan was relatively delayed, which results in delayed management and would affect negatively final adult height. Close follow up for growth in children should be an integral part of primary health care systems including developing countries, where such practice may be sub-optimal. Abnormal growth warrants early referral to pediatric endocrinology service for early diagnosis and management.

Comparison between insulin tolerance test and clonidine stimulation test in the exploration of growth hormone deficiency

Salma Abadlia, Bchir Najla, Chadia Zouaoui, Hadami Ben Yamna, Anaam Ben Chehida & Haroun Ouertani
Military Hospital of Tunis, Endocrinology, Tunis, Tunisia

Introduction
Growth hormone deficiency (GHD) is a rare cause of delay of growth. However, it is primordial to screen for it since its presence leads to a specific treatment which improves statural prognosis. GHD should be confirmed through stimulation tests such as Insulin Tolerance test (ITT) or Clonidine Stimulation Test (CST). The objective of our study was to compare these two diagnostic tools.
Methods
We conducted a retrospective study in the endocrinology service of the military hospital of Tunis that involved 25 patients who were referred to our department for exploration of growth delay. The GH responses of participants were compared according to the test used (ITT or CST). GHD was retained if GH $<$ 10 ng/mL. A severe GHD was retained if GH $<$ 05 ng/mL.
Results
The mean age of the sample was 12 $\pm$ 3 years with male predominance (80%). Almost half of the sample (46%) had a clinical severe growth delay. GH peak during ITT was 2.12 $\pm$ 1 vs 4.09 $\pm$ 3 during CST ($P = 0.08$). When using ITT, the majority of participants 94% had severe GHD, while only 60 % presented severe GHD if CST was used ($P = 0.04$).
Conclusion
ITT seems to be significantly more sensible in the exploration of the somatotropic axis

Polyuria-polydipsia syndrome revealing primary potomania : a diagnostic challenge

Najoua Lassoued[1], Fatma Zaouali[2], Arige Abid[1], Yassmine Abdelkafi[1], Mahmoud Alzir[2], Zantour Baha[1] & Sfar Mohamed Habib[1]
[1]Tahar Sfar University Hospital, Endocrinology Department, Mahdia, Tunisia; [2]University of Monastir, Family Medicine Department, Monastir, Tunisia

Introduction
Polyuria-polydipsia syndrome (PUPDS) requires a comprehensive diagnostic approach as it can reveal serious medical conditions. We report the case of a patient consulting for PUPDS related to a primary potomania.
Case presentation
A 41-year-old patient with a history of multiple psychostimulants use was admitted for acute PUPDS after emotional shock and paucisymptomatic SARS-CoV-2 infection. Diuresis was estimated at 6 liters per 24 hours. During the interview, the patient reported psychostimulants withdrawal for over a year. He

did not have tumor syndrome. Urinary density was <1005. A brain MRI was performed showing persistent hyperintensity on T1-weighted image of the posterior pituitary, ruling out a diagnosis of central diabetes insipidus. However, this diagnosis was not entirely ruled out by the hypothesis of acute-onset ADH deficiency due to COVID-19 infection. Given the importance of PUPDS, the patient was given desmopressin with marked clinical improvement. A Fluid deprivation test was done two months later. The patient concentrated his urine and ADH level was normal. Therefore the diagnosis of primary potomania was maintained and the patient was referred to psychiatric clinic.
Discussion:
Primary potomania is a psychopathology that represents a differential diagnosis with diabetes insipidus and remains a diagnosis difficult to maintain until another organic cause is ruled out.

Wolfram Syndrome: Case report

Ben Salem Maram, Marwa Chiboub, Meriem Adel, Manel Jemel & Ines Kammoun
National Institute of Nutrition, Department of Endocrinology, Tunis, Tunisia

Background
Wolfram syndrome is an autosomal recessive neurodegenerative disease. It is secondary to the mutation of WFS1 gene. It combines a tetrad of pathologies known also as DIDMOAD (Diabetes Insipidus, Diabetes Mellitus, Optic Atrophy and Deafness).
Case presentation
We report a case of 31-year-old women with medical history of type 1 diabetes since the age of 3 years old. She suffered from decreased visual acuity since the age of 5 years old and the ophthalmological examination showed an advanced bilateral optic atrophy with no signs of diabetic retinopathy. She experienced many episodes of urinary tract infections and urologic examination and ultrasound findings were consistent with a neurogenic bladder. She recently consulted for polyuria and polydipsia and the dehydration test confirmed the diagnosis of diabetes isipidus. The diagnosis of Wolfram syndrome was highly suspected and a genetic study was done searching for the WFS1 mutation.
Conclusion
Wolfram syndrome should be considered in patients with diabetes mellitus and optic atrophy, which are the first signs of the disease. The condition should be evaluated in a multidisciplinary manner and specific tests are necessary to make a precise diagnosis and disclose all components of the syndrome in order to improve patients' prognosis.

EP824

A case of a persistent hypernatremia secondary to adipsic central diabetes insipidus

Salma Salhi, Ibtissem Oueslati, Asma Ben Hamida, Sahar Abidi, Anis Grassa, Meriem Yazidi & Melika Chihaoui
La Rabta University Hospital, Department of Endocrinology, Tunis, Tunisia

Introduction
Central diabetes insipidus is a rare condition that typically manifests as polyuria-polydipsia syndrome. Polydipsia helps to maintain normal natremia. Herein, we report the case of persistent hypernatremia in a patient admitted for inaugural diabetic ketoacidosis and hyperosmolar hyperglycemic syndrome.
Observation
A 53-year-old woman was referred to our department for inaugural diabetic ketoacidosis and hyperosmolar hyperglycemic syndrome. Her past medical history included herpetic meningoencephalitis complicated by confusion, amnesia, and adipsia. On physical examination, she was apyretic, hemodynamically stable, and confused with signs of isolated extracellular dehydration. Laboratory investigations showed hyperglycemia at 30 mmol/l, hypernatrémie at 169 mmol/l with a plasma hyperosmolarity at 386.3 mOsm/l. The patient received rehydration with isotonic saline solution and insulin therapy. Ketosis was controlled with normalization of blood glucose. However, hypernatremia persisted (148-158 mmol/l) as much as the hyperosmolarity (321-336). Urine output was quantified at one liter/24h. Natriuresis was 54 mmol/l and urinary osmolarity was 205 mOsm/l suggesting hypotonicity. After administration of desmopressine, the natriuresis normalized and the urinary osmolarity rose to 743 mOsm/l. The diagnosis of central diabetes insipidus associated with adipsia was established and the patient was treated with desmopressine. The pituitary hormonal investigation showed isolated central hypothyroidism. Pituitary magnetic resonance imaging was normal.
Conclusion
Our case describes an uncommon presentation of central diabetes insipidus with no polyuria. The impaired sensation of thirst may be responsible for an atypical presentation of central diabetes insipidus called hypernatremia-hypodipsia syndrome.

Pituitary cystic images: difficult diagnosis

Rahal Amel[1,2]
[1]Medecines, Endocrinology, Algiers, Algeria; [2]Hopital Bologhine Ibn Ziri, Endocrinology, Algiers, Algeria

Introduction
The most frequent cystic lesions in the pituitary region are: cystic adenomas, Rathke's pouch cysts and craniopharyngiomas. But sometimes the diagnosis can be difficult.
Clinical case
This is the case of a women patient who consulted at the age of 20 for a pituitary cystic process revealed by secondary amenorrhoea; evoking in the first place a Rathke's pouch cyst. Hormonal assessment reveals tumour-related hyperprolactinemia; the diagnosis of cystic prolactinoma is evoked. It is the response to anti-dopaminergic medical treatment and the morphological response to MRI that leads to the diagnosis of a probable cystic prolactin adenoma.
Conclusion
A radiological image can only be interpreted with caution because it is the set of clinical and biological characteristics that allow a definitive diagnosis to be made.

DOI: 10.1530/endoabs.90.EP825

EP826

Cushing's disease in children: review of 3 cases

Rahal Amel & Lylia Akli
Hopital Bologhine, Endocrinology, Algiers, Algeria

Introduction
Cushing's disease is defined as hypercortisolism caused by excessive secretion of ACTH from a pituitary adenoma. Cushing's disease is a rare entity in children
Observation
We report the case of 3 children with Cushing's disease including 2 boys and 1 girl, the mean age at the diagnosis was 12.6 years. Clinically, weight gain was constant in all children, a delay in statural growth was noted in 2 children, signs of catabolism were found in one child. Biologically, the hormonal exploration reveal an ACTH-dependent hypercorticism Morphologically, the adenoma was visualised on MRI in one patient; however, the size of the adenoma was 4 mm requiring petrous sinus catheterisation. Petrous sinus catheterisation was used in all our children; this examination objectified a Centro peripheral gradient in 2 cases; but was non-contributory in the 3rd child. In terms of treatment: only one child with very severe cushing's disease was operated by transphenoidal approach on 3 occasions with failure, requiring bilateral adrenalectomy complicated by Nelson's syndrome, treated with radiotherapy and dostinex. The other 2 children are currently awaiting pituitary surgery and are on anticortisol therapy.
Discussion
Endogenous cushing's syndrome in children is rare, the most common cause remains cushing's disease. Often, in these children, the tumours are very small and cannot be detected on MRI. Despite the difficulty of this delicate procedure, petrosal sinus catheterisation was able to make the diagnosis in two out of three children.
Conclusion
Cushing's disease in children is rare;. Its management represents a real challenge requiring the use of a specialised multidisciplinary team

Resistant to treatment prolactinoma: report of two cases

Aicha Lachkhem[1], Abdelkader Yahi[2], Benabdelatif Katia[3], Abderrahim Derriche[4], Ould Kablia Samia[5], Ahcen Staifi[6] & Hakim Derradji[7]

[1]Central Military Hospital, Endocrinology, Algeria; [2]Central Military Hospital, Endocrinology, Algiers, Algeria; [3]Central Army Hospital, Algiers, Algeria; [4]Central Hospital Military, Radiology, Algiers, Algeria; [5]Central Army Hospital, Endocrinology; [6]Central Military Hospital, Ophthalmology, Algiers, Algeria; [7]Central Military Hospital, Neurosurgery, Algiers, Algeria

Introduction
Prolactin-secreting tumors or prolactinomas comprise the most common pituitary tumor type, acconting of 47-66% of all pituitary tumors. These tumors can be treated with dopaminergic drugs (DA) however 10-15% of prolactinomas are DA resistant.
Case 1
A 39 years old man followed for a geant agressif prolactinoma discovered following a progressive decline in visual acuity and associated with visual impairment (diplopia), the MRI of the sellar region (magnetic resonance imaging) (Figure1) had shown a voluminous endosellar process. Hormonal work-up revealed a serum prolactin level of 174,8 ng/ml and pituitary deficiencies. The ophthalmic examination found bitemporal hemianopia. The patient was then started on dopamine agonist (cabergoline 02mg/week). Two months later, the patient consults at the emergency unit for vomiting, headaches and reduced visual acuity, suggestive of apoplexy. The MRI reveals a clear increase in the sellar process at the expense of the sellar portion wich fills the entire optochiamatic citern, lifting and compressing the optic chiasm and reaching the Monro holes with the onset of dilatations of the lateral ventricles, the patient had a transphenoidal partial adenomectomy. The histological analysis confrmed a PRL tumor classified grade IIb Trouillas 2013 and the Ki67 was 12%. The MRI related two months later showed a slight tumor reduction (24x43x29mm) so the dopamine agonist was continued at the dose of 3,5mg/week. Three months later; the MRI demonstrated an increase in volume, the decision for chemo-radiotherapy such as the STUPP protocol (radiotherapy associated to 75mg/m2 of Tomozolomide). Suddenly our patient died one moth later during the Covid 19 pandemia.
Case 2
A 37 years old women followed for a resistant prolactinoma discovered following a galactorrhea and spaniomenorrhea. Hormonal work-up revealed a serum prolactin level of 292,9 ng/ml without pituitary deficiencies and the MRI of the sellar region had shown a macroadenoma. The patient was then started on dopamine agonist (cabergoline 0,5mg/week with gradual increase in doses up to 3,5mg/week. The hormonal control was never obtained and the MRI shown a 50% increase. The patient had a transphenoidal adenomectomy.
Conclusion
Prolactinomas are the most prevalent functioning pituitary adenomas and the easiest to treat by endocrinologists, being in the majority of cases responsive to medical treatment with DAs. However, up to 15% of cases are resistant, locally invasive and depict an aggressive growth pattern.

Panhypopituitarism of unknown aetiology in a young adult – a case report

Pedro Souteiro, Sara Santos, Joana Oliveira, Isabel Inácio, Ana P Santos & Isabel Torres
Portuguese Institute of Oncology Francisco Gentil do Porto, Endocrinology Department, Porto, Portugal

Introduction
Hypopituitarism is a rare diagnosis that is mainly due to primary pituitary neoplasms and their treatment. There are rarer causes such as hemorrhage/ischemia, traumatic brain injury, infections and infiltrative lesions.
Clinical case
We herein present an 18-year-old male patient diagnosed with acute promyelocytic leukemia at the age of 14, with no evidence of central nervous system invasion in several lumbar punctures during his follow-up. He was treated with chemotherapy (without cranial radiotherapy), being in remission for 10 months before he presented to the Endocrinology Clinic due to thyroid dysfunction: TSH 0.15 (0.27-4.20) uUI/mL and FT4 0.69 (0.80-1.67) ng/dl. He was asymptomatic, with a height of 164 cm (family target height of 167 cm) and pubertal Tanner stage 4. A second blood sample revealed a TSH of 5.32 (0.27-4.20) uUI/mL and a FT4 of 0.41 (0.80-1.67) ng/dl. Facing the suspicion of a central hypothyroidism, a pituitary panel was requested, showing low cortisol levels [1.68 (5.0-25.0) mg/dl with an inappropriately normal ACTH, a slightly high prolactin [54.4 (4.04-15.20) ng/ml], low IGF1 [60.1 (132-476) ng/ml (z-score -3.39)] and a low total testosterone leves [231 (300-1200) ng/dl] (calculated free testosterone of 3.87ng/dl). FSH and LH were normal. He was sequentially started on hydrocortisone 15 mg/day, levothyroxine 100 mg and testosterone 250 mg every 6 weeks. Brain MRI was performed and showed a discrete thickening of the pituitary stalk, measuring 4mm, with signal enhancement after gadolinium contrast, which had been known for at least 3 years. Hemochromatosis and plasmacytic hypophysitis were ruled out considering normal iron kinetics and IgG4 levels. Currently, the patient remains in leukemia remission, undergoing replacement therapy for three of the affected pituitary axes, and considering supplementation with growth hormone.
Conclusion
In this case, the laboratorial and imaging studies have not unequivocally identified the cause of hypopituitarism. Genetic combined pituitary hormone deficiency syndromes are unlikely considering his age at diagnosis, his height and normal puberty development. Pituitary leukemic infiltration remains a diagnostic hypothesis despite its rarity and considering that central nervous system involvement has never been documented in the several lumbar punctures that were performed.

Central diabetes insipidus caused by a Lymphocytic infundibuloneurohypophysitis

Meriç Dökmetaş[1], Esra Demir[1], Alper Çağrı Karcı[2], Hatice Sebile Dökmetaş[2], Hikmet Zeynep Ağaoğlu[1], Esma Eren[1], Onur Şahin[1] & Ayşenur Akkoyun[1]
[1]Istanbul Medipol University, Internal Medicine, Istanbul, Turkey; [2]Istanbul Medipol University, Endocrinology, Istanbul, Turkey

Lymphocytic infundibuloneurohypophysitis (LINH) is rarely reported due to lymphocyte infiltration in the neurohypophysis. Causes of central diabetes insipidus include idiopathic diabetes insipidus (DI), primary or secondary tumors or infiltrative diseases (such as Langerhans cell histiocytosis, lymphocytic hypophysitis), neurosurgery and trauma.
Case
A 59-year-old female patient presented with complaints of fatigue for 1 month, dry mouth and drinking a lot of water. In the blood tests of the patient, Serum glucose: 97 mg / dL (70-100), Blood urea nitrogen: 35 mg / dL (6-20), creatinine: 0.7 mg / dL (0.7-1.2), sodium: 152 mmol / L (136-145), potassium (K): 4.8 mmol / L (3.5-5.1), hemoglobin: 14.6 g/dl (12.6-17.4), CRP: 8 mg/l (<5), TSH: 2.2 µIU/mL (0.2-4.2), free T4: 1.2ng/dl (0.9-1.7), cortisol: 11 mg/dl (6-18), FSH: 29 mIU/mL (1.5-13), LH : 16 mIU / mL (1.7-8.6), ACTH: 15 ng/l (7-63), prolactin: 30 µg / L (5-10), Ca: 9 (8.6-10 mg/dl), Parathormone: 54 (N: 15-65 pg/ml), ESR: 26 mm (2-20), HbA1c: 5.7%, ANA and ANCA profile: negative, ACE: 23 U/l (13-63), Plasma osmolality : 313 mOsm/l, urinary osmolality: 124 mOsm/l, urine density : 1003. At the 6th hour of the water restriction test, the patient lost 600 g of weight, the urine output decreased by 50cc, the urine density increased to 1009 and sodium to 167 mmol/l. There was a 15% increase in urine osmolality after desmopressin. In the patient's pituitary MRI, the infindibulum was thick and the hyperintensity of the neurohypophysis disappeared in T1 sequence. Nothing was found in the examinations performed for malignancy screening and colonoscopy. The patient was diagnosed with partial central DI due to Lymphocytic infundibuloneurohypophysitis. In our case, clinical diagnosis was made without biopsy. Since the patient did not have deficiencies in other pituitary hormones, treatment with only desmopressin 10 µg intranasal spray was continued.
Conclusion
Although Lymphocytic infundibuloneurohypophysitis is rare, it should be kept in mind in the differential diagnosis of patients presenting with central diabetes insipidus.

Two diabetes insipitus cases due to Langerhans cell histiocytosis

Hatice Sebile Dökmetaş[1], Onur Şahin[2], Hikmet Zeynep Ağaoğlu[2], Esma Eren[2], Ayşenur Akkoyun[2], Meriç Dökmetaş[2] & Oğuz Kaan Türk[2]
[1]Istanbul Medipol University, Endocrinology, Istanbul, Turkey; [2]Istanbul Medipol University, Internal Medicine, Istanbul, Turkey

Introduction
Langerhans cell histiocytosis (LCH) is a neoplastic histiocytic disorder that characterized by proliferation of abnormal Langerhans cells. The most typical organs affected by LCH are the skin and bones, though it can also affect the pituitary gland, central nervous system, liver, spleen, lungs, and other organs.

Case 1
36 year old man presented with polyuria, polydipsia and right hip pain lasting about 4 months. The pain increased in the last month. MRI of the hip resulted as lytic bone lesions. To further investigate a PET/CT was performed. PET/CT scan showed the patient had multiple lytic lesions on his left scapula, left maxilla, right 7-8-9th costae, T10-L1 vertebrae, sacrum, right iliac, right acetabular joint, and left ischium. A biopsy from one of the lytic bone lesions pathology is reported as LCH. In the fluid deprivation procedure, repeated urine tests showed no increase in the urine density, therefore the patient accepted as Central Diabetes Insipitus (CDI). The patient was prescribed 120 mg nasal desmopressin. Tests were not compatible with pituitary insufficiency. MRI of the pituitary revealed histiocytosis and stalk invasion. The patient recieved 12 cycles of cytarabine, 6 cycles of high-dose methotrexate and vemurafenib 2 x 960 mg as chemotherapy.
Case 2
35 year old man presented with polyuria, polydipsia and was diagnosed as CD at 2016 and prescribed 2x120 mg nasal desmopressin. The patient reported back discomfort and jaw pain during the subsequent appointments in 2018 and 2019, respectively. In the year 2020 the pathology result of the molar tooth and mandibula came as LCH. The patient recieved six cycle of vinblastine and prednizolon as the initial chemotherapy. After 5 months of drug-free follow up, radiotherapy was administered to the iliac bone, right shoulder and mandibula. The patient's symptoms do not improve in the following six months, and this is considered as disease progression. The patient then recieved eleven cycle of vinblastin 10 mg in the year 2021. The most recent PET/CT scan revealed remission of the illness. His pituitary functions were not compatible with pituitary insufficiency.
Discussion
Despite its rarity, LCH should be considered when making a differential diagnosis for patients who have central diabetes insipidus.

Pituitary Abscess – A challenge to diagnose preoperatively
Waqar Ahmad[1], Matthew Nichols[1], Karen Johnson[1], Claire Nicholson[2], Yaasir Mamoojee[3] & Ashwin Joshi[1]
[1]Sunderland Royal Hospital, Endocrinology and Diabetes, Sunderland, United Kingdom; [2]Royal Victoria Infirmary, Neurosurgery, Newcastle Upon Tyne, United Kingdom; [3]Royal Victoria Infirmary, Endocrinology and Diabetes, Newcastle Upon Tyne, United Kingdom

Background
Pituitary abscess is rare but a serious intrasellar infection. It should be considered in the differential diagnosis of the sellar masses due to its high morbidity and mortality rates. Despite recent advances in radiological investigations, it remains a challenge to make a definitive diagnosis preoperatively [1]. We present a case of pituitary abscess who presented with pan hypopituitarism and central diabetes insipidus.
Case presentation
A 34-year-old man with no significant past medical history was referred to the medical unit with a low serum cortisol (14 nmol/l). He had a 3 month history of fatigue, polyuria, polydipsia, cold intolerance and reduced libido, as well as a 1 week history of frontal headache worse with coughing and movement. No visual disturbances were present. Clinical examination and observations were normal. Routine blood tests revealed no electrolyte abnormalities with mild leucocytosis. Further investigations demonstrated pan hypopituitarism with secondary adrenal insufficiency, central hypothyroidism, and secondary hypogonadism. Central diabetes insipidus was suspected. Hydrocortisone, levothyroxine and testosterone were started initially, then desmopressin added due to ongoing polyuria, all with good symptomatic effect. MRI pituitary with contrast showed a 13x9mm lesion with peripheral enhancement and cystic-like component within the pituitary gland. Following referral to the pituitary MDT, he underwent endoscopic trans-sphenoidal pituitary surgery where pus was noted in the pituitary fossa. Drainage of the pituitary abscess was performed. Pus samples grew *Staphylococcus aureus*. He was treated with intravenous cefotaxime then switched to oral linezolid for a total of 4 weeks' treatment. Post-operative MRI showed reduction in the cystic pituitary lesion. Patient remained on hormone replacement therapy.
Conclusion
To conclude we can say that, despite rarity of the condition and radiological uncertainty, the history of recent infection or surgery of nearby structures or immunosuppression makes it highly suspicious of pituitary abscess. Although these risk factors were not apparent in our case. Prompt surgical drainage of the abscess followed by prolonged antibiotic therapy and hormonal replacement remains the main stay of treatment [2].

An Atypical Presentation of Hypopituitrism
Raisa Minhas[1], Keefah Bashir[1], Catherine Mitchell[1], Yong Ling[1], Giridhar Tarigopula[1], Mustafa Alansari[1], Florian Wernig[2] & James Tomlinson[2]
[1]Hillingdon Hospital, Diabetes Endocrinology, London, United Kingdom; [2]Imperial College, London, United Kingdom

A 48-year-old male presented with headache, cough and recurrent nose bleeds. Clinical examination showed saddle shape nose deformity. His past medical history included primary hypothyroidism diagnosed at the age of 10 years, was taking levothyroxine. His brother had a Rathke's cleft cyst, surgically removed. His blood test were as follows: Sodium 125mmol/l, TSH 0.10mU/l, free T4 10.2pmol/l, freeT3 2.6pmol/l, cortisol < 28nmol/l, prolactin 240mU/l, FSH 1.8U/l, LH 0.3U/l. He was commenced on prednisolone 3mg and continued on levothyroxine 125mg. Initial CT Head showed suprasellar lesion with right sided mastoiditis. MRI pituitary showed a centrally cystic sellar and suprasellar lesion with peripheral enhancement, thickening of the pituitary stalk and abnormal signal in retro-chiasmatic tracts. Visual field (VF) assessment showed a left temporal superior visual field defect with normal right vision. The differential diagnosis was cystic macroadenoma, atypical hypophysitis or previous apoplexy. Pituitary MDT discussion advised to send off a vasculitis screen that showed weakly positive c-ANCA, PR3 antibody positive at 7.3 IU/ml (normal range upto 1.9). All other antibodies were negative including negative TB Elispot. A repeat VF assessment however, showed progression to bitemporal quadrantanopia. A diagnosis of ANCA-associated vasculitis was established and prednisolone was increased to 60 mg. A pituitary biopsy was considered if no improvement in visual fields. A repeat MRI after 6 weeks showed interval reduction in size with central cystic cavity collapsing down thus confirming likely an inflammatory process responding to glucocorticoid treatment. Once started on high-dose steroids, he reported polyuria and polydipsia with normal blood glucose levels. Awater deprivation test was consistent with a diagnosis of cranial diabetes insipidus which was managed with desmopressin. He was commenced on rituximab 1g, two weeks apart followed by a gradual reduction of prednisolone to meintenance dose of 3mg. Although he was eventually found to have hypogonadotrophic hypogonadism however wasn't started on testosterone replacement due to absence of any symptoms. Subsequently, he showed good clinical and radiological improvement and was able to return to work. On repeat MRI further reduction in size of pituitary gland was noted, normal thickness of stalk and uniform contrast enhancement. He remains under regular clinical follow up with a plan to continue 6-monthly rituximab infusions for remission maintenance and periodic pituitary MRI surveillance. This case posed a diagnostic challenge given the absence of many systemic features of vasculitis. In addition, it highlights the delayed diagnosis of posterior pituitary dysfunction which was unmasked by the high dose steroids. It also emphasizes the importance of the MDT approach to manage such cases.

Case Series of Cranial Diabetes Insipidus secondary to Presumed Lymphocytic Hypophysitis Presenting During Pregnancy
Shaan Sahota, Lydia Sinclair, Edel Casey, Gideon Mlawa, Chineze Otigbah, Funmi Akinlade, Jonathan Pollock & Nemanja Stojanovic
Barking Havering and Redbridge University Trust, United Kingdom

Introduction
We present two pregnant women who were referred to obstetric endocrinology service with polyuria and polydipsia. They were investigated and treated for diabetes insipidus (DI). In both cases, the underlying pathophysiology was ADH insufficiency secondary to autoimmune lymphocytic hypophysitis. There are currently no consensus guidelines on the diagnosis of DI during pregnancy. These cases highlight best practice and endorse MDT management of chronic hypopituitarism.
Cases
Patient 1 was referred at fifteen weeks gestation with excessive thirst and polydipsia. She had a background of autoimmune lymphocytic hypopysitis (aged 16) diagnosed after resection of a presumed pituitary macroadenoma. She had been well off endocrine replacement in the interim 14 years but remained amenorrhoeic (she declined HRT). She conceived with IVF and became symptomatic with D.I. at 5 weeks' gestation. She had a water deprivation test

during her pregnancy and outside of pregnancy, the result would have been normal. She was treated with dDAVP, stopping after delivery. Patient 2 was also referred at twenty weeks' gestation with thirst (drinking twenty litres/day) and nocturia. Her symptoms had started during a previous pregnancy two years previously, which ended in miscarriage. In her second pregnancy the symptoms became much worse. A random serum/ urine osmolality showed 310 mosmol/ kg and 37 mosmol/kg respectively. A non-contrast MRI showed symmetrical enlargement of the pituitary stalk, suggestive of autoimmune lymphocytic hypophysitis. She was treated with dDDAVP with prompt resolution of her symptoms and remains on treatment.
Discussion
Cranial DI is a state of increased thirst and water loss due to deficient ADH secretion. The diagnosis is complicated by physiological changes during pregnancy. Pregnancy is a state of fluid retention, mediated by changes in water homeostasis; pregnant women feel thirst at lower serum osmolarities and pass higher volumes of urine. Both of our patients had a primary deficiency of ADH to due lymphocytic hypophysitis. In one of the patients, the damage was subclinical and unmasked by pregnancy. In pregnancy the vasopressinase activity of placental cystine aminopeptidases leads to a 3-4 fold increase in ADH catabolism. Their pituitary glands were unable to meet this increased demand. Differential diagnosis is HELLP syndrome / liver impairment. This was ruled out in our patients. Our patients were treated successfully with desmopressin, which is safe in pregnancy and required regular monitoring for water intoxication and hyponatremia. dDAVP is more resistant to placental vasopressinases than endogenous ADH.

The Role of Medical therapy and Radiotherapy in the management of Pituitary Macroprolactinomas

Robert English[1,2], Sanjali Ahuja[1,2], Miriam Lowe[1,2], Alaina Khan[1,2], Maisha Hayat[1,2], Bashir Mahamud[1] & Gideon Mlawa[1]
[1]Queen's Hospital, United Kingdom; [2]Barts and The London School of Medicine and Dentistry, Queen Mary University of London, Charterhouse Square Campus, London, United Kingdom

Introduction

Background
Pituitary adenomas can be divided into functioning pituitary adenoma (FPA) and non-functioning pituitary adenoma (NFPA). Pituitary adenomas can also be classified based on their size as microadenoma(< 1cm) or macroadenoma (> 1cm).
Cases
1. A 33-year male was admitted with a 4-month history of headaches, generalized aches and pains, weight loss, lethargy, and erectile dysfunction. He was reviewed by the Endocrine team and his hormonal profile showed TSH 2.62, FT4 4.2, FT3 3.7, 9 am cortisol 37, Prolactin 12,000, LH 2.5, FSH 5.4, testosterone 1.7. IGF-1 was 211. He was started on Cabergoline and responded well with normalization of prolactin level to 217. His testosterone level improved alongside LH and FSH. He did not require surgical intervention or Radiotherapy 2. A 63-year-old man presented to Emergency with headaches and visual disturbance. He was reviewed by the neurology team and was found to have bi-temporal hemianopia. CT head revealed a pituitary mass. His past medical history includes erectile dysfunction, gynecomastia, and general lethargy. His blood test revealed a low testosterone level, low LH, and low FSH. Of note, his prolactin level was > 100,000. MRI pituitary revealed pituitary macroadenoma with suprasellar extension. He was started on cabergoline with some response and normalization of his visual field. His prolactin level initially dropped to < 500 however further rose to > 20,000 despite the dose escalation of cabergoline to 10mg weekly. MRI demonstrated significant tumour enlargement and an increase in size. He was treated with external beam radiotherapy, with a reduction in tumour size and an improvement of prolactin to around 3000. The patient was switched to the maintenance dose of quinagolide 300mg once a day and the prolactin level improved to < 3000.
Discussion
Most pituitary prolactinomas respond well to dopamine agonists as demonstrated by case 1. The remission rate with cabergoline or bromocriptine is about 70-90%(3,4). Radiotherapy should be considered for patients with pituitary macroprolactinoma which is unresponsive to medical therapy as demonstrated in case 2.
Conclusion
The 1st line of treatment for pituitary prolactinomas is a dopamine agonist(2,3,4). Radiotherapy should be considered in those patients not responding to medical therapy.

Pituitary metastasis from colon cancer in a young patient

Ana Ferreira, Ângela Dias & Luisa Raimundo
Hospital Garcia de Orta, Almada, Portugal

Introduction
Pituitary metastases account for approximately 1% of pituitary lesions, most frequently originating from lung or breast cancer. We describe a case of a pituitary metastasis from colon cancer, a rare origin.
Case report
a 36 year-old male, previously healthy, came to the emergency department for new onset jaundice and fever. He also had headaches for the last 3 months, and for the last month diplopia, left palpebral ptosis and low libido. Physical examination confirmed jaundice (sclera and skin), low weight, abdominal pain at the right upper quadrant, left palpebral ptosis and right III and VI nerve paralysis. Abdominal-pelvic CT revealed hepatomegaly with several lesions (suggesting metastases), multiple mesenteral, lombo-aortic, pelvic and inguinal adenopathies and an infiltrative mass in the sigmoid colon. The remaining investigation confirmed the diagnosis of metastatic colon cancer with obstructive jaundice and cholangitis. Brain MRI showed an extensive, infiltrative sellar and clival mass, with suprasellar extension causing optic chiasm and hypothalamic compression, bilateral cavernous sinus invasion (knosp 4), sphenoid sinus invasion and bone erosion and extension to petrous bone apex with left Meckel cavum obliteration, suggestive of metastasis in this clinical picture. 18F-FDG PET-CT revealed high uptake by the sellar lesion (as well as for the primary tumor and remaining metastases). Pituitary function tests revealed pan-hypopituitarism and slight prolactin elevation. He was started on hydrocortisone and levothyroxine. A few days later, the patient complained of increased thirst and urinary output (polyuria confirmed by 24h urine collection), with dehydration at physical examination. Diabetes insipidus was confirmed, so desmopressin was started. The patient started complaining of decreased sensation in the left upper face and it was decided to do palliative radiation treatment (30Gy), that was ineffective for symptom control and he died shortly after the end of treatment, with progressing systemic disease. Overall, the patient survived for 2 months after diagnosis and never started systemic treatment for his cancer nor transsphenoidal surgery was considered because his physical condition never allowed to.
Conclusion
Although it was not confirmed histologically, aggressive characteristics in MRI, 18F-FDG uptake, diabetes insipidus and a confirmed metastatic colon cancer diagnosis, makes pituitary metastasis the most likely diagnosis. There are only a few cases of pituitary metastases from colon cancer described in literature, usually presenting with visual complaints, most of them treated surgically, with poor prognosis.

Clinical profile of Acromegaly patients in a teritary endocrine center in Kathmandu, Nepal

Ansumali Joshi, Smriti Khadka, Srijana Karmacharya & Sushmita Shrestha
Kathmandu Diabetes and Thyroid Centre, Endocrine, Lalitpur, Nepal

Nepal has limited data on acromegaly patients. We did a retrospective study of acromegaly patients who were diagnosed in our center or were referred to our center. We included 10 patients of acromegaly who presented in our center from January 2018 to December 2022. Four (40%) were males and six (60%) were females. Their mean age was 38.70 +/- 6.51 years, ranging from 31 to 50 years. The mean BMI was 26.13 +/-1.77 kg/m^2. The most common presenting symptom was joint pain (90%) followed by headache and peripheral neuropathy (40% each). Three patients (30%) patients had visual problems with visual defects. All patients had acral enlargement, prominent supraorbital ridge and prognathism. Increased sweating was seen in 3 patients (30%). Four (66.66%) out of six female patients had menstrual abnormalities; one forty-four years old patient had amenorrhea for two years and another female of thirty-one years of age had amenorrhea for eight months. Hypertension was seen in three (30%) patients and diabetes was seen in seven (70%) patients. One (10%) patient had hypothyroidism. All patients had elevated basal GH and IGF1. Mean basal GH was 48.78 +/- 43.67 ng/ml, ranging from 6.36 to 160 ng/ml with median of 44.29 ng/ml. Mean IGF-1 was 515.25 +- 316.03 ng/ml ranging from 117 to 954 ng/ml with median of 522.65 ng/ml. Hyperprolactinemia was seen in two (20%) patients while secondary hypogonadism was seen in one (10%) patient and secondary hypercortisolism was seen in one (10%) patient. One (10%) patient had pituitary microadenoma whereas nine (90%) patients had pituitary macroadenoma. Seven patients (70%) underwent surgery to remove pituitary adenoma and three patient (30%) refused surgery. Out of seven patients who had surgery, six patients (60%)

underwent endoscopic trans-sphenoidal surgery and one (10%) patient underwent transcranial pituitary adenectomy. Post operatively one patient (10%) developed diabetes insipidus, one (10%) patient developed third cranial nerve palsy and hypocortisolism. The mean GH of seven patients who underwent surgery was 10.22 +/- 7.73 ng/ml and IGF-1 was 398.90 +/-268.35 ng/ml ranging from 143 to 879 ng/ml. None of the patients had remission. Three (30%) patients received second line treatment. Among them two (20%) patients underwent radiotherapy; 1(10%) received EBRT (External beam radiation therapy) and 1(10%) underwent gamma knife surgery. One patient (10%) received Sandostatin (Octreotide LAR). One (10%) of our patient had to undergo resurgery- transphenoidal pituitary surgery.

Hyperprolactinemia in a patient with the kidney failure: a rare case of macroprolactinoma and autosomal dominant polycystic kidney disease

Ana Majic Tengg & Vlatka Pandzic Jaksic
Clinical Hospital Dubrava, Department of Endocrinology, Diabetes, Metabolic Diseases and Clinical Pharmacology, Zagreb, Croatia

Introduction
Autosomal dominant polycystic kidney disease (ADPKD) is an inherited kidney disease characterized by the development and growth of cysts causing a progressive kidney enlargement and the end-stage renal disease (ESRD). The incidence of brain aneurysms in patients with ADPKD is high thus screening is recommended. The association of pituitary incidentalomas and ADPKD is rarely described in the literature. All reported pituitary adenomas in patients with ADPKD were functional growth hormone (GH) secreting adenomas. We represent a rare case of macroprolactinoma in a patient with ADPKD and ESRD.
Case presentation
A 43-year-old male with ADPKD and ESRD, treated with chronic haemodialysis, was referred to a Magnetic Resonance Imaging (MRI) of the head as a part of the pre-transplantation evaluation. The MRI scan showed the sella turcica filled with an enlarged pituitary gland protruding cranially into the suprasellar cistern, raising and shortening the infundibulum, and reaching the lower contour of the optic chiasm and nerves. The pituitary gland had total dimensions of 21 x 12 x 17 mm (CC x AP x LL). The patient was referred to an endocrinologist, and a laboratory examination was performed. The results were as follows: elevated prolactin level > 4255.3 mIU/l (n.r. 56.0 - 278.4), low FSH 0.88 IU/l (n.r. 1.27 - 19.26) with LH 4.99 IU/l (n.r. 1.24 - 8.62), total testosterone 8.22 nmol/l (n.r. 5.21 - 23.70), sex hormone binding globulin 26.8 nmol/l (n.r. 13.3 - 89.5) and free testosterone 185 pmol/l (n.r. 170 – 660). The function of thyrotropic, corticotropic and somatotropic cells was normal. The patient did not complain of mass effect symptoms, such as a headache or visual field disturbance, and his visual field examination was normal. He had no symptoms of hypogonadism and was a father of one child. A diagnosis of a prolactin-secreting pituitary macroadenoma (macroprolactinoma) was made and the bromocriptine therapy was started. After two months, the prolactin level was normalized (175.6 mIU/l; n.r. 56.0 - 278.4), together with the FSH level. The bromocriptine therapy was continued, while the check-up pituitary MRI is planned 6 months after the initiation of the therapy.
Conclusion
Hyperprolactinemia is a common endocrine abnormality in patients with the kidney failure, most often not requiring a specific treatment. This case report highlights that a patient with the kidney failure and extremely high prolactin levels, especially if accompanied with a headache or visual field disturbance, needs to be examined for a prolactinoma.

EP838

A sheehan's syndrome revealed by cardiovascular collapse

Imane Boubagura, Neima Hassan, Ghizlane El Mghari & Nawal El Ansari
Department of Endocrinology, Diabetology and Metabolic Diseases, University Hospital of Marrakech, Marrakech, Morocco

Introduction
Sheehan syndrome (SS), or postpartum pituitary necrosis, is a rare but potentially serious complication of postpartum. we describe a patient whose diagnosis of sheehan's syndrome was delayed and revealed by a cardiovascular collapse.
Case report
A 36 year old femele patient, admitted to the intensive care unit in a state of septic shock due to pyelonephritis, was intubated, ventilated and put on noradrenaline in SAP and antibiotic therapy, in view of the non-improvement and low blood pressure figures despite the filling and vasoactive drugs, as well as hypoglycemia with a hyponatremia of 110 and hyperkalemia of 6 on the ionogram, acute adrenal insufficiency was suspected and the 8-hour cortisol level confirmed the diagnosis (0.8 mg/dl), patient put on intravenous hydrocortisone hemisuccinate. The evolution was marked by an improvement, patient extubated and weaned from vasoactive drugs, the interrogation revealed an antecedent hemorrhagic childbirth with absence of milking and absence of return of childbirth, and the patient kept an important asthenia in postpartum but and consulted each time for a digestive picture made of abdominal pains and nausea put under symptomatic treatment without the diagnosis of adrenal insufficiency being suspected. The patient was then admitted to the endocrinology department for further management with evidence of a gonadotropic, corticotropic and thyrotropic deficit, the somatotropic axis was not explored, the pituitary MRI was without anomalies.
Discussion
This observation is typical of Sheehan's syndrome, both in its clinical presentation and in the diagnostic errors that it can cause.
Conclusion
Postpartum pituitary necrosis is a difficult diagnosis in the acute phase and is often overlooked. This diagnosis should be evoked in any patient who has had a collapse during childbirth, whatever its cause, in front of the appearance of early headaches or a meningeal syndrome, and/or in front of the later appearance of the classic signs of pituitary insufficiency (absence of lactation, weight loss, asthenia, arterial hypotension, secondary amenorrhea)

Adipsic Diabetes Insipidus After Transsphenoidal Surgery for Supra-sellar Intraventricular

Ludmila Astafyeva, Inna Badmaeva, Yuliya Sidneva, Irina Klochkova, Dmitry Fomichev, Ilya Chernov & Pavel Kalinin
Burdenko Neurosurgery Center, Moskva, Russia

Presented case demonstrates a rare diencephalic pathology — adipsic diabetes insipidus (ADI) with severe hypernatremia in a 58-year-old woman after ttranssphenoidal removal of stalk intraventricular craniopharyngioma. ADI was diagnosed because of hypernatremia (150–155 mmol/l), polyuria (up to 4 liters per day) and absence of thirst. Normalization of wa- ter-electrolyte balance occurred on the background of desmopressin therapy and sufficient hydration in postoperative pe- riod. After release from the hospital, the patient independently stopped desmopressin therapy and did not consume an adequate amount of fluid of the background of polyuria. This led to severe hypernatremia (155–160 mmol/l) and rough mental disorders. Patients with ADI need closely monitoring of medical condition and water-electrolyte parameters, appointment of fixed doses of desmopressin and adequate hydration.

Severe hyponatremia in hospitalized patient caused by hypopituitarism due to empty sella

Nino Tedoradze, Nino Akiashvili, Nino Kukuladze & Otar Dikhaminjia
Caucasus Medical Center, Tbilisi, Georgia

Background
Hyponatremia is the most common electrolyte disorder in clinical practice, whereas severe hyponatremia can be life-threatening if not diagnosed and managed appropriately. Severe hyponatremia can be the only presentation of several endocrine and non-endocrine diseases, and investigation for underlying causes and its appropriate management can be potentially life-saving. Severe hyponatremia is frequently overlooked as the presenting manifestation hypopituitarism. Herein, we describe a case of delayed diagnosis of hypopituitarism due to empty sella.
Case report
A 61-year-old patient was treated in a hospital for pneumonia, hyponatremia, when he developed seizure and coma. After two weeks of treatment, the patient was discharged, but on the next day his condition worsened with fatigue, dizziness, nausea, progressive somnolence, and was re-hospitalized in our emergency department. Upon admission, BMI = 16.3 kg/m^2, BP = 125/80 mm/Hg, HR = 79, RR = 19. Laboratory tests revealed severe hyponatremia (Na = 109 mmol/l), with normal potassium and glucose levels. IV infusion of 3.0%NaCL was initiated instantly with increase in sodium levels ≈6 mmol/l per 24h in order to avoid further neurological complications. Further tests:

serum osmolality 227 mOsm/kg, urine osmolality 493 mOsm/kg H<inf>2</info>O, urine sodium 118 mmol/l, serum cortisol 1.62 µg/dl (5,27-22.45), ACTH 12.10 pg/mL (0.1–46.0), FT4 0.43 ng/dl (0.89–1.76), FT3 0.9 pg/ml (3.1-6.8), TSH 1.91 µIU/mL (0.35–5.5). Other investigations unremarkable. He had been diagnosed with hypothyroidism (unknown etiology) 40 years ago, and was on levothyroxine 50 µg since then. According to the clinical and laboratory findings, he was diagnosed with hypopituitarism—secondary adrenal insufficiency, central hypothyroidism. Pituitary MRI revealed empty sella syndrome. Patient was started on IV hydrocortisone instantly and levothyroxine dose was increased in a few days. After hydrocortisone initiation, patient's symptoms resolved with complete biochemical and clinical improvement. He was discharged on 20 mg hydrocortisone and 100 µg levothyroxine daily without any worsening during follow-up visits.

Conclusion

Our case demonstrates the importance of management of severe hyponatremia along with comprehensive workup to establish the cause of hyponatremia and appropriate management. Adequate treatment of hyponatremia in our patient led to a complete recovery without consequences.

Sheehan's syndrome presenting as post-partum depression : a case report

Ikrame Qasdi, Lamya Echchad, Hasna Ouirar, Zainab Elmazuni, Kaoutar Rifai, Iraqi Hinde & Mohamedelhassan Gharbi
Ibn Sina University Hospital, Endocrinology and Metabolic Diseases, Rabat, Morocco

Introduction

Sheehan's syndrome or Simmond's disease is a partial or complete postpartum hypopituitarism caused by pituitary infraction and necrosis that usually occurs as a complication of massive postpartum hemorrhage or severe hypotension during or after labor and delivery. We present the case of Sheehan's syndrome presenting postpartum depression.

Case

A 40 years old woman, referred to our department by her psychiatrist for exploration of central hypothyroidism. Her medical history is marked by the occurrence of postpartum depression one month after delivery for which she was put under antidepressant and anxiolytic for about 4 months. Her last pregnancy, the childbirth was a full-term vaginal delivery at home which was complicated with profuse bleeding that required transfusion. The evolution was marked by the inability to lactate her child and the cessation of her menstrual cycles after the delivery. The physical examination at the time of admission revealed an ill-looking patient, bradyphrenia, asthenia, cold extremities, pallor, pronounced wrinkles, rarefaction of body hair and atrophied breasts The biological assessment showed a corticotropic insufficiency with a 8 am cortisol of 26ng/ml, a thyrotropic insufficiency of central origin with FT4 below 1pmol/l and a hormonal profile of hypogonadotropic hypogonadism The hypothalamic-pituitary MRI was requested and came back in favor of an intrasellar arachnoidocele. The patient was put on hydrocortisone, levothyroxine. The evolution was marked by the improvement of her well-being. One month later, she was started on oestrogen and progesterone hormonal therapy.

Discussion & Conclusion

The psychiatric features of hypopituitarism can be attributed to a combination of hypothyroidism, hypoglycemia and hypocortisolism, and have been shown to spontaneously resolve under adequate hormone replacement. In fact, medical and obstetric history, and physical examination are of paramount importance in the diagnosis as most patients will consult for nonspecific symptoms which cause delays in management.

Spontaneous involution of a cystic pituitary adenoma

Maria Zhao Montero Benítez[1], Paloma González Lázaro[1], Antonio Moreno Tirado[1], Pedro Jimenez Torrecilla[1], Cristina Contreras Pascual[2], Florentino Del Val Zaballos[1], Amparo Lomas Meneses[1] & Inés Gómez García[1]
[1]Hospital General La Mancha Centro, Alcázar de San Juan, Spain; [2]Hospital Santa Bárbara, Soria, Spain

Pituitary adenomas (PAs) account for 15-20% of intracranial tumors. PA with a cystic component are characterized in the MRI by a sellar, symmetrical, round or ovoid mass that enhances on T1- or T2-weighted images but does not concentrate gadolinium. We present the case of a 48-year-old man who in a headache study by Neurology requested a CT scan showing a cystic pituitary macroadenoma of 1.25cm confirmed by pituitary MRI. In the initial analysis, the pituitary function was preserved, but in the follow-up he was diagnosed with central hypothyroidism and hypogonadotrophic hypogonadism, so replacement treatment was started. In addition, a visual field study was performed, being normal. As it was a clinically non-functioning asymptomatic pituitary adenoma, we opted for conservative follow-up without surgery. During the follow-up of the patient, a control pituitary MRI requested three years later revealed a significant decrease in the size of the pituitary lesion with cystic semiology, with dimensions of 8x3mm. This decrease in size was confirmed in subsequent imaging tests, although the hormone deficits presented by the patient persisted. Nonfunctioning PAs can go unnoticed for years, and be diagnosed incidentally or when they grow and produce compressive symptoms (headaches, visual impairment) or hormonal deficiencies. In patients with asymptomatic, clinically nonfunctioning pituitary incidentalomas it is recommend conservative follow-up without surgery, with periodics MRI. Macroadenomas have a propensity to grow, but it has been seen that a small percentage (approximately 10%) may undergo spontaneous volume regression, perhaps due to silent ischemia, so continuous follow-up with repeated imaging is justified. Periodic reassessment of pituitary function is recommended in patients with macroincidentalomas because they are at risk of developing hypopituitarism. Medical therapy of pituitary incidentalomas has not been systematically studied. The reported efficacy of do pamine agonist, somatostatin analogues, and GnRH analogues varies widely. In the present case, there was a significant decrease in the size of the PA during follow-up without surgical or medical treatment, hence the importance of periodic radiological follow-up. In some cases, when tumor size regression occurs, pituitary function can be restored, a fact that did not occur in our case, so we will continue with clinical, radiological and biochemical follow-up of the patient.

Acromegaly: predictive factors for long-term remission

Cherchir Faten, Sabrine Mekni, Sawsen Essayeh, Sahar Abidi, Nadia Mchirgui, Imen Rojbi, Ibtissem Ben Nacef & Karima Khiari
Hospital Charles Nicolle, Endocrinology, Tunis, Tunisia

Introduction

The management of acromegaly is commonly based on selective transsphenoidal adenomectomy (STA) as a first-line treatment, and other therapeutic options including somatostatin analogues (SA), dopamine agonists (DA) and radiotherapy as second-line treatment or in case of operative contraindications. The aim of our study was to assess the remission rate and to determine the predictive factors for long-term remission in acromegalic patients.

Methods

We conducted a retrospective study including 27 acromegalic patients followed in the endocrinology department of Charles Nicolle hospital during the period from 1989 to 2022. Clinical, biochemical, imaging and therapeutic data were extracted from medical records. According to hormonal outcome, patients were subdivided into two groups: remission vs improvement/stabilization.

Results

There were 16 (59%) women and 11 (41%) men with a mean age at the diagnosis of acromegaly of 46.6 $\pm$ 13.7 years. The median (IQR) initial GH level was 21.6 ng/ml (7.8-47.0). STA, SA, DA and radiotherapy were used in 67, 22, 4 and 26% of cases, respectively. Long-term remission was obtained in 10 patients (37%), while most patients (63%) had a persistent disease (improvement or stabilization). Patients who underwent STA had a significantly higher remission rate compared with unoperated patients ($P = 0.009$). We did not found significant correlations between adenoma size, initial GH and post-therapeutic GH levels. We did not observe significant associations between remission rate and the following parameters: age, sex, locoregional invasion, pituitary deficiencies, vision loss, use of SA, DA and radiotherapy.

Conclusion

The prognosis of acromegaly depends mainly on early and effective tanssphenoidal resection of somatotroph adenoma. Medical treatment and radiotherapy can not lead to remission unless combined with STA.

A case report of pituitary macroadenoma presenting with visual disturbance due to suspected cataract

Furhana Hussein[1], Man-Yan Cheung[2], Gideon Mlawa[3] & Mahamud Bashir[4]
[4]Queen's Hospital, Endocrinology and Diabetes/Acute Medicine, London, United Kingdom; [2]Queen's Hospital, Acute Medicine, London, United

Kingdom; [3]Queen's Hospital, Endocrinology and Diabetes, London, United Kingdom; [4]Queen's Hospital, London, United Kingdom

Introduction
Pituitary adenomas are benign tumours of the pituitary gland with an estimated prevalence rate of approximately 17%. Around 1 in 600 people have macroadenoma (>1cm) that can present with variety of visual problems classically as bitemporal hemianopia due to compression of the optic chiasm.
Case presentation
50-year-old male was admitted with 3months history of worsening headache and 4months of visual disturbances. Initially he was seen in an eye clinic and diagnosed with cataract however, on the day of his cataract operation was told he does not have cataract and was sent for further investigations. In the past 4weeks his headaches had escalated to 10/10 pain severity scale that was not relieved by analgesia and his vision was getting worse. He reports of change in shoe size and his ring no longer fitting. He complained of increased frequency of urination, snoring at night-time and intermittent sweating. On examination he was found to have bitemporal hemianopia more severe on the right inferior quadrants, reduced nasal field on the right eye but rest of the cranial nerves were intact. His lower jaw was producing but no evidence of overbite or large hands. Nil significant past medical history.
Investigations
MRI pituitary showed large pituitary lesion measuring 4.8x1.7x2.9 cm extending into suprasellar cistern and compressing the optic chiasm and the hypothalamus and part of the floor of the third ventricle. The lesion is extending downward into the sphenoid sinus.
High prolactin 12788
Low cortisol level of 34
Low T4 (3.4) and T3 (2.8) (TSH normal)
Low FSH (0.9) and LH (<0.3)
Low testosterone(<0.1)
Low IGF-1 (60)
Management
Referred to the neuro-pituitary MDT. Commenced on cabergoline and prolactin decreased from 12788 to 2846 after one week Also started on hydrocortisone 10mg twice daily and levothyroxine 50micrograms daily. Endoscopic transsphenoidal surgery for pituitary lesion was carried out.
Discussion
Visual disturbances in particular bitemporal hemianopia is a common clinical presentation in pituitary macroadenomas however, in this case the patient initially presented at an Eye Clinic hospital and was diagnosed as cataract which is not common. Pituitary macroadenoma in particularly prolactinomas can be managed conservatively with dopamine agonist such as cabergoline however, in certain cases such as patients with resistant or intolerance to domine agonist, or worsening vison an endoscopic transsphenoidal surgery may be offered.
Conclusion
It is important to consider cranial or pituitary issues as differentials when seeing patients complaining with headache and visual changes.

Retrospective Evaluation of Pituitary Adenomas from clinical, laboratory and medical aspects

Duygu Kesebi Isganderov[1], Medine Nur Kebabcı[2], Göknur Yorulmaz[2], Aysen Akalın[2] & Fatma Belgin Efe[2]
[1]Evliya Çelebi Eğitim Ve Araştırma Hastanesi, Internal Medicine, Kutahya, Turkey; [2]Eskişehir Osmangazi University Hospital, Internal Medicine, Eskisehir, Turkey

Pituitary adenomas arise from adenohypophyseal cells and progress with increased comorbidity and mortality. It is important to examine the diagnosis, prevalence, course and treatment of the subgroups of the disease in our country because pituitary adenomas are seen in the most productive periods of life and have important clinical results. In our study, 667 pituitary adenoma patients who applied to Eskişehir Osmangazi University Medical Faculty Hospital Endocrinology Department between 1980-2018 were evaluated retrospectively and observationally. The information of the patients was scanned from the hospital information management system and outpatient clinic patient files. Scanned information; age, gender, age of diagnosis, follow-up year, application complaint, size, location, hormone levels at the time of diagnosis and after treatment, type of medical treatment used, number and type of operation of pituitary adenoma, before medical or surgical treatment and post-adenoma size and if any, residual/recurrent pituitary adenoma size, chiasma compression, postoperative hormone activity, history of RT for adenoma. 171 (25.6%) were nonfunctional adenomas, 356 (53.4%) were prolactinomas, 121 (18.1%) were acromegaly, 16 (2.4%) were Cushing disease and 3 (0.4%) were TSHoma. 340 (51.1%) microadenomas, 195 (29.1%) macroadenomas, 132 (19.8%) invasive macroadenomas were detected. It should be kept in mind that delay in diagnosis will cause important problems such as decrease in quality of life, disability, preparing the ground for additional diseases, and showing a mortal course. As a result, the information obtained from the careful examination and the request for the relevant laboratory and radiological tests will lead us to early diagnosis.

Cyclic cushing syndrome: a case report

Hind Ouakrim, Rania Dassoufi, Sana Rafi, Ghizlane El Mghari & Nawal El Ansari
Chu Mohamed Vi Marrakesh - Drh, Endocrinology, Marrakesh, Morocco

Introduction
Intermittent Cushing's syndrome is characterized by alternating episodes of hypercorticism with periods of eucorticism. It is a rare but well-defined entity and should be known. It remains a diagnostic challenge sometimes particularly difficult in endocrinology, we report a case.
Case presentation
A 22-year-old diabetic patient on metformin, who consulted us because of a weight gain with the appearance of stretch marks for 2 months. The clinical examination revealed severe obesity with TTP, aconthosis nigricans, complete and flagrant clinical cushing syndrome. At this time, we could not explore the patient hormonally. The hypothalamic-pituitary MRI showed a pituitary microadenoma measuring 3.3*2.4mm. The workup for cushing's syndrome was unremarkable except for diabetes with a HBa1C of 7%. After 5 months, the patient had regression of stretch marks with a significant weight loss of 9kg, and hypoglycemic malaise motivating the discontinuation of diabetes treatment. The diagnostic workup for cushing's syndrome, including urine cortisol levels and a 1mg overnight dexamethasone suppression test, was normal. The diagnosis of cushing's disease with cyclic hypercorticism was considered. The management consisted of a quarterly clinical and biological evaluation
Discussion
The diagnostic criteria for intermittent cushing's syndrome include three episodes of hypercorticism and two episodes of eucorticism, although these criteria are valid for most patients, they can be difficult to achieve especially if the intercycle phase is large. Our patient presented with a clinically diagnosed episode of hypercorticism followed by an episode of spontaneous eucorticism. The fluctuating clinical presentation and discordant biochemical findings make this intermittent Cushing syndrome extremely difficult to diagnosis. Frequent measurements of urinary cortisol or better salivary cortisol level are reliable and practical diagnostic tools, and should be repeated, especially when clinical signs and symptoms reappear.
Conclusion
This observation illustrates the diagnostic challenge of intermittent Cushing's syndrome, so clinicians should be aware that hypercorticism may occur periodically and actively search for it in all patients with suspected Cushing's syndrome.

EP847

Outcome of Bilateral Adrenalectomy in Cushing's Syndrome

Chtioui Sara, Jaddi Oussama, Sana Rafi, El Mghari Tabib Ghizlane & Nawal El Ansari
Mohammed VI University Hospital Center, Department of Endocrinology, Diabetes, Metabolic Diseases and Nutrition, Marrakech, Morocco

Introduction
Cushing disease is the most common cause of endogenous hypercortisolism. Pituitary surgery is the first-line treatment and bilateral adrenalectomy is the option of last resort due to its severe consequences.
Observation
This is a 24-year-old patient followed for cushing disease revealed by a severe cushing syndrome, a urinary cortisol at 20 times normal and negative dexamethasone suppression test with a pituitary microadenoma on MRI. He was operated with an anatomopathological result of an acidophilic pituitary adenoma expressing anti prolactin and anti ACTH antibodies with a proliferation index (KI 61) at 1%. The exploration in post-pituitary surgery revealed the persistence of the severe Cushing's syndrome with discovery of a right adrenal

mass in favor of an adenoma. The patient underwent bilateral laparoscopic adrenalectomy with no histological evidence of malignancy. He was put on replacement therapy. The symptoms of hypercortisolism improved (weight, hypertension, diabetes, depression).
Discussion
Cushing disease is responsible for severe morbidity and its management is a therapeutic challenge. Bilateral adrenalectomy was chosen as the last resort in our case, given the severity of symptomatology. Monitoring by adrenocorticotropic hormone and pituitary MRI is necessary because of the risk of developing Nelson's syndrome.

Opposite tumoral and hormonal responses to low-dose pasireotide in Cushing's Disease
Andreea Serban[1], Benedetta Zampetti[1], Andrea Saladino[2], Iacopo Chiodini[1] & Renato Cozzi[1]
[1]ASST Niguarda, Endocrinology, Milan, Italy; [2]IRCCS Carlo Besta, Neurosurgery, Milan, Italy

Pasireotide (Pas) is a multireceptor-targeted somatostatin analogue approved for the treatment of patients with Cushing's Disease (CD) who fail or are poor candidates to surgery. Pas markedly improves signs and symptoms of the disease, reduces urinary free cortisol (UFC) up to its normalization in 55% of patients and pituitary tumour size in up to 100%. Here we present a patient with severe recurrent CD treated with Pas and showing opposite results between hormonal levels and pituitary tumour size. A 54-year-old woman was diagnosed with CD in 2008. A right 8 mm intrasellar adenoma was totally removed by TNS. After seven years the disease recurred (UFC 4x Upper Limit of Normal Range (ULNR), ACTH 60 pg/ml, reference range 9-52) and MRI showed an intrasellar right adenoma tightly close to cavernous sinus (CS). She underwent a second TNS surgery, but, in spite of an apparent total removal of the adenoma, hypercortisolism worsened (UFC 40x ULNR, ACTH 237 pg/ml). MRI showed a tiny remnant of the adenoma adjacent to CS and ketoconazole (Kcz) was started at 800 mg/daily dose. Due to the persistence of pathological UFC levels, sc 600 μg bid Pas was added. The combination therapy firstly induced UFC and ACTH normalization (0.8x ULNR, 33 pg/ml, respectively) and later on hypoadrenalism, so that Kcz was withdrawn and Pas maintained, due to its higher efficacy and aiming to control the size of the adenoma remnant. Pas obtained a marked clinical improvement, diabetes mellitus occurred requiring metformin and dulaglutide. Three months after Pas starting the pituitary MRI showed a slight tumor shrinkage. Due to the occurrence of hypoadrenalism, a steroid replacement therapy was started. Adrenal insufficiency persisted notwithstanding the orogressive tapering of Pas dose to 150 mg once daily. Pituitary MRI performed at 12 and 24 mos during low (150 mg once daily) Pas dose showed a few millimeters increase of the remnant, whereas ACTH levels remained normal (31 pg/ml). Diabetes mellitus remitted, requiring only dietotherapy. This report suggests that in CD Pas induces an opposite effect between hormonal profile and the increase of pituitary tumor size. This peculiar phenomenon might be a consequence of unusual low doses of Pas needed to control hormonal hypersecretion

Ophthalmological complications in acromegaly: prevalence and associated factors
Cherchir Faten, Sabrine Mekni, Sawsen Essayeh, Wafa Ben Hilel, Nadia Mchirgui, Imen Rojbi, Ibtissem Ben Nacef & Karima Khiari
Hospital Charles Nicolle, Endocrinology, Tunis, Tunisia

Introduction
Somatotropin macroadenomas are associated with a considerable risk of ophthalmological impairment. The aim of our study was to determine the prevalence of ophthalmological complications and their associated factors in patients with acromegaly.
Methods
We conducted a retrospective study including 28 patients with somatotropin adenomas and followed in the endocrinology department of Charles Nicolle Hospital. Clinical, biochemical and imaging data were collected. Ophthalmological findings (visual acuity, visual field and fundus) were also recorded.
Results
There were 17 women and 11 men. The mean age at the diagnosis of acromegaly was 45.9 $\pm$ 13.9 years. Ophthalmological examination showed reduced visual acuity (RVA), visual field defects and papilledema in 25, 36 and 22% of cases, respectively. GH nadir during oral glucose tolerance test ($P<$ 10-3) and the tumor size ($P=0.001$) were significantly higher in patients with suffering from RVA. ACTH and cortisol levels were on the contrary lower among these patients ($P=0.001$). Aggressive tumors ($P=0.038$), optic chiasm invasion ($P<$ 10-3) and corticotroph deficiency ($P=0.022$) were associated to an increased risk of vision loss. Visual acuity was negatively correlated with tumor size ($r=$-0.727; $P<$ 10-3) and the number of pituitary deficiencies ($r=$-0.621; $P=0.005$). However, age, sex, cavernous or sphenoidal sinus invasion did not have a significant association with RVA.
Conclusion
Optic pathway compression, caused by somatotropin macroadenomas exposes to a considerable risk of vision loss. Tumor size, aggressive tumors, optic chiasm invasion, GH nadir level and the number of pituitary deficiencies help to predict that risk.

Intrasellar arachnoid cysts – a benign entity with significant clinical impact: report of two cases
Cristina Iancu[1], Andreea Vladan[2], Dorin Bica[3], Serban Radian[1,2] & Catalina Poiana[1,2]
[1]National Institute of Endocrinology CI Parhon, Bucharest, Romania; [2]Carol Davila University of Medicine and Pharmacy, Deptartment Of Endocrinology, Bucharest, Romania; [3]Neurohope, Bucharest, Romania

Introduction
Intrasellar arachnoid cysts are rare and clinically resemble nonfunctional pituitary adenomas. Arachnoid cysts should be considered in the differential diagnosis of cysts developing in the sellar region, together with cystic pituitary adenoma, craniopharyngioma, epidermoid cysts, and Rathke's cleft cysts. Symptomatic cysts are operated but can recurr.
Case presentation
We present 2 cases of compressive intrasellar arachnoid cysts occurring in elderly patients who presented with severe loss of vision.
Case 1
A 75-year-old woman presented with bitemporal hemianopsia and recurrent falls without loss of consciousness. Cerebral MRI showed a sellar and suprasellar cystic lesion measuring 25/23/20mm, compressing the pituitary gland and the optic chiasm. Endocrine assessment was not performed. The patient underwent cyst resection and fenestration by transcranial microsurgery, with marked improvement of vision and visual fields. Pathology confirmed an arachnoid cyst. 9 months post-surgery, vision and visual fields deteriorated and a cyst recurrence was diagnosed on MRI. Repeat surgery resulted in visual improvement. The patient presented in our service 8 months after the second surgery with dizziness and severe asthenia. Hormonal tests revealed p nhypopituitarism and disconnection hyperprolactinemia (56.25 ng/mL). Hydrocortisone and L-thyroxine replacement were given. Visual fields were again affected, but subjective vision was good and the patient active and independent and the pituitary MDT recommended active monitoring of visual function and MRI.
Case 2
An 85-year-old woman with a history of tachycardia-bradicardia syndrome, an implanted pacemaker, aortic stenosis and heart failure, presented with long-standing (2 yrs) severe visual impairment "I see only half of people" and physical asthenia. Computerized visual field testing revealed findings atypical for the optic chiasm compression: right eye temporal hemianopsia and superior nasal quadrantanopsia and left eye paracentral visual field defect with superior nasal quadrantanopsia. A pituitary CT scan showed an enlarged sella turcica with fluid density, compressing the pituitary gland and optic chiasm. Laboratory tests demonstrated gonadotroph insufficiency and moderate hyperprolactinemia, without corticotroph and thyrotroph insufficiency. The patient and her family were against surgery. Pituitary MDT recommended close monitoring. We are trying to arrange an MRI scan, taking the pacemaker into account.
Conclusion
Intrasellar arachnoid cysts can affect pituitary function and visual function, requiring surgery. We describe two severely symptomatic cases, one with recurrence following repeat surgery and one with a patient refusal of surgery. Pituitary function should be assessed by hormonal tests pre- and post-operatively and replacement should be prescribed as needed.

Echocardiographic features in patients with prolactinoma long-term treated with dopamine agonists

Diandra Carmen Giuca[1,2], Cristin Constantin Vere[1,3], Ileana Nitu[4], Cristina Capatina[2,5], Ionela Baciu[2,5], Iulia Florentina Burcea[2,5], Nicoleta Baculescu[2,5], Serban Radian[2,5], Găloiu Simona Andreea[2,5], Raluca Trifanescu[2,5] & Catalina Poiana[2,5]

[1]Craiova University of Medicine and Pharmacy, Internal Medicine, Craiova, Romania; [2]C.I. Parhon National Institute of Endocrinology, Pituitary and Neuroendocrinology, Bucharest, Romania; [3]Clinical Emergency County Hospital, Internal Medicine, Craiova, Romania; [4]C.I. Parhon National Institute of Endocrinology, Cardiology, Bucharest, Romania; [5]Carol Davila University of Medicine and Pharmacy, Endocrinology, Bucharest, Romania

Background

Dopamine agonists (DAs) were associated with valvular dysfunction in patients with Parkinson's disease due to their fibrotic effect through the serotoninergic receptor. It is more difficult to prove the same effects in patients with prolactinoma due to the lower doses, variable doses and the longer follow-up period.

Aim

To assess echocardiographic features in patients with prolactinoma under DA treatment.

Methods

Files of 91 patients diagnosed with prolactinoma were retrospectively assessed; 27 patients had at least one transthoracic echocardiographic (TTE) evaluation and were included in the analysis – 19 men and 8 women, median age at diagnosis 35 years-old (16-76), followed-up for a median of 5.4 years (0.2-18.4), macroadenomas prevailed (26 of 27 adenomas); median prolactin at diagnosis was 1363.7 ng/mL (75.5-30554). All subjects were treated with DAs – 25 with cabergoline (CAB) only, 1 with bromocriptine (BRC) only and one with both, consecutively. Median maximum CAB dose was 3.25 mg/week (0.5-14) with a median cumulative dose of 842.4 mg*year. Excepting 5 subjects, the rest were cured/controlled. Prolactin was measured by chemiluminescence.

Results

TTE was performed in only 29.7% of patients, despite high doses, long-term duration of DA treatment and presence of cardiovascular risk factors. All 27 patients had at least one classic cardiovascular risk factor (CVRF) – male gender (70%), age >55 years in men and >65 years in women (26%), smoking (19%), obesity (44%), dyslipidemia (78%), arterial hypertension (33%), diabetes mellitus (4%) and chronic kidney disease (33%). In average, the subjects had 3 CVRF Sixteen (60%) of patients had abnormal TTE during follow-up: 33% left ventricular hypertrophy (LVH), 40.7% had at least one grade I-II/IV valvular regurgitation (25.9% mitral and tricuspid and/or aortic, 11.1% isolated mitral, 3.7% isolated tricuspid); left ventricular function was normal in all patients but one, who showed mildly reduced left ventricular ejection fraction; 7 patients showed diastolic dysfunction. Maximum CAB dose $>$ 2 mg/week was associated with mitral regurgitation ($P < 0.05$). No patient required withdrawal of DA due to valve involvement. Study limitations include the small number of patients and non-standardized TTE evaluation.

Conclusion

TTE is still underperformed in long-term DA treated prolactinoma patients. Although atrio-ventricular regurgitation (mitral, tricuspid or both) was more frequent in our series than that reported in the general population, regurgitations were mild and clinically nonsignificant. Due to high prevalence of associated cardiovascular risk factors, lifestyle changes should become part of prolactinomas' approach.

Three spontaneous pregnancies on active acromegaly, possible event !

Abdelkader Yahi[1], A Lachkhem[1], H Derradji[1,2], A Staifi[3], A Derriche[4] & S Ould-Kablia[1]

[1]Central Hospital, Endocrinology, Algers, Algeria; [2]Central Hospital, Neurosurgery, Algers, Algeria; [3]Central Hospital, Ophtalmology, Algers, Algeria; [4]Central Hospital, Radiology, Algers, Algeria

Pregnancies in women with acromegaly are rare. Data from the literature report the absence of fetal malformation, a rarely symptomatic increase in adenomatous volume, a possible risk of gestational diabetes and gravidic hypertension in women not controlled before pregnancy. We report the case of a 32-year-old woman, nulliparous, who consults for spaniomenorrhea associated with chronic headaches, in whom the diagnosis of acromegaly was suspected in the face of a very discreet acquired dysmorphic syndrome. Endogenous hypersomatotropism that cannot be curbed by OGTT was confirmed, with the presence of a pituitary macro-adenoma measuring 12 mm long on the hypothalamic-pituitary MRI. Surgical management was referred to the discovery of an evolving pregnancy of 08 weeks of amenorrhea (SA). The pregnancy was carried to term without incident. The morphological reassessment made at three months post-partum objectified an increase in the volume of the adenoma with an extension to the right cavernous sinus, consequently adenomectomy by trans-sphenoidal way was carried out, with the persistence of a tumoral residue. A few months later, in the face of the non-taking of contraception and despite the non-control of the disease by medical treatment, a second spontaneous pregnancy was diagnosed, carried to term without incident except for headaches and vesicular lithiasis diagnosed in the second trimester. The patient underwent a cholecystectomy two months after delivery. A third spontaneous pregnancy was discovered one month later despite hypersomatotropism. The occurrence of pregnancy during acromegaly is a rare situation. The risk of increased tumor volume, pregnancy-induced hypertension and gestational diabetes are reported, however close monitoring of these patients is required.

Aggressive Cushing's: A Rare Case of Pancreatic ACTHoma in a Young Female

Oscar Paulo Reyes, Ana Denise Sison, Diana Colleen Dimayuga & Michael Villa

St. Luke's Medical Center - Global City, Internal Medicine, Taguig, Philippines

Introduction

Adrenocorticotropic hormone-producing pancreatic neuroendocrine neoplasm is a rare type of pancreatic neuroendocrine tumor that causes ectopic adrenocorticotropic hormone syndrome. Cushingoid manifestations and metabolic abnormalities can occur rapidly. High index of suspicion is required for early diagnosis.

Case

A 31-year-old Filipino female presented with facial and ankle swelling that occurred 6 weeks before the visit. She also had acne, easy bruising, amenorrhea and frequent mood swings. There was reported weight gain of 3 kg a month prior. She had no known comorbidity, and had no unusual family history. At the time of admission, blood pressure of 130/80mmHg, pulse of 92/min, respiratory rate 20/min and temperature of 37.2C. Her BMI was 28kg/m2. She had muscle atrophy of the upper and lower extremities, facial flushing, posterior cervical fat pad, abdominal violaceous striae, and skin pigmentation. Her external genitalia was normal, Tanner Stage 5 consistent with adult pattern. Neurologic exam was unremarkable. She was examined for Cushing's syndrome. On initial tests, glucose was 406 mg/dl, HbA1C 10.7%, TSH 0.122 (NV: 0.55-4.78), Free T3 0.77 (NV: 2.3-4.2), Free T4 0.58 (NV: 0.89-1.76). Creatinine was 0.86 mg/dl, sodium was 140 mEq/l, potassium was 2.1 mEq/l showing hypokalemia. There was leukocytosis on her blood count, white blood cells 15,310/mm3 (neutrophils 94%, lymphocytes 3%). In the low-dose dexamethasone suppression test (DST), the serum cortisol concentration was 991.03nmol/l. Her adrenocorticotrophic hormone (ACTH) level was elevated at 577pg/mL. After high-dose DST, the serum cortisol concentration was $>$ 1750 nmol/l. No tumor was observed on pituitary magnetic resonance imaging. On abdominal computed tomography (CT) , a large, lobulated, heterogeneously-enhancing mass arising from the pancreatic body and tail measuring 7.5cm x 10cm x 10.9cm was seen. The mass had infiltrated the gastric fundus, and encased the splenic artery. Multiple non-calcified subcentimeter pulmonary nodules were observed on chest CT. CT-guided biopsy of the pancreatic mass was done. On microscopic examination, numerous atypical cells arranged with small clusters and sheets and scattered singly were found in the tumor. The cells had small to enlarged, hyperchromatic, ovoid to round nuclei and scant to ample delicate cytoplasm. On immunohistochemical staining, the tumor cells were stained positive for synaptophysin and chromogranin A, which are both neuroendocrine markers, as well as ACTH. However, the patient died prior to any definitive management.

Conclusion

ACTHoma is a very rare disease that causes hypercortisolemia. Reporting of similar cases will provide insight into its clinical features, immunohistochemical characteristics, diagnosis, therapy, and prognosis.

Risk of neoplasms in acromegaly : a monocentric retrospective study

Faten Haj Kacem Akid, Wafa Belabed, Abdel Mouhaymen Missaoui, Nadia Charfi, Nabila Mejdoub, Dhoha Ben Salah & Mohamed Abid
Hedi Chaker University Hospital, Department of Endocrinology and Diabetology, Sfax, Tunisia

Background and aim
Acromegaly is a rare condition caused by an excessive secretion of growth hormone (GH) and insulin-like growth factor1 (IGF-1), which are responsible for exaggerated somatic growth, cardiometabolic disturbances and an increased neoplastic risk. This study aims to assess the tumorigenic potential of GH excessive secretion.
Patients and Methods
We conducted a retrospective study (1997-2020) at the Endocrinology department of Hedi Chaker University Hospital, Sfax, Tunisia. We involved 30 patients diagnosed with acromegaly, whose clinical, biochemical, and imaging peculiarities were collected from medical charts. Our patients benefited from a targeted screening for the more frequent neoplasia.
Results
Patients had a mean age of 45.8 ± 12.4 years with a male predominance (51.7%). Symptoms had been evolving for 5.1 ± 5.4 years. Acromegaly was secondary to a somatotropic adenoma in 96.7% and to a Growth hormone–releasing hormone (GHRH)-secreting pancreatic tumor in 3.3%. Clinical screening for breast cancer (breast palpation) and prostate cancer (digital rectal examination) did not reveal any suspicious lesions. Abdominal ultrasound showed one or more organomegalia in 33.3%: splenomegaly (16.7%), hepatomegaly (16.7%) and nephromegaly (8.3%). Colonoscopy performed in 14 patients was normal in 8 cases and showed polyps in 6 cases. Biopsy of the polyps did not reveal any signs of malignancy. Cervical ultrasound revealed a multi-nodular goiter in 16.7% and thyroid nodules in 11.1% of cases. Cytological study of suspected nodules confirmed their benign character.
Discussion
Despite remarkable therapeutic advances, 15-24% of deaths in acromegaly are due to cancer. The most reported neoplasia are gastrointestinal, thyroid, lung, breast and prostate. It is suggested that uncontrolled hypersecretion of GH/IGF-1 may promote the growth of tumor lesions, the carcinogenesis of pre-neoplastic lesions or the recurrence of previously treated cancers. Some studies also implicate genetic and epigenetic proto-oncogenes specific to acromegaly.

Carcinoid Syndrome With Mesenteric Ischemia

Ozlem Alkan, Damla Köksalan, Alev Selek, Zeynep Canturk & Berrin Cetinarslan
Kocaeli University Faculty of Medicine, Endocrinology and Metabolism, Kocaeli, Turkey

Introduction
Carcinoid tumors are included in the neuroendocrine tumor family. They are usually seen in the gastrointestinal tract and are asymptomatic unless liver metastases are present.
Case Report
A 44-year-old male patient was admitted with chronic crampy abdominal pain, diarrhea, and redness of the face and neck. He was admitted to the emergency department for abdominal pain many times before and was hospitalized in the general surgery department with the diagnosis of ileus. Abdominal CT and MRI enteroclysis were performed, metastases in the liver, increased wall thickness in the intestinal loops in the inferior of the umbilicus, and dilatation compatible with the intraperitoneal adenopathies and proximal ileus were observed. Biopsy taken from the mass in the liver was reported as neuroendocrine metastasis. In the patient who was found to have 25-fold higher 5-HIAA levels in the urine for 24 hours, systemic octreotide LAR 30 mg was started, considering carcinoid syndrome. Gallium 68 PET-CT was performed and Intense increased activity uptake in the small intestine segment at the level of the umbilicus was evaluated in favor of a possible primary focus. Multiple metastases in the liver and one metastasis in the sacrum were detected. After the first dose of octreotide treatment, the complaints of redness partially regressed, but the abdominal pain continued and gradually increased. Oral intake was stopped, but the patient whose abdominal pain did not regress was taken to an emergency operation. Widespread implants were seen in the peritoneum and omentum during A mass causing shrinkage in the small intestine mesos at 150 cm from the ligament of Treitz. It was observed that blood supply was impaired in the intestinal loops up to the middle part of the ascending colon. Necrosed areas were excised. After the operation, the complaint of pain regressed, and he was discharged with enteral nutrition solution supplementation.
Conclusion
It was thought that the patient developed mesenteric ischemia, possibly secondary to the substances released, or with a fibrotic structure that may occur in the mesentery. Although abdominal pain and diarrhea are seen in carcinoid syndrome, other causes of abdominal pain should also be reviewed.

Controlling intracellular cortisol: Can HSD-1 inhibition reduce Cushing's syndrome morbidity and minimize adrenal insufficiency risk?

Frank Czerwiec[1], David A. Katz[1] & Paul M Stewart[2]
[1]Sparrow Pharmaceuticals, Inc., Clinical Development, Portland, United States; [2]University of Leeds, Medicine, Leeds, United Kingdom

Endocrinologists focus on circulating and excreted cortisol for diagnosis of, and to assess severity and treatment response in, Cushing's syndrome (Cs). However, in Cs, morbidity is mediated by excess cortisol binding to intracellular glucocorticoid (GC), mineralocorticoid (MC), and non-genomic receptors. We and others have demonstrated that 11b-hydroxysteroid dehydrogenase type 1 (HSD-1) is the source of about half of intrahepatocellular cortisol in healthy adults, patients with diabetes, and patients with mild hypercortisolism. The circulating concentration of cortisol is higher than cortisone, yet its bioavailability is limited, due to the former's greater affinity to plasma proteins. Free circulating cortisol and cortisone concentrations are similar, the latter providing a reservoir of "inactive" GC that enters cells and is rapidly converted by HSD-1 to cortisol. Patients with severe hypercortisolism who are deficient in HSD-1 activity showed no cortisol-related morbidity. A HSD-1 inhibitor prevented the deleterious effects of prednisolone on glycemic control and osteocalcin in a Phase 1 clinical trial. Mice without the *Hsd11b1* gene (which encodes HSD-1) or treated with a HSD-1 inhibitor were protected from glucose intolerance, hyperinsulinemia, hepatic steatosis, adiposity, hypertension, myopathy, dermal atrophy, and trabecular bone loss associated with GC administration. In states of glucocorticoid excess, liver HSD-1 activity is enhanced, as assessed by the HSD-1 ratio of urinary excreted cortisol/cortisone metabolites. Administration of a HSD-1 inhibitor to such patients could reduce Cs morbidity via reduction of the cortisol (or HSD-1 metabolized medications, e.g., prednisolone) available to intracellular receptors. Furthermore, unlike current Cs treatments that are associated with substantial adrenal insufficiency risk, under full and sustained HSD-1 inhibition autonomously produced or ACTH-stimulated cortisol remains elevated in the circulatory pool, available to enter cells and act at GC, MC or non-genomic receptors at concentrations likely sufficient to prevent adrenal insufficiency. Those model predictions are under evaluation in ongoing Phase 2 clinical trials of the HSD-1 inhibitor SPI-62 in patients with ACTH-dependent Cushing's syndrome, autonomous cortisol secretion, and (in combination with prednisolone) polymyalgia rheumatica. Until further direct experience in these conditions is gathered, we still advise caution in patients with modest autonomous cortisol secretion, who may have suppressed ACTH and atrophied normal adrenal tissue, particularly in situations where stress-dose, non-precursor GC steroids should be considered (e.g., use hydrocortisone not cortisone acetate, or prednisolone not prednisone).

Dual Endocrinopathy – a Case Vignette

Wenhui Huang
Tan Tock Seng Hospital, General Medicine, Singapore, Singapore

Initial Presentation (February 2018)
A 54 years old Chinese male attended the Emergency Department of a public hospital in February 2018 for psychotic symptoms of 1-month duration. He has a past medical history of bifrontal craniotomy 20 years ago for brain tumour. A computed tomography scan of the head was performed which showed increased pituitary fossa and suprasellar space soft tissue. A pituitary hormone panel was performed **[Table 1]**. He was diagnosed with Grave's disease and started on oral Carbimazole 5mg OM and given an Endocrinology outpatient appointment. Subsequent Follow Up (June 2018) He was seen in an Endocrinology outpatient clinic in June 2018 with the following blood test result [Table 2]. His Carbimazole was reduced from 5mg OM to 2.5mg OM.
Another Emergency Department Attendance (October 2018) He attended the Emergency Department of another hospital in Oct 2018 for headache & giddiness. A thyroid panel was performed **[Table 2]**. Evolving central hypothyroidoism with panhypopituitarism was suspected. A short synacthen test and a repeat pituitary panel confirmed this. Magnetic resonance imaging of the brain subsequently confirmed the presence of a pituitary macroadenoma.
Learning points
• This is a rare case of concurrent Grave's Disease and panhypopituitarism
• Interim treatment with carbimazole further confounded interpretation of the thyroid panel trend
• Long term treatment is unpredictable and will require close monitoring

Table 1

Hormonal Test	Reference Range	Results [Feb 2018]
8am Cortisol		
Adrenocorticotrophic Hormone (ACTH)	1.6-13.9pmol/l	404
Random Growth Hormone (GH)	<3.0 mg/l	0.07

The efficiency of treatment with growth hormone replacement therapy in children with idiopathic growth hormone deficiency in Albania

Adela Shkurti
Spitali Villa Maria, Tiranë, Albania

Background
The idiopathic growth hormone (GH) deficiency is defined as the shortest height (-2 SD) without any further pathologies, including a detailed hormonal and radiological evaluation.
Objective and hypotheses
The evaluation of the efficiency of treatment with somatropin in children with idiopathic gh deficiency in Albania.
Methods
The study is based on the survey of 50 children of different ages, diagnosed with idiopathic GH deficiency by the pediatric endocrinology department of "Mother Theresa" University Hospital Center, excluding those children diagnosed with Turner Syndrome, chronic renal disease, GH resistance, SGA and IUGR. We evaluated the efficiency of the 1st, 2nd, 3rd-year treatment with somatropin, and measured the height (in cm/SD), the bone age, the values of GH and IGF-1, while using the Tanner-Whitehouse and Bayley-Pinneau method for the forecast of the height.
Results
The study involved 50 children, 43 male (86%) and 7 female (14%), who have showed up at the pediatrics ward between 2001- 2009. The median period of the treatment given was 4.6 years (3-10 yrs). The height at the moment the patients were first diagnosed was 118.3 ±13.1cm; after the 1st year of treatment with somatropin, the stature reached 129.7 ± 12.6 cm; after the 2nd year 137.8 ±12.3 cm and after the 3rd year, the height reached 144.9 ±12 cm. Growth velocity in the 1st year of the treatment was 11.4 ± 2.8cm/y, in the 2nd year it was 8.14 ± 2.13cm/y, while after 3 years of the treatment's initiation it reached 26.74 ± 5.4cm/y. The patients appeared to have a differentiation in height based on the Standard Deviation (SD) -4.6 SD ±1.2. The first year of the treatment saw an improvement in the patients' statures, with a SD of -3.4 ± 1.3 and it was found the most beneficial.
Conclusions
The study found that the first year of the treatment was the most beneficial for the patients'height growth, with the GH treatment not resulting in any major side effects.

GH deficiency caused by a macroprolactinoma: difficulty of management

Dorra Dorraelguiche, Bchir Najla, Annaam Ben Chehida, Baltagi Myriam, Zouaoui Chadia & Haroun Ouertani
Military Hospital, Endocrinology, Tunis, Tunisia

Introduction
The use of GH treatment in patients with macroadenomas and GH deficiency is of concern to the clinician due to the theoretical stimulation of tumor regrowth by GH substitution. We report the case of an 18-year-old adolescent with a macroprolactinoma causing delayed stature and puberty.
Observation
We report the case of an 18-year-oldadolescent who consulted for gynecomastia with delayed stature and puberty. Physical examination displayed a statural delay of -3 standard derivation with a statural age of15 years. He had also pubertal delay and gynecomastia with Tanner stage of G2P2A1 The bone age was 13 years and six months according to the Greulich and Pyle method. The hormonal investigation showed markedly elevated plasma prolactine level of 4279mui/l. The evaluation of the other pituitary axes showed a normal thyroid function test. Therefore, it revealed a gonadotropic insufficiency (testosterone = 3.2mmol/l FSH = 3.28mui/ml LH = 1.23mui/ml) and a complete GH deficiency confirmed by 2 stimulation tests (insulin hypoglycemia test and clonidine test). The diagnosis of a macroprolactinoma was retained based on tumoral level of prolactinemia and pituitary magnetic resonance imaging revealing a pituitary macroadenoma of 10 mm long axis. The patient was put on a dopaminergic agonist: cabergoline 1.5 mg per week with good clinical and hormonal evolution. However, the difficulty was to substitute GH deficiency for fear of progression of the tumorous mass. It is the common opinion that GH substitution should not be consistently started in patients with macroprolactinoma for the reason that spontaneous recovery of hypothalamic pituitary function which has been inhibited by high PRL levels. But given the bone age limit and the non-promiscuity of the tumor and the optic chiasma, the decision was to initiate a recombinant GH treatment. The evolution was characterized by a good clinical response (gain of 11 cm in 9 months), without showing signs of tumor progression.
Discussion
In the literature, rare cases of combined treatment (dopaminergic agonist and somatotropin) have been reported but the treatment appeared to be effective in restoring growth velocity, also it seems to be safe as it did not show any progress on tumor growth. However, limited experience with the use of such combined therapy in children and adolescents warrants careful monitoring and on-going evaluation.

A Case of Acute Psychosis Triggered by Anabolic Steroid Abuse

Cyrine Bey[1], Wafa Abdelghaffar[1], Ach Taieb[2], Nadia Haloui[1], Mariem Ines Bouzid[1] & Rym Rafrafi[1]
[1]La Marsa, Mental Health Department, Tunisia; [2]Farhat Hached, Endocrinology, Sousse, Tunisia

Introduction
Professional athletes commonly use anabolic-androgenic steroids (AAS) to enhance performance. AAS include testosterone and its numerous synthetic analogs. AAS have numerous adverse effects among which central nervous system effects that include psychosis, delirium, mania and depression. Trenbolone is an AAS medication which is used in veterinary medicine for cattle muscle growth. What makes Trenbolone interesting is that it's also capable of inducing Selective androgen receptors modulators (SARM)-like effects. SARMs, as opposed to classic AAS, exert their action in a tissue-selective manner, providing the anabolic effects and suppressing the prostate adverse effects. However, Trenbolone remains different and needs to be evaluated through proper investigation. Herein, we report a case highlighting acute psychiatric effects of Trenbolone use in a young male.
Case Presentation
It's about a 20yo male, who was admitted in the orthopedics department for polytrauma after defenestration during a psychotic break. No personal or familial history of mental health issues or substance abuse were found initially. 2months prior to admission, the patient started to brutally present disorganized behavior and aggressiveness. He started experiencing persecutory, religious and messianic delusions, as well as auditive hallucinations. CT scan, liver sampling, renal function and thyroid hormones were normal. Blood numeration was normal excluding meningo-encephalitis. Blood and urine toxicology screen were normal. A testosterone dosage found low testosterone levels (3.51ng/mL). A hypogonadotrophic hypogonadism was confirmed via suppressed FSH and LH levels. Pituitary MRI was performed in order to exclude organic lesions, and was normal. All the available data were consistent with a chronic steroid intake. After multiple interviews, the patient confessed that symptoms started concurrently with Trenbolone intake. The first few days in orthopedics the patient appeared to be reluctant and disorganized, but after 2weeks he didn't display any psychotic symptoms or disorganized behavior. Testosterone levels returned to normal (5.5 ng/mL) after one month of intake. We concluded on a steroid-induced psychosis that we treated with 1mg risperidone.
Conclusion
AAS disturb the endogenous production of testosterone, which may persist months after drug withdrawal, thus explaining the low levels of testosterone in our patient. AAS can strongly affect the psyche and can induce psychotic features that are likely to be dose and drug dependent. In consequence, it's important to assess its mechanisms of action and subsequent symptoms to evaluate its safety.

A polyuro polydipsic syndrome revealing a somatotropic adenoma in apoplexy: a case report

Ali Halouache[1], Caimae Zouna[2], Isouani Jad[1] & Guerboub Ahmed Anas[1]
[1]Hopital Militaire d'Instruction Mohamed V, Endocrinology, Rabat, Morocco; [2]CHU Avicenne, Endocrinology, Rabat, Morocco

Introduction
Pituitary apoplexy is an acute infarction and/or hemorrhage of the normal or tumoral pituitary gland. It is a rare mode of revelation of pituitary adenomas, and the only situation where the pituitary adenoma can be complicated by a diabetes insipidus.
Case report
Mrs Amina. Y, 54 years old, has been followed for 8 years for diabetes mellitus treated with metformin, and dyslipidemia under statins, presents in consultation for a severe polyuro-polydipsic syndrome, the urinary osmolarity was 95mOsmol/l confirming the diagnosis of diabetes insipidus. In her history, the patient reported a syndrome of intracranial hypertension with intense headaches, vomiting and visual disturbances dating back one month neglected by the patient and treated with analgesics. A cerebral MRI was performed, showing a pituitary macroadenoma in apoplexy, the visual field was affected, and the fundus was without anomalies. The workup showed a corticotropic insufficiency (cortisol level at 08h collapsed to 10 ng/l) and a thyrotropic insufficiency which were substituted. The patient was put on desmopressin with a good clinical and biological evolution. Regarding the secretory work-up, the clinical examination revealed signs in favour of an acrofacial syndrome (ring sign, change of shoe size). The IGF1 level confirmed the somatotropic character of the adenoma.
Discussion
Pituitary apoplexy is a rare but serious complication of pituitary adenoma. Considered as an emergency, Its clinical presentation associates a syndrome of intracranial hypertension, pituitary insufficiency and visual disorders that can go as far as blindness; brain imaging allows to confirm the diagnosis, and the treatment is urgent, based on hormone replacement therapy and tumor excision by Trans sphenoidal approach. Its onset is most often sudden and noisy, but more rarely, the remodeling, even massive, may be little or not symptomatic and the lesion revealed by visual disorders of progressive onset, by moderate headaches, intermittent or migraine-like, or even a secretory insufficiency as was the case in our patient in whom diabetes insipidus was the revealing element, which is the particularity of our observation.
Conclusion
The pituitary apoplexy is rare, but its gravity underlines the interest to think about it in front of any cranial symptomatology in the patients having a known pituitary adenoma, this reasoning becomes difficult, when the apoplexy is revealing, and even more difficult when the presentation is progressive and/or atypical, only the cerebral imagery, carried out in front of the slightest suspicion will make it possible to decide

Prolactinoma and Pregnancy

Belhadi Leila, Bensbaa Salma, Nassim Essabah Haraj, Siham El Aziz & Asma Chadli
University Hospital Center Ibn Rochd, Department of Endocrinology and Metabolic Diseases, Casablanca, Morocco

Introduction
Prolactin adenomas are the most common pituitary adenomas. Although the pituitary increases in size and the prolactinoma increase gradually during normal pregnancy; prolactinomas do not contraindicate pregnancy but require strict monitoring.
Goals
To study the impact of pregnancy on the development of prolactin pituitary adenomas.
Materials and methods
Retrospective descriptive cohort study conducted in the endocrinology department of the CHU Ibnou Rochd Casablanca in pregnant patients followed for prolactin pituitary adenomas
Results
We report 7 pregnancies in 5 women, whose average age is 33 years: there is a single micro adenoma and 4 macro adenomas, 4 patients had thyrotropic insufficiency and 2 patients had corticotropic insufficiency. The average duration of evolution before pregnancy was 4 years and all our patients were treated with cabergoline with an average dose of 1.5 mg/week. When the pregnancy was discovered, only one patient stopped the treatment. A pituitary MRI was performed on 3 of our patients during pregnancy objectifying a quasi-stable appearance of the adenoma. Two patients were complicated by gestational diabetes. The pregnancies were carried to term, vaginally in 3 cases and cesarean section in 3 patients ; 3 patients breastfed with good clinical evolution.
Conclusion
The evolution of prolactinomas during pregnancy is variable. This may justify the continuation of dopaminergic agonist treatment during pregnancy, with close monitoring.

Pituitary apoplexy and prolactinomas. About a case series

Sergio Logwin[1], Fabiola Romero[1], Gabriela Canata[1], Maria Lis Alarcón Bernal[2] & Dahiana Ferreira[2]
[1]Hospital de Clinicas, Endocrinology, Asuncion, Paraguay; [2]Institute of Prevision Social, Endocrinology, Asuncion, Paraguay

Introduction
Pituitary apoplexy describes the ischemic or hemorrhagic phenomenon that occurs in a previous pituitary adenoma. It may be the first manifestation of a pituitary gland adenoma.

Case 1
Female 31 years old macroprolactinoma in irregular treatment with cabergoline for three months Amenorrhea from the age of 14. Decreased visual acuity and oppressive headache. MRI pituitary apoplexy. Hospitalized and discharged with cabergoline and prednisone. Days later genital hemorrhage, a 12-week gestation was confirmed.
Case 2
Male, 40 years old. Two-month history of bitemporal hemianopsia, headache and nausea. MRI Pituitary apoplexy in a 3.5 cm adenoma. Prolactin >1000 ng/dl, other pituitary hormones decreased. Case 3: 53-year-old male, visual acuity deterioration and bilateral gynecomastia. Elevated prolactin. MRI Pituitary gland adenoma. Treatment with cabergoline is started. At 6 months improvement in visual acuity and decrease in prolactin level and tumor size. At 8 months, intense headache, vomiting and sensorium deterioration. New MRI: Extensive area of necrosis and intratumoral hemorrhage.
Discussion
We present 3 cases of prolactinomas that presented apoplexy due to pregnancy, large size of the adenoma and associated with treatment with cabergoline. The state of pregnancy is striking, although pituitary stimulation by estrogens. Its findings are truly exceptional. Another factor associated with pituitary apoplexy is large tumor although this association is generally more frequent non-functioning adenomas Dopaminergic agonists are risk factors for pituitary apoplexy, they cause lactotroph apoptosis. However, the frequency of this effect is rare, since they are drugs of choice in the treatment of prolactinomas.

Asprosin, a novel adipokine, in the mouse hypothalamus: expression and *in vitro* effect on GT1-7 cells proliferation and GnRH secretion. Preliminary data

Dominika Wachowska[1,2], Natalia Respekta[1,2], Patrycja Kurowska[1], Anna Błasiak[3], Joëlle Dupont[4] & Agnieszka Rak[1]
[1]Institute of Zoology and Biomedical Research, Jagiellonian University, Laboratory of Physiology and Toxicology of Reproduction, Kraków, Poland; [2]Doctoral School of Exact and Natural Sciences, Jagiellonian University, Kraków, Poland; [3]Institute of Zoology and Biomedical Research, Jagiellonian University, Departament of Neurophysiology and Chronobiology, Kraków, Poland; [4]INRAE, UMR85, Unité Physiologie de la Reproduction et des Comportements, Nouzilly, France

Introduction
Asprosin, a novel adipokine, is a circulating hormone mainly secreted by white adipose tissue. Asprosin is encoded by the penultimate 2 exons of the fibrillin 1 (*FBN1*) gene. Protein product of *FBN1* is profibrillin-1, which undergoes a proteolytic cleavage by furin enzyme to produce mature fibrillin-1 and asprosin. Literature data indicated that asprosin is involved in the development of diabetes, obesity, cardiomyopathy, cancer, and polycystic ovarian syndrome. Moreover, asprosin is able to affect various cellular and physiological processes like appetite stimulation, insulin secretion, glucose release, apoptosis and inflammation through activation of Olfr734, an olfactory G-protein-coupled receptor. However, whether it can regulate the hypothalamic cells function has not been yet investigated. This study intended to examine *i*) the mRNA and protein levels of asprosin/Olfr734/furin in mouse hypothalamus and GT1-7 cells and *ii*) *in vitro* effect of asprosin on GT1-7 cells proliferation and GnRH secretion.
Materials and Methods
To measure the mRNA (real time PCR) and protein (Western blot) expression of asprosin/Olfr734/furin we used hypothalamus collected from C57BL/6J female mice at diestrous ($n=3$) as well as mouse hypothalamic GT1-7 cells. Moreover, immunolocalization of asprosin/Olfr734/furin were analyzed in GT1-7 cells. To study effect of asprosin on cells proliferation (AlamarBlue test) and GnRH secretion (ELISA), GT1-7 cells were cultured with recombinant mouse asprosin at doses 1, 10, 100 ng/ml. Statistical analysis was performed in Graph Pad Prism 7 software, using one-way ANOVA and Tukey's test ($n = 5$, $P< 0.05$).
Results
We demonstrated mRNA and protein expression of asprosin/Olfr734/furin both in mouse hypothalamic and GT1-7 cells. Moreover, we detected asprosin/Olfr734/-furin signals in GT1-7 cells. We noted a modulating effect of asprosin on GT1-7 cells proliferation and GnRH secretion.
Conclusion
Our preliminary findings suggest that the novel adipokine asprosin may play a regulatory role in the mouse hypothalamus.

Immunotherapy-induced Endocrinopathy: A Case Report

Ben Ali Khaoula, Loukil Fatma, Busieau Pauline, Potier Louis, Marion Camoin, Hanen Bouaziz, Hasanain Al Mukh, Aurelie Carlier & Jean François Gautier
Bichat Claude Bernad Hospital, Endocrinology, Diabetology and Nutrition, Paris, France

Introduction
Immunotherapy is an effective therapeutic choice increasingly prescribed in oncology. Endocrine toxicity is described among its side effects.
Methods
A case of a patient treated with immunotherapy since January 2022 is hospitalized in the endocrinology department in Bichat Hospital.
Results
Mr K, aged 46, treated with of anti-CTA4 and anti-PD1 inhibitors for melanoma. A month after the treatment the findings showed an acute adrenal insufficiency with a cortisol level at 14.9 nmol/l. An intravenous hydrocortisone treatment was initiated then relay orally. Besides, a Peripheral hyperthyroidism was noted (TSH was undetectable with FT4 at 3.5 N) secondary to Hashitoxicosis with anti TG and anti TPO antibodies at >10N, cervical ultrasound was normal. We opted for therapeutic abstention in view of the absence of clinical signs of hyperthyroidism. Prolactinemia was slightly elevated justifying the realization of MRI pituitary which was normal. The Control at 2 months showed: a cortisol at 584.9 nmol / L and ACTH at 22.7 pmol / l, the synacthen test showed the persistence of peripheral adrenal insufficiency with cortisol at T0 at 230 nmol /l, T60 at 261 nmol/l and AC TH at 50pmol/l hence the maintenance of hydrocortisone. Passage into peripheral hypothyroidism with TSH at 10N hence the treatment with Levothyroxine.
Conclusion
this case illustrates the possibility of occurrence of peripheral adrenal insufficiency under immunotherapy (less described in the literature than central involvement) justifying clinical and biological monitoring of the corticotropic axis throughout the duration of treatment with immunotherapy.

Null cell adenoma: case report

Aicha Lachkhem[1], Abdelkader Yahi[1], Ould Kablia Samia[1], Abderrahim Derriche[2], Ahcen Staifi[3] & Hakim Derradji[4,5]
[1]Central Military Hospital, Endocrinology, Algiers, Algeria; [2]Central Military Hospital, Radiology, Algiers, Algeria; [3]Central Military Hospital, Ophtalmology, Algiers, Algeria; [4]Central Military Hospital, Algiers, Algeria; [5]Central Military Hospital, Neuro-Surgery, Algiers, Algeria

Introduction
Pituitary adenomas, more recently referred to as pituitary neuroendocrine tumors (PitNets) from other organs, are common neoplasms comprising 10 to 20% on intracranial tumors. Null cell adenoma is a diagnosis of exclusion that requires immunonegativity for all adenohypophyseal hormones and a lack of cell type-specific transcription factors. It represents 0,6% of all pituitary tumors.
Case
A 55 years old women with a history of treated thyroid vesicular carcinoma in remission currently. Followed for a geant agressif adenoma discovered following a headaches and a progressive decline in visual acuity associated with visual impairment (diplopia). The MRI (magnetic resonance imaging) of the sellar region had shown a voluminous endosellar process measuring 55x44x32mm, partially encysted with haemorrhagic changes, compressing the optic chiasm and invading the left cavernous sinus (KNOSP03). Hormonal workup revealed a serum prolactin level of 192ng/ml and gonadotropic deficiency. The ophthalmic examination found bitemporal hemianopia. The patient was then started on dopamine agonist (cabergoline) with a gradual increase in doses up to 3,5mg/week for two months. Then the patient only consulted a year later while having kept the same therapy. The MRI reveals a slight increase in the side of the process becoming KNOSP4. She had a transphenoidal adenemectomy. The histological analysis confirmed after three attempts a null cell adenoma (IHC for pituitary hormones and transcriptor factors). Four months later, the ophthalmic examination shown a stability and the MRI of the sellar region had shown the persistence of a voluminous tumor remnant discreetly lateralized on the left almost completely filling the optochiasmatic cistern, measuring 24x19 mm in the transverse axes, extended over a height of 32 mm, hyposignal in T1 and hypersignal in T2 wiehgted image, heterogeneous, enhanced discreetly and peripherally after injection of gadolinium salts.

Conclusion
Null cell adenoma represents a challenging diagnostic group of tumors. Close collaboration of the "pituitary team" is essential for a precise diagnosis and will contribute to the optimal treatment of the patient. New classifications, novel prognostics markers, and emerging imaging and therapeutic approaches will need to be evaluated to better serve this unique group of patients.

Co-secreting TSH and GH pituitary adenoma

Chayma Besrour, Marwa Chiboub, Ben Salem Maram, Meriem Adel, Manel Jemel, Hajer Kandara & Ines Kammoun
National Institute of Nutrition, Endocrinology, Tunis, Tunisia

Introduction
Thyrotropin-secreting pituitary tumors (TSH-omas) are a rare cause of hyperthyroidism and account for 0.5 to 3 percent of all functioning pituitary tumors and much less than 1 percent of all cases of hyperthyroidism. The co-secretion of thyrotropin (TSH) and growth hormone (GH) in pituitary adenoma is extremely rare. Only a few cases have been reported.
Observation
We report the case of a 40-year-old man who consulted an ophthalmologist for headache, and left monocular temporal hemianopia. A brain MRI revealed a 3 cm pituitary macroadenoma with an opto-chiasmatic impact. In front of this adenoma, a hormonal pituitary assessment showed a central hyperthyroidism with a high TSH level at 6.83 mUI/l and a high FT4 level at 42 ng/l, a co-secretion of growth hormone; GH level at 4.2 ng/ml, IGF1 level at 268,27 ng/mL and a failure of GH suppression at the oral glucose tolerance test, a gonadotropic insufficiency; FSH 0.9 UI/l, LH 1.2 UI/l, Testosterone 0.57 ng/ml, a reassuring cortisol level at 430 nmol/l and a normal prolactin level at 30 ng/mL. The patient was put under antithyroid drugs and referred to a neurosurgical center for a surgical treatment.
Conclusion
TSH-omas with associated hypersecretion of other pituitary hormones are found in 24.8% of cases. Hypersecretion of GH, resulting in acromegaly, is one of the most frequent associations (15.1%) along with prolactin secretion (8.4%). This may be explained by the fact that somatotroph and lactotroph cells share with thyrotropes common transcription factors. Surgery remain the usual first line of therapy, and further treatment by radiotherapy or somatostatin analogue is discussed case by case.

Evolutionary and hormonal aspects after transphenoidal surgery for cushing's disease

Gorchene Asma, Taieb Ach, Nassim Ben Hadj Slama, Ghada Saad, Ben Abdelkarim Asma & Molka Chadli Chaieb
Farhat Hached Hospital, Endocrinology Department, Sousse, Tunisia

Introduction
Cushing's disease (CD), a hypercorticism caused by an ACTH-secreting pituitary adenoma, was associated with a 5-year survival of only 50%. Although advances in management have significantly reduced mortality, the results of transsphenoidal surgery, the gold standard in the treatment of CD, vary from patient to patient.
Objective
The aim of our study is to evaluate the results of transsphenoidal surgery in CD (evolution, complications) and to determine the factors that can predict this evolution.
Materials and Methods
This is a retrospective study of 12 patients hospitalized in the endocrinology department of CHU Farhat Hached, between 1987 and 2010 who underwent a transsphenoidal surgery for CD.
Results
Our sample consisted of 8 women and 4 men. The average age was 38.3 (24-48). Pituitary MRI came back normal in one case, revealed a microadenoma in 7 cases and a macroadenoma in 4 cases. Pathological examination confirmed the diagnosis in 8 cases, and 4 reports were unavailable. Remission was obtained in 6 cases (50%), Recurrence occurred in 3 cases (25%) with an average time frame of 8 years (3 -17 years), one of which benefited from radiotherapy with remission. Persistent disease was observed in 3 patients, one of whom was a candidate for revision surgery (the patient refused the operation), the other received radiotherapy without remission and died from complications related to hypercorticism. The third required simple monitoring. Two out of the 3 recurrences did not develop adrenal insufficiency (AI) while one developed transient adrenal insufficiency (with a recurrence time frame of 17 years), while 4 of the six remissions developed prolonged AI. Regarding complications of transsphenoidal surgery, there were two uncomplicated meningeal breaches, 3 cases of diabetes insipidus, one of which is definitive, and one case of sinusitis.
Conclusion
Transsphenoidal surgery is an effective means of treatment for Cushing's disease, however after successful treatment there is an increased risk of recurrence over time warranting prolonged lifelong follow-up. Subjects who have experienced postoperative adrenal insufficiency have a lower risk of recurrence, especially in case of a prolonged one. Depending on the postoperative biological findings, further treatment may be necessary (radiotherapy, surgery).

A chordoma of the sphenoidal region: diagnostic challenge

Imane Boubagura, Ghizlane El Mghari & Nawal El Ansari
Department of Endocrinology, Diabetology and Metabolic Diseases, University Hospital of Marrakech, Marrakech, Morocco

Introduction and Backgrounds
Pituitary adenomas emerge from the adenohypophysis and are confined to the region of the sella turcica, however, other sites may be involved as a result of extension infiltration, or ectopic location, the ectopic involvement of the sphenoid is rare.
Case Report
Our case illustrated a woman patient with an ectopic invasive macroprolactinoma diagnosed as a chordoma of the skull base. In Our case, the first histological examination was consistent with a coincidental Intrasellar Chordoma and Pituitary adenoma, Immunostaining was positive for synaptophysin and prolactin with a Ki67 index of 7%, suggestive of an invasive prolactinoma, in addition to the existence of vacuolated cells with foamy Cytoplasm resembling to hysaliphorous cells suggested the diagnosis of chordoma. However, immunohistochemical study using brachyury and S-100 protein have shown a negative stain. Thus, the diagnosis of chordoma was excluded.
Discussion and Conclusion
Thus, it is particularly important to maintain ectopic pituitary adenomas in sphenoidal or clival locations as the main differential diagnosis of chordoma; because the diagnosis can have significant implications on the management of the tumor, and can give us a golden opportunity for more conservative management (in our example managed with dopamine agonists), if the diagnosis can be made preoperatively rather than retrospectively based on histology.

Reset Osmostat Syndrome: When Hyponatremia Become «A Normal». Diagnostics, Case Report

Ludmila Astafyeva, Inna Badmaeva, Irina Klochkova, Oleg Sharipov, Yuliya Sidneva, Olga Gadjieva, Boris Bashiryan, Pavel Kalinin, Andrei Lubnin & Aleksandr Konovalov
Burdenko Neurosurgery Center, Moskva, Russia

Reset osmostat syndrome (ROS) is characterized by a change of normal plasma osmolality level (decrease or increase), which leads to chronic dysnatremia (hypo- or hypernatremia). We have described a Clinical case of ROS and chronic hyponatremia in a patient with chordoid glioma of the III ventricle. It is known that the patient had previously been diagnosed with hyponatremia (131-134 mmol/l). She has not hypothyroidism and hypocorticism. There is normal filtration function of the kidneys was (CKD-EPI 91.7 ml/mi/1,73m2). Urine osmolality and sodium level were studied to exclude of concentration kidney function disorder. During first three days after removal of the tumor of the third ventricle (chordoid glioma, WHO Grade II), the sodium level decreased to 119 mmol/l. Repeated infusions of 200-300 ml hypertonic 3% sodium chloride solution, gluco- and mineralocorticoid therapy was ineffective, increasing plasma sodium levels by 2-3 mmol/l with the return to the initial level during 6-8 hours. Hypopituitary disorders did not develop after surgery. With further observation, the sodium level remained within 126-129 mmol/l for 6 months after surgery. The water load test make exclude the classic syndrome of inappropriate secretion of

antidiuretic hormone, and confirmed the diagnosis of RSO. Because of absence of clinical symptoms associated with hyponatremia, no medical correction was required, patient was recommended to clinical follow-up.

Central diabetes insipidus in adolescents : Not always a craniopharyngioma

Nabila Zeryouh, Yousra Laalaoua, Hamdane Chaymae, Messaoudi Najoua, Siham Rouf & Hanane Latrech
Faculty of Medicine and Pharmacy, University of Mohammed 1st, Department of Endocrinology-Diabetology and Nutrition, Mohammed VI University Hospital Center, Oujda, Morocco

Introduction
Central diabetes insipidus reflects a serious underlying pathology in children. The etiologies are dominated in pediatric population by: central nervous system (CNS) tumors and malformations, histiocytosis, postoperative, radiation, and trauma injury to the hypothalamic-pituitary region. We report in this work three observations illustrating rare etiologies of pediatric central diabetes insipidus in the endocrinology-diabetology and nutrition department of the Mohammed VI University Hospital Center of Oujda in the eastern of Morocco.
Observations

Observation n°1
A 17-year-old female patient, with a history of influenza-like illness on probable COVID19 infection, admitted for exploration of a polyuria-polydipsia syndrome associated with headaches and significant decrease in visual acuity. An MRI of the hypothalamic-pituitary region has shown a hyperintense aspect of the pituitary gland on the T2 sequence with exaggerated enhancement of the gland after injection, pituitary height measured at 8 mm suggesting hypophysitis. The diagnosis was supported by the clear improvement both visually and diabetes insipidus after corticosteroid therapy.
Observation n°2
A 15-year-old female patient consulted for a polyura-polydipsia syndrome associated with headaches. An MRI of the hypothalamic-pituitary region has been realized showing an intra- and supra-sellar tumor process, with irregular contours, T1 isosignal, T2 hypersignal, heterogeneously enhancing and delimiting several cystic areas. A transphenoidal surgery was performed and the anatomopathological study came back in favor of a pituitary tuberculosis. The sputum testing for tuberculosis and quantiferon assay were negative, but the tuberculin skin testing was positive. The patient received anti-bacillary treatment with good evolution.
Observation n°3
A 15-year-old child with no notable pathological history was admitted for a polyura-polydipsia syndrome and secondary enuresis associated with frontal headaches. Biological explorations confirmed the central origin of diabetes insipidus. An MRI of the hypothalamic-pituitary region was performed showing a sellar mass in spontaneous T1 hypersignal, with a heterogeneous signal in T2, not enhancing after injection of Gadolinium, with a mass effect on the posterior pituitary, evoking a Rathke's cleft cyst in apoplexy.
Discussion-Conclusion
These three cases reflect the complexity of the diagnosis and the etiological polymorphism of central diabetes insipidus in children, making its management more delicate. Hence the interest of a meticulous etiological investigation in which hypothalamic-pituitary MRI plays an essential role, in the hypothesis of a tumoral lesion of this anatomical region.

Diabetes Insipidus caused by autoimmune lymphocytic hypophysitis resulting in diagnosis and cure of Diffuse Large B-Cell Lymphoma

Lydia Sinclair, Shaan Sahota, Sanjiv Chawda, Maureen Heath, Louise Dulley, Jonathan Pollock, Victoria Clough & Nemanja Stojanovic
Barking, Havering And Redbridge University Hospitals NHS Trust, United Kingdom

Introduction
Association between lymphoma and pituitary dysfunction is well documented, though most commonly through mechanism of infiltrative pituitary metastasis, or primary lymphoma of the pituitary, rather than autoimmune lymphocytic hypophysitis. Here we present a highly unusual case whereby investigation into the cause of Diabetes Insipidus with radiological features of lymphocytic hypophysitis, led to diagnosis and cure of Diffuse Large B-cell lymphoma (DLBCL). Diabetes Insipidus with an MRI suggestive of autoimmune hypophysitis has been described. However, to our knowledge this is the first case where this presentation has been attributed to a paraneoplastic phenomenon.
Case Presentation
A 67-year-old lady presented to her GP with sudden onset polyuria and polydipsia associated only with a three-day headache. Her GP astutely diagnosed diabetes insipidus. MRI pituitary was highly suggestive of lymphocytic hypophysitis, with enhancement of the pituitary gland, thickening and heterogeneous enhancement of the pituitary stalk, and absence of posterior pituitary lobe T1 hyperintensity. Serum osmolality was 308 mosmol/kg; paired urinary osmolality was 132 mosmol/kg. Anterior pituitary function tests were normal. She experienced complete and instantaneous resolution of symptoms with Desmopressin. Comprehensive investigation into the underlying cause of her clinical and radiological presentation included CT Chest/Abdomen/Pelvis which revealed heterogenous sclerosis of multiple vertebral bodies. MRI whole spine demonstrated widespread bone marrow changes throughout the spine supporting a diagnosis of metastatic disease. Clinical examination remained normal. Myeloma screen and Mammogram were normal. Several attempts at vertebral bone biopsy proved unfruitful. PET-CT demonstrated multi-focal FDG avid sclerotic foci throughout the axial and proximal appendicular skeleton. No primary lesion or organomegaly was identified. Eventually, histopathology from a CT-guided biopsy of the left ilium revealed high-grade Diffuse Large B-Cell Non-Hodgkin Lymphoma of Germinal Centre Cell (GCC) type. She completed 6 cycles of R-CHOP chemotherapy. Subsequent PET-CT showed complete metabolic response.
Discussion
Differential diagnosis of hypophysitis is broad. In this case, we propose that DLBCL presented with paraneoplastic hypophysitis. Alternative serendipitous identification of concurrent DLBCL in a patient with autoimmune lymphocytic hypophysitis is possible. Initial MRI findings were typical of lymphocytic hypophysitis. Interval MRI four months later showed spontaneous regression of stalk changes, prior to lymphoma treatment commencing. Whilst low-grade lymphomas can be associated with waxing and waning phenomenon, this is not the case with CNS lymphoma. Paraneoplastic autoimmune hypophysitis is becoming increasingly recognised. Cases of anti-PIT-1 driven paraneoplastic autoimmune hypophysitis causing anterior pituitary dysfunction have been described. Paraneoplastic posterior pituitary dysfunction may be an emerging area of interest.

Clinical and biological peculiarities of non-functioning pituitary adenomas in the Tunisian population: a monocentric study

Abdel Mouhaymen Missaoui, Nabila Rekik Majdoub, Siddiqa Soomauroo, Faten Haj Kacem Akid, Dhoha Ben Salah, Fatma Mnif, Nadia Charfi, Mouna Mnif, Mouna Elleuch & Mohamed Abid
Hedi Chaker University Hospital, Department of Endocrinology, Sfax, Tunisia

Background and Aim
Non-functioning pituitary adenoma (NFPA) is the second most common subtype of pituitary adenomas. This study aims to detail the clinical and biological particularities of NFPA in the Tunisian population.
Patients and Methods
A retrospective descriptive study of 35 patients followed for NFPA was conducted between 2000 and 2022 at the endocrinology Department of Hedi Chaker University Hospital, Sfax, Tunisia.
Results
The mean age was 52.1 $\pm$ 11.4 years with a male predominance (61.3%). The diagnosis of NFPA was motivated by tumoural syndrome in 77.4% of cases or by signs of hypopituitarism in 9.7% of cases. In 12.9%, it was an incidental discovery of a pituitary incidentaloma. The majority of NFPA were macroadenomas (90%). The initial clinical presentation was dominated by headache (90.3%) and visual impairment (80.6%). Visual field loss was observed in 30% of patients; 26.7% of them had bilateral visual field loss. In 3.2% of patients, NFPA caused bilateral blindness. The patients suffered from signs of pituitary insufficiency which could affect one or more axes: the corticotropic axis was the most affected (67.7%), followed by the thyroid (41.9%) and gonadotropic (41.9%) axes. Only 6.5% had somatotropic or lactrotropic insufficiency at the time of the biological evaluation. Disconnection hyperprolactinemia was observed in 26.7% with values exceeding 60 ng/ml in only 10% of cases.

Discussion
The diagnosis of NFPA is often delayed due to a long insidious evolution, especially in males. It is generally revealed by signs of tumor compression, sometimes severe, such as visual impairment, or by signs of anterior pituitary insufficiency. Surgery is the standard treatment. The earlier the diagnosis is made, the more complete the surgical resection will be.

Prevalence and factors associated with pituitary apoplexy in non-functioning adenomas

Abdel Mouhaymen Missaoui, Nabila Rekik Majdoub, Siddiqa Soomauroo, Faten Haj Kacem Akid, Dhoha Ben Salah, Fatma Mnif, Nadia Charfi, Mouna Mnif, Mouna Elleuch & Mohamed Abid
Hedi Chaker University Hospital, Department of Endocrinology, Sfax, Tunisia

Objective
To determine the prevalence and the associated factors of pituitary apoplexy (PA) in non-functional pituitary adenomas (NFPA).
Patients and Methods
A retrospective analytical study of 35 patients followed for NFPA between 2000 and 2022 was conducted at our institution. A pituitary magnetic resonance imaging (MRI) scan was performed in all patients.
Results
The mean age was 52.1 ± 11.4 years, with a male predominance (61.3%). The primary reason for consultation was pituitary tumor syndrome (77.4%). Rarely, signs of hypopituitarism may inaugurate the clinical presentation (9.7%). Headache and visual disturbances dominated the initial presentation in 90.3% and 80.6% of cases, respectively. Underlying pituitary insufficiencies were frequently observed, namely those affecting the corticotropic (67.7%), thyroid (41.9%), and gonadotropic (41.9%) sectors. A pituitary MRI showed a macroadenoma in 90%. The prevalence of pituitary apoplexy in NFPA was 25.8%. Clinical factors significantly associated with PA were: inaugural hypopituitarism (OR = 0.22; $P = 0.018$), gonadotropic insufficiency (OR = 4.25; $P = 0.023$), lactotropic insufficiency (OR = 5; $P = 0.013$) and bilateral visual field amputation (OR = 1.636; $P = 0.049$). Tumor size > 4cm (OR = 0.19; $P = 0.011$) and the presence of hemorrhagic remodeling (OR = 5.83; $P = 0.001$) were also predictive factors of pituitary apoplexy.
Discussion
Pituitary apoplexy is the clinical expression of a hemorrhage and/or ischemia of a pituitary adenoma. This situation may require urgent surgical treatment. Our work allows us to identify patients with NFPA at risk of apoplexy based on several accessible clinical and radiological markers, such as tumor size > 4cm, the presence of inaugural hypopituitarism, and significant visual field amputation.

Non-functional pituitary adenomas: management and therapeutic outcomes in the Tunisian population

Abdel Mouhaymen Missaoui, Nabila Rekik Majdoub, Siddiqa Soomauroo, Faten Haj Kacem Akid, Dhoha Ben Salah, Fatma Mnif, Nadia Charfi, Mouna Mnif, Mouna Elleuch & Mohamed Abid
Hedi Chaker University Hospital, Department of Endocrinology, Sfax, Tunisia

Objective
To assess the management and therapeutic outcomes of non-functioning pituitary adenomas (NFPA) in the Tunisian population.
Patients and Methods
We conducted a retrospective descriptive study of 35 patients followed for NFPA between 2000 and 2022 at the endocrinology department of Hedi Chaker University Hospital.
Results
The mean age was 52.1 ± 11.4 years, with a male predominance (61.3%). The majority of tumors were between 1 and 2 cm in size (46.7%). In half of the cases (53.1%), surgical treatment was performed. Pituitary apoplexy (35.3%), optic tract invasion (29.4%), and large tumor size (23.5%) were the main indications for surgery in our series. Tumour resection was often incomplete with remnants in 71.4%. The tumor residue size was > 3cm in 63.6% of the surgeries. Second-line treatment was indicated for 54.5% of patients, including re-do surgery (18.8%), radiotherapy (18.8%), or medical treatment (18.8%). No second-line treatment was performed in 45.5% of cases despite the persistence of a tumor remnant. Post-operatively, an improvement in visual disorders (53.8%) was generally obtained at the cost of stabilization or worsening of pituitary insufficiency in 92.4%. The average follow-up time was less than 5 years for 60% of our patients.
Discussion
Complete remission is difficult to achieve in NFPA compared to secreting adenomas. The recurrence and progression rate of NFPA after initial surgery varies from 15-66%. This rate may be reduced to 2-28% after adjuvant radiotherapy. Long-term clinical and radiological monitoring is strongly recommended.

Growth hormone deficiency in pseudohypoparathyroidism type 1a: a case report

Faten Haj Kacem Akid[1], Wafa Belabed, Abdel Mouhaymen Missaoui, Wajdi Safi, Mouna Elleuch, Nadia Charfi, Fatma Mnif, Nabila Mejdoub, Mouna Mnif & Mohamed Abid
Hedi Chaker University Hospital, Department of Endocrinology and Diabetology, Sfax, Tunisia

Introduction
Pseudohypoparathyroidism (PHP) type 1a is a genetic disorder associated primarily with resistance to parathyroid hormone (PTH). Its pathogenesis has been linked to dysfunctional G-protein-mediated signaling. Since the G unit is an ubiquitary protein, its mutation can lead to variable hormonal dysfunction. In this context we report the case of a patient followed in our department for multihormone resistance.
Case report
A 9 years old boy, born at term to healthy consanguineous parents, presented to our department for delayed growth. Medical history revealed congenital hypothyroidism and PHP diagnosed respectively at 3 and 5 years of age. He was under supplemental calcium, active vitamin D and thyroid hormone replacement. Physical examination revealed a short stature with a height of 90 cm (– 3 s.d), signs of Albright hereditary osteodystrophy (AHO) and a scoliosis. Hormonal investigations revealed a partial growth hormone (GH) deficiency (GH peak at 6.58 ng/mL after propranolol-glucagon test), a hypocalcemia (1.64 mmol/l) contrasting with high PTH levels (68 pg/ml). The pituitary magnetic resonance imaging (MRI) was normal. Regarding the AHO features and the multiple hormonal resistances, PHP type 1a was suspected. In line with this hypothesis, the GH deficiency would be due to GHRH resistance. Genetic assessment of the GNAS1 gene, encoding the α-subunit of the G protein (Gαs) confirmed the presence of a missense mutation in exon 1 (c.154G > A, p.Glu52Ly). Treatment with recombinant GH was initiated and resulted in 7 cm gain within 7 months. At the most recent visit at the age of 10, both calcemia and TSH were within normal ranges.
Conclusion
We report a patient with PHP type 1a displaying PTH, TSH and GHRH resistance. Our case highlights the importance of GH status evaluation in all patients with known mutation in Gαs gene and supports the hypothesis that this mutation is the basis for multiple hormone resistance in pseudohypoparathyroidism. Further studies will be necessary to determine the possible beneficial effects of GH replacement in these patients.

Clinico-biological profile of hypopituitarism associated with somatotropic adenomas

Faten Haj Kacem Akid, Wafa Belabed, Abdel Mouhaymen Missaoui, Mouna Elleuch, Fatma Mnif, Dhoha Ben Salah, Nabila Mejdoub, Mouna Mnif & Mohamed Abid
Hedi Chaker University Hospital, Department of Endocrinology and Diabetology, Sfax, Tunisia

Background and aim
Acromegaly is mostly due to a somatotropic adenoma. Regarding its insidious nature, this adenoma is often revealed at an invasive stage when one or more hormonal insufficiencies are already installed. This study aims to describe the clinical and biological features of hypopituitarism associated with somatotropic adenomas.
Patients and Methods
We conducted a retrospective study at the Endocrinology department of Hedi Chaker University Hospital, Sfax, Tunisia. We involved 29 patients diagnosed with acromegaly, whose clinical, biochemical, and imaging peculiarities were collected from medical charts.
Results
The mean age at diagnosis was 45.8 ± 12.4 years with a male predominance (51.7%). The mean duration of symptoms was 5.1 ± 5.4 years. Pituitary tumor syndrome (30%) and acrofacial dysmorphia (16.6%) were the main reasons for consultation. Signs of hypocortisolism were reported by 34.5% of patients, notably asthenia ($n=9$) or weight loss ($n=2$). Corticotropic insufficiency was biologically confirmed in 16.6% cases. Hypogonadism was clinically observed in 26.6%. Erectile dysfunction ($n=4$), secondary amenorrhea ($n=3$) and primary infertility ($n=1$) were the revealing circumstances. Biological exploration of the gonadotropic axis confirmed its insufficiency in 33.3%. Clinical hypothyroidism affected 13.8% of patients, with psychomotor slowing in the foreground ($n=4$). Thyroid insufficiency was found in 16.6% of cases. In our cohort, the hypopituitarism was dissociated in 40%, with a remarkable predominance of the co-occurrence of gonadotropic and thyroid insufficiency ($n=3$). Panhypopituitarism was noted in only one case.
Discussion
Various degrees of hypopituitarism may be present at the time of diagnosis of a GH adenoma, affecting up to ¾ of patients. The potential mechanism would be pituitary cell compression or destruction or even hemorrhagic necrosis. The gonadotropic sector is the first to be affected. The corticotropic and thyroid deficits seem to be delayed and more partial.

Pituitary Tumours and Learning Difficulties-An Association or Incidental Finding?

Mahamud Bashir, Lubna Etbinah, Ayodeji Oyesanya, Kirtanya Ramachandran, Mohammed Mohammed, Anara Karaca & Gideon Mlawa
BHRUT, Endocrinology and Diabetes, London, United Kingdom

Introduction
Pituitary tumours one of the most commonly occurring intracranial neoplasms accounting for up to the 15 % of all intracranial neoplasms. Pituitary tumours are often associated with overproduction of hormones or, when they are large, they cause mass effect on surrounding neural structures which are adjacent to their typical location in the Sella turcica. Due to their multifaceted effects pituitary tumours may cause cognitive impairment due hormonal deficiency or mass effect on key cognitive areas of the brain. There is limited research on the impact of slow growing tumours and their impact on cognitive function.
Cases 1
A 26-year-old lady was admitted with general lethargy and leg swelling in her legs and being generally unwell. She had a history of epilepsy, long-standing amenorrhea and autism. Her hormone profile showed low cortisol level and hypopituitarism. she commenced hormonal replacement which improved her symptoms. MRI pituitary revealed a cystic pituitary mass with suprasellar extension (2.9x1.4 cm)

Blood test result table below

TSH	T4/T3	CORTISOL	LH/FSH	PROLACTIN
3.09	T4-3.2	14	LH 0.7, FSH 2	983

9/12/2022 SHORT SYNACTHEN TEST
ACTH-8
Cortisol-23
Cortisol 116
Cortisol-164

Case 2
A 20-year-old presented with right-sided visual dysfunction and headaches, diplopia and blurred vision in the right eye. There was no other focal neurology. He had history of Autism/learning disabilities diagnosed at age of 16 years. On examination, there was a partial right-sided third nerve palsy, with a fixed dilated right pupil. The right sixth nerve and fifth nerve showed no deficit. The fundi appeared within normal limits. MRI pituitary showed a large right-sided seller/cavernous sinus tumor partly cystic. The Sella was slightly enlarged at 12mm AP diameter. Normal biochemical hormonal profile. Admitted for Endoscopic Transsphenoidal Debulking of pituitary mass subsequently developed diabetes insipidus. He is on Desmopressin replacement and has achieved good fluid balance. Post-operative MRI was normal.
Discussion/Conclusion
Pituitary adenomas are slow-growing tumours that are classified basis of whether they secrete hormone or not. The benign nature of these tumours often means that they may be overlooked and remain untreated, with patients developing serious comorbidities that reduce their quality of life. Several studies have indicated that the physical compression from tumour might play a role in cognitive impairment as evidenced by the slow improvement observed post-surgical resection of tumour. We recommend doing MRI of the brain for patient with latent adolescent learning disabilities or difficulties

What About Neuro-Endocrine Recovery After Pituitary Apoplexy?

Chtioui Sara, Alhyane Meryam, Sana Rafi, El Mghari Tabib Ghizlane & El Ansari Nawal
Mohammed VI University Hospital Center, Department of Endocrinology, Diabetes, Metabolic Diseases and Nutrition, Marrakech, Morocco

Introduction
Pituitary apoplexy is a serious medical complication of a pre-existing pituitary adenoma characterized by a variety of clinical symptoms ranging from mild headache to neurologically impaired and finally comatose patients.
Case report
We report a case of apoplexy in a large prolactinoma resulting in empty sella syndrome with a successful pregnancy. Our patient is a 31-year-old female, with a history of macroprolactinoma for approximately 7years. Who presented to our hospital with a history of severe headache, vomiting and visual disorders, she was pregnant in 24 weeks of amenorrhoea. The magnetic resonance imaging (MRI) was in favor of a stroke of the pituitary macro-adenoma. The hormonal exploration finds a corticotropic and thyrotropic insufficiency. A trans-sphenoid aspiration excision of the pituitary adenoma was performed urgently. MRI of control showed: total decompression of the optic chiasma. The patient had no further complaints during the pregnancy and at 38 weeks gestation she delivered a healthy baby.3months after delivery (7months after pituitary apoplexy), the pregnancy test was positive. An MRI was repeated which showed empty sella syndrome. The decision was to discontinue cabergoline and follow the patient regularly until delivery. The MRI was repeated and showed the same findings with a normal visual field test. The hormonal exploration showed nor mal thyrotropic function despite the withdrawal of substitution (the patient had stopped), and she still asymptomatic with a minimal dose of Hydrocortisone (5mg). This findings led us to discuss the recovery of hypothalamic pituitary axis ?. The hormonal tests are reported after delivery because our patient is currently pregnant in the first trimester.
Discussion
Pituitary apoplexy is a very rare cause of sudden headache in pregnancy and should be considered a medical emergency because of possible hormonal insufficiency. Surgery can significantly improve headache and both the endocrine and neuro-ophthalmic outcomes. Patients with severe neuro-ophthalmological deficits treated with early surgery can achieve an excellent recovery.

Neuroendocrine neoplasms of the larynx: A small case series

Houas Jihene[1], Kechiche Jawaher[1], Ghammam Monia[1], Ben Arfi Taissir[1], El Omri Malika[1], Bellakhdher Mouna[1], Hasni El Abed Yosra[2], Meherzi Abir[1], Kermani Wassim[1] & Abdelkefi Mohamed[1]
[1]ENT Department and Neck Surgery of Farhat Hached Hospital, Sousse, Tunisia; [2]Endocrinology Department Farhat Hached Hospital, Sousse, Tunisia

Introduction
Laryngeal neuroendocrine neoplasms are very rare malignancies comprising less than 1% of all laryngeal neoplasms.
Methods
Retrospective study including 5 cases of pharyngolaryngeal neuroendocrine tumors.
Results
The average age was 49 years ranging from 35 to63 years with a sex ratio of 4. The average consultation delay was 8 monthes. All patients patients were tobacco users. the chief complaint was dysphonia and dyspnea. Indirect laryngoscopy objectified a tumoral lesion arising from the left aryepiglottic region in one case, a tumoral lesion taking the 3 levels of the larynx with a fixed hemilarynx in 3 cases. One patient already had known lymph node involvement upon presentation. The staging assessment did not show distant metastases in all cases. The anatomopathological study of the biopsies with immunohistochemical analysis was in favor of a well-differentiated carcinoid tumor in 1 case, of small cell neuroendocrine tumor in 3 cases and of a poorly differentiated high-grade neuroendocrine in 1 case. Therapeutic management consisted of radio-chemotherapy in 2 cases, total laryngectomy in 2 cases and total pharyngolaryngectomy in 1 case. One patient developed locoregional recurrence and 2 distant metastases.
Conclusion
Laryngeal neuroendocrine tumors are extremely rare and heterogenous malignancies. It requires aggressive treatment and active follow-up.

Clinical case of partially resistant prolactinoma

Yulia Ukhanova[1] & Irena Ilovayskaya[2]
[1]Moscow Regional Research and Clinical Institute named by M.F. Vladimirsky, Neuroendocrine Unit, Department of Endocrinology, Moscow, Russia; [2]Moscow Regional Research and Clinical Institute named by M.F. Vladimirsky, Neuroendocrine Unit, Department of Endocrinology, Moscow, Russia

In real practice, pituitary adenomas may have non-specific clinical manifestations. Patients are consulted by doctors of various specialties, but not endocrinologists. In confirmation of this we would like to present a Clinical case Male patient D. experienced severe headache at the age 39 y.o., was consulted by the neurologist. MRI demonstrated a pituitary macroadenoma 35x36x36 mm in size (22680 mm3) with supra-para-infrasellar growth. The neurosurgeon recommended surgical treatment. However, the patient referred to an endocrinologist. During the survey the patient noted that his weight has increased over the past 7 years by 20 kg, and his libido decreased. A hormonal examination showed very high levels of total and monomeric prolactin without any signs of hypopituitarism (see tab. 1). Cabergoline was prescribed in initial dose 0,5 mg/week. According to prolactin levels, the dose was up titrated to maximal 4.5 mg/week. The patient's condition improved during the first year of treatment: headache disappeared completely, body weight decreased by 8 kg, erectile function was restored. But normalization of the prolactin level was not achieved. Considering clinical improvement, decreasing prolactin levels and tumor volume, as well as the patient's desire, it was decided to continue drug therapy, the prolactin level and the adenoma volume gradually decreased. After 6 years of treatment (at the age of 45), prolactin level normalized for the first time. Total weight loss was 25 kg from the entire period of treatment. Tumor volume decreased by 82.5% compared with the parameter before treatment. The patient is currently taking cabergoline at the same dose of 4.5 mg (9 tabs)/week. Due to high dose of cabergoline, the patient undergoes echocardiography annually to exclude pathological changes in the valvular apparatus of the heart - no changes were noted.

Table 1

Parameter		Reference range
Total prolactin	**104700 mIU/l**	**39–422**
Monomeric prolactin	**98500 mIU/l**	**22–340**
IGF-1	284 ng/ml	111-284
TSH	0,923 mIU/l	0,4-4
T4 free	11,3 pmol/l	9-22
LG	1,24 mIU/l	1,14-8,75
FSG	1,23 mIU/l	0,95-11,95
Total testosterone	6,0 nmol/l	5,76-30,43
SGBH	16,7 nmol/l	13-71
Cortisol, 8.00	197 nmol/l	101–536
24-hour urinary free cortisol	406 nmol/l/day	138-524

Conclusions
1. This Clinical case demonstrates long term follow up male patient with partially resistant macroprolactinoma
2. Long-term use of maximum doses of cabergoline for 6 years was safe
3. The multidisciplinary approach to the treatment of patients with pituitary adenomas is necessary.

Growth hormone deficiency and celiac disease: an association not to be missed

Khaoula Gorgi, Lamya Echchad, Loubna Guissi, Kaoutar Rifai, Hinde Iraqi & Mohamed El Hassan Gharbi
Ibn Sina University Hospital, Endocrinology, Rabat, Morocco

Introduction
Celiac disease (CD) is an autoimmune enteropathy, induced by dietary gluten in genetically predisposed subjects, which manifests itself, most often, by digestive signs but also extra-digestive signs, in particular failure to thrive (FTT), nevertheless it is necessary to remain vigilant with regard to a real associated somatotropic deficit.
CASE
A 14-years-old male patient, followed for a celiac disease since the age of 6 years, under a strict gluten-free diet, referred to our consultation for a severe failure to thrive. A workup was performed in favor of low IGF1 level with complete insufficient Growth hormone (GH) response to insulin hypoglycemia test. In addition, the hypothalamic- pituitary MRI was in favor of pituitary hypotrophy. Growth hormone replacement therapy was initiated with good clinical outcome.
Discussion & Conclusion
The coexistence of CD and Growth Hormone deficiency (GHD) is rare and estimated at 0.02 to 0.26%. The GHD could be a result of CD or an association of the two conditions. The mechanism of the impairment of hypothalamic control of GH secretion is not very clear. Malnutrition could have a direct effect on the circulating gluten peptides in the brain, affecting the hypothalamic and pituitary control. Also, it has been suggested that a systemic autoimmune inflammatory reaction involving TNF-alpha could have a negative interference in growth. In the other hand, the presence of antibodies against the hypothalamus and the pituitary gland may be suggested as an autoimmune origin of this association especially in the presence of morphological findings on hypothalamic-pituitary MRI.

Hypoplasia of the corpus callosum revealed by staturoponderal growth retardation: about a clinical observation

Imane Boubagura, Sana Rafi, Ghizlane El Mghari & Nawal El Ansari
Department of Endocrinology, Diabetology and Metabolic Diseases, University Hospital of Marrakech, Marrakech, Morocco

Introduction
The corpus callosum is the most important of the interhemispheric commissures, its fibers called callosal radiations have a transverse direction. They connect different points of the neocortex. The corpus callosum represents the neopallial commissure; it has indeed a phylogenetic development modeled on that of the neocortex. Hypoplasia of the corpus callosum is included in a rare polymalformative syndrome characterized by agenesis of the corpus callosum (CC), distal limb anomalies, minor craniofacial anomalies and intellectual deficit.

Observation
We report the case of a girl aged one year and 2 months, referred to us at the endocrinology department for staturo-ponderal growth retardation, weight and height <-2 DS, with delayed psychomotor acquisition. In whom the clinical examination objectives: axial hypotonia, cleft lip and palate, delayed dentition = 2 lower and upper median incisors (corresponds to the development of a 7 months old baby), no low hairline, normal aspect of the OGE. A brain magnetic resonance imaging (MRI) was performed on her showing hypoplasia of the corpus callosum with partial agenesis of her knee, without any other anomaly of the brain parenchyma.
Discussion
In acrocallosis syndrome (ACS), craniofacial anomalies include macrocephaly with a prominent forehead and occiput, hypertelorism, a large anterior fontanel, a short nose with a wide nasal bridge and anteverted nostrils, and a short mandible. Anencephaly has been observed as well as supernumerary bone in the anterior fontanel, calvarial defect or Dandy Walker malformation. Hypoplasia or agenesis of the corpus callosum is the major characteristic sign of the syndrome. It may be associated with arachnoid cysts in about one third of cases and with various other cerebral anomalies (hypoplasia of the medulla oblongata, temporal lobe or bridge, micropolygyria and hypoplasia or agenesis of the cerebellar vermis with a characteristic "molar tooth" sign). The vast majority of patients have an intellectual disability which is severe in 80% of cases with a marked psychomotor delay. Hypoplasia of the corpus callosum is defined as thinning and/or narrowing of the entire corpus callosum. It occurs after the 20th week of gestation.
Conclusion
The corpus callosum plays an important role in the praxis and gnostic psychic functions that require the participation of both hemispheres; its fibers connect especially the associative areas. Its alteration plays a determining role in intellectual failure at its highest level.

Crooke's Cell Adenoma:Aggressive Corticotroph Adenoma

Nwe Ni Aung, Fatima Azad & Nouman Butt
Portsmouth Hospitals University NHS Trust, Diabetes and Endocrinology, Portsmouth, United Kingdom

Introduction
Crooke's cell adenomas are nonneoplastic corticotropes with cytoplasmic accumulation of cytokeratin filaments in response to glucocorticoid excess. They are rare subtype of corticotrope adenomas presenting less than 1 % of pituitary adenomas.
Case
52 years old man attended Ophthalmology Clinic with 2 months history of right-sided reduced vision. He had a history of posterior polymorphous corneal dystrophy with a left corneal transplant and left cataract. As there was new bitemporal visual field loss, MRI was requested which showed a large pituitary macroadenoma (4x3x4 cm) with bilateral cavernous, sphenoid and ethmoid sinuses invasion with significant displacement of optic chiasm. Urgent endoscopic endonasal excision of the pituitary tumour was performed, however, due to size and location of the tumour, there was a limitation in safe resection and decompression of optic chiasm. Histology showed pituitary adenoma with focal expression of ACTH and high Ki67 index. Although the patient is obese with BMI of 45, there were no clinical signs of Cushing syndrome. After the operation, due to high ACTH 108 ng/l (reference range 0-46 ng/l), performed 24 hours urinary free cortisol and 1 mg dexamethasone suppression test which all came back normal. Repeated MRI three months after operation showed residual lesion involving sella, suprasellar cistern and left cavernous sinus with residual optic chiasm compression. He was referred to Neuro-Oncology team for consideration of radiotherapy due to ACTH expression and limited resection.47 GY radical radiotherapy was performed, unfortunately, MRI 3 months post radiotherapy showed an enlarged supra-sellar component to 17 mm from 12 mm with increased chiasmatic compression. Further endoscopic endonasal excision was performed and the patient become partial hypopituitarism requiring hydrocortisone and desmopressin replacement. The histology of pituitary adenoma is consistent with Crooke cell adenoma. Due to it aggressive nature, pituitary MDT suggested consideration for Temozolamide if further regrowth of the tumour. He then has two subsequent MRIs 6 months apart and remains stable appearances and is currently on regular MRI monitoring.
Conclusion
Crook's cell adenomas are aggressive in comparison to typical corticotrope adenomas. Most Crook's cell adenoma present as invasive macroadenomas with a high chance of recurrence therefore close surveillance is important for further management.

Pituitary profile blood tests were normal and the results were:

Tests	Results	Reference range
TSH	0.89 mu/l	0.34-5.6
T4	15 pmol/l	7.7-15.1
LH	4.6 iu/l	
FSH	7.6 iu/l	
Cortisol	319 nmol/l	
Prolactin	256 mu/l	55.4-276
Testosterone	5.8 nmol/l	8-22
IGF-1	20.8 nmol/l	6.3-27.4

Acromegaly may be associated with gynaecological and skin forms of cancer

Daniela Ioana Iulia Greere[1,2], Ionela Baciu[1,2], Cristina Capatina[1,2] & Catalina Poiana[1,2]
[1]C.I. Parhon National Institute of Endocrinology, Pituitary and Neuro-endocrine Disorders, Bucharest, Romania; [2]Carol Davila University of Medicine and Pharmacy, "C.I.Parhon" Department of Endocrinology, Bucharest, Romania

Introduction
Acromegaly is a rare disease usually caused by growth hormone (GH) secreting pituitary adenomas (PA) and associated with a series of complications, including tumours. The most prevalent tumour types are colonic adenomas, colorectal cancer (1) and nodular goiter (2). We present two acromegaly cases attending our center that associate cervical cancer and another that associates melanoma.
Clinical cases

Case 1
A 56-year-old female patient diagnosed with GH secreting PA underwent two transsphenoidal surgeries, gamma knife radiosurgery and required treatment with lanreotide, pegvisomant and cabergoline to achieve biochemical control. Eleven years after diagnosis, the patient developed postmenopausal metrorrhagia; Pap smear and endometrial biopsy described *squamous carcinoma*. The patient underwent radical hysterectomy and pelvic lymphadenectomy. Histopathogical report (HP) showed poorly differentiated cervical squamous cell carcinoma – radiotherapy and cisplatin were then recommended.
Case 2
A 34-year-old female patient diagnosed with GH secreting PA underwent transsphenoidal surgery, gamma knife radiosurgery and necessitated lanreotide, pegvisomant and cabergoline to achieve biochemical control. Four years after diagnosis, the patient had a successful spontaneous normal pregnancy, followed by regular spontaneous menstruation. Six years later, the patient became spontaneously pregnant again, but the gynecological exam identified a 40 mm cervix lesion. Biopsy showed moderately differentiated *adenocarcinoma* – the patient underwent second-trimester therapeutic abortion, neoadjuvant radio-therapy, radical hysterectomy and pelvic lymphadenectomy. HP described chronic inflammatory ulcerative process.
Case 3
A 40-year-old female patient diagnosed with mixed GH and prolacting secreting PA underwent transsphenoidal surgery, high-voltage radiotherapy and achieved biochemical control under pegvisomant and cabergoline. Eight years after diagnosis, dermatology consultation recommended excision of two scapulae nevi. HP described *melanoma*, Clark level II.
Conclusion
Exposure to high levels of GH and Insulin-like growth factor I in acromegaly are potential contributors to cancer pathogenesis by endocrine and paracrine mechanisms (3). Further epidemiological studies are required to establish whether acromegaly would be associated with increased risk for cancer other than colonic and thyroid. Thus, cancer screening programmes designed for the general population are to be thoroughly applied in acromegaly patients.

Non-secreting pituitary adenomas: clinical, biological, radiological and therapeutic aspects: a review of 17 cases

Zeineb Rekaya, Najla Bchir, Fatma Ben Zaied, Anaam Ben Chehida, Zouaoui Chadia & Haroun Ouertani
Hopital Militiare Principal de Tunis, Endocrinology, Tunis, Tunisia

Non-secreting pituitary adenomas (NSPA) are relatively rare benign tumors their prognosis depends essentially on their endocrine and ophthalmological repercussions the aim of our study is to outline their clinical, biological, radiological aspects, and the therapeutic choice.
Methods
Retrospective study of 17 patients with non secreting pituitary adenomas.
Results
We identified 17 patients with NSPA split into 12 women and 5 men with a sex ratio of 2.3. The average age was 47 years (+/-16.9). The circumstances of discovery were pituitary insufficiency in 17.6% of cases, an incidentaloma in 11.8% of cases, and a tumor syndrome in 70.6% of cases. Patients presented with headaches in 76.5% of cases and a decrease in visual acuity was noted in 64.7% of cases.47.1% of MRI cases were macroadenomas with invasion of the optic chiasma in 41.2% of cases. Necrotic remodeling was observed in 23.5% of cases and hemorrhagic remodeling in 17.6% of cases. The hypophysiogram study showed gonadotropic insufficiency in 47.1% of patients, followed by corticotropic insufficiency in 35.3% of cases. A hyperprolactinemia of disconnection was noted in 17.7% of the cases surgery was indicated in 36.4% of the cases given the damage of the optic chiasma the evolution during the follow-up was marked by the appearance of a pituitary deficit or more in 17.6% of the patients.
Conclusion
NSPA are most often discovered due to a tumoral syndrome, generating a pituitary insufficiency essentially gonadotropic and corticotropic. The operative indication is set according to the size, the evolutivity and the proximity of the optic tracts.

Lymphocytic hypophysitis simulating a pituitary adenoma

Imane Boubagura, Ilham Midhat, Sana Rafi, Ghizlane El Mghari & Nawal El Ansari
Department of Endocrinology, Diabetology and Metabolic Diseases, University Hospital of Marrakech, Marrakech, Morocco

Introduction
Lymphocytic hypophysitis is a rare inflammatory disease of the pituitary gland of autoimmune origin, related to a diffuse infiltration of the pituitary gland sometimes leading to severe hypopituitarism. It is frequent in pregnant or postpartum women.
Case report
A 28 year old female patient, followed up for pituitary microadenoma with prolactin for 5 years under dostinex 1 tablet/week who reported headaches with visual acuity decrease with signs of corticotropic and gonadotropic insufficiency, pituitary MRI showed an intrasellar process of 3.6*2.5 mm, at FO : AV at 10/10 in ODG with diplopia, the CV was discreetly altered and the hormonal assessment objectified a corticotropic, and gonadotropic deficit. In the meantime, the patient presented for 1 year a polyuropolydipsic syndrome, the diagnosis of an osmotic polyuria following a hypercalcemia in the framework of a multiple endocrine neoplasia type 1 with pituitary adenoma was evoked but the calcemia was normal, the urinary osmolarity was low at 200 making evoke a polyuria insipidus a test of hydric restriction is planned. In view of this polyuropolydipsic syndrome of insipid appearance and the tumor syndrome which is not explained by the microadenoma, a lymphocytic hypophysitis was evoked and the workup was completed by antinuclear and anti-DNA antibodies.
Discussion
Lymphocytic hypophysitis is a rare autoimmune disorder predominantly affecting young women and is most often manifested by headache, visual disturbances or hypopituitarism. This observation shows the interest to think about it in front of a pituitary adenoma picture especially when it is a microadenoma not explaining the tumor syndrome and the polyuropolydipsic syndrome.

EP889

Disease Control on Lanreotide in a Patient with Acromegaly

Ekoundzola Joel Rudy, Sana Rafi, Ghizlane El Mghari & Nawal El Ansari
CHU Mohammed VI Hospital, Endocrinology, Diabetology, Metabolic Disease and Nutrition, Marrakesh, Morocco

Introduction
Medical treatment of acromegaly with somatostatin analogues (SAs) has been used for a long time and is a well-established treatment in cases where surgery, which is the first-line treatment, is impossible or inadequate. We report a case of acromegaly under control after initiation of Lanreotide.
Observation
Patient aged 59 years, referred for acromegaloid dysmorphic syndrome initially with tumor syndrome with IGF1 workup at 729 ng/mL (normal: 59 to 206) and at MRI presence of a pituitary macroadenoma with sphenoidal extension of "32 × 32 × 26 mm, enveloping the right carotid artery. In the workup, an unbalanced diabetes with HbA1c at 12% under insulin, a carpal tunnel syndrome confirmed by EMG, a sleep apnea syndrome and a colonic diverticulosis without any sign of malignancy, the rest is unremarkable. The patient underwent two neurosurgical operations. The last follow-up MRI showed no tumor residue contrasting with a still elevated IGF1 of 624 ng/ml. He was put on Lanreotide at a dose of 120 mg/mol. The evolution under treatment is marked by clinical improvement, decrease of the IGF1 level to 173 ng/mL with a control MRI still without tumor residue, as well as the balancing of diabetes with HbA1c at 6.5% under RHD, a regression of the carpal tunnel syndrome.
Discussion and conclusion
Although surgical treatment is the first line of treatment in acromegaly, treatment with SA is well established and is mainly used after insufficient surgical intervention, but also as primary medical treatment when surgery cannot be performed and finally when IGF1 concentration remains high despite the absence of tumor residue.

EP890

Case report of a patient with paraganglioma diagnosed after surgery

Katerina Cheshlaroska Markushoska[1], Tatjana Milenkovic[2], Hristina Cheshlaroska[3], Belma Bilaloglu Jovanoska[2] & Arta Tafa[4]
[1]General Hospital "Borka Taleski", Prilep, Macedonia; [2]University Clinic of Endocrinology, Diabetes and Metabolic Disorders, Skopje, Macedonia; [3]Faculty of Medicine, Skopje, Macedonia; [4]General Hospital - Struga, Struga, Macedonia

Introduction
Paraganglioma is a tumour derived from extra-adrenal chromaffin cells of the sympathetic paravertebral ganglia of the thorax, abdomen and pelvis. About 36 % to 60 % of the paragangliomas are functional secreting norepinephrine and normetanephrine, which cause hypertension. Non-functional paragangliomas can produce Chromogranin A. Paragangliomas also arise from the parasympathetic ganglia located along the glossopharyngeal and vagal nerves in the neck and at the base of the skull. Only about 5 % of these tumours secrete catecholamines.
Material and methods
The patient is a female, 51 years old. A few months before consulting the Endocrinology outpatient clinic, during an ultrasound examination of the abdomen, a tumorous lesion size 70 x 69 x 51 mm was detected - localized in front of the vena cava inferior. This finding was confirmed with Computed Tomography. She was not evaluated by an endocrinologist before the surgery. With a post-operative diagnosis of "St. post extirpationem TU v. cava inferior" and a histopathology report of paraganglioma, the patient consults the Endocrinology outpatient clinic: anamnestic without any symptoms both pre- and post-operatively and denial of past illnesses. From the outpatient laboratory analysis, metanephrine and vanillylmandelic acid in

24-hour urine were in the reference range and had an elevated value of Chromogranin A. A computed tomography scan of the abdomen and chest and a PET/CT scan with IV application of 18 F-FDG were performed, which did not reveal any local recurrence or distant metastases. During the follow-up, due to elevated chromogranin A values, a full body scan and SPECT/CT scan were performed after an i.v application of a somatostatin analogue. No pathological accumulations of a somatostatin analogue were registered.

Conclusion

Paragangliomas are rare neuroendocrine tumours. Malignancy is defined as the presence of metastasis at presentation or during follow-up, a metastasis is defined as the presence of chromaffin tissue in non-chromaffin organs. Paragangliomas commonly metastasize (30 %-50 %) to the liver, lungs, lymph nodes and bones. Metastases are usually functional, 80 % secrete norepinephrine and normetanephrine. It is essential that paragangliomas are acknowledged, because biochemical and imaging pre-operative evaluation is necessary, which is significant for perioperative and postoperative follow-up.

Suprasellar Germinoma with Hypopituitarism and Central Diabetes Insipidus

Ozlem Kanburoglu Meletli, Cigdem Birinci, M. Cuneyt Bilginer, Hulya Coskun, Irfan Nuhoglu, Ozge Ucuncu & Mustafa Kocak
Karadeniz Technical University Faculty of Medicine, Department of Endocrinology and Metabolism, Trabzon, Turkey

Introduction

Germinomas, which are the most common germ cell tumors of the central nervous system, may present with different symptoms depending on the location and are localized in the 20-30% suprasellar region. Here, we aimed to present a case of suprasellar germinoma with central diabetes insipidus, hypogonadism and secondary adrenal insufficiency.

Case Report

A 27-year-old male patient presented with dry mouth, polydipsia, polyuria and nocturia for 6 months. There were weakness, blurred vision and erectile dysfunction. Neurological and other system examinations were normal. He did not have a chronic disease and did not take any medication. There was a history of smoking. Laboratory examinations (Table-1) revealed central hypogonadism, low cortisol level and elevated prolactin. Hydrocortisone replacement was started due to secondary adrenal insufficiency in the patient who did not respond to the insulin tolerance test and glucagon stimulation test performed for secondary adrenal insufficiency due to low cortisol level. Fluid restriction test was performed due to low urine density; it was compatible with central diabetes insipidus and the patient was started on desmopressin. Pituitary magnetic resonance imaging (MRI) revealed a 12.2x12.7 mm suprasellar mass behind the pituitary stalk. There was no contact with the optic chiasm. On eye examination, the visual field and optic disc were normal. HCG level, a tumor marker, was high. The patient was consulted with medical oncology and neurosurgery; because the suprasellar lesion was in a risky location for resection, histological examination could not be performed and it was concluded that it was a germinoma as a result of radiological and biochemical evaluations. Since it is known that intracranial germinomas have high radiosensitivity, radiotherapy was planned for the patient in the first stage. In the follow-ups, it was observed that the disease activity decreased and the adrenal insufficiency and diabetes insipidus clinic regressed.

Conclusion

Germinomas are highly treatable lesions when diagnosed early. Since visual symptoms, endocrinopathies such as diabetes insipidus and hypopituitarism may be present in suprasellar lesions, they should be managed by a multidisciplinary team consisting of neurosurgeon, endocrinologist, ophthalmologist, radiation and medical oncologist.

Table 1 Laboratory Results

Parameter	Result	Referenge Range
Follicle Stimulating Hormone	<0.2 IU/l	1.27-19.26
Luteinizing Hormone	<0.2 IU/l	1.24-8.62
Total Testosterone	125 ng/dl	150-684
Prolactin	59.53 µg/l	2.64-13.13
Adrenocorticotrophic Hormone	33.7 ng/l	<46
Cortisol	11.32 µg/dl	
Thyroid Stimulating Hormone	0.81 mIU/l	0.41-6.80
Free T4	0.66 ng/dl	0.57-1.24
Urine Densitiy	1005	1010-1030
Human Chorionic Gonadotropin	38.7 IU/l	0-5

A diagnostic dilemma

Muhammad Shoaib Zaidi
King Saud University Medical City, University Diabetes Center, Riyadh, Saudi Arabia

Introduction

Nasopharyngeal carcinoma is a rare entity with a predominant geographic distribution in North Africa, Arctic, Southern China and Southeast Asia.

Case Presentation

32 yrs old, single, Saudi, male, had presented to our hospital on 26.11.2022. He had 2 months history of undocumented fever, blackish oral lesions, anorexia and profound weight loss(20kgs). He had become fully dependent and bed-bound. No addictions, allergies or high risk behaviours. Systemic review and family history-unremarkable. 7 yrs back, the patient had a road traffic accident with resultant left hemiparesis and aphasia, but was independent & mobile with support, till the current illness. On further evaluation, the patient was diagnosed to have poorly differentiated and metastatic Nasopharyngeal carcinoma [Vitally stable. GCS-E4M4V1 = 9/15, left sided flexion contractures & weakness. He was unkempt, markedly dehdrated & cachectic, with poor dentition & oral hygiene. Had blackish, necrotic lesions with crusting, over the dorsum of tongue, uvula & hard palate. CT scan brain, neck, facial bones(infiltrative and destructive nasopharyngeal & skull base soft tissue mass, invading sellar & suprasellar areas(1.5 x 4.7 cms), with erosion of the sella turcica and clivus. Besides, involvement of both cavernous sinuses, sphenoid sinus, left internal jugular vein, posterior nasal cavity, facial bones and bilateral retropharyngeal and left (necrotic) cervical lympadenopathy, was noted). CT chest-multiple indeterminate lung nodules, largest(13mms) in right lower lobe, suggestive of metastases. CT abdomen & pelvis-absent spleen, destructive bony lesions of right sacral ala and S1 vertebral body, suspicious of metastases. Multiple biopsies from the nasopharyngeal mass-poorly differentiated, Nasopharyngeal carcinoma (Negative for EBV, p16, fungal, TB & positive for CK 5/6]. He also had Panhypopituitarism (TSH 0.834mIU/l[0.25-5], FT4 9.42pmol/l[12-22], S. Cortisol AM 535nmol/l[137.9-686.7], Short Synecthen test normal, ACTH 0.33pmol/l(2.2-13.2), Prolactin 703mIu/l[86-324], LH 0.30mIU/l[1.7-8.6], FSH 2.34mIU/l[1.5-2.4], S. Testosterone 0.087nmol/l[8.64-29]). The patient had developed Cranial diabetes insipidus during hospitalization(with polyuria, S.Na + 156 mmol/l, Osmolality(-Serum312.19mOsm/kg [250-326], Urine185mOsm/kg[50-1400]). He was also found to have right corneal perforation with bilateral exposure keratopathy. Other significant laboratory derangements-normochromic anemia(Hb 10.4g/dl), hypoalbuminemia(S.Albumin 30.5g/l), deranged coagulation & Throat C/S + for Candida krusei & Yeast spp. He underwent emergent, right eye tectonic corneal grafting, bilateral amniotic memrane transplant and bilateral tarsorrhaphy. He was managed with Desmopressin, Low dose Thyroxine, maintenance steroids and an anti-fungal. The Tumor board consensus was to keep the patient on DNR status and for palliative care, in view of his Palliative performance scale(30%).

Conclusion

A multi-speciality team-work led to the exact diagnosis & the issues like corneal perforation, diabetes insipidus and Pan-hypopituitarism were addressed.

A case of ectopic ACTH syndrome in squamous cell lung cancer

Hatice Sebile Dökmetaş[1], Ayşenur Akkoyun[2], Esma Eren[2], Onur Şahin[2], Meriç Dökmetaş[2], Hikmet zeynep Ağaoğlu[2] & Oğuz Kaan Türk[2]
[1]Istanbul Medipol University, Endocrinology, Istanbul, Turkey; [2]Istanbul Medipol University, Internal Medicine, Istanbul, Turkey

Cushing's syndrome as a result of ectopic adrenocorticotropic hormone (ACTH) secretion, is associated with various tumors. Lung squamous cell carcinoma (LUSC) causing ectopic ACTH syndrome is a very rare condition. A 70-year-old male patient with a history of LUSC was admitted to our clinic for evaluation of worsening delirium and hypokalemia. Two courses of pembrolizumab were administered to our patient who was diagnosed with LUSC a month ago. At presentation, neurological examination revealed disorientation, agitation and

visual hallucinations. There were no signs of a Cushingoid appearance. Laboratory assessment showed a serum potassium of 2.8 mmol/l (3.1-5.5), glucose of 120 mg/dl (70-100), basal plasma cortisol of 39,3 µg/dl (6-18), ACTH 92,1 pg/mL (7,2-63,3) and post-1 mg dexamethasone serum cortisol 40,9 µg/dl. A high dose dexamethasone (8 mg) suppression test did not result in suppression of the cortisol levels (64,8µg/dl). Brain MRI was taken and no abnormality was detected in the pituitary gland. The patient's adrenal glands were evaluated as normal in the abdominal imaging. According to the results, the patient was diagnosed with ectopic ACTH syndrome. Metyrapone treatment was started to block cortisol secretion.

Key words
Ectopic ACTH syndrome, squamous cell lung cancer, delirium

DOI: 10.1530/endoabs.90.EP893

Clinical features and outcomes of an FSH-secreting pituitary adenoma: a case report

Abdel Mouhaymen Missaoui[1], Nabila Rekik Majdoub, Siddiqa Soomauroo, Faten Haj Kacem Akid, Mouna Elleuch, Fatma Mnif, Nadia Charfi, Mouna Mnif, Dhoha Ben Salah & Mohamed Abid
Hedi Chaker University Hospital, Department of Endocrinology, Sfax, Tunisia

Introduction
Pituitary adenomas are the most frequent sellar tumors in adults. Depending on their hormonal profile *in vivo* and on immunohistochemistry, they present different clinical profiles and progression outcomes. Thus, we report a case of an FSH-secreting pituitary adenoma.
Observation
The patient SG is 63 years old. He complained of intermittent headaches associated with a progressive decrease in visual acuity. Ophthalmological examination revealed bilateral papillary atrophy and visual field amputation. A pituitary MRI revealed a 23 mm pituitary macroadenoma responsible for a bulging sellar diaphragm and a rightward deviation of the pituitary stalk. It came into contact with the optic chiasm and engulfed both internal carotid arteries. The patient reported the onset of erectile dysfunction, decreased libido, and disappearance of morning erections without gynecomastia. The hormonal evaluation showed the integrity of the corticotropic and thyroid axis, a hypogonadotropic hypogonadism profile, and disconnection hyperprolactinemia (37.5ng/ml). Due to the threatened visual prognosis, the patient underwent surgery. Intraoperative observation highlighted the presence of a hemorrhagic tumor adherent to the lateral wall of the cavernous sinus which could not be completely resected. The anatomopathological study concluded with an FSH-secreting pituitary adenoma (FSHoma). Adjuvant external radiotherapy is recommended for this patient.
Discussion
FSHomas secrete increased gonadotropins and/or their subunits in an often biologically inactive form. Their clinical presentation is poor and remains dominated by the mass effect responsible for visual complications and signs of hypopituitarism. Surgery remains the only effective treatment option.

Osteoporosis as a complication of acromegaly

Kamilė Antanavičiūtė & Birutė Žilaitienė
Lithuanian University of Health Sciences, Endocrinology Department, Kaunas, Lithuania

Context
Acromegaly is associated with many complications, which affects multiple systems, such as cardiovascular, respiratory, metabolic, muscles and bones. Osteoporosis and osteoporosis fracture are commonly neglected comorbidity of this rare disease. Usual manifestation of this skeletal complication is skeletal fragility and vertebral fractures, but prior research confirms, that other location fractures can be found as well.
Case illustration
We report the case of a 54-year-old woman, admitted with elevated blood pressure, hot flushes, episodes of intensive headaches, metacarpophalangeal joints pain, carpal tunnel syndrome, morning stiffness of joints. In 2018, laboratory test (increased insulin-like growth factor (IGF-1) 62,0 nmol/l (16,0 – 42,8)) in addition to clinical findings suspected acromegaly. MRI of the head was performed and pituitary macroadenoma was identified, size 34x46x35 mm, invading the left cavernous sinus. Histologically, macroadenoma was non-granulated with expression of Pit-1 transcription factor. Subtotal transsphenoidal adenectomy was performed in 2018. After surgery, somatostatin receptor ligand (SRL) Lanreotide 90 mg per week was prescribed, but IGF-1 concentration remained above normal range 42,1 nmol/l. Treatment was changed to Pasireotide LAR 40 mg every 28 days, but IGF-1 persisted uncontrolled. Patient started Cabergoline incrementally. Unfortunately, control head MRI demonstrated increased size of adenoma. In May 2020, according to the decision of multidisciplinary team, stereotactic radiotherapy surgery was performed. After surgery, Cabergoline 2 mg 2 times per week was continued. Six months after surgery IGF-1 level normalized – 22,7 nmol/l, growth hormone (GH) level remained increased 8,4 mU/l (0 – 6,3 mU/l). Eight months after radiosurgery patient admitted to the hospital with a fracture of the acetabulum, without dislocation, no surgery was required. The fracture occurred after a fall at home. DXA was performed, femoral neck T- score was -2,5. Osteoporosis was diagnosed. The patient was prescribed with Denosumab 60 mg every 6 months. No other bone fracture was registered since.
Discussion
Studies confirm that exceeded secretion of IGF-1 and GH enhances deterioration of bone and can lead to osteoporosis or even bone fractures. Unfortunately, the management of bone impairment in patients with acromegaly still need more attention, since the acknowledgement of this complication sometimes left forgotten.

Polyuria-polydipsia syndrome : diagnosis approach through a case report

Zineb Ait Si Ali, Jaddi Oussama, Sana Rafi, Ghizlane El Mghari & Nawal El Ansari
Centre Hospitalo-Universitaire Mohammed Vi Marrakech, Department of Endocrinology, Diabetology, Metabolic Diseases and Nutrition, Marrakech, Morocco

Introduction
Polyuro-polydipsia syndrome (PPS) is defined by urine excretion rate more than 3L per day, associated with a parallel increase in oral fluid intake. It poses problems of positive and etiological diagnosis. We discuss in this observation the modalities of exploration of PPS and its main etiologies.
Case report
A 60-year-old patient, diabetic for 10 years, controlled on metformin, admitted for PPS evolving for 37 years. Clinical examination was normal. Considering a decrease in visual acuity, Pituitary-MRI was requested, which was normal. Blood glucose levels were between 0.9-1.5g/l, the calcium and phosphorus levels were normal. The basal Natremia was 137mmol/l and the basal urinary osmolarity was 180mosm/l. Water deprivation test was performed, and showed progressive urine concentration, decrease in hourly diuresis (250ml at H0 $=>$ 40ml at H5 and H6) and increase in urine osmolarity (181.7mosm/l $=>$387.2mosm/l). The test was stopped after H6 due to the patient's intolerance to thirst, thus the test was not completed by the administration of desmopressin. Copeptin measurement was not performed (unavailable). The diagnosis of primary polydipsia was retained and the patient was referred to the psychiatric department. During his follow-up, after 3 sessions of psychotherapy, we noted a clear clinical improvement (drinks: 7L/24h vs 19L/24h).
Discussion
Antidiuretic hormone (ADH) and thirst are the main determinants of water homeostasis. Disturbances of these regulatory mechanisms lead to PPS, which includes three different entities: central diabetes insipidus, nephrogenic diabetes insipidus, and primary polydipsia. Determining the correct diagnosis is crucial as

treatment strategies vary considerably. The first step in the diagnostic approach is to confirm PPS and to demonstrate its hypotonic or osmotic character. Water deprivation test combined with desmopressin administration is the diagnostic gold standard. However, it has several limitations and may not accurately distinguish patients with primary polydipsia from partial forms of central and nephrogenic diabetes insipidus. Direct measurement of ADH during the water deprivation test has not been widely adopted. Copeptin has been evaluated in PPS and appears to be a useful candidate biomarker for differential diagnosis. Pituitary-MRI is helpful to determine the possible etiology of central diabetes insipidus or if the water deprivation test is inconclusive. It is ordered as a first-line examination if the initial clinicobiological context already points to central diabetes insipidus.
Conclusion
Water deprivation test remains the "gold standard" for the etiological diagnosis of PPS. Copeptin could considerably improve the diagnostic accuracy of this test, thus allowing better management.

Different etiologies of the endocrine hyponatremia

Natia Margvelashvili[1,2], Natia Shonia[1,2], Nino Zavrashvili[1,2], Ketevan Chanturishvili[1,2], Qetevan Gvazava[1,2] & George Arjevanidze[1]
[1]Tbilisi Institute of Medicine, Endocrinology, Tbilisi, Georgia; [2]David Tvildiani Medical University, Endocrinology, Tbilisi, Georgia

Hyponatremia is the most common disorder of electrolytes encountered in clinical practice, occurring in 15-30% of acutely or chronically hospitalized patients. Although many cases are mild and relatively asymptomatic, hyponatremia is nonetheless important clinically because: acute severe hyponatremia can cause substantial morbidity and mortality; overly rapid correction of chronic hyponatremia can cause severe neurological deficits and death. We present Clinical cases of endocrine hyponatremia due to different etiologies.
Case I
48 y/o male was hospitalized in our clinic due to increased blood pressure, agitation and anxiety. Shortly after admission patient developed tonic-clonic seizure with suppression of cognition, bradypnea and was intubated. Lab work revealed very low sodium levels (Na-109 mmol/l). Patient's medical history reveals history of clinical depression, which was treated with SSRI. In 12.2022 he was consulted by an endocrinologist due to complaints of polyuria and polydipsia. Based on findings, patient was misdiagnosed with ADH deficiency syndrome (central DI) and was prescribed intranasal desmopressin. Preadmission clinical manifestations (polydipsia, polyuria) and laboratory findings (hyponatremia, low serum osmolality) correspond more with the diagnosis of primary polydipsia. Based on patient's objective findings, diagnosis was re-evaluated and proper medical treatment was initiated which led to improved outcome.
Case II
73 y/o female with multiple hospitalizations due to hyponatremia was admitted to our clinic due to complaints of weakness, confusion, nausea. Lab findings revealed hyponatremia, which was associated with quetiapine fumarate, prescribed by her psychiatrist, but switching her medication did not improve her sodium levels. Hyponatremia due to hypervolemia (CHF), SIADH induced by quetiapine fumarate were excluded. Further laboratory testing revealed secondary adrenal insufficiency. Head MRI showed pituitary microadenoma. Patient was prescribed hydrocortisone which markedly improved her overall condition with no further episodes of hyponatremia.
Case III
57 y/o female with a history of somatotroph adenoma was treated with transsphenoidal surgery. Few days after the surgery patient developed nausea, weakness and confusion. Lab assessment revealed hyponatremia. Diagnosis of SIADH was made and patient was instructed to restrict water consumption. In conclusion, the initial diagnostic approach to the adult patient with hyponatremia consists of a directed history and physical examination as well as selected laboratory tests. Some elements of the history, findings of physical exam, laboratory tests are usually already available, and guide the subsequent diagnostic approach.

Acromegaly: Clinico-biological and radiological features

Cherchir Faten, Sabrine Mekni, Sawsen Essayeh, Sahar Abidi, Nadia Mchirgui, Imen Rojbi, Ibtissem Ben Nacef & Karima Khiari
Hospital Charles Nicolle, Endocrinology, Tunis, Tunisia

Introduction
Acromegaly results from an autonomous hypersecretion of growth hormone (GH) typically by a pituitary adenoma, commonly revealed by a dysmorphic syndrome. The aim of our study was to describe clinico-biological and radiological features of acromegaly.
Methods
We conducted a retrospective study including 28 patients with acromegaly followed in the endocrinology department of Charles Nicolle Hospital. Clinical, biochemical, ophthalmological and imaging data were extracted from medical records.
Results
The mean age of our patients was 45,9 $\pm$ 13,9 with a sex ratio (F/M) of 1.5. Dysmorphic features, obesity, high blood pressure, electrical left ventricular hypertrophy, hepatomegaly, goiter and Galactorrhea were found in 96, 50, 61, 29, 25, 41 and 26% of cases, respectively. Obstructive sleep apnea was detected in 57% of patients. Pituitary evaluation showed corticotrop (41%), thyrotropin (19%) and gonadotropin deficiencies (67%). Disconnection hyperprolactinemia and cosecretion of prolactin were found in 33 and 4% of cases, respectively. Metabolic complications included diabetes (43%), prediabetes (36%), hypertriglyceridemia (57%), hypercholesterolemia (39%), low HDL-cholesterol level (73%), hypercalcemia (11%), hyperphosphoremia (29%) and hypercalciuria (22%). The median (IQR) GH was 24 (8-50) ng/ml. The mean size of adenomas was 20.4 mm [extremes :7mm-38mm]. Aggressive macroadenomas were detected in 14% of cases. Adenomas were invading optic chiasm (37%), cavernous sinus (30%) and sphenoidal sinus (11%). Tumor size was positively correlated with GH level ($r=0.731$, $P<$ 10-3) and negatively correlated with age ($r=$-0.387, $P=0.042$). Patients with aggressive adenomas were younger ($P=0.028$) and had lower cortisol levels ($P=0.002$).
Conclusion
The morbimortality of acromegaly is aggravated by its cardiovascular, respiratory, metabolic and ophthalmological complications that worsen the global prognosis.

EP899

Ophthalmological complications in acromegaly

Faten Haj Kacem Akid, Wafa Belabed, Abdel Mouhaymen Missaoui, Mouna Elleuch, Fatma Mnif, Nabila Mejdoub & Mohamed Abid
Hedi Chaker University Hospital, Department of Endocrinology and Diabetology, Sfax, Tunisia

Background and aim
Acromegaly is a rare condition caused by an excessive secretion of growth hormone (GH) and insulin-like growth factor1 (IGF-1), which are responsible for exaggerated somatic growth and cardiometabolic disturbances. This study aims to describe the ophthalmologic complications seen in acromegaly.
Patients and Methods
We conducted a retrospective study (1997-2020) at the Endocrinology department of Hedi Chaker University Hospital, Sfax, Tunisia. We involved 30 patients diagnosed with acromegaly, whose clinical, biochemical, and imaging peculiarities were collected from medical charts. All patients had an ophthalmologic examination with a visual field.
Results
The mean age of diagnosis was 45.8$\pm$12.4 years with a male predominance (51.7%). The mean delay of diagnosis was 5.1$\pm$5.4 years. Pituitary tumor syndrome (PTS) (30%) and acrofacial dysmorphia (16.6%) were the main reasons for consultation. Pituitary MRI revealed a somatotropic macroadenoma in 82.8% of cases. Visual disorders related to STH were noted in 42.8% of our patients, such as monocular blindness ($n=2$), diplopia ($n=4$) and visual blur ($n=7$). A decrease in visual acuity was observed in 21.4%. Ophthalmological examination revealed papilledema and optic atrophy in 10.7% and 7.1% of cases respectively. Bitemporal hemianospsia (14.3%) and temporal quadranopsia (3.6%) were the most common visual field alterations.
Discussion
Somatotropic adenomas are characterized by an insidious evolution and a mostly a delayed diagnosis. Visual disorders generally translate a tumoral invasion at the expense of the cavernous sinus and the optic tracts. The initial evaluation of the visual impact by an ophthalmologic examination, visual field and pituitary MRI is

strongly recommended. Preservation of the visual prognosis remains one of the major objectives of the treatment. A close collaboration between endocrinologist, neurosurgeon and ophthalmologist is necessary during all therapeutic steps.

Pituitary Macroadenoma and hypercalcaemia - An association or an incidental finding?

Maisha Hayat[1], Robert English[1], Sanjali Ahuja[1], Miriam Lowe[1], Alaina Khan[1], Bashir Mahamud[2], Mikhail Nozdrin[2] & Gideon Mlawa[2]
[1]Barts and The London School of Medicine and Dentistry, Queen Mary University of London, Charterhouse Square Campus, United Kingdom; [2]Queen's Hospital, United Kingdom

Introduction
Multiple Endocrine Neoplasms (MEN) are a group of rare hereditary tumours which have strong predisposition to endocrine organs. MEN1 is an autosomal-dominant inherited neoplasm with a broad genetic phenotype, characterised by synchronised or asynchronous triad neoplasms localised in the anterior pituitary, parathyroid and pancreas (Kamilaris and Stratakis, 2019; Li *et al*., 2022). Despite advances in the fields of diagnostic techniques and therapies, MEN1 continues to be associated with severe morbidity and mortality primarily due to malignant neuroendocrine tumours. Numerous combinations of both endocrine and non-endocrine manifestations have been described for MEN1 in literature (Singh, Mulji and Jialal, 2021; Newey and Newell-Price, 2022; Kamilaris and Stratakis, 2019).
Case report
61 year old lady presented to hospital feeling unwell and complaining of occipital headaches, visual disturbance, abdomen pain secondary to constipation, vomiting, and generalised body aches. She had extensive past medical history including permanent pacemaker inserted in 2017, ischaemic heart disease (NSTEMI 2016), aortic regurgitation with dilated ascending aorta measuring 48mm (2021), chronic kidney disease (stage 4), hypertension, obstructive sleep apnea, atrial fibrillation, and primary hyperparathyroidism. Her blood test on admission showed severe hypercalcaemia with serum calcium of 3.6, urea 8.1, creatinine 182 and elevated PTH. She was then commenced on IV fluids, and IV pamidronate to manage her calcium levels. CT head was done which showed a pituitary macroadenoma. The CT scan was reviewed by the neurosurgery team and with view surgical resection. In subsequent multidisciplinary team discussions, it was decided that transsphenoidal debulking of the suprasellar tumour was to be undertaken in order to preserve her remaining vision. She successfully underwent microscopic transsphenoidal debulking of the large pituitary adenoma on 29/07/22. She is currently on Hydrocortisone 10mg and Levothyroxine. Histological analysis of the biopsy revealed that the tumour had the following features: The tumour is overwhelmingly SF-1 positive, and there were several tumour cells with occasional LH and very rarely FSH positive. In addition, there are scattered populations of pit-1 positive cells within the tumour, and these correspond to TSH-positive labelling.
Discussion
MEN-1 is associated with a variety of non-malignant adenomas, the majority of these abnormalities are non-functional (Yoshida *et al*., 2011). It is widely reported that the vast majority of cases initially present with primary hyperparathyroidism. Nevertheless, the main neoplastic symptom patients present with is usually due to tumour mass effect, some tumours secrete chemicals that often result in manifestation of endocrine paraneoplastic syndromes (Li et al., 2022).

EP901

Obesity prevalence in patients with acromegaly

Faten Haj Kacem Akid, Wafa Belabed, Abdel Mouhaymen Missaoui, Mouna Elleuch, Nabila Mejdoub, Dhoha Ben Salah & Mohamed Abid
Hedi Chaker University Hospital, Department of Endocrinology and Diabetology, Sfax, Tunisia

Background and aim
Acromegaly is a rare condition caused by an excessive secretion of growth hormone (GH) and insulin-like growth factor1 (IGF-1), which are responsible for exaggerated somatic growth and cardiometabolic disturbances. This study aims to determine the prevalence of obesity in patients with acromegaly
Patients and Methods
We conducted a retrospective study (1997-2020) at the Endocrinology department of Hedi Chaker University Hospital, Sfax, Tunisia. We involved 30 patients diagnosed with acromegaly, whose clinical, biochemical, and imaging peculiarities were collected from medical charts.
Results
The mean age of diagnosis was 45.8 ± 12.4 years with a male predominance (51.7%). The mean duration of symptoms was 5.1 ± 5.4 years. Acromegaly was due to a somatotropic adenoma in 96.7%. An exceptional case of ectopic secretion of GHRH by a pancreatic neuroendocrine tumor was reported. The average weight was 82.5 ± 13 Kg (extremes: 62-120 Kg). The average BMI was 28 ± 7.2 Kg/m^2(extremes: 17.5-40.5 Kg/m^2). The BMI was normal in 18.6% of patients while 40.7% were overweight. We report an increased prevalence of obesity of 40.7%. The mean waist circumference was 97.7 cm (range 75-129 cm) in men and 100.3 cm (range 85-129 cm) in women. An android distribution of fat was found in 11 patients (5 men, 6 women), a prevalence of 36.6%.
Discussion
GH and IGF-1 are counterregulatory hormones that antagonize the metabolic effects of insulin in the liver and adipose tissue, creating a state of insulin resistance and altering fat distribution in acromegalic patients. Adipose tissue hyperplasia-hypertrophy, related to GH/IGF-1 excess, would aggravate the risk of obesity in this population. These adipose disturbances can regress in 10% of cases after surgical treatment.

EP902

Hyperparathyroidism and Prolactinoma: MEN1 or incidental association?

Benlafqih Maryame, Sana Rafi, Ghizlane El Mghari & Nawal El Ansari
Arrazi Hospital, Faculty of Medicine and Pharmacy of Marrakech, Mohammed VI University Hospital, Endocrinology, Marrakech, Morocco

Introduction
Primary hyperparathyroidism and prolactinoma can be associated as part of a MEN1. However, the association of the two pathologies can also be seen outside of a syndrome predisposing to endocrine tumors.
Case presentation
F.L., a 33-year-old woman followed for end-stage renal failure, during her follow-up hyperparathyroidism was discovered without any idea of the culprit and the victim: is the renal failure secondary to hyperparathyroidism or the other way around? The patient presented with severe headaches and bilateral blindness, an MRI of the pituitary was requested showing a pathological process of the base of the skull measuring 41 * 36.5 * 31 compressing the optic chiasm, and a biological assessment was performed with a prolactin level of 600 ng/ml. The diagnosis of prolactinoma was retained.
Discussion
MEN1 is an autosomal dominant disease due to a mutation of the MEN1 gene which codes for menin. Patients with MEN1 syndrome have endocrine (parathyroid, entero-pancreatic) and non-endocrine tumors (lipomas, angiofibromas, collagenomas, etc.). Primary Hyperparathyroidism is a common condition and less than 5% of cases are related to MEN1. It affects 90% of patients with MEN1, and Pituitary adenomas on the other hand affect about 40% of patients. These are often macroadenomas (85%). The predominant adenomas are prolactin adenomas (about 60%), and it is more voluminous than sporadic adenomas. Pancreatic involvement affects 75-90% of MEN1 carriers (multiple gastrinomas, multifocal insulinomas).
Conclusion
In our case, it is difficult to decide whether the association of prolactinoma and hyperparathyroidism is fortuitous or within the context of MEN1, especially since the primary origin of hyperparathyroidism cannot be confirmed.

Obesity, insulin resistance and hyperandrogenism are implicated in the progression of liver stiffness (LS) in women with PCOS

Aikaterini Stefanaki[1], Dimitrios Karagiannakis[2], Georgios Georgiopoulos[1], Lina Michala[3], Ioannis Ilias[4], Jiannis Vlachogiannakos[2], George Papatheodoridis[2] & George Mastorakos[5]
[1]Alexandra General Hospital, Athens, Greece., Department of Clinical Therapeutics, School of Medicine, National and Kapodistrian University of Athens, Greece; [2]Laiko General Hospital, Medical School, National and Kapodistrian University of Athens, Academic Department of Gastroenterology, Greece; [3]Alexandra General Hospital, Athens, Greece., 1st Department of Obstetrics and Gynecology, School of Medicine, National and Kapodistrian University of Athens, Greece; [4]Elena Venizelou General Hospital, Athens, Greece., Department of Endocrinology, Diabetes and Metabolism, Athens, Greece; [5]ARETAIEION Hospital, School of Medicine, National and Kapodistrian University of Athens, Greece, Unit of Endocrinology, Diabetes Mellitus and Metabolism, Athens, Greece

Introduction
Non-alcoholic fatty liver disease (NAFLD) has become the leading cause of chronic liver disorders in Western countries, encompassing a spectrum of diseases ranging from simple steatosis to liver fibrosis and cirrhosis. Polycystic Ovary Syndrome (PCOS), the most common endocrine disorder of women during the reproductive period, is often implicated with NAFLD.
Aim
To investigate the potential involvement of PCOS on the aggravation of NAFLD by investigating the associations among insulin resistance (IR) or hyperandrogenism with the degree of liver fibrosis as expressed by liver stiffness (LS) and specific markers (hepatokines).
Methods
Forty-nine women with PCOS (based on the National Institutes of Health criteria) and 32 age- and BMI- matched healthy controls were included. IR was defined by the AUC-GLU, AUC-INS, HOMA-IR, QUICKI and FIRST-SECOND PHIS calculated from oral glucose tolerance tests. Hepatokines (fetuin-A, adiponectin, FGF-21) were measured. LS was assessed by Transient Elastography.
Results
For all participants, median age was 27 (range: 20-35) years, median BMI was 25 (19-35.2) kg/m^2 and median waist circumference (WC) was 94 (60-125) cm. All patients with PCOS had statistically significant greater LS values compared to controls (6.1 ± 0.9 vs 5.5 ± 0.9 kPa; $P=0.05$). According to BMI, patients and controls were subdivided in normal-weight controls ($n=14$; 17.3%), overweight controls ($n=18$; 22.2%), normal-weight PCOS ($n=26$; 32.1%) and overweight PCOS ($n=23$; 28.4%). Regarding LS, normal-weight PCOS, overweight controls and overweight PCOS, all had statistically significant greater LS values compared to normal-weight controls (5.5 ± 0.9, 6 ± 0.5, 6.2 ± 0.8 vs 4.7 ± 0.7 kPa, respectively; $P< 0.05$ for each comparison), whereas LS values were significantly greater in overweight PCOS compared to normal-weight PCOS (6.2 ± 0.8 vs 5.5 ± 0.9 kPa; $P< 0.05$). Statistically significant correlation was found between LS values and $\Delta4\alpha$ ($r=0.242$, $P=0.03$), but not with testosterone concentrations. Regarding LS and IR markers, statistically significant correlations were found in overweight PCOS between LS and AUC GLUC ($r=0.517$ $P=0.07$); in normal-weight controls between LS and adiponectin ($r=-0.537$, $P=0.05$), and in overweight controls between LS and HOMA IR, QUICKI, FIRST PHIS, SECOND PHIS, AUC INS, and adiponectin, respectively ($r=0.743$ $P=0.001$, $r=0.727$ $P=0.001$, $r=0.504$ $P=0.03$, $r=0.510$ $P=0.03$, $r=0.475$ $P=0.05$, $r=-0.646$ $P=0.04$, respectively).
Conclusions
PCOS and obesity are related to development of LS. The role of IR seems pivotal in the development of LS, whereas that of hyperandrogenism seems moderate. Interestingly, it appears that the co-existence of PCOS and obesity potentially promote more intensely the progression of LS.

Morphofunctional and receptor status of endometrium in women with autoimmune thyroid diseases and pregnancy loss

Ksenia Fris[1,2], Elena Andreeva[1] & Nadezhda Platonova[1]
[1]Endocrinology Research Centre, Department of Endocrinology, Moscow, Russia; [2]Endocrinology Research Centre, Gynecological Endocrinology, Moscow, Russia

Objective
To determine the incidence of endometrium pathology in women with autoimmune thyroid pathology and history of reproductive losses, including an assessment of histological images and immunohistochemical (IHC) analysis of the endometrial receptor status.
Materials and methods
A prospective cohort study included a clinical and instrumental examination of 84 women aged 18 to 45 years with a history of 1 to 3 consecutive pregnancy losses. Patients were divided into 3 main groups: I - with primary hypothyroidism due to autoimmune thyroiditis (AITD) during drug treatment, II-euthyroid women with increased thyroid peroxidase antibody positive (TPOAb$^+$) titers, III- without thyroid dysfunction. The control group – IV($n=21$) consisted of women who have previously given birth and were planning pregnancy. To perform immunomorphological evaluation, we studied the results of endometrium biopsy, obtained using an aspiration curette (Pipelle) during the luteal phase of the menstrual cycle. As the second step, we used IHC analysis to evaluate the expression of steroid receptors (ERα, PR) in endometrial tissue.
Results
The study of endometrium aspiration biopsy identified high incidence of endometrium pathology in the main groups. In group I, the frequency of luteal phase insufficiency ($P=0.014$) was statistically significant in the context of unchanged progesterone serum level. IHC analysis found reduced expression of ERα in the stromal epithelium and glands in groups I and II as compared to group III ($P< 0.05$) and group IV ($P< 0.05$). Reduced indicators of PR expression were identified in stroma and glands in group I in comparison to other groups ($P< 0.05$).
Conclusions
Morphological changes of the endometrium and impairment of its receptor apparatus in women with either primary hypothyroidism due to AITD or with increased titers TPOAb$^+$ are a basis for considering this category of women high risk for an unfavorable outcome of pregnancy and for determining the appropriateness of their examination at the pregravid stage.
Key Words: pregnancy loss, autoimmune thyroiditis, immunihistochemical analysis, steroid receptors, ERα, PR.

DOI: 10.1530/endoabs.90.EP904

EP905

Olfactory bulbs and genetic defects in adolescents with Kallmann syndrome and normosmic hypogonadotropic hypogonadism

Igor Chugunov, Kristina Kokoreva, Viktoriya Vladimirova & Olga Bezlepkina
Endocrinology Research Centre, Moscow, Russia

Objective
To assess olfactory bulbs sizes and define the most common molecular defects in adolescents with congenital isolated hypogonadotropic hypogonadism.
Materials and Methods
Single-centre comparative study. 36 patients were included. The main group consisted of 21 patients with mean age of 15.9 years (17 boys, 4 girls) with congenital isolated hypogonadotropic hypogonadism (IHH): 13 - with Kallmann syndrome (KS), 8 – with normosmic isolated hypogonadotropic hypogonadism (nIHH). Kallmann syndrome was diagnosed due to complaints of hypo/anosmia. Olfactory bulbs width and height were assessed via MRI. Molecular-genetic studies were provided in all patients from main group. 15 patients were enrolled as controls (6 girls, 9 boys). Groups were matched for age, height and weight.
Results
Olfactory bulb malforrmations were founded in 20 out of 21 patients: bilateral olfactory bulb hypoplasia was diagnosed in 7, bilateral aplasia – in 4, unilateral hypoplasia – in 6, unilateral aplasia -2, aplasia of the one bulb and hypoplasia of another - 1. Olfactory bulb defects were found in 7 out of 8 nIHH children with no complains of hypo/anosmia. Height and width of olfactory bulbs were significantly smaller in main group in comparison with controls ($P< 0.05$ via Mann–Whitney U test). Median of right bulb height was 1.0 mm [0.2;1.2] in patients from the main group vs. 3.0 [2.5;3.2] in control group. Median of right bulb width was 1,0 mm [0.2;1.7] in patients from the main group vs. 2.5 [2.0;3.0] in control. Median of left olfactory bulb height was 0.8 mm [0.0;1.1] in main group vs. 3.0 [2.7;3.2] in controls. Median of left olfactory bulb width was 0.4 mm [0.0;1.1] in main group vs. 2.5 [2.0;3.0] in comparison with control group. There were no statistically significant differences in olfactory bulb sizes between patients with KS and nIHH ($P> 0.05$). Molecular defects were identified in 9 patients: defects in FGFR1 were found in 4 out of 9 patients, CHD7 - 3, KAL1-1, FGF17 - 1. 5 defects were identified as variants of uncertain significance, 2 as likely pathogenic and 2 as pathogenic.
Conclusion
Bilateral olfactory bulb hypoplasia is a reliable sign of hypogonadotropic hypogonadism: it was identified in every third adolescent with congenital IHH. All pathogenic genetic variants were in FGFR1 and were associated with

uni/bilateral olfactory bulbs hypoplasia. Normal sense of smell doesn't rule out olfactory bulbs defects.

Individuals treated for gender dysphoria with medical and/or surgical transition who subsequently detransitioned: a survey of 7 detransitioners

Emilia Gomez Hoyos[1], Esther Delgado Garcia[1], Cristina Mercedes Catalina Fernandez[2], Carmen Rodriguez Fernandez[2], Maria Antonia Maniega Rubio[2], Laura Cuadrado Clemente[3], Rebeca Jimenez Sahagun[1], Maria Jose Bartolome Albistegui[4], Ana Ortolá Buigues[1] & Daniel De Luis Roman[1]
[1]Hospital Clinico Universitario de Valladolid, Endocrinology and Nutrition, Valladolid, Spain; [2]Hospital Clinico Universitario de Valladolid, Mental Health, Valladolid, Spain; [3]Hospital Universitario Doctor Peset, Endocrinology, Spain; [4]Hospital Clinico Universitario de Valladolid, Pediatrics, Valladolid, Spain

Introduction
Detransition is the act of stopping or reversing a gender medical, social or surgical transition. The study's purpose was to describe our experience with a group of transsexual people in detransition phase.
Material and methods
A cohort of 204 people with gender incongruence attending the Identity Gender Unit Hospital Clinico of Valladolid from January 2014 to December 2022 was studied. Seven of those participants detransitioned and were asked for their reasons, gender identity in detransition phase, and which social, medical, and surgical steps they took to detransition.
Results
Seven detransitioners were natal male. At the beginning of the detransition the age was 24[14-43] years and at started transition was 17[15-19] years. They remained transicioned for a duration of 2 [1-29] years. Most (6/7) had transitioned both medically and socially. Three also had surgical transition (mammoplasty). Mental health diagnoses before the onset of transition was: Anxiety (1/7), Eating disorders (1/7), Autism spectrum disorders (2/7). The mayority (4/7) received an adequate evaluation from mental health professional before starting transition and psychological support during transition. Reasons for destransition included: change in gender identity (3/7), satisfied (1/7) and dissatisfied (1/7) by the physical results of the transition, exploring alternative non-medicalised ways of living their identities and bodies (2/7). Nearly all participants medically detransitioned by ceasing cross-sex hormones (6/7). At the time of detransition 4/7 maintain a female gender identity and reports no gender dysphoria. Only two detransitioners were dissatisfied with their decision to transition and five were satisfied with their decision to detransition.
Conclusion
There are many different reasons and experiences leading to detransition. Medical detransition following the reaffirmation of a transgender identity is not uncommon. Comprehensive care by a multidisciplinary and experienced team is essential.

Synergy between vitamin D and estradiol in PCOS patients affected by COVID-19 infection

Zelija Velija Asimi[1,2], Dzevad Hajrovic[1], Selma Behmen[1] & Azra Burekovic[3]
[1]UniMed - University Polyclinic, Sarajevo, Bosnia and Herzegovina; [2]Sarajevo School of Science and Technology, Sarajevo Medical School, Ilidža, Bosnia and Herzegovina; [3]Sarajevo University Clinical Center, Sarajevo, Bosnia and Herzegovina

Introduction
Polycystic ovary syndrome (PCOS) affects 5-10% of reproductive aged women. PCOS also manifests a chronic pro-inflammatory state. Estradiol is known to modulate the actions of immune cells, and, therefore, the antiviral mechanisms of these cells could also be modified by this hormone stimulus. In the presence of vitamin D, the binding energy of the spike protein to ACE2 was increased and transferring Apo to Locked S conformer of spike trimer was facilitated. Together, the interaction between spike protein and ACE2 can be disrupted by vitamin D. Potential use of estradiol and vitamin D to reduce virus invasion and replication needs clinical investigation.
Aim
To evaluate the relation between vitamin D and estrogen in PCOS women affected by COVID-19 infection.
Methods
A cohort observational study was conducted. Of the total of 283 PCOS women, 129 affected by COVID-19 infection between March 1, 2021. to June 30, 2022. Ninety-two of them were included in the study. Inclusion criteria were no supplementation with Vitamin D and estrogen, and SARS-CoV-2 test positive. The control group involved 59 PCOS patients not affected by COVID-19. Serum 25-hydroxyvitamin D (vitamin D), C-reactive protein (CRP), erythrocyte sedimentation rate (ESR), lipid profile, fasting serum glucose, basal insulin, homeostasis model analysis of insulin resistance index (HOMA-IR), TSH, PRl, FSH, LH, 17β-estradiol, and total testosterone were determined. The main outcome were Vitamin D and estradiol levels in PCOS patients with COVID-19 infection compared to women without COVID-19 infection, categorized into mild, moderate, or severe infection according to WHO classification.
Results
After adjusting for age, BMI, insulin resistance and smoking status we found an association between low estradiol and vitamin D, and risks for COVID-19 adverse outcomes. In the fully adjusted model, PCOS women with low vitamin D and low estradiol had a 22% increased risk of COVID-19 (HR: 1.25 (1.05-1.46), $P = 0.01$).
In conclusion
It is tempting to hypothesize that the synergy between vitamin D and sex hormones could contribute to the COVID-19 outcome in PCOS patients.

Assessment of Social Functioning in People with Female-to-Male Gender Dysphoria

Emre Durcan[1], Senol Turan[2], Selver Yaylamaz[1], Basak Ecem Bircan[1], Yasin Kavla[2], Serdar Sahin[1], Cem Sulu[1], Sabriye Sibel Taze[2], Hande Mefkure Ozkaya[1] & Pinar Kadioglu[1]
[1]Istanbul University-Cerrahpasa, Cerrahpasa Medical School, Division of Endocrinology and Metabolism, Department of Internal Medicine, Turkey; [2]Istanbul University-Cerrahpasa, Cerrahpasa Medical School, Department of Psychiatry, Turkey

Background/Aim
In literature, many previous studies adressed that Gender-affirmig Hormone Therapy (GAHT) improves the factors affecting social functioning such as self-esteem, mental well-being, behavioral health and quality of life. In this study, we aimed to quantitatively evaluate the effects of the GAHT on social functioning using a psychiatric scale in people with female-to-male (FtM) in Türkiye.
Methods
The single center, cross-sectional study included 77 people with FtM Gender Dysphoria (GD) who were followed-up with for GAT at the Psychiatry or Endocrinology, Metabolism and Diabetes outpatient clinics, between January and April 2022. The sociodemographic data form and Social Functioning Scale (SFS) were used. Informed consent was obtained from all individual participants included in the study. Statistical analyses were performed using the Statistical Package for the Social Sciences (SPSS) software (version 21.0).
Results
We examined a total of 77 people with FtM; 41 had received GAHT and 36 had not received GAHT with a mean age of 24.7 $\pm$ 4.5 years. In people with FtM who received GAHT, 75.6% had received hormone therapy under the supervision of a doctor and the median duration of the hormone therapy was 12 (IQR = 5-36) months. When the SFS scores are evaluated from the point of GAHT, people with FtM who received hormone therapy had more social functioning than those who did not, with regard to the SFS total ($P = 0.01$), social engagement/withdrawal ($P = 0.001$), interpersonal behavior ($P = 0.002$) and pro-social activities ($P = 0.027$) subscales scores. On the other hand, people with FtM who undergone bilateral mastectomy had higher scale scores that predicted more social functioning than those had not. Finally, the SFS total ($r = 0.272$, $P = 0.017$), pro-social activities ($r = 0.239$, $P = 0.036$) and recreation ($r = 0.236$, $P = 0.039$) subscales scores were positively correlated with real-life experience in people with FtM.
Conclusions
The findings of our study indicate that people with FtM GD receiving GAHT and/or undergoing bilateral mastectomy have a significantly increased social functioning. As expected, it can be said that the real-life experience is effective on social functioning in these people.

Dose-related risk of hypertension development in young female transgender patients treated with cyproterone acetate

Alba Hernandez-Lazaro[1], Borja Santana Ojeda[1], Carlos Rios-Gomez[1], Ricardo Jose de Leon-Durango[1], Claudia Arnas-Leon[1,2], Carmen Acosta-Calero[3], Agnieszka Kuzior[2], Maria del Pino Perez-Garcia[1], Maria del Sol Sanchez-Bacaicoa[1] & Francisco Javier Martinez Martin[1,2]
[1]Hospital Universitario de Gran Canaria Dr. Negrín, Endocrinology & Nutrition, Las Palmas de Gran Canaria, Spain; [2]Hospitales Universitarios San Roque, Endocrinology & Nutrition, Las Palmas de Gran Canaria, Spain; [3]Hospital Universitario de Gran Canaria Dr. Negrín, Cardiology, Las Palmas de Gran Canaria, Spain

Introduction
We have recently reported that the use of cyproterone acetate (CPA) is associated with a highly significant increase of the risk of hypertension development after 5 years (adjusted hazard ratio 0.227, $P < 0.001$) in young transgender women. Due to the risks associated with the prolonged use of CPA (including the development of meningioma), the EMA presently recommends avoiding the use of doses > 10 mg CPA daily if possible. In fact, acceptable efficacy for androgen blockade in female transgender people has been reported with doses as low as 10 mg daily, but in our country the only available presentation is a 50 mg pill and dosages < 25 mg daily are impractical, while the standard protocols recommend doses up to 100 mg daily, depending on the clinical and analytical results.
Methods
Retrospective review of the clinical records of the transgender women < 30 years old, treated with CPA plus estradiol and followed for 5 years, stratified according to their cumulative dosage of CPA:
- A: up to 6500 mg (mean up to 25 mg/day)
- B: 6501 to 13000 mg (mean >25 -50 mg/day)
- C: 13001 to 18500 mg (mean >50-75 mg/day)
- D: 18501 to 26000 mg (mean >75-100 mg/day)

Hypertension was diagnosed when a repeated clinical sitting BP ≥ 140/90 mmHg or ambulatory (ABPM or systematic HBPM) ≥ 135/85 mmHg was present in a previously normotensive patient. All patients gave their informed consent.
Results
Data from 56 transgender women continuously treated with CPA + estradiol for at least 5 years were obtained. The adjusted yearly hypertension incidence was 4.96% vs. 0.98% in women treated with estradiol without androgen blockade. There were 6/25/18/7 patients in the strata A/B/C/D and their adjusted yearly hypertension incidence was 2.3%/4.2%/5.9%/7.6% ($P < 0.001$ for the difference).
Conclusions
There is a clear-cut dose dependence in the development of hypertension associated with CPA + estrogen treatment in young transgender women. However, even relatively low (up to 25 mg/day) dosages of CPA are apparently associated with significantly increased risk of hypertension development. Considering also other risks associated to the CPA plus estradiol combination (meningioma, obesity, depression, low libido, liver toxicity, thrombophilia, hyperprolactinemia...), we conclude that the use for this indication should be reconsidered. We cannot however exclude that very low dosages, in the order of 10 mg/day, may be safe for hypertension development.

Undercarboxylated Osteocalcin/GPRC6A: A Bone Testis Crosstalk

Kenda Jawich[1], Luca De Toni[2], Sahar Al-Fahoum[3], Marwan AHalabi[3], Andrea Dinisio[2], Maria Santa Rocca[2] & Alberto Ferlin[2]
[1]Faculty of Pharmacy, Damascus University, Department of Biochemistry and Microbiology, Damascus, Syria; [2]University of Padova, Andrology, Padua, Italy; [3]Damascus University, Department of Biochemistry and Microbiology, Damascus, Syria

Purpose
Undercarboxylated-Osteocalcin (ucOCN), acting on its putative receptor GPRC6A, was shown to stimulate of testosterone (T) production by Leydig cells in rodents, in parallel with the hypothalamus-pituitary-gonadal axis (HPG) mediated by luteinizing hormone (LH). The aim of this cross-sectional study is to evaluate the association among serum ucOCN, *rs2247911* polymorphism of GPRC6A gene and the endocrine/reproductive pattern in a cohort of infertile males, possibly identifying an involvement of the ucOCN-GPRC6A axis on testis function.
Methods
172 males, including 74 oligozoospermic, 58 azoosperminc patients and 58 normozoospermic controls, were prospectively recruited at the Orient Hospital for Infertility, Assisted Reproduction and Genetics in Syria (Study N. 18FP), from July 2018 to June 2020. Outpatient evaluation included the clinical history and anthropometrics and a fasting blood sampling for hormonals, serum OCN (both carboxylated and undercarboxylated), glycemic and lipid profile and screening for *rs2247911* GPRC6A gene polymorphism.
Results
Higher serum ucOCN associated with higher T and HDL-cholesterol (respectively: $r = 0.309$, $P < 0.001$ and $r = 0.248$, $P = 0.001$), and with lower FSH ($r = -0.327$, $P < 0.001$) and LDL-cholesterol ($r = -0.171$; $P = 0.018$). Patients bearing the GG genotype of *rs2247911* had higher sperm coung compared to GA genotype ($P = 0.043$) and, compared to both AG and AA genotypes, higher serum T ($P = 0.004$, $P = 0.001$) and lower triglycerides levels ($P = 0.002$, $P < 0.001$). Upon normalization for LH levels and body mass index, *rs2274911* and ucOCN were significantly associated with higher serum T at linear stepwise regression analysis ($P = 0.013$, $P = 0.007$).
Conclusions
Our data suggest the involvement of ucOCN-GPRC6A axis in the regulation of T production by the testis complementary to HPG.

Position and Characteristics of adolescents diagnosed as PCOS under the original Rotterdam criteria but excluded under the 2018 updated guideline

Jinju Kim[1,2], Kyu Ri Hwang[2,3], Sunmie Kim[1,2] & Young Min Choi[4,5]
[1]Healthcare System Gangnam Center, Seoul National University Hospital, Obstetrics and Gynecology, Seoul, South Korea; [2]Seoul National University College of Medicine, Obstetrics and Gynecology, Seoul, South Korea; [3]SMG-SNU Boramae Medical Center, Obstetrics and Gynecology, Seoul, South Korea; [4]Grace Hospital, Obstetrics and Gynecology, Goyang, South Korea; [5]Seoul National University College of Medicine, The Institute of Reproductive Medicine and Population, Medical Research Center, Seoul, South Korea

Background and Aims
Polycystic ovary syndrome (PCOS) usually develop symptoms during adolescence. However, diagnosis in adolescents is challenging because physiologic development overlap typical manifestation of PCOS. Recently, an international evidence-based PCOS guideline development group recommended that ultrasound should not be used for the diagnosis of PCOS in those with a gynecological age of < 8 years. Thus, girls with irregular menstruation (IM)/PCO or hyperandrogenism (HA)/PCO cannot be diagnosed as PCOS if they do not pass 8 years since menarche. This study aimed to investigate the characteristics of these excluded girls.
Methods
We included subjects who were between 2- 8 years since menarche. Adolescent PCOS ($n = 315$) was diagnosed according to the 2003 Rotterdam criteria like adults. A total of 428 girls served as controls.
Results
In 315 girls with PCOS, numbers of the IM/HA/PCO, IM/HA, HA/PCO and IM/PCO phenotypes were 206 (65.4%), 30 (9.5%), 12 (3.8%) and 67 (21.3%), respectively. According to the 2018 guideline, 79 girls (25.1%) with HA/PCO (15.2%) or IM/PCO (84.8%) phenotypes are not diagnosed as PCOS. These girls who had changes in diagnostic status were designated as “increased risk” group. As expected, PCOS group showed the worst metabolic profiles (degree of generalized and central obesity and frequency of IR, prediabetes or diabetes and metabolic syndrome) and a higher hirsutism score than those of the other two groups. About 90% of the “increased risk” group were lean, which was similar to the controls. However, they showed worse metabolic profiles (mean BP, TG, fasting insulin and HOMA-IR levels) than did the controls, but showed similarly elevated profiles with those of PCOS. The “increased risk” group showed similarly elevated serum LH levels and LH/FSH with those of the PCOS.
Conclusions
One-fourth of the adolescent girls who were diagnosed as PCOS based on the original Rotterdam criteria were excluded from the diagnosis of PCOS using the 2018 guideline. Although these ‘increased risk’ girls do not fulfil the diagnostic criteria of PCOS, they visited hospital due to menstrual abnormality or hyperandrogenic symptoms, and showed significantly worse metabolic and androgenic profiles than did controls. And they shared considerable metabolic and hormonal features with PCOS. About 90% of ‘increased risk’ girls were lean, but they were not metabolically reassuring group. A practical approach to them would involve controlling symptoms and regularly evaluating them regarding newly-developed or worsening PCOS-related symptoms or metabolic abnormalities.

Quantification of miRNAs (miR4743-5p, miR149-5p, and miR331-5p) in the placenta of south Indian pregnant women with Early and Late onset of Preeclampsia

Ramesh Bangaraiahgari[1], Rajesh Bangaraiahgari Bangaraiahgari[2], Ramakanth Bhargav Panchangam Panchangam[3], Udaya Kumar N Nelagiri[4], Srinivas Vudathala[5], Vinaya Vijayan[6], Rajkiran Reddy Banala[7] & Chakrapani Bangaraiahgari[8]
[1]Arundathi Institute of Medical Sciences, Biochemistry, Hyderabad, India; [2]Arundathi Institute of Medical Sciences, Anatomy, Hyderabad, India; [3]Bhargav Endocare Hospital, Endocrine and Metabolic Surgery, India; [4]Arundathi Institute of Medical Sciences, Pediatrics, Hyderabad, India; [5]Arundathi Institute of Medical Sciences, CRl, Hyderabad, India; [6]Apollo Institute of Medical Sciences and Research, Physiology, Hyderabad, India; [7]Sunshine Hospital, R&D, Hyderabad, India; [8]Chakri Neuro Hospital, Neurology, Nizamabad, India

Background
Preeclampsia (PE) is a multifactorial and multisystem disorder, with unknown pathophysiology, but factors such as defective trophoblast invasion and narrowing of spiral arteries may be contributing to the onset of PE and affecting mother and foetus development. Early prediction of PE may improve the surveillance and prognosis of hypertension in pregnant women in preventing associated complications. Therefore, it is essential to find markers for the detection of PE in the pre-symptomatic stage and miRNA can be considered as biomarkers for early diagnosis.
Objectives
To create complete profile of miRNA with the help of next-generation sequencing in placental tissues collected from Early Onset of Preeclampsia (EOPE; $<$ 34 weeks) and Late Onset of Preeclampsia (LOPE; $\geq$34 weeks) patients and for the identification potential biomarkers playing a role in aberrant placental development and to understand the pathophysiology of PE. Placental tissues were collected from three patient groups (Control [n = 30], EOPE [n = 30], and LOPE [n = 30]) and performed miRNA profiling by Illumina sequencing, downstream analysis for identification, quantification and expression profiling is done by the quantifier.pl script and miRDeep2.pl script.
Outcome measures
Sequence analysis showed novel miRNAs that were disease-specific and common among all studied groups, suggesting the underlying placental pathologies in EOPE and LOPE.
Results
The real-time PCR analysis of 3 miRNAs (miR4743-5p, miR149-5p, and miR331-5p) was done and observed differential expression in all three patient groups. miRNA4743-5p was found to be significantly expressed EOPE when compared to control and LOPE samples. Similarly, expression of miR331-5p was significant in LOPE samples as compared to other groups and the expression of miR149-5p was only observed in control group.
Conclusion
The integrative expression analysis of these 3 miRNAs (miR4743-5p, miR149-5p, and miR331-5p) have given a hope for early diagnosis of PE and associated complications in pregnant women.

Association between circulating adiponectin levels and androgen excess in polycystic ovarian syndrome

Valentina Soldat Stankovic[1,2], Sinisa Stankovic[3], Snjezana Popovic Pejicic[1], Tamara Dojcinovic[1,2], Jelena Malinovic Pancic[1,2], Gabrijela Malesevic[1,2] & Djuro P. Macut[4]
[1]Faculty of Medicine, University of Banja Luka, Internal Medicine, Banja Luka, Bosnia and Herzegovina; [2]University Clinical Centre of the Republika Srpska, Endocrinology, Banja Luka, Bosnia and Herzegovina; [3]Faculty of medicine, University of Banja Luka, Nuclear Medicine, Banja Luka, Bosnia and Herzegovina; [4]University of Belgrade - Faculty of Medicine, Endocrinology, Beograd, Serbia

Background
Low adiponectin levels in polycystic ovarian syndrome (PCOS) have been largely attributed to obesity which is common among these patients. In addition, evidence also suggests that low adiponectin in PCOS may be related to androgen excess in these women. Therefore, the aim of the present study was to examine the association of adiponectin levels and androgens in women with PCOS.
Methods
A total of 60 women with PCOS who met the 2003 Rotterdam diagnostic criteria and 60 age and body mass index matched controls without PCOS were recruited. We determined anthropometric parameters, metabolic and endocrine indicators, serum adiponectin, and inflammatory markers, and statistically analyzed the results.
Results
PCOS women had significantly lower adiponectin level ($P<$ 0.01) compared to healthy women. The adiponectin level correlated inversely with body mass index (BMI), waist circumference (WC), body fat mass, tryglicerides, homeostasis model assessment HOMA IR, $AUC_{insulin}$, $AUC_{glucose}$, total testosterone, dehydroepian-drosterone sulfate (DHEAS) and free androgen index (FAI) and positively with sex hormone-binding globulin (SHBG) and high-density lipoprotein cholesterol (HDL) in the PCOS group. In multivariate logistic regression, BMI and FAI were significant independent determinants of adiponectin cut-off level of 7.7μg/ml.
Conclusions
In conclusion, our results confirm that adiponectin concentrations change according to variations of BMI in women with PCOS. They also suggest the role of androgen excess in obesity and adipose tissue dysfunction in PCOS women

Kisspeptin Levels in Different Polycystic Ovary Syndrome (PCOS) Phenotypes

Presiyana Nyagolova[1], Mitko Mitkov[1], Maria Orbetzova[1] & Dora Terzieva[2]
[1]Medical University Plovdiv, Endocrinology and Metabolic Diseases, Plovdiv, Bulgaria; [2]Medical University Plovdiv, Clinical Laboratory, Plovdiv, Bulgaria

Objective
To compare kisspeptin levels between different phenotypes of PCOS and to analyze the correlation between kisspeptin and PCOS-related hormonal and metabolic disturbances.
Patients and methods
The study included 87 women with PCOS, and a control group of 27 clinically healthy women, corresponding in age and BMI to the patients with PCOS. Circulating levels of luteinizing hormone (LH), follicle-stimulating hormone (FSH), testosterone (T), sex-hormone binding globulin (SHBG), thyroid stimulating hormone (TSH), prolactin, fasting insulin, dehydroepiandrosterone sulfate (DHEA-S) and kisspeptin were measured.
Results
There are 4 phenotypes in women with PCOS – A (oligoanovulation, hyperandrogenism and polycystic ovaries) (n=33), B (oligoanovulation and hyperandrogensim) (n=21), C (hyperandrogenism an polycystic ovaries) (n=19) и D (oligoanovulation and polycystic ovaries) (n=15). There were no significant differences in age (P=0.615) and BMI (P=0.223) between the 4 PCOS subgroups. We found difference in terms of BMI (p = 0.003) only between phenotype A and the control group. We did not find any significant difference between the four PCOS subgroups in terms of kisspeptin, LH, FSH, LH/FSH, E2, TSH, fasting insulin, and prolactin. T levels were significantly higher in phenotype A compared to phenotype D (P=0.028), and DHEA-S was significantly higher in phenotype B compared to phenotype D (P=0.045). In the PCOS group we found a positive correlation between kisspeptin and age (r= 0.250; P= 0.019), BMI (r= 0.259; P= 0.02), FAI (r= 0.354; P= 0.001), A4 (r= 0.435; $P<$ 0.001), fasting insulin (r= 0.299; P= 0.005), and negative one with SHBG (r= -0.319; P= 0.003), DHEA-S (r= -0.282; P= 0.008), PR(r= -0.249; P= 0.020).
Conclusions
Our results indicate that kisspeptin levels are comparable between different PCOS phenotypes and with the control group. Kisspeptin might be associated with metabolic disturbances in PCOS women.
Key Words
PCOS, phenotypes, kisspeptin

Genetic bases of hereditary gonadotropin-dependent precocious puberty

Anna Kolodkina, Dina Khabibullina, Olga Bezlepkina & Valentina Peterkova
Endocrinology Research Centre, Moscow, Russia

Background
Nowadays, single nucleotide polymorphisms in genes *KISS1, KISS1R, MKRN3, DLK1* have been described as the leading cause of precocious hypothalamic-pituitary axis activation in children. Genetic testing in patients with hereditary forms of precocious puberty (PP) can expand our knowledge in underlying molecular mechanisms of the disease. The diagnosis of genetic bases is necessary for genetic counselling.
Aim
To access clinical characteristics and define genetic defects in patients with hereditary forms of gonadotropin-dependent precocious puberty.
Materials and Methods
21 patients with positive family history were enrolled into the study: 8 patients were with paternal disease history, 6 – with maternal. 7 patients had siblings with diagnosed PP. The full-exome sequencing was conducted in all the patients.
Results
The median of patients age at the time of the examination was 7,2 years [6,5; 7,7]. Single nucleotide variants were identified in 13 (62%) of patients. *MKRN3* gene defects were the most common: 10 out of 13 patients had defect in this gene. The rest of the group had defects in genes associated with neuroontogenesis and neuroendocrine regulation mechanisms of hypothalamic-pituitary axis: *MAP-K8IP3* (OMIM no. 605431), *POU1F1* (OMIM no. 173110) and *NPFF1R* (OMIM no. 607448).
Conclusion
MKRN3 defects are the most common genetic cause of hereditary forms of gonadotropin-dependent PP which is consistent with worldwide data.

Coexistence of Turner syndrome and Rokitansky-Küster-Hauser

Faten Haj Kacem Akid, Oumeyma Trimeche, Mouna Mnif, Abdel Mouhaymen Missaoui, Dhoha Ben Salah, Mouna Elleuch, Mnif Fatma, Nadia Charfi, Nabila Rekik Majdoub & Mohamed Abid
Hedi Chaker Hospital, Endocrinology, Sfax, Tunisia

Introduction
Turner syndrome (TS) is a genetic condition, that results from the complete or partial loss of the second X chromosome in phenotypic females. Typically, patients with TS have growth retardation, altered pubertal development and facial dysmorphism. It's also associated with other comorbidities.
Aim
Here we report a rather rare finding which is the association of TS and Rokitansky-Küster Hauser (RKH) and we discuss the possible ethiopathogenic links between these two congenital conditions.
Case
A 16-year-old girl was referred to the Endocrinology department at the Hedi Chaker hospital in Sfax, Tunisia, for growth retardation and delayed puberty. Sha had no particular familiar nor personal medical history. She was the offspring of a consanguineous couple. On physical examination, she had a short height of 147 cm (-2 standard deviations), a normal weight of 54 kg (10^{th} percentile). She had dysmorphic features: Pterygium Colli and cubitus valgus. She also had café au lait spots disseminated all over her body. Additionally, she had a primary amenorrhea and pubertal delay as testified by the absence of secondary sexual characteristics at the age of 16. Hormonal evaluation revealed low estradiol (10 pg/ml) associated with high levels of FSH and LH: 107 mui/ml and 31 mui/ml, respectively, confirming thus the diagnosis of primary ovarian insufficiency. The karyotype confirmed our suspicion since it unveiled the presence of X monosmy. A pelvic ultrasound was also performed and since it showed the absence of ovarian structures as well as the absence of uterus, a pelvic MRI was carried out. This latter exam confirmed the absence of ovaries and uterus. However, it showed a normal aspect of vagina and the presence of feminine urethra. These imaging findings are attributable to RKH.
Conclusion
Although rare, RKH and TS can be associated. The coexistence of these two conditions further complicates the management of infertility in patients with TS.

Developmental neuro-toxicity evaluation of endocrine-disrupting chemical butylparaben

KangMin Kim, YongIn Kim & Eui-Bae Jeung
Chungbuk National University Gaesin Campus, Veterinary Medicine, Cheongju-si, South Korea

Butylparaben is an endocrine disrupting chemical (EDC) which is used as antimicrobial preservative in many cosmetic products. EDCs are structurally diverse class of synthetic and natural compounds. EDCs can cause non-communicable diseases such as obesity, type 2 diabetes, and neurodevelopmental disease. Present study investigated that whether exposure to butylparaben during maternal pregnancy could cause the offspring's neuronal development disorder. *In vitro* study butyl paraben promoted apoptosis and inhibited proliferation of Sox1-GFP cell. The mRNA expressions for ER stress were evaluated. Furthermore, *in vivo* study for developmental neuro toxicity test battery for butylparaben was carried out. Butylparaben 100 mg/kg, 50 mg/kg was treated for pregnant mouse from E10.5 to weaning period. The result of behavior test shows abnormal cognitive, social and anxiety like behavior in butyl paraben treated mice. *In vitro* study, ER stress genes was evaluated, BiP, CHOP, and AFT6 were significantly up-regulated following treatment with EDC. From these results, butylparaben is a potential neuro developmental toxicant.

Background
Non-classic adrenal hyperplasia (NCAH), comparatively a rare disease, is characterised by mild to moderate hyperandrogenemia, hirsutism, oligomenorrhea, insulin resistance which incidentally are the hallmarks of polycystic ovary syndrome (PCOS)- a common disorder among reproductive aged women. The data on 17-hydroxyprogesterone (17-OHP)serum levels in NCAH has been reported globally but there is limited data available regarding the normal range among healthy Indian reproductive age women.
Aim
We aimed to evaluate serum 17-OHP levels among healthy women of reproductive age from India as a reference range.
Materials and methods
A total of around 450women of reproductive age (18-40years) were recruited from different urban [$n=226$ (50.2%)]and rural[$n=224$ (49.8%)]regions of the country. The anthropometric, clinical and biochemical parameters were obtained using standard uniform questionnaire. The samples from all the subjects were collected during their follicular phase of menstrual cycle and assessment of 17-OHP was carried out using ELISA method (DiaMetra S.r.l., Segrate, Italy). The 95% of the reference distribution was estimated using 2.5^{th} - 97.5^{th}percentile limits.
Results
The mean $\pm$SD of age and body mass index (BMI) of participants was 30.12 $\pm$ 6.32years and 22.8 ± 3.36 kg/m^2 respectively. The age of menarche for the subjects was reported to be 13.05 ± 1.35years). The mean percentages of 17-OHP serum levels among recruited subjects were 0.49 ± 0.259ng/ml with the median of 0.49ng/ml and range between 0.0059–2.0 ng/ml. The 2.5^{th} - 97.5^{th}percentiles of 17-OHP among subjects at 2.5^{th}; 5^{th}; 10^{th}; 25^{th}; 50^{th}; 75^{th}; 90^{th}; $95^{th}$and 97.5^{th}were reported as 0.09; 0.959; 0.15; 0.30; 0.65; 0.85; 0.81; 0.85 and 1.19 respectively.

Conclusion
This study is first of its kind to collect a data from a large representative sample of reproductive age Indian women. The data will serve as a reference range among healthy women of reproductive age.

Serum AMH in women with polycystic ovary syndrome

Jinju Kim[1,2], Kyu Ri Hwang[2,3], Sunmie Kim[1,2] & Young Min Choi[4,5]
[1]Healthcare System Gangnam Center, Seoul National University Hospital, Obstetrics and Gynecology, Seoul, South Korea; [2]Seoul National University College of Medicine, Obstetrics and Gynecology, Seoul, South Korea; [3]SMG-SNU Boramae Medical Center, Obstetrics and Gynecology, Seuol, South Korea; [4]Grace Hospital, Obstetrics and Gynecology, Goyang, South Korea; [5]Seoul National University College of Medicine, The Institute of Reproductive Medicine and Population, Medical Research Center, Seoul, South Korea

Background and Aims
Anti-Müllerian hormone (AMH) is secreted by granulosa cells of ovarian follicles. Since AMH reflects the number of antral follicles and the pronounced androgen secretion from follicles/stroma in women with polycystic ovary syndrome (PCOS) remains until late reproductive age, the age related relationship between AMH in women with PCOS are of interest.
Methods
Women with PCOS (aged 15–42 years) ($n=537$) participated in the study. AMH level according to age groups were investigated. The relationships between AMH and androgenic, metabolic, hormonal and ovarian parameters were also studied. Finally, multiple regression analysis was done to evaluate determinants of serum AMH level in women with PCOS.
Results
From 537 women with PCOS, 375 patients showed clinical and/or biochemical hyperandrogenism, and the remaining 162 patients did not show. Mean serum AMH level was significantly higher in hyperandrogenic patients (10.38 ng/ml, 95% CI, 9.71 - 11.09) compared with that of non-hyperandrogenic ones (8.74 ng/ml, 95% CI 7.98 - 9.58) ($P=$ 0.004). Serum AMH levels showed no differences according to different age groups (Table 1) and remained stable throughout the ages (Figure 1). In Pearson's correlation analysis, serum AMH showed significant positive correlations with total testosterone, free testosterone, log free androgen index, androstenedione, DHEAS, LH levels, mean antral follicle number and ovarian volume. A multiple linear regression model was used to determine variables which were associated with AMH level. Age did not contribute significantly to the model. Only LH, total testosterone, and mean antral follicle number contributed significantly to serum AMH levels.
Conclusions
Serum AMH levels remained high until late reproductive age and did not show significant variation according to the age groups. Hyperandrogenic PCOS patients showed higher AMH levels than that of non-hyperandrogenic patients. LH, total testosterone, and antral follicle number were main contributors to serum AMH levels irrespective of age

Androgen insensitivity resulting in a disorder of gonadal development 46XY

Kaoutar El Moatamid, Talbi Dounia, Boutheina Mohamed Ali, Kaoutar Rifai, Hinde Iraqi & Mohamedelhassan Gharbi
Ibn Sina University Hospital, Endocrinology, Rabat, Morocco

Introduction
Androgen insensitivity syndrome (AIS) is a genetic sexual developmental disorder (DSD) inherited in an X-linked recessive mode, responsible for 30 to 70% of cases of DSD 46, XY. Androgen insensitivity can be complete (CAIS), partial (PAIS) or mild depending on the degree of receptor sensitivity to androgen stimulation
Case report
A 17-year-old female patient with a history of inguinal hernia operated in childhood who was admitted for exploration of primary amenorrhea. it presents clinically a female external genital phenotype with a male genotype. Hormonal investigations revealed high level of LH at 20.37 mui/ml, FSH at 5.88 mui/ml, high testosterone at 3.61 and low estradiol at 16pg/ml. Ultrasound and pelvic MRI showed two latero-vesical formations which could be related to male gonads. This was a complete androgen insensitivity for which a gonadectomy with estrogen-progestogen replacement therapy was made.
Discussion
CAIS is a rare entity; however, it is the most common cause of 46 XY DSD, accounting for 60% of cases. The experts recommend that a karyotype should be performed in any girl presenting an inguinal hernia. In rare cases, the diagnosis is made later in life when the patient presents an infertility or during adolescence which is the case for our patient. Ultrasound, plays an important role in the diagnosis; it confirms the absence of any uterine or ovarian structure and shows the testicles in a variable position. In our patient Ultrasound and pelvic MRI showed the absence of uterine structure with 2 laterovesical formations related to male gonads. A gonadectomy is often performed due to the risk of malignant degeneration of the ectopic testicles, followed by hormone replacement therapy
Conclusion
The diagnosis of AIS is a challenge for doctors; its management is complex and requires a multidisciplinary approach

Effects of Low-Carbohydrate Diet vs. Mediterranean Diet on Growth Factors in Women with PCOS: A Randomized Controlled Trial

Elena Vasukova[1], Ekaterina Zaikova[2], Olga Kalinina[2], Inga Gorelova[3], Irina Pyanova[1], Elena Bogatyreva[3], Elena Vasilieva[3], Maria Kokina[2], Elena Grineva[4] & Polina Popova[2]
[1]Almazov National Medical Research Centre, Research Laboratory of Endocrine Diseases in Pregnancy, Institute of Endocrinology, Saint Petersburg, Russia; [2]Almazov National Medical Research Centre, World-Class Research Center for Personalized Medicine, Saint Petersburg, Russia; [3]Almazov National Medical Research Centre, Saint Petersburg, Russia; [4]Almazov National Medical Research Centre, Endocrinology Institute, Saint Petersburg, Russia

Background
Polycystic ovary syndrome (PCOS) is the most common endocrine disorder in women of reproductive age. Ovarian fibrosis and altered angiogenesis have been discussed as important factors in the pathogenesis of PCOS. Lifestyle modification is the first step in the treatment of PCOS. However, a specific composition of diet that should be included in a lifestyle change program has not been determined.
The aim
Of the study was to compare the effects of low-carbohydrate diet (Low-Carb) and Mediterranean diet on the growth factors in women with PCOS.
Methods
62 patients with PCOS were randomized into two groups according to the recommended diet: Low-Carb ($n=32$) and Mediterranean ($n=30$). The study protocol is described at clinicaltrials.gov (NCT05272657). Fasting serum samples were collected at baseline and after 3 months of dieting. Seven growth factors were analyzed in the serum employing Luminex®xMAP™ (Merck, Germany): epidermal growth factor (EGF), fibroblast growth factor 2 (FGF2), fms-related tyrosine kinase 3 ligand (FLT3L), platelet-derived growth factor AA (PDGF-AA), platelet-derived growth factor AB/BB (PDGF AB/BB), vascular endothelial growth factor a (VEGF-a) and transforming growth factor a (TGF-a).
Results
The Mediterranean diet decreased the levels of FLT3(medians before and after diet were 13.2 and 10.3 pg/ml respectively, $P=$ 0.002), PDGF AA (5361 and 4660 pg/ml, $P<$ 0.001), PDGF AA/BB (46328 and 44910 pg/ml, $P=0.001$), TGF-a (10.8 and 10.5 pg/ml, $P=0.021$) and VEGF-a (275 and 228 pg/ml, $P=0.008$). The low carbohydrate diet, on the contrary, increased the levels of FLT3(10.7 and 12.4 pg/ml, $P<$ 0.001), PDGF AA/BB (47465 and 48404 pg/ml, $P=0.005$) and FGF 2 (59.4 and 60.7 pg/ml, $P=0.007$). When comparing the median changes between the two diets, the difference was significant for TGF-a ($P=0.010$), FLT3($P<$ 0.001), FGF2($P=0.001$), PDGF AA and PDGF AA/BB ($P<$ 0.001).
Conclusion
The Mediterranean diet reduced the levels of growth factors FLT3L, PDGF AA, PDGF AA/BB, TGF-a, VEGF-a, while the Low-Carb diet produced no changes in TGF-a, VEGF-a, EGF, PDGF AA and increased the levels of FLT3L, PDGF AA/BB and FGF 2.

Association of Bardet-Biedl syndrome with Differences of Sex Development and pituitary hypoplasia

Soraya Benammar Ammar, Nadjia Benabadji, Mohammed Mahieddine Benghani & Mohammed El Amine Amani
University Hospital Oran, Faculty of Medicine Oran, Algeria

Introduction
Bardet-Biedl syndrome (BBS) is a rare autosomal recessive genetic disorder involving hypogonadism manifested by cryptorchidism, micropenis and/or delayed puberty
Observation
We report the case of a 13 year old child, who was consulted for obesity and whose physical examination showed major signs of SBB: global obesity, polydactyly, learning difficulties and visual disorders. Genital examination revealed a 1 cm genital tubercle with a single orifice and two genital swelling without palpable gonads. Biological investigations revealed hypogonadotropic hypogonadism, corticotropic insufficiency, low AMH with a non-stimulable HCG test and a 46XY male karyotype. Pelvic MRI did not show any gonads or internal genitalia but noted ectopy and malrotation of the right kidney. The diagnosis of a testicular regression syndrome is very likely in this case. At the fundus photography: presence of bilateral retinal dystrophy with high myopia. At the hypothalamohypophyseal level: a strong pituitary hypoplasia was objectified.
Discussion
BBS is a rare autosomal recessive multisystem ciliopathy. The incidence of BBS is 1 in 150,000–160,000 in Europe and North America. BBS is caused by a dysfunction of the gene coding for proteins that are implicated in the function of the primary cilia and in important signaling pathways. The core features of the syndrome include retinal degeneration, obesity, polydactyly, cognitive impairment, renal anomalies and urogenital malformations. To date, pathogenic variants in 26 genes have been shown to be involved in the molecular basis of this rare ciliopathy. To our knowledge, only one study conducted on 11 children with BBS found among them 7 cases of pituitary abnormalities, 4 of which showed hypoplasia. While no association with a testicular regression syndrome has been described. This makes our patient the first described association of these 3 pathologies.

Response to Growth Hormone Therapy in A Patient with Williams-Beuren Syndrome

Sara Ragbi, Nassim Essabah Haraj, Siham El Aziz & Asma Chadli
Uhc Ibn Rochd, Endocrinology and Metabolic Disorders, Casablanca, Morocco

Introduction
Williams-Beuren syndrome (WBS) is a rare neurodevelopmental disorder with distinctive facial appearance, cardiovascular anomalies, impaired somatic growth and infantile hypercalcemia. Growth retardation is a common clinical feature in patients with Williams-Beuren syndrome. We report a boy with Williams-Beuren syndrome, who was found to have growth hormone deficiency and is responding well to growth hormone therapy
Observation
The patient is a 20 years old boy with consanguineous parents, born at term but we had no idea about his birth weight. He was referred to our hospital for hyperglycemia revealing diabetes. Clinical examination revealed a growth retardation, his length was 88 cm (below the 4rd percentile; SDS) and weight was 18 kg (3rd percentile), he had typical facial features including low nasal bridge, long philtrum, prominent lips with open mouth, peri-orbital fullness. On cardiological evaluation, ECG and cardiac echography revealed a normal cardiac anatomy and function without evidence of supravalvular aortic stenosis or peripheral pulmonary artery stenosis. Calcium levels were normal. Endocrine screening yielded a low IGF-I level (19.26 ng/ml) and a high TSH level of 500 mUI/l. Prolactin levels were elevated 118 ng/ml. Cortisol levels were normal. CT of the brain revealed a pituitary hypertrophy without clearly detectable circumscribed adenoma. Bone age according to Greulich and Pyle was of 1 year 6 months Treatment with human growth hormone (hGH) was started to which our patient responded well. Now, at the age of 22 years, his height is 106 cm (he gained 18 cm) but his weight is still 19 kg. Bone age increased and TSH levels are normal under treatment (levothyroxine 75 mg).
Conclusion
It is recommended to evaluate growth hormone IGF-I axis or at least screening by IGF-I measurements in all patients with this syndrome and short stature. GH deficiency might contribute to growth failure in patients with WBS. hGH therapy shows good response in these cases

Cytogenetic Study of Primary Ovarian Insufficiency: About 90 Cases

Salwa Ben Yahia, Lilia Kraoua, Hela Belil, Faouzi Maazoul & Ridha Mrad
Charles Nicolle Hospital, Department of Congenital and Hereditary Diseases, Tunis, Tunisia

Background
Primary Ovarian Insufficiency (POI) is defined as the loss of ovarian function before age 40. It is characterized by menstrual disturbance with raised gonadotropins (>25 UI/l). It can manifest as primary amenorrhea (PA) or secondary amenorrhea (SA). The causes of POI include chromosomal and genetic defects, autoimmune processes, chemotherapy, radiation, infections, and surgery. However, the etiology remains unidentified in 80% of cases referred to as idiopathic POI.
Material and Methods
We report the clinical and cytogenetic study of 90 patients diagnosed with POI, collected at the Department of Congenital and Hereditary Diseases of Charles Nicolle Hospital in Tunis (Tunisia) over a period of 7 years from January 2016 to December 2022. R-banded chromosome analysis on cultured peripheral blood lymphocytes was performed in all patients.
Results
The 90 patients were referred for PA (36/90), SA (19/90), POI (26/90), and spaniomenorrhea (9/90). Their average ages were 22.9 years (14-39 years), 22.9 years (17-36 years), 32.8 years (18-40 years), and 23.6 years (14-40 years), respectively. Hormonal assessment data reported in only 46 medical files (46/90) showed high levels of FSH (>25 UI/l) in the 46 patients. Pelvic imaging was performed for 33 patients (26 ultrasounds and 7 MRIs) and revealed anomalies in 17 patients consisting in the absence of uterus and/or vagina (4/17), non-visualized ovaries (10/17), or hypoplastic ovaries (3/17). Karyotype showed anomalies in 12 patients (13.3 %): a Turner syndrome in 8/12 patients due to monosomy X in 5/8 patients (mosaic 3/5, homogenous 2/5), mosaic Xq isochromosome in 2/8 patients, and a mosaic ring X chromosome in 1/8 patient, all of them having PA, a supernumerary marker chromosome in one patient with SA (1/12), a balanced translocation 46,X,t(X;17)(q21.3;q22) in one patient with SA (1/12) and 46,XY Karyotype in two patients with female phenotype, gonadal dysgenesis and PA(2/12).
Conclusion
These results are consistent with those reported in the literature. Indeed, in our study, chromosomal anomalies were responsible for 13.3% of POI cases vs 10-13% in the literature, the majority of which are X chromosome abnormalities. According to this high rate of chromosomal abnormalities, the karyotype must be performed for all patients with non-iatrogenic POI as recommended by the European Society of Human Reproduction and Embryology (ESHRE,2015).

Serum AMH levels and insulin resistance in women with Hashimoto thyroiditis

Agnieszka Adamska[1], Angelika Buczyńska[2], Marta Olszewska[1], Justyna Łapińska[1], Aleksandra Łobacz[2], Katarzyna Winnicka[1], Katarzyna Siewko[1], Anna Popławska-Kita[1] & Adam Krętowski[1,2]
[1]Medical University of Białystok, Department of Endocrinology, Diabetology and Internal Medicine, Białystok, Poland; [2]Medical University of Białystok, Clinical Research Centre, Białystok, Poland

Objective
Women with Hashimoto thyroiditis (HT) could have fertility problems. Serum anti-Müllerian hormone (AMH), which reflects functional ovarian reserve, is decreased in women with HT. The aim of the present study was to investigate the relation between serum levels of AMH and insulin resistance in women with HT compared to control group.
Patients and methods
We examined 193 women: 37 subjects with HT, without previous history of treatment with L-thyroxin, and 156 control women. Serum concentrations of AMH, TSH, thyroid hormones, insulin, glucose, HbA1c, lipids were assessed. HOMA-IR was calculated.

Results
We did not observed differences in serum concentration of AMH in women with HT in comparison to the control group ($P=0.26$). We also did not noticed differences in serum levels of TSH, thyroid hormones, glucose, insulin, HOMA-IR, HbA1c and lipids between studied groups (all $P>$ 0.05). In women with HT, we observed relationships between serum levels of AMH and insulin ($r=0.34$, $P=0.03$), we also observed that AMH levels was connected with HOMA-IR ($r=0.36$, $P=0.02$) in women with HT. However, we did not find relation between serum concentration of AMH and HOMA-IR in the control group ($r=$-0.03, $P=0.68$).
Conclusions
We observed in women with HT connection between insulin resistance and marker of functional ovarian reserve.

Growth hormone treatment in SGA children leads to worsening of insulin resistance parameters without beneficial effects on lipid profile – a 3-year retrospective study

Maria Silva[1,2,3], Joao Sergio Neves[1,2,3,4], Carla Costa[5], Rita Santos Silva[5], Sofia Ferreira[5], Davide Carvalho[1,2,3] & Cíntia Castro-Correia[5]
[1]São João Universitary Hospital Center, Serviço de Endocrinologia, Diabetes e Metabolismo, Porto, Portugal; [2]Faculdade de Medicina da Universidade do Porto - FMUP, Porto, Portugal; [3]i3S - Instituto de Investigação e Inovação em Saúde da Universidade do Porto, Porto, Portugal; [4]Faculdade de Medicina da Universidade do Porto - FMUP, Departamento de Cirurgia e Fisiologia, Porto, Portugal; [5]São João Universitary Hospital Center, Unidade de Endocrinologia Pediátrica, Porto, Portugal

Background
Children who were born small for gestational age (SGA) and who do not have adequate catch-up growth until 4 years old have indication for treatment with recombinant human growth hormone (rhGH). The metabolic consequences of this treatment are relatively unknown.
Objective
To evaluate the effect of rhGH treatment on insulin sensitivity and lipid profile.
Materials and methods
A retrospective observational study of children born SGA who underwent rhGH therapy was performed. Data was assessed before treatment and yearly (three-year follow-up).
Results
A total of 25 SGA children were included. The median age of the children at rhGH treatment was 5.0 (IQR 4.0-9.0) years old. A statistical significant increase in IGF-1 was observed in all years of follow-up. Fasting plasma glucose increased during follow-up, with significant differences in first and third year. Fasting insulin and HOMA-IR values tended to increase, with significant differences observed during the second and third year. The analysis on lipid profile (total cholesterol, high-density lipoprotein cholesterol, low-density lipoprotein cholesterol and triglycerides) was not statistically significant. Height (Z-score) increased significantly (basal: −3.0; first year: -2.3; second year: −2.1; third-year -2.1). The effect of rhGH treatment on stature (ΔZ-core) was not relatable with insulin resistance, lipid profile or age at beginning of treatment.
Conclusion
Fasting plasma glucose, fasting insulin and HOMA-IR increased significantly during follow-up. No significant differences were found on lipid profile. No relation was found between the effect on height and metabolic consequences.

A Late Diagnosed Case of Charge Syndrome

Alperen Onur İşler & Uğur Ünlütürk
Hacettepe University School of Medicine, Division of Endocrinology and Metabolism, Department of Internal Medicine, Ankara, Turkey

Background
CHARGE Syndrome is a rare inherited congenital disorder [1]. The name reflects the initials of the clinical findings (Coloboma, Heart disease, Atresia of the choanae, Retarded growth and mental development, Genital anomalies, Ear malformations, and hearing loss). The disease has four major findings expressed as 4C; ocular coloboma, choanal atresia, cranial nerve abnormalities, and characteristic ear anomalies [2].
Objective
Here, a case of CHARGE syndrome, which had no ocular coloboma and choanal atresia findings but had other features and was diagnosed genetically at a late age, was discussed.
Case
The 20-year-old male patient who had no problems during delivery had recurrent pneumonias. He was operated because of vascular ring compression on his esophagus. Inner and outer ear anomalies and mixed hearing loss were present. His neurological development was retarded. Block appearance was detected in the cervical vertebrae. Orchiopexy was performed at 2-3 years because of his undescended testis. Hypogonadotropic hypogonadism was found with micro genitalia. In his family history, there were consanguinity and suspicious deaths in his siblings. In physical examination, his final height was 172 cm. He had a short neck, an atypical facial appearance, prominent auricles, abnormal ears, short philtrum, low nuchal hairline, mild kyphoscoliosis, gynecomastia, and micro genitalia. Pubic and axillary hair growth was insufficient. At the age of 18, a heterozygous mutation in the *CHD7* gene (p. Gnl 171Ter) was detected in a genetic examination. Because of delayed puberty and hypogonadotropic hypogonadism, choriogonadotropin alfa was started.
Conclusion
In CHARGE syndrome, neural crest-derived organ anomalies develop due to mutations in the *CHD7* gene [1, 3]. Some of the major findings such as coloboma and choanal atresia may not be present in some cases with a genetic mutation [4]. In our case, other features of the syndrome were observed. Genetic consultation should be requested for patients with characteristic CHARGE syndrome features, even if not all major features are present.

Postponed gonadectomy until adulthood for a patient with a novel mutation in androgen receptor gene: a case report

Ruta Navardauskaite[1,2], Rasa Traberg[3], Dalius Malcius[4], Eva Rimkute[1] & Romualdas Tomas Preiksa[1,5]
[1]Department of Endocrinology, Medical Academy, Lithuanian University of Health Sciences, Kaunas, Lithuania; [2]Coordinating center for rare and undiagnosed diseases Lithuanian University of Health Sciences hospital Kauno Klinikos, Kaunas, Lithuania; [3]Department of Genetics and Molecular Medicine, Medical Academy, Lithuanian University of Health Sciences, Kaunas, Lithuania; [4]Department Pediatric Surgery, Medical Academy, Lithuanian University of Health Sciences, Kaunas, Lithuania; [5]Institute of Endocrinology, Medical Academy, Lithuanian University of Health Sciences, Kaunas, Lithuania

Introduction
Androgen insensitivity syndrome rare X linked disorder that is typically characterized by evidence of feminization of the external genitalia at birth, abnormal secondary sexual development in puberty, and infertility in individuals with a 46,XY karyotype. Complete androgen insensitivity syndrome (CAIS) usually is recognized only at the teenage age due to primary amenorrhea. Recently, gonadectomy for patients with CAIS are postponed due to a mild risk of malignancy.
Case report
This report refers 15.3-year-old patient, assigned as female, who presents with primary amenorrhea. Physical examination observed the female appearance and normal external genitalia with a 4 cm length of vagina, puberty maturation was evaluated B4P1-2 (by Tanner stage). Laboratory examination showed high levels of testosterone and anti-Müllerian hormone, and normal levels of gonadotropins and estradiol; the uterus was absent but observed bilateral solid formations in the pelvic MRI. Chromosome analysis confirmed a 46,XY karyotype. Sanger sequencing of AR (NM_000044.6) gene from blood leukocytes DNA was performed and a novel hemizygous likely pathogenic variant c.232_241del p.(Gln78ArgfsTer94) was detected. This variant also confirmed in the testicular tissue DNA. The diagnostic laparoscopy was performed, and histological analysis of the bilateral gonads showed the immature testis tissue with Sertoli and Leydig's cells. During laparoscopy, also open processus vaginalis was found. Contralateral inguinal hernia was operated on in infant age. The CAIS was

confirmed. Gender was assigned as female, but gonadectomy was postponed and hormonal therapy by estrogen did not initiate due to normal level of estrogen and bone mineral density (BMD).
Conclusions
Historically, the gonadectomy for individuals with CAIS was performed after conforming diagnosis at various ages to avert the risk of gonadal malignancy. Recently, gonadectomy is postponed until early adulthood age (25–30 y.o.). Postponed gonadectomy prevents postsurgical hypogonadism which might have negative effects on cardiovascular health and BMD [1].

Turner patient with positive SRY gene: Case report

Marwa Chiboub, Asma Ben Hamida, Radhouen Gharbi, Hajer Kandara & Ines Kammoun
National Institute of Nutrition, Department of Endocrinology, Tunis, Tunisia

Introduction
Many studies demonstrated that 40%-60% of Turner patients were 45,X monosomy in blood lymphocytes, whereas the remaining patients had a structurally abnormal X- or Y-chromosome or were mosaics with a second cell line containing a normal or an abnormal sex chromosome.
Case Summary
Five years old girl was brought to pediatric clinic for short stature. On exam, her height was 92 cm (<3th percentile), body weight was 13.3 kg (<3th percentile). She had neither cubitus valgus deformity nor webbed neck. Knuckle sign was negative. Audiometry, echocardiography, kidney ultrasonography were all immature. Her karyotyping revealed 45,X and FISH analysis indicated that the *SRY* gene was positive. After diagnosis of Turner syndrome, growth hormone had been given for the treatment of short stature. At the age of fifteen, her height was 149 cm (+2 SD) and her body weight was 68 kg (>97th percentile). Estradiol replacement was started at the age of 15 years and 10 months. On pelvic echography, the uterus and both fallopian tubes looked immature, but both gonads looked streak in appearance. Because SRY gene was positive, exploratory laparoscopy was indicated for prophylactic removal of dysgenetic gonads.
Conclusion
It is recommended that individuals with Turner syndrome be screened for Y chromatin. Detection of this will provide information and guidance to individuals with Turner syndrome, especially in terms of the risk of developing gonadoblastoma, with advanced clinical consultation.

Clinical characteristics of men with primary hypogonadism in late-onset hypogonadism

Du Soon Swee
Singapore General Hospital, Endocrinology, Singapore, Singapore

Late-onset hypogonadism (LOH) remains a debatable entity in terms of diagnosis and management. However, the finding of primary hypogonadism (PHG) in ageing men, in the absence of organic cause, provides an unequivocal biochemical diagnosis. Indeed, it has been established in European Male Ageing Study (EMAS) that PHG, and not secondary hypogonadism, is strongly associated with advanced age and multi-comorbidities. That would be consistent with the underlying pathophysiology of Leydig cell dysfunction occurring with ageing process. PHG in ageing men (LOH-PHG) is a relatively rare disorder, affecting only 2.7% (54/1991) of the EMAS baseline cohort (after exclusions). Some of the associated clinical features described were decreased sexual function, lower haemoglobin level and increased insulin resistance. In the current report, baseline clinical characteristics of ten middle-aged to older men diagnosed with LOH-PHG are described. This is a single centre study based on the experience of a specialised Men's Health clinic under the Endocrinology service in Singapore General Hospital. Men with a T <10.5 nmol/l and a LH >9.4 U/l were considered to have PHG. Patients were self-referred, or referred from either primary care or other specialities for suspicion of low testosterone. Mean age of diagnosis of hypogonadism was 66 years (range 55-77). All men had 3 or more co-morbidities. Baseline prevalence of common chronic conditions is as follow – Overweight (BMI > 25 kg/m2): 80%, Diabetes mellitus: 50%, Hypertension: 80%, Hyperlipidaemia: 100%, Coronary artery disease: 50%, Cerebrovascular disease: 20%, Chronic kidney disease: 40%, Osteoarthritis of knee: 20%, Parkinson disease: 10%. At diagnosis, the mean Follicle Stimulating Hormone (FSH) and Luteinising Hormone (LH) levels were 44.3 ± 15.0 IU/l and 22.8 ± 8.5 IU/l respectively, while the mean total Testosterone (T) level was 5.9 ±1.9 nmol/l. Eight men had a haematocrit of <43%; the other two had 46.1% and 48.7%. The mean PSA level was 2.0 ± 1.8; one individual with an elevated PSA had a normal prostate biopsy subsequently. All men were symptomatic at presentation. Besides erectile dysfunction (70%), the chief presenting complaints were mostly related to loss of muscle strength and energy (60%), reflecting the concern of loss of physical function. Three patients had distressing vasomotor symptoms including hot flushes and sweating accompanied by mood swings, poor concentration and impaired sleep quality, with one of them being treated for mood disorder prior to diagnosis of LOH. Interestingly, spironolactone-induced gynaecomastia was the primary indication for hormonal evaluation in two men.

Clinico-biological and etiological analysis of patients followed for hirsutism

Sawsen Nouira, Taieb Ach, Gorchene Asma, Ghada Saad, Asma Ben Abdelkarim & Molka Chadli Chaieb
Hospital Farhat Hached, Sousse, Tunisia

Introduction
Hirsutism is defined as excessive pilosity development in women in androgen-dependent areas. It is the main revealing sign of hyperandrogenism. It is a frequent reason for consultation in Endocrinology.
Methods
This is a retrospective study of 82 records of patients hospitalized for exploration of hirsutism in the endocrinology department of Farhat Hached Hospital in Sousse, over a period of 20 years from 1997 to 2017.
Results
The mean age of the patients was 25 years, with extremes of 16 to 38 years. Family history included hirsutism in 41%, diabetes in 29%, hypertension in 22%, and obesity in 13%. Among the patients, 18% were diabetic, with a single case of type 1 diabetes, and 14% were hypertensive. Menstrual disorders such as spaniomenorrhea were observed in 70% of the cases, 23% had secondary amenorrhea. Primary infertility had been found in 6% of cases. Hirsutism appeared in the pubertal period in 40% of cases and in the post-pubertal period in 60% of cases. The major site of hirsutism was the face in 53% of patients. Assessment of hirsutism by the Ferriman-Gallway score showed mild hirsutism in 30% of cases, moderate in 44% of cases and severe presentation in 26% of cases. Overweight had been observed in 42% of the cases, 30% were obese, while 30% of the patients were at normal range. An android distribution of obesity was found in 25% of cases. Acanthosis nigricans was present in 17% of cases, Cushing's syndrome in 10% and signs of virilization in 3.6%. Biological investigations showed an increase in total testosterone level in 84% of cases. The etiologies found were: polycystic ovary syndrome (PCOS) in 60% of the cases, idiopathic hirsutism in 20% of the cases, Cushing's syndrome in 11% of the cases (5 cases of Cushing's disease and 4 cases of cyclic Cushing's disease), congenital adrenal hyperplasia by 21-hydroxylase deficiency with a late onset in 5% of the cases, and hyperprolactinemia in 4% of the cases.
Conclusion
PCOS is the most common etiology of hirsutism, which develops progressively with a peripubertal onset. However, a careful etiologic investigation is always necessary in order not to miss an ovarian or adrenal virilizing tumor origin in case of recent and rapidly evolving hirsutism.

Multisystemic maccune albright syndrome: what is the management

Rahal Amel[1,2]
[1]Medecines, Endocrinology, Algiers, Algeria; [2]Hopital Bologhine Ibn Ziri, Endocrinology, Algiers, Algeria

Introduction
Maccune albright syndrome; is a rare disorder resulting from the involvement of several organs; the phenotype is variable depending on the clinical manifestations linked to the importance of the tissues affected by the mutation.

Case report
In our patient, the diagnosis was not made until she was 8 years old, despite some suggestive signs: as café au lait skin macules at birth and early forearm bone fractures at the age of 3 years. At 8 years; she presents all the manifestations of the syndrome:
- peripheral precocious puberty: the patient is classified as S3 P3 and the mother reports 2 episodes of vaginal bleeding Hormonal assessment shows an elevated oestradiol level of 326 pg/ml with suppressed FSH and LH. Ultrasound of the internal genitalia shows a pubere uterus with cysts.
- multiple polyostotic fibrous dysplasia disease: Technetium-99 scintigraphy scan showing increased tracer uptake in areas of fibrous dysplasia, including the skull, spine, humerus, costal grill distal third of the right ulna spine and sacroiliac bones.
- Peripheral FT3 hyperthyroidism: thyroid ultrasound revealed an enlarged thyroid with multiple cystic anechoic formations in both lobes
Discussion
Management of Mccune Albright syndrome is cumbersome; diagnosis is often unrecognised; late in our patient, but there is no doubt about the diagnosis. Our patient has a combination of bone, skin, gonadal and thyroid involvement. In order to detect and identify occult bone damage, we performed a bone scan, which revealed multiple damage justifying a complete clinical and radiological assessment and rigorous monitoring. The patient does not have disabling bone pain that warrants biphosphonate treatment. The height obtained after treatment with androcur and synthetic antithyroid drugs is acceptable: the patient has a height of 165 mm; Radical treatment of hyperthyroidism will be discussed with a preference for total thyroidectomy.
Conclusion
Maccune Albright Syndrome is rare but the management of these children is quite heavy and continues into adulthood. In our patient, despite a multi-systemic form, the target size is correct; there are no deformities or major fractures and no functional impotence, despite the delay in diagnosis Monitoring of these patients continues throughout their lives as the disease remains active and requires multidisciplinary management in order to watch out for any complications or sarcomatous or mammary transformation

Ovarian steroid cell tumor – a rare cause of androgen excess in a young woman

Patricia Christina Codreanu[1], Miruna Sinziana Chiper[1], Alexandru Filipescu[1,2] & Carmen Gabriela Barbu[1,2]
[1]Elias Emergency Universitary Hospital, Bucharest, Romania; [2]Carol Davila University Of Medicine And Pharmacy, Bucharest, Romania

Introduction
Signs of hyperandrogenism are frequent complaints for young adults and adolescents and a common cause of presentation to endocrinology service. Even if polycystic ovary syndrome is the most frequent etiology, differential diagnosis is mandatory. (1,2)
Case report
We present the case of a 26-year-old female patient, obese, smoker, with a personal history of polycystic ovary syndrome and a family history of diabetes mellitus, who presented to our endocrinology clinic for the investigation of secondary amenorrhea and recently installed hirsutism. Clinically, the patient presents menstrual irregularity (last menstrual cycle 8-9 month ago), hirsutism (Ferriman Gallwey score 16) and acne; BMI 32.05 kg/m^2. Biological assessment revealed hyperandrogenism (testosterone 263,5 ng/dl, androstenedione 20,347 ng/ml and 17-OH-Progesterone 29,361 nmol/l) while normal gonadotropins levels, presence of insulin-resistance (HOMA-IR 3,7) and normal values of DHEAS, Prolactin, Estradiol, beta-HCG, inhibin. Cortisol hypersecretion/insufficiency was excluded and the thyroid function was normal. Transvaginal ultrasound identified the left ovary transformed into a tumor mass, inhomogeneous, hyperechoic, well-defined, well vascularised, measuring 4.4/4.2/4.8 cm. Laparoscopic excision of the tumor was performed. Histopathological and immunohistochemical examination confirmed a benign ovarian steroid cell tumor (NOS), with lipid rich cytoplasm (mitotic index 2/10< HPF, Ki67 4%, diffuse positivity for inhibin, calretinin and focal positivity for Melan A). Postoperatively, androgens values ameliorated - testosterone and androstenedione normalized (29,10ng/dl and 1,8ng/ml), 17-OH-Progesterone decreased but still mildly high (7,575nmol/l), the rest of the blood results being normal and clinically - menstrual cycles regulated without significant hirsutism amelioration and the patient lost weight (BMI 29,9 kg/m^2).
Conclusion
Ovarian steroid cell tumours NOS, even if are rare, should be considered in any case of hyperandrogenism and excluded if elevated androgens levels are present. We identified a rare cause of hyperandrogenism in this patient even though many other causes were possible. Due to the fact that our patient wants to remain pregnant, it was decided to perform only the resection of the tumor, with the preservation of ovarian tissue.

Assessment of metabolic control indicators in women of reproductive age with polycystic ovarian syndrome

Elena Makhlina[1], Oksana Kononova[2] & Yana Navmenova[3]
[1]Gomel State Medical University, Chairs Internal Medicine No. 1 with courses in endocrinology and hematology, Gomel, Belarus; [2]Gomel State Medical University, Chair Internal Medicine No. 2 with the course FPKiP, Gomel, Belarus; [3]The Republican Research Center for Radiation Medicine and Human Ecology, Endocrinology, Gomel, Belarus

The objective is to assess the presence of possible correlation between the calculated body fat percentage (BFP) indicator and indicators of metabolic control in women of reproductive age with polycystic ovarian syndrome (PCOS).
Materials and Methods
The study included 80 women with a diagnosed PCOS according to the Rotterdam criteria. All study participants underwent standard general clinical studies with the determination of body mass index (BMI), waist circumference (WC) and laboratory tests (total cholesterol (TC), high density lipoproteins (HDL), non-HDcholesterol (non-HDcholesterol), glycated hemoglobin (Hb1c), C-peptide and insulin). The Visceral Obesity Index (VOI) and BFP were calculated. Mathematical analysis was carried out using the Statistica 10 program (StatSoft, USA). Differences were considered statistically significant at $P < 0.05$.
Results and Discussion
The results of the anthropometric study showed that the median BMI was 25.00 [20.00;29.50] kg/m2, the median WC was 85.00[69.00;90.00] cm, the median VOI was 0.79 [0.39; 1.46], BFP 30.35 [24.60 35.98]. Pro-inflammatory biomarkers were assessed, as median CRP was 0.83[0.44;2.12] mg/l, median fibrinogen was 3.70 [2.90;4.40]g/l. When assessing the state of lipid metabolism, it was found that the median values of blood lipid spectrum indicators were: TC 4.54[4.00; 4.92] mmol/l., HD1.57[1.28; 2.11] mmol/l, non-HDcholesterol 2.78[2.40; 3.52] mmol/l. Median Hb1c was 4.90[4.60;5.20] %, insulin 11.00[5.50;15.90]ng/ml, C-peptide 2.05[1.28; 2.84]ng/ml. Based on the results of the correlation analysis, a significant direct relationship was determined between the BFP and the VOI value ($r=0.75$; $P < 0.05$), WC ($r=0.88$; $P < 0.05$), insulin level ($r=0, 56$; $P < 0.05$), C-peptide level ($r=0.59$; $P < 0.05$), non-HDcholesterol value ($r=0.60$; $P < 0.05$), CRP level ($r=0.78$; $P < 0.05$). Correlation between BFP and the Hb1c level ($r=0.09$; $P > 0.05$), fibrinogen ($r=0.45$; $P > 0.05$) was not noted.
Conclusion
Estimated indicator of BFP is directly correlated with indicators of carbohydrate and fat metabolism in women of reproductive age with polycystic ovarian syndrome.

Testosterone therapy in chronic liver disease

Jelena Andric[1], Ivona Šamle[1], Mirna Hrabar[1], Tonci Bozin[2] & Vlatka Pandzic Jaksic[1]
[1]University Hospital "Dubrava", Department of Endocrinology, Diabetes and Metabolic Diseases, Zagreb, Croatia; [2]University Hospital "Dubrava", Department of Gastroenterology, Hepatology and Clinical Nutrition, Zagreb, Croatia

Background
Several clinical features of chronic liver disease, such as sarcopenia, anaemia, low bone mass and gynecomastia are similar as manifestation of hypogonadism. Decreased testosterone levels are common in patients with severe liver disease and are associated with worse clinical outcomes and mortality.
Case Presentation
A 33-year-old patient was admitted to the hospital due to severe alcoholic hepatitis. He was in poor general condition, icteric, encephalopathic with

peripheral edema and mild ascites. Due to high Maddrey score, corticosteroid therapy was initiated, leading to a gradual decrease in bilirubin and liver enzymes but his clinical condition remained poor. The patient lost 23 kg of body mass within 2 months and his body mass index (BMI) was 21 kg/m2. The SARC-F score (Strength-Assistance walking-Rice from a chair-Climb Stairs-Falls) was 4. Laboratory findings suggested hypogonadotropic hypogonadism (LH 1.92 IU/l, FSH 1.65 IU/l) with very low free testosterone levels (32 pmol/l, ref. range 170 - 660) corrected for albumin and SHBG. Transdermal therapy with 25 mg/day of testosterone gel was initiated. Liver enzymes were slightly elevated (< 1.5 ULN) at the time of administration of testosteron and glucocorticoid therapy was discontinued. A month later, free testosterone was 151 pmol/l and there was a clinical increase in muscle strength and mobility. Dose of 50 mg/day was continued. Body mass further increased (BMI 24 kg/m2); the patient became fully independent in performing physical tasks while free testosterone reached normal levels (251 pmol/l). Liver parameters improved and no side effects occurred. We decided to continue testosterone therapy until further recovery of liver function.
Conclusion
Due to high incidence of hypogonadism, testosterone levels should be assessed in younger patients with severe liver diseases. The transdermal administration of testosterone therapy avoids hepatic circulation and prevents potential occurrence of hepatotoxic effects. It dramatically improved frailty in our patient and similar results have already been described, but this therapeutic option is still not widely prescribed. Further research on long term risk and benefits of transdermal testosterone therapy in chronic liver diseases is required.

Treatment Challenges of a virilized female with 46 XX CAH diagnosed at the age of 13

Rana Almudhammed[1,2]
[1]Diyala College of Medicine, Department of Medicine, Baghdad, Iraq; [2]Diyala College of Medicine, Baghdad, Iraq

Introduction
DSD is a group of disorders by which there is discrepancy between genomic sex and phenotypical sex. Most of cases of DSD are picked up during neonatal period due to ambiguous genitalia. Few cases are diagnosed in adolescence or even at puberty due to various causes like mild ambiguity, complete phenotype sex reversal, lack of breast development and primary amenorrhea, we review a case of 46XX CAH girl due to CYP21 hydroxylase deficiency which was diagnosed late at the age of 13 and the implication of late diagnosis on disease control, mental and sexual aspects.
Methods
13-year-old female presented with progressive features of virilization started at the age of 10 including deepening of the voice, muscular features, severe hirsutism modified Ferriman-Gallwey Score 4, absence of breast, balding, ambiguous genitalia (grade 2 Prader) She is a daughter of consanguineous marriage. She has no depressive symptoms and perceive her self as a female but she is sexually attracted to females.
Labs
Diagnosis of 21 hydroxylase deficiency (simple virilizing form) with no features of cortisol deficiency, we started steroid replacement as hydrocortisone. No satisfactory response clinically to steroid after 6 months of treatment, patient gained weight so decided to stop medication and lost to follow up, she came again 2 years later but she refused steroid so I started potent anti androgen (Flutamide)250 mg once daily Plus COC, withdrawal bleeding occurred after 3 cycles, mild improvement in Hirsutism and psychological wellbeing after 6 months of treatment. However, her sex orientation didn't change raising the question about the impact of long exposure of the brain to androgens and highlight the concept of brain virilization.

Hb	16	%
S.K	3.9	145
S, Na		
Meq Testosterone	3.5	ng/ml
	12	nmol/l
LH	0.5	i.u.
FSH	4.5	i.u.
DHEAS	More than 1000	mg
ACTH	450 pg	
Cortisol	450	nmol
Basal17-OH progesterone	12000	ng/dl
	360	nmol
Estradiol	126	Pg
Karyotype	XX	
CT	Negative for tumor, diffuse bilateral enlargement	
Pelvic imaging	Normal sized uterus and ovaries	
Renin	1.4	ng/ml/hr

Conclusion
Current available therapies of CAH have limitations and difficult to balance the hyperandrogenism hypercortisolism arms, the effect of long-term exposure of the brain to androgens should be widely investigated in terms of gender identity, gender role and sex orientation and whether the available therapies address or reverse these issues.

Preventing female virilisation: role of antenatal dexamethasone

Sanaa Bammou, Sana Rafi, Ghizlane El Mghari & Nawal El Ansari
Mohamed VI University Hospital Center, Department of Endocrinology, Diabetology, Metabolic Diseases Nutrition, Marrakesh, Morocco

Introduction
Antenatal treatment with dexamethasone in pregnancies affected by congenital adrenal hyperplasias (CAH) therefore suppresses fetal androgen production and prevents virilisation of female infants. Antenatal DXM is reported to be efficacious, preventing or ameliorating virilisation in 80–85% of cases.
Case report
23-year-old patient pregnant at 6 weeks, not known of having congenital adrenal hyperplasia (CAH), concept of consanguineous marriage 1 degree; she had a history of 2 children followed up for a classic form of HCS, the first died at the age of 1 and 10 months and the 2 child died on D26 of life. After having made a prenatal diagnosis where an analysis of the SRY gene on fetal circulating DNA showed the absence of this gene, which confirms the female sex of the fetus. An obstetrical ultrasound was done which objectified a pregnancy estimated at 6 weeks with suspicion of clitoral hypertrophy (At 16 weeks), in view of this observation the patient was referred to us for additional care and possible dexametasone. On questioning, the patient did not report any signs of hyperandrogenism. All evolving in a context of unquantified moderate weight loss and asthenia without signs of adrenal insufficiency. The clinical examination showed no melanoderma or slate spots, BP= 105/71mmHg, RR = 19 cycles/min. CF=81bpm? BMI = 28.68 kg/m2. Tanner: S5P5. the patient was put on 1.5 mg/d of dexamethasone divided into 3 doses. A monthly measurement of DHEAS and cortisol was requested. The Decrease of plasma concentrations of cortisol and DHEAS in the mother testifies to good fetal adrenal suppression. A low-calorie diet and monitoring of blood pressure and blood sugar to detect signs of under or overdose of corticosteroid therapy. Ultrasound monitoring of the fetus done each month, the first ultrasound done 1 month after Dexamethasone treatment shows the disappearance of the clitoral hypertrophy seen on the initial ultrasound. patient gave birth at 38 weeks of amenorrhea by caesarean section, the newborn is female, the birth weight is 2 Kg 600, the external genitalia are normal The newborn was hospitalized in the neonatology department for monitoring and screening of The congenital adrenal hyperplasia.
Conclusion
CAH is an uncommon but important and ethically complex condition where there are significant maternal and fetal risks both with and without antenatal treatment. It is time for the historical recommendation of administering prenatal DXM to all pregnancies of high-risk families for CAH to be reevaluated.

A case of Leydig cell tumor in an adult patient with Klinefelter syndrome

Salma Salhi, Ibtissem Oueslati, Meriem Yazidi, Asma Ben Hamida & Melika Chihaoui
La Rabta University Hospital, Department of Endocrinology, Tunis, Tunisia

Introduction
Leydig cell tumor is rare, accounting for 1% of testicular tumors. Klinefelter syndrome is most often associated with extra-gonadal germ cell tumors. Its association with testicular tumors remains less frequent. Herein, we report the case of a Leydig cell tumor of the testis in a patient with Klinefelter syndrome.
Observation
A 46-year-old man was referred to our department for hypogonadism. His past medical history included type 2 diabetes. He presented with erectile dysfunction and decreased libido. On physical examination, he had a body weight of 96.5 kg, a height of 175 cm, a body mass index of 31.5 kg/m^2, no gynecomastia, decreased pubic hair, hypotrophic soft testicles with a hard left nodule, and a penis length of 6.5 cm. Biological investigations showed hypergonadotropic hypogonadism.

Estradiol level and tumor markers were normal. Semen analysis showed azoospermia. The karyotype showed a chromosomal formula of 47.XXY. Testicular ultrasound showed bilateral testicular atrophy with a left testicular nodule measuring 9.4×7.4 mm. The patient underwent a left orchidectomy and the histological examination concluded to a benign Leydig cell tumor.
Conclusion
The physiopathology of Leydig cell tumor remains unclear. It is suggested that the elevation of LH in patients with Klinefelter syndrome induces Leydig cell hyperplasia and tumor development. Orchidectomy represents the golden standard therapeutic option. After surgery, a long-term follow-up is indicated to exclude recurrence or metastasis.

An Intellectual Development Disorder Revealing A Rare Variant of the Klinefelter Syndrome – 48, XXXY: A Case Report

Ikram Amira, Loubna Guissi, Manal Azriouil, Kaoutar Rifai, Iraqi Hinde & Mohamedelhassan Gharbi
Ibn Sina University Hospital, Department of Endocrinology and Metabolic Diseases, Rabat, Morocco

Introduction
Klinefelter syndrome is a sex chromosomal aneuploidy caused by an addition of X chromosome in males (47,XXY). 48,XXXY is a rare variant of this syndrome which is characterised by the presence of two additional X chromosomes in males and is estimated to occur in 1/50 000 male births. Here we describe a rare case of a 48, XXXY Klinefelter's variant in a 17 years old patient revealed by an intellectuel development delay.
Case Report
The patient was a 17 years old male, born to non-consanguinous parents after full term normal delivery. He was undergoing psychotherapy for intellectuel development delay and referred to our department for etiologic research. Clinical examination revealed a normal facial morphology with a tall stature; the presence of a delayed puberty and a micropenis are the significant features observed in the present case. The hormonal assessment was in favor of a hypergonadotropic hypogonadism profil. The cytogenetic analysis revelealed a variant of klinefelter syndrome: 48,XXXY.
Discussion
The presence of one or more additional X chromosome(s) above the typical 46,XY in males leads to testicular dysgenesis and hypergonadotropic hypogonadism, and thus, 48,XXXY is often considered a variant of Klinefelter syndrome (47,XXY) because of these shared features. However, patients with this variant have an increased risk of congenital malformations, additional medical problems, more complex psychological involvement and thus a more severe prognosis compared to patients with 47,XXY The intellectuel problem in our patient indicate the effect of the two extra X chromosomes, wherein each extra X is associated with an IQ decrease of approximately 15-16 points. Early confirmation of the diagnosis is essential for therapeutic management and genetic counselling.

Testicular Regression Syndrome: A Case Report

Ikram Amira, Manal Azriouil, Kaoutar Rifai, Iraqi Hinde & Mohamedelhassan Gharbi
Ibn Sina University Hospital, Department of Endocrinology and Metabolic Diseases, Rabat, Morocco

Introduction
Testicular regression syndrome is defined as partial or complete absence of testicular tissue in the presence of a normal 46,XY male karyotype. This syndrome is very rare with an estimated prevalence of 1 case/20.000 males. Here we decribe a case of a testicular regression syndrome in an 18 years old patient.
Case Report
We report the case of an 18 years old male patient followed for testicular regression syndrome since the age of 2, which was diagnosed by: The absence of palpable gonads with micropenis on the clinical examination, the absence of testicles in normal or ectopic position on the abdominopelvic and scrotal ultrasound, the hypergonadotropic hypogonadism profil, a 46,XY karyotype and the presence, at laparoscopy, of an inguinal testicle without spermatic cord measuring 13 mm on the right side and a cystic formation with a 3x7 mm tissue margin on the left one. The patient was put on androgen substitution therapy, with currently a good clinical evolution: penis with a normal size with grade 5 pilosity. Testicular prostheses with psychological support are planned.
Discussion
Testicular regression syndrome (TRS) is defined by a complete or parteil absence of tescticular tissue which may be uni- or bilateral. TRS is more common on the left side and is usually accompanied by a closed internal ring and compensatory hyperplasia of the controlateral testis. This syndrome is also known as vanishing testis, and presents clinically as nonpalpable testis. The phenotype is variable depending on the period when the gonadal regression occurs in utero. Indeed, in the presence of normal male external genitalia, it can be assumed that the fetal testis was present and functional during the early period of development with sufficient androgen production to ensure normal or subnormal male external genitalia development. In this condition, gonadal regression occurred late in fetal life, beyond the 12th week of pregnancy. However, in the presence of a micropenis, as in the case of our patient, some authors have suggested the prior presence of an intrinsic alteration of the testicular tissue before its regression.

Case report - Charge syndrome, a rare entity in the differential diagnosis of primary amenorrhea

Henrique Pina, João Dinis Martins, Vitória Duarte, Sílvia Guerra, José Maria Aragüés & Cristina Valadas
Hospital Beatriz Ângelo, Endocrinology, Loures, Portugal

Primary amenorrhea is characterized by the absence of menstruation after the age of 14 without the development of secondary sexual characteristics or after the age of 16 with the development of these. Hypogonadotropic hypogonadism (HH) corresponds to an uncommon etiology of primary amenorrhea. In HH, the differential diagnosis includes Kallmann Syndrome, isolated hypogonadotropic hypogonadism and CHARGE Syndrome. The CHARGE syndrome corresponds to an extremely rare syndrome, with an incidence of 0.1-1.2/10 000 characterized by the classic association of **C**oloboma, congenital **H**eart disease, choanal **A**tresia, **R**etardation in growth and/or development, **G**enital anomalies and anomalies from the **E**ar. It is an autosomal dominant disease, although most cases are sporadic due to de novo mutations. The exact pathophysiological mechanism of the disease is not known, but it seems to result from abnormalities of brain differentiation, namely in the migration of GnRH neurons. The CHD7 gene is the only known gene associated with CHARGE syndrome, being mutated in 75-95% of patients who meet clinical criteria for the typical form of the disease. We present the Clinical case of a patient with the diagnosis of CHARGE Syndrome since the 1st year of age, referred to an endocrinology consultation due to primary amenorrhea. Adolescent, 15 years old, CHARGE syndrome with bilateral coloboma, patent ductus arteriosus, undergoing heart surgery at age 2, profound sensorineural deafness, attention deficit disorder with autism spectrum disorder, chronic kidney disease and obesity. On physical examination Tanner stage 2 (breast 1, pubic hair 3, axillary hair 1), otherwise asymptomatic. Analytically with hypogonadotropic hypogonadism (FSH 0.4 mIU/ml, LH <0.1 mUI/ml, 17-ßeta Estradiol <19.0 pg/ml), remaining pituitary function unchanged. Gynaecological ultrasound showed prepubertal uterine morphology, with a medium-sized uterus, smaller in size for the age group, measuring 29 x 7 x 14 mm. The patient was started on 20 mg ethinyl estradiol + 150 mg desogestrel. Withdrawal bleeding was present 2 months after starting therapy. With the aim of inducing the expected gradual pubertal maturation and reducing the risk of osteoporosis/cardiovascular disease, except in cases where there is an absolute contraindication, young women with primary amenorrhea and incomplete sexual development should start estrogen therapy. We submit this Clinical case given the rarity of the entity and its importance in the differential diagnosis of primary amenorrhea.

Correlation between metabolic and hormonal parameters in PCOS

Rim Khlif
Faculté de Medecine de Sfax, Department of Endocrinology, Sfax, Tunisia

Introduction
Polycystic ovary syndrome is a very heterogeneous disease. Clinical and para clinical findings in such patients varies from one patient to another.
Aim
The aim of our work is to study the clinical and para clinical profile of PCOS.
Methods
This is a retrospective descriptive study of patients with PCOS followed in the endocrinology department of Hedi Chaker University Hospital of Sfax, Tunisia. PCOS + was diagnosed based on the Rotterdam Consensus definition.
Results
We collected 50 patients. The average age was 24.56 years +/- 6, 5. Subfertility was objectified in 64.7%. Family history of PCOS was reported in 10% of cases. The mean BP was 120/100 mmHg. The mean body mass index was 32.39 +/- 8.93, this could be related to the lack of physical activity (2% were actif). Despite that, only 7 women were obese. Hirsutism was noted in 85% of cases. However, the average of testosterone was at 0,66. Mean FSH, LH and estrogen levels were respectively 5.16, 10 and 52, 62 UI/ml. We have noted that 38 patients had spaniomenorrhea. Microcystic ovaries were reported in 68% of cases. The lipid balance total cholesterol levels varied between 3.22 mmol/l and 12.41mmol/l with an average of 5.12 mmol/l. We have also recorded blood sugar levels in the average of 5.6 mmol/l with a glycated hemoglobin at 5.9 % and mean insulinemia at 12,38 UI/ml.
Discussion
Until today, no consensus for the management of PCOS. Thus, a better understanding of the PCOS is necessary for a structured and well codified management. A study on a larger number of patients is recommended to better study the variability of the clinical and paraclinical profile of PCOS.

Correlation between metabolic and hormonal parameters in PCOS

Rim Khlif
Faculté de Medecine de Sfax, Department of Endocrinology, Sfax, Tunisia

Introduction
Polycystic ovary syndrome is a pathology increasingly observed in women of childbearing age, in whom changes in hormonal and metabolic balance have been recorded
Aim
The aim of our work is to find Correlations between metabolic and hormonal parameters in PCOS patients
Methods
This is a retrospective descriptive and analytic study of patients with PCOS followed in the endocrinology department of Hedi Chaker University Hospital of Sfax, Tunisia between 2010 and 2022
Results
50 patients were included. Mean age was 24 ± 6, 5 years. PCOS has been diagnosed at the age of 22, 5 ± 6, 17 years on average. Diabetes was found in 22% of cases overall, dysthyroidism was found in 24% of cases. However, 4% of patients were dyslipidemic. Obesity was noted in 14% of patients and 4% presented a cardiovascular event.12 women of 32 (37%) have metabolic syndrome. Prolactin was inversely correlated with LDlevel (r=-0,444). No correlation was found between HBA1C and testosterone (r= -0,277, P=0, 54). HBA1C was correlated with estrogen levels(r=0, 85, P= 0, 05). Fasting blood sugar was not correlated with FSH levels (r= -3,57, P= 0,62). The same goes for the correlation between cholesterol and estrogen levels (r=-1,04, P= 0,57).
Conclusion
This study showed a very probable relationship between metabolic and hormonal parameters. Taking these relationships into account is essential in the care of our patients.

Late-discovered mosaic Klinefelter syndrome with severe osteoporosis and obesity

Ivona Šamle, Jelena Andric, Mirna Hrabar & Vlatka Pandzic Jaksic
University Hospital Dubrava, Department of Endocrinology, Diabetes and Metabolic Diseases, Zagreb, Croatia

Background
Bone mineral density measurement sometimes reveals osteoporosis that is a consequence of undiagnosed or neglected long-standing health disorders. These secondary causes of osteoporosis should be carefully investigated, especially in men.
Case Presentation
A 63-year-old male complained of back pain and was referred to endocrinology clinic due to a poor densitometry finding indicating osteoporosis. He presented with severe obesity (body mass index 40.5 kg/m^2), grade IV gynecomastia, Tanner IV genital appearance with descended testes. A spine X-ray detected compressive osteoporotic fractures in four thoracic vertebrae (Genant's grade 1 and 2). Laboratory results showed overt hypergonadotropic hypogonadism, mild normocytic anemia, vitamin D deficiency with plasma glucose and HbA1c in the prediabetes range. Peripheral blood cytogenetic analysis revealed mosaic form of Klinefelter syndrome 47,XXY/46,XY - 19 out of 21 metaphases had XXY trisomy. The patient has been married with no children and has never engaged in infertility evaluation. He had no interest in testosterone treatment for sexual dysfunction and focused only on preventing skeletal difficulties. Severe osteoporosis was treated with teriparatide for two years, followed by risedronate. His lumbar pain improved and no new fractures occurred. During follow-up his hypertension was poorly controlled and he developed diabetes, but declined bariatric surgery.
Conclusions
Bone and metabolic complications in patients with Klinefelter syndrome are mainly related to testosterone deficiency. However, testosterone replacement has not yet been approved for osteoporosis treatment due to lack of evidence that it reduces fracture risk. The benefits of testosterone on cardiometabolic disorders were found, but it is necessary to weigh them against potential risks of this therapy in older patients with established comorbidities. Although effective control of male hypogonadism symptoms is usually reported, patients with Klinefelter syndrome might exhibit psychological, cognitive, and social issues that interfere with timely diagnosis, their preference for masculinization and adoption of a healthy lifestyle.

Down syndrome: Experience of the medical genetics laboratory of Ibn Rochd University Hospital of Casablanca

Fatima Zahra Outtaleb[1], Tazzite Amal[2], Gazzaz Bouchaib[3] & Dehbi Hind[1,2]
[1]Ibn Rochd University Hospital, Laboratory of Medical Genetics, Casablanca, Morocco; [2]Faculty of Medicine and Pharmacy, Hassan II University, Cellular and Molecular Pathology Laboratory, Casablanca, Morocco; [3]Royal Gendarmerie, Genetics Analysis Institute, Casablanca, Morocco

Trisomy 21 or Down syndrome is the most common autosomal aneuploidy and the leading genetic cause of intellectual disability worldwide. It is a genetic disease, resulting from the presence of a supernumerary chromosome for the 21st chromosomal pair. It is responsible for a phenotype associating a dysmorphic syndrome, malformations (cardiac, digestive, urinary...), psychomotor retardation, and can be accompanied by other pathologies and complications (epilepsy, leukemia...). We report here the results of a retrospective study conducted at the Medical Genetics Department of the Ibn Rochd University Hospital in Casablanca, from January 2003 to December 2018, with the aim of studying the clinical and cytogenetic aspects of trisomy 21, assessing the risk factors, and highlighting the role of genetic counseling and medical and paramedical management of this syndrome. The study identified 262 cases followed for suspected trisomy 21. Among these 262 cases, we retained 64 patients with trisomy 21 confirmed by standard karyotype. The ratio was 3 boys to 4 girls. The average age at diagnosis was 4 years and 7 months. The average age of the mothers giving birth to these patients was 32.54 years. The major clinical signs in the study population were facial dysmorphia, cardiac abnormalities, hypotonia, psychomotor retardation and intellectual disability. Karyotype results showed that 92.19% of the patients had free and homogeneous trisomy21, 6.25% had mosaic trisomy, and 1.56% had unbalanced translocation. Early and multidisciplinary care by health professionals is essential to improve the quality of life of the trisomic 21 child and his or her family. On the other hand, genetic counselling must be systematic, in order to calculate the risk of recurrence, and to propose a possible prenatal diagnosis.
Key words
Trisomy 21, genetic counseling, prenatal diagnosis.

46 xy disorders of sex development (dsd): a case report

Farah Elgharroudi, Nawal El Ansari & Ghizlane El Mghari
CHU Mohammed VI, Endocrinology, Marrakech, Morocco

Introduction
Sexual differentiation depends on a succession of events, each stage of which may be the site of abnormalities resulting in sexual ambiguitý.
Case report
17-year-old female patient, consults for primary amenorrhea. On physical examination the morphotype is female, height is normal, secondary sexual characteristics are Tanner stage 1 with sexual ambiguitý Prader stage 4, No palpable testes with a subpenile Orifice. Pelvic ultrasound showed the presence of small bilateral oval subvesical images seat of small cystic areas that may be related to seminal vesicles, absence of images suggestive of uterus or ovaries. pelvic MRI showed images compatible with prostate, seminal vesicles and aplastic penis. Hormonal exploration showed hypergonadotropic hypogonadism, testosterone was 3ng/dl, and the karyotype was male, allowing us to make the diagnosis of a pure XY ADS 46. Concerning the therapeutic management, the patient will benefit from a gonadectomy with a vaginoplasty.

Edwards' syndrome: Study of a case series
Fatima Zahra Outtaleb[1], Tazzite Amal[2], Gazzaz Bouchaib[3] & Dehbi Hind[1,2]
[1]Ibn Rochd University Hospital, Laboratory of Medical Genetics, Casablanca, Morocco; [2]Faculty of Medicine and Pharmacy, Hassan II University, Cellular and Molecular Pathology Laboratory, Casablanca, Morocco; [3]Royal Gendarmerie, Genetics Analysis Institute, Casablanca, Morocco

Trisomy 18, or Edwards syndrome, is a chromosomal disorder, due to the presence of a supernumerary chromosome 18. Worldwide, it is estimated to have a prevalence of 1/6000 live births, of which the most affected are female. Infants with trisomy 18 have a high mortality rate, secondary to the lethal malformations associated with this syndrome. The objective of this study is to describe the clinical and cytogenetic characteristics of these patients and to demonstrate the value of genetic counseling. This is a cross-sectional descriptive study conducted over a period of 5 years, from July 2015 to April 2019, at the medical genetics department of the University Hospital of Ibn Rochd in Casablanca. Five patients with Edwards syndrome were admitted to the department, with a female predominance; 3 girls and 2 boys (sex ratio = 0.67). The mean age at diagnosis was 37.40 $\pm$ 23.98 days (9 days-2 months). Trisomy 18 was clinically suggested in two cases because of facial dysmorphia and malformative syndrome characteristic of the chromosomal anomaly, whereas two patients were hospitalized in an intensive care unit for decompensated heart failure due to congenital heart disease. Finally, one patient presented with respiratory distress in the newborn with a poly-malformative syndrome at the time of diagnosis. The karyotype performed confirmed the diagnosis of trisomy 18 free and homogeneous in all five patients, and genetic counseling was performed. Genetic counselling is a specialized preventive medicine consultation, which allows the risk of recurrence to be calculated for any chromosomal anomaly, including Edwards syndrome. Thus, for a couple with a child with free and homogeneous trisomy 18, the probability of recurrence in the next pregnancy is 1%. In cases where trisomy 18 is partial, and therefore secondary to a structural anomaly, it is necessary to perform a karyotype in the parents to eliminate carriers with a balanced translocation, because the probability of recurrence is greater. The incidence of trisomy18 also increases with advanced maternal age. Furthermore, the complexity and severity of the clinical picture and the high rate of neonatal and infant mortality emphasize the importance of prenatal diagnosis of this disease.
Keywords
trisomy18, facial dysmorphia, prenatal diagnosis.
DOI: 10.1530/endoabs.90.EP947

Klinefelter syndrome diagnosed late in a person with motor and cerebral infirmity
Nour El Houda Bedrane & Khiter Chafika
Hôpital de Lucie & Raymond Aubrac, Crosne, France

Introduction
Klinefelter syndrome is a genetic condition that results when a boy is born with an extra copy of the X chromosome. Klinefelter syndrome is a genetic condition affecting males, and it often isn't diagnosed until adulthood. It is manifested by gynecomastia, small testicles, erectile dysfunction, infirtility …
Observation
70-year-old male patient with motor and cerebral infirmity, several fractures following minimal trauma. Hospitalized for imbalance of type 1 diabetes and the clinical examination found bilateral gynecomastia, microtesticles and the patient was beardless. Bone densitometry shows severe osteoporosis. Testosterone was low at 1.1 nmol/l, FSH high at 28.3 IU/l, LH also high at 11.1 IU/l. Karyotype analysis revealed a 47 XXY chromosome formula.
Conclusion
Klinfelter syndrome diagnosed late, masked by mental retardation, Consider examining patients and requesting a hormonal assessment in the presence of trabecular osteoporosis.

Primo-secondary amenorrhea: When autoimmune polyendocrine syndrome divert the course of a Rathke's cleft cyst
Nabila Zeryouh[1], Yousra Laalaoua[1], Hamdane Chaymae[1], Salma Derbel[1], Siham Rouf[1] & Hanane Latrech[2]
[1]Faculty of Medicine and Pharmacy, University of Mohammed 1st, Department of Endocrinology-Diabetology and Nutrition, Mohammed VI University Hospital Center, Oujda, Morocco; [2]Faculty of Medicine and Pharmacy, University of Mohammed 1st, Department of Endocrinology-Diabetology and Nutrition, Mohammed VI University Hospital Center, Morocco

Introduction
Secondary or primo-secondary amenorrhea suggests central damage of the hypothalamic-pituitary axis or peripheral damage of the reproductive system. It must be carefully investigated with an essential hormonal workup to determine the etiology and initiate the appropriate treatment.
Observation
We report the case of a 21-year-old patient, admitted for exploration of a primo-secondary amenorrhea associated with a pituitary tumor syndrome made of retro-orbital headaches, without vomiting nor visual acuity decrease, with sometimes hot flashes. Clinically, the patient had a good development of secondary sexual characteristics. She was in clinical euthyroidism without dysmorphic syndrome. Biologically: 17 B Estradiol was less than 12 pg/ml with elevated gonadotropins, collapsed AMH and normal karyotype. Anti-TPO antibodies were positive with normal TSHus. Radiologically: Hypothalamic-pituitary MRI revealed of a Rathke's cleft cyst of 6 mm and uterus was hypoplasic on Pelvic ultrasounds. Finally, Eye examination and Goldman's visual field were normal.
Discussion-Conclusion
This observation reflects the complexity of the etiological diagnosis of primo-secondary amenorrhea while two disorders at different levels of the hypothalamic-pituitary-ovarian axis are associated: Rathke's cleft cyst and primary autoimmune ovarian insufficiency as part of a type 2 autoimmune polyendocrine syndrome. Thus, although the diagnosis may be obvious, further investigation should be required to support the diagnosis and to avoid misinterpretation of a true underlying etiology.

Curschmann Steinert disease and related endocrine disorders
Mennani Fatima Ezzahra, Ouidad Douali, Sana Rafi, Ghizlane El Mghari & Nawal El Ansari
Centre Hospitalo-Universitaire Mohammed VI Marrakech, Endocrinology, Marrakech, Morocco

Introduction
Steinert's myotonic dystrophy (SMD) is a neuromuscular disorder with a multisystem distribution. It is a genetic disease with autosomal dominant transmission. It may be associated with various endocrine disorders.

Observation
We report the case of a 47-year-old patient followed for DM since the age of 18, diabetic under insulin therapy for 20 years, hypertensive for 1 year under losartan 50 mg/d who was referred to us for evaluation of the endocrine impact of his disease. On examination, the patient reported significant asthenia, polyuropolydipsic disorder with 5 nocturnal awakenings, erectile dysfunction, decreased libido and weight gain. Examination: conscious patient, with significant psychomotor slowing down, bilateral congenital ptosis, overweight (BMI = 26.2 kg/m2), normocardial at 91bpm, his blood pressure was 148/72 mmHg, areas of lipodystrophy on the left arm, his thyroid was not palpable. External genitalia examination was normal, her osteotendinous reflexes were weak. On biology, the HbA1c was 12.60%, the thyroid balance: TSH: 1.32 mIU /l T4 21.2pmol/l, the testosteronemia was 4.96 mg/l with gonadotropins: FSH at 4.5 ui /l and LH at 6.7ui /l and a normal prolactinemia, the lipid balance objectified a total hypercholesterolemia at 2.98g/l. The management was based on the reinforcement of the hygienic-dietary rules, the intensification of the insulin therapy and the setting on atorvastatin. The evolution was favorable.
Discussion
Steinert's myotonic dystrophy is the most common muscular dystrophy in adults [1]. It is an autosomal dominant inherited neuromuscular disorder characterized by myotonia and progressive muscle atrophy. It is multisystemic and highly variable in clinical expression [2]. The endocrine abnormalities most commonly associated with DSM are dysthyroidism, diabetes, peripheral gonadal insufficiency, increased risk of hyperlipidemia, nonalcoholic fatty liver disease, erectile dysfunction, benign and malignant thyroid nodules, bone fractures, miscarriage, premature delivery, and labor failure during delivery. Circulating levels of parathyroid hormone and corticotropic hormone may be elevated, but the mechanisms of these associations are unclear [3-4]. DM is responsible in our patient for poorly controlled diabetes and total hypercholesterolemia. The thyroid workup ruled out hypothyroidism despite the suggestive clinical signs, hypogonadism was also ruled out.
Conclusion
DM does not only concern the neurologist, but requires a multidisciplinary management in which the endocrinologist finds his place both in the screening and in the management. A systematic search for endocrinopathies could help prevent certain complications.

Application of a novel multimodal-based deep learning model for prediction of recurrence in patients with papillary thyroid carcinoma

Dong-Hwa Lee[1], Jee-Woo Choi[2], Geun-Hyeong Kim[2], Seung Park[3] & Hyun Jeong Jeon[1]
[1]Chungbuk National University College of Medicine and Chungbuk National University Hospital, Internal Medicine, Cheongju, South Korea; [2]Chungbuk National University Hospital, Medical AI Research Team, Cheongju, South Korea; [3]Biomedical Engineering, Chungbuk National University Hospital, Cheongju, South Korea

Background
Thyroid cancer is the most common endocrine malignancy, and papillary thyroid carcinoma (PTC) is the most frequent type of thyroid malignancy. Although the mortality rate is low, some patients experience cancer recurrence during follow-up periods. Early detection of recurrence helps improve the outcomes of patients and reduce the socioeconomic burden. In this study, we investigated the accuracy of a novel multi-modal prediction model by simultaneously analyzing numeric and time-series data to predict recurrence in patients with PTC after thyroidectomy.
Methods
We analyzed patients with thyroid carcinoma who underwent thyroidectomy at Chungbuk National University Hospital between January 2006 and December 2021. To detect PTC recurrence, we acquired clinical data, including demographic information, ultrasonography (US) reports, pathology reports, whole-body iodine scan, and thyroid function test results. We propose a novel multimodal-based deep learning model for predicting PTC recurrence. The proposed model uses numerical data, including clinical information at the surgery, and time-series data, including TFT results after the surgery. For the model training with unbalanced data, we employed weighted binary cross-entropy with weights of 0.8 for the positive (recurrence) group and 0.2 for the negative group.
Results
Our dataset consists of 1,613 patients, including patients who 1,550 non-recurrence PTC and 63 recurrence PTC, who underwent thyroidectomy. Patients with recurrence had larger tumor size, more multiplicity, and a higher frequent male ratio than those without recurrence. We performed 4-fold cross-validation on the dataset to evaluate the model performance. The proposed model achieved an average AUROC of 0.9622, F1-score of 0.4603, sensitivity of 0.9042, specificity of 0.9077. When applying our proposed model, experimental results show that it can predict recurrence at least one year before recurrence.
Conclusions
Our study results demonstrated that the multi-modal prediction model for predicting PTC recurrence after thyroidectomy showed good performance. In clinical practice, it might help in the early detection of recurrence during follow-up in patients with PTC after thyroidectomy.

Alemtuzumab-Induced Severe Ophthalmopathy in Relapsing-Remitting Multiple Sclerosis: Experience at A Single Center

Pablo Rodríguez de Vera Gómez[1], Antonio Manuel Garrido Hermosilla[2], Mariola Méndez Muros[1], Francisco Javier Toyos Sáenz de Miera[3], Rocío López Ruiz[4] & Tomás Martín Hernández[1]
[1]hospital Universitario Virgen Macarena, Endocrinology and Nutrition, Sevilla, Spain; [2]Hospital Universitario Virgen Macarena, Ophtalmology, Sevilla, Spain; [3]Hospital Universitario Virgen Macarena, Reumatology, Sevilla, Spain; [4]Hospital Universitario Virgen Macarena, Neurology, Sevilla, Spain

Objectives
To identify risk factors for the development of Graves' Orbitopathy (GO) in patients with Relapsing Remitting Multiple Sclerosis (RRMS) treated with Alemtuzumab, as well as to analyze the clinical behavior of this entity based on a case series.
Methods
Retrospective observational study with real-life data. Patients with RRMS who received at least one cycle of Alemtuzumab in the period 2014-2022 in aMS reference unit in Spain were included. During post-treatment follow-up, the development of Graves' disease (GD) and GO was documented in the included cases, being assigned to one of three possible subgroups: a) No GD or GO, b) GD without GO, c) GD and GO.
Results
134 patients were included. Mean follow-up was 5.98 years (SD:3.23) since initiation of Alemtuzumab. 90/134 cases (67.1%) had neither GD nor GO, 38/134 (28.4%) had GD without GO and 6/134 (4.5%) had GD and GO. The incidence of GO in patients with GD was 13.64% ($n=6/44$). The annual of pre-Alemtuzumab outbreak rate was higher in the group that developed GO (2.4 vs 1.39 GD-noGO and 1.38 noGD-noGO, $P=0.03$), as was the presence of first-degree family history of autoimmune hypothyroidism (33.3% vs 13.2% GD-noGO and 5.2% noGD-noGO, $P=0.017$). Cases that developed GO presented with respect to the GD-noGO group higher levels of f-T4 (4 vs 2.3 ng/dl, $P=0.009$), f-T3 (13 vs 6.2 pg/ml, $P=0.033$) and TRab (34.77 vs 16.27 IU/l, $P=0.016$), in addition to clinical symptomatology (83.3% ($n=5/6$) vs 38.9% ($n=14/38$), $P=0.04$) and goiter (83.3% ($n=5/6$) vs 23.5% ($n=8/38$), $P=0.01$). The need for total thyroidectomy was higher in the group that developed GO (66.7% ($n=4/6$) vs 18.4% ($n=7/38$), $P=0.027$). Of the 6 diagnosed cases of GO, $n=3$ were moderate/severe and active forms (mean CAS: 4.3 points). Treatment with Tocilizumab (anti-IL6) was indicated in all of them due to refractoriness to corticosteroid treatment ($n=1/3$) or contraindication to it ($n=2/3$). In all three cases, inactivation of the disease (CAS <3) was documented after Tocilizumab, with improvement of proptosis and palpebral retraction. No retraction surgery was indicated in any case.
Conclusions
The presence of first-degree relatives with hypothyroidism, a high annual baseline outbreak rate or the development of GD with high levels of f-T4, f-T3 and TRAb can be considered risk factors for the development of GO in patients treated with Alemtuzumab. Treatment with Tocilizumab may be a useful option in the treatment of cases with elevated activity index.

COVID-19 – a trigger of autoimmune thyropathy disorders?

Evgeniia Kolpakova, Alina Elfimova, Larisa Nikankina & Ekaterina Troshina
Endocrinology Research Centre, Institute of Clinical Endocrinology, Moscow, Russia

Introduction
Research into autoimmune disorders associated with COVID-19 in the middle of an ongoing COVID-19 pandemic is an important and urgent challenge. We focus on the potential relationship between coronavirus infection and other autoimmune diseases, and the positive therapeutic effect of the treatment of severe forms of COVID-19 with drugs traditionally used in the treatment of rheumatological diseases. The results of this study are a starting point for understanding the mechanisms of related to potential breakdown of immunological tolerance and the development of thyroid autoimmune diseases during COVID-19.
Materials and Methods
This prospective single-center, case-control study included 41 patients hospitalized at the National Endocrinology Research Centre with a clinical and laboratory analysis diagnosis of COVID-19 and bilateral polysegmental viral pneumonia, as well as 78 healthy individuals who have never had a coronavirus infection. Both groups were comparable in terms of gender and age. To assess the functional status of the thyroid gland all patients underwent observation of the thyroid-stimulating hormone (TSH), T3free, T4free, antibodies to thyroid peroxidase, antibodies to the TSH receptor. Their thyroid profile was assessed in both the acute period of the disease as well as 6 months after recovery. The markers of the inflammatory process were assessed: 27 signal molecules of cytokines and chemokines. In patients from the first group, the study of the following cytokine levels was carried out in both the acute period of the disease as well as 6 months after recovery: IL-1b, IL-1ra, IL-2, IL-4-10, IL-12, IL-13, IL-15, IL-17, Eotaxin, FGF, GM-CSF, G-CSF, IFN-g, IP-10, MCP- 1, MIP-1a and -1b, PDGF-bb, RANTES, TNF-a, VEGF.
Results
Manifest hypothyroidism was detected in 2.4% of patients, and at subclinical levels in 7.3% of patients 6 months after the onset of coronavirus infection, in addition to an increase in antibodies to thyroid peroxidase 6 months after recovery from coronavirus infection was detected ($P = 0.023$). In the group of patients with increased antibodies to thyroid peroxidase after undergoing COVID-19, statistically significantly high levels of IL-4 ($P = 0.033$), IFN-g ($P = 0.007$), and Eotaxin ($P = 0.008$) were obtained. An increase in antibodies to the TSH receptor was revealed in the group of patients with severe COVID-19 who did not receive pathogenetic therapy with tocilizumab in the acute period of the disease ($P = 0.046$).
Conclusion
Our research shows that the COVID-19 may be a trigger of autoimmune thyropathy disorders.

The reduction of peripheral blood Treg differentiated fractions and the CD25 expression in Patients with Graves' disease after Radioactive Iodine Therapy

Margarita Dudina[1,2], Andrey Savchenko[3], Sergey A. Dogadin[1,2], Alexander G. Borisov[3], Vasiliy Belenyuk[3] & Daria Fomina[1]
[1]Krasnoyarsk State Medical University, Internal disease, Krasnoyarsk, Russia; [2]Krasnoyarsk Regional Clinical Hospital, Endocrinology, Krasnoyarsk, Russia; [3]Federal Research Center «Krasnoyarsk Science Center» of the Siberian Branch of the Russian Academy of Sciences, Scientific Research Institute of medical problems of the North, Laboratory of Molecular and Cell Physiology and Pathology, Krasnoyarsk, Russia

Background
Foxp3(+) regulatory T cells (Treg) play a leading role in developing immune tolerance through active suppression in Graves' disease (GD). The influence of radioactive iodine therapy (RAI) on the differentiated fractions of Treg of GD patients is still poorly understood.
Aim
To estimate the differentiated fractions of blood Tregs and the CD25 expression in patients with GD after RAI.
Materials and Methods
In total, 36 women with recurrent GD (age mean [range] = 46.34 ± 14.32 years [27–59] and 42 age-and sex-matched healthy control subjects were recruited into the study. All patients treated with thiamazole for at 5 months (2 – 9) and withdrawal 14 days before RAI. All patients had a fixed 400-700 MBq radioactive iodine (^{131}I) dose orally. For the immunophenotyping of Treg differentiating fractions, each whole blood sample (100 μL) was stained using FITC-labeled mouse anti-human CD62l, PE-labeled mouse anti-human CD127, ECD-labeled mouse anti-humanCD45R0, PC5.5-labelled mouse anti-human CD25, PC7-labelled mouse anti-human CD4 (clone T4, cat. 6607101, Beckman Coulter, Indianapolis, IN, USA), A-A700-labelled mouse anti-human CD3 and A-A750-labelled mouse anti-human CD45. The CD25 expression assessed by MFI.
Results
Lower absolute counts of Treg ($CD3^+CD4^+CD127^{Low}CD25^{High}$) were found in GD patients before RAI in comparison with healthy controls ($P < 0.001$). In GD patients up to six month after RAI the absolute and percentage Tregs content was lower relative to initial levels ($P < 0.001$). In GD patients before and 1, 3 and 6 month after RAI a significant decrease in the percentages of "naïve" ($CD45R0^-CD62L^+$) and terminally differentiated ($CD45R0^-CD62L^-$) Tregs was established relative to the control, and on 3 and 6 months after RAI a significant decrease of this Treg differentiated fractions was observed relative to the values detected in patients before and 1 month after RAI ($P < 0.001$). Against the background of compensated hypothyroidism in GD patients on 3 and 6 months after RAI we observed a significant decrease than in healthy individuals in expression of MFI CD25 on "naïve" and terminally differentiated Tregs ($P < 0.001$), and central memory Tregs ($CD45R0^+ CD62L^+$) ($P < 0.001$).
Conclusion
There is expanding knowledge on new Treg imbalance that is crucial for the development of GD. The role and importance of "naïve" and terminally differentiated Treg in the pathogenesis of GD allows not only a better understanding of the mechanisms of development and reccurence of these diseases, but also helps to define immunotherapy targets that can be restored by increasing the number and function of Tregs.

Oxidative stress and the level of NAD(P)-dependent dehydrogenases of blood neutrophils in patients with compensated and relapse Graves' hyperthyroidism ongoing thiamazole treatment

Margarita Dudina[1,2], Andrey Savchenko[3], Sergey A. Dogadin[1,2] & Ivan Gvozdev[3]
[1]Krasnoyarsk State Medical University, Internal disease, Krasnoyarsk, Russia; [2]Krasnoyarsk Regional Clinical Hospital, Endocrinology, Krasnoyarsk, Russia; [3]Federal Research Center «Krasnoyarsk Science Center» of the Siberian Branch of the Russian Academy of Sciences, Scientific Research Institute of medical problems of the North, Laboratory of Molecular and Cell Physiology and Pathology, Krasnoyarsk, Russia

Background
Oxidative stress is involved in the pathogenesis of Graves hyperthyroidism (GH) and a disbalance of the cell redox state is associated with thyroid hyperfunction and the reccurence of the disease.
Aim
To study the level of reactive oxygen species (ROS) and NAD(P)-dependent dehydrogenases of peripheral blood neutrophils in patients with compensated and relapse GH ongoing thiamazole.
Materials and Methods
The study included 96 women with onset of Graves' disease, aged 20 to 65 years, ongoing thiamazole. At the follow-up examination three months after the start of thiamazole all patients divided into two groups, respectively, compensated and relapse hyperthyroidism. The level of ROS was studied using a 36-channel chemiluminescence analyzer "BLM-3607" and characterized by: Tmax – the rate of chemiluminescent reaction, Imax - the maximum level ROS synthesis and the area under the chemiluminescence curve (S - total synthesis of ROS for 90 minutes). The activity of NAD(P)-dependent dehydrogenases in neutrophils was determined using the bioluminescent method.
Results
In relapse GH patients, the indicator S of spontaneous and zymosan-induced lucigenin-dependent chemiluminescence increases significantly, both relative to the control and to the values of GH compensated patients ($P < 0{,}001$). Luminol-dependent chemiluminescence in GH relapsed patients demonstrated more than tenfold increase of S relative to the control, but no statistically significant differences were found in GH compensated patients. In GH patients both groups the activity of the studied NAD-dependent oxidoreductases (NAD-GDH and MDH), auxiliary dehydrogenase reactions (NADP-GDH and NADP-ICDG) and NADH-dependent reactions (NADH-LDH and NADH-MDG) is increased ($P < 0{,}001$). A high level of NADH-dependent glutamate dehydrogenase was observed in GH relapse patients, both relative to the control and GH compensated patients ($P < 0{,}001$). In GH compensated patients compared to control the low activity of Lactate dehydrogenase was revealed ($P < 0{,}001$). In GH relapse patients the

levels of G6PDH and NADP-GDH activity are correlated with S spontaneous lucigenin-dependent chemiluminescence ($r = 0.74$, $P < 0.001$, in both cases) and Imax spontaneous luminol-dependent chemiluminescence ($r = 0.69$, $P = 0.003$ and $r = 0.65$, $P = 0.005$, respectively).
Conclusion
In GH compensated patients the level of oxidative stress mainly affects the primary ROS production, which is associated with hyperthyroidism compensation and the immunosuppressive effect of thiamazole. In GH relapse patients, there are more changes in the production of secondary ROS, indicating the activation of cellular response immunological mechanisms, that determined by the features of intracellular metabolism and may play an important role in the recurrence of the disease.

Conversion from longstanding hypothyroid Hashimoto's thyroiditis to Graves' disease. Clinical characteristics from a large patient cohort

Joachim Feldkamp[1], Shari Muenstermann[1], Rainer Görges[2] & Franz Ruderich[1]
[1]University Bielefeld, Klinikum Bielefeld, Endocrinology and Diabetes, Bielefeld, Germany; [2]University Essen, Nuclear Medicine, Essen, Germany

The transition of hypothyroidism from Hashimoto's thyroiditis into hyperthyroidism (Graves' disease) is uncommon, and the underlying causes are still unknown. We studied clinical characteristics in patients with the conversion of preexisting Hashimoto's thyroiditis to Graves' disease compared to patients with Hashimoto's thyroiditis or Graves' disease alone.
Patients and Methods
Retrospective comparative case series of 42 patients (mean age 53 years, 95%-CI [47.9;58]) with preexisting hypothyroidism due to Hashimoto's thyroiditis who developed hyperthyroidism (Graves' disease with positive TSH receptor antibodies). Data were compared with 30 patients with Hashimoto's thyroiditis (mean age 48.5 years, 95%-CI [44;53]) and 38 patients with Graves' disease (mean age 48.5 years 95%-CI [44;53.9]). In all three groups, female patients were predominant (Female to male ratio case group 38:4, Hashimoto group 26:4 and Graves' disease 36:2). Social data (age, sex, origin, marital status, number of children, residential environment, occupational status, stressful life events, smoking, and alcohol), clinical data (body mass index, concomitant diseases, concomitant medication, therapy for thyroid dysfunction) and biological data (TSH, freeT3, free T4 and thyroid antibodies) were analyzed.
Results
Hypothyroid patients were treated for a mean time of 12.2 years before they developed hyperthyroidism. The mean dose of levothyroxine to maintain euthyroidism was 92 micrograms per day. Before manifestation of hyperthyroidism, patients who converted to Graves' disease showed significantly higher TSH values (Wilcox-test $P=0.003$) and significantly lower T4 values (Wilcox-test $P=0.02$) than patients with Hashimoto's thyroiditis alone. Compared to patients with Hashimoto's and Graves' disease, conversion patients were significantly more likely to take concomitant medications. No significant difference was found in the social factors of patients with conversion compared with Hashimoto's and Graves' disease controls. Alcohol consumption and smoking status were comparable. No differences were seen in TSH, T3 and T4 levels in hyperthyroidism between conversion patients and patients with Graves' disease and in the distribution of thyroid-specific antibodies between case and control patients.
Conclusion
Smaller case series have been published regarding patients with conversion from Hashimoto's thyroiditis to Graves' disease. So far, our study is the largest case series and the only one with a comparison of patients with Hashimoto's thyroiditis or Graves' disease alone. There was a significant difference in the TSH and T4 levels between conversion patients before manifestation of Graves' disease and Hashimoto's patients. No difference could be seen in the other clinical parameters. In the future, genetic and immunological studies may identify factors separating these disease entities better.

Rising preoperative TPO titers decrease the risk for differentiated thyroid cancer in a linear fashion: a retrospective analysis of 1620 consecutive thyroid surgeries

Dimitra Bantouna[1], Ioannis Zoupas[2], Juan C Jaume[3], Shanawaz Imam[4], Sarantis Livadas[5,6], Nicholas Angelopoulos[7], Evaggelos Karvounis[8] & Rodis Paparodis[3,9]
[1]Private Practice, Patras, Greece; [2]National and Kapodistrian University of Athens, Medical School, Athens, Greece; [3]University of Toledo College of Medicine and Life Sciences, Center for Diabetes and Endocrine Research, Toledo, United States; [4]University of Toledo College of Medicine and Life Sciences, Center for Diabetes and Endocrine Research, Toledo, OH, United States; [5]Athens Medical Center, Endocrinology, Diabetes and Metabolism, Athens, Greece; [6]Endocrinology, Diabetes and Metabolism Clinics, Private Practice, Athens, Greece; [7]Endocrinology, Diabetes and Metabolism Clinics, Private Practice, Kavala, Greece; [8]Euroclinic Hospital, Endocrine Surgery Center of Excellence, Athens, Greece; [9]Endocrinology, Diabetes and Metabolism Clinics, Private Practice, Patras, Greece

Introduction
Chronic lymphocytic thyroiditis is an important risk factor for differentiated thyroid cancer (DTC) in surgical series, but the role of thyroid peroxidase antibodies (TPO) seems less clear in that regard. We designed the present study to evaluate that effect in our large patient population.
Methods
We recruited subjects operated with total thyroidectomy in 4 sites (USA: 1, Greece: 3) during a period of 14 consecutive years. We gathered data on TPO antibodies titers measured with commercially available radioimmunoassays, and reviewed data on surgical pathology. TPO $\geq$ 34IU/ml was deemed high (TPO+). Odds ratios (OR) for DTC were calculated with Fischer's exact test. $P < 0.05$ was deemed significant.
Results
We reviewed data on 8,425 thyroid surgeries, and TPO titers were available for 1,620 subjects: DTC $n=702$ (43.3%), benign pathology (BEN) $n=918$ (56.7%), TPO+ $n=524$ (32.3%) and TPO- (<34IU/ml) $n=1096$ (67.7%). DTC was found with a lower frequency in TPO+ (183/524, 34.9%) compared to TPO- (519/1096, 47.4%) subjects, OR 0.60 (0.48-0.74, $P < 0.0001$). Subjects with the lowest TPO titers had the highest rate of DTC: TPO< 10IU/ml $n=338/635$ (49.3%), TPO 34-100IU/ml $n=69/162$ (42.6%), TPO 100-500IU/ml $n=70/168$ (41.7%), TPO 500-1000IU/ml $n=16/50$ (32.0%), TPO >1000IU/ml $n=28/144$ (19.4%), $P < 0.0001$.
Conclusions
High TPO Antibodies appear protective against DTC in our large multicentre cohort of patients operated with a total thyroidectomy. Rising preoperative TPO titers confer linearly increasing protection against DTC in the surgical specimen. More research is needed to fully understand the role of thyroid autoimmunity in the genesis of DTC.

Accuracy of the European Thyroid Imaging Reporting and Data System (EU-TIRADS)

Mohamed Masmoudi, Chaima Zitouni, Wadii Thabet, Ezer Chebil, Mehdi Hasnaoui & Khelifa Mighri
Taher Sfar Hospital, ENT Department, Mahdia, Tunisia

Introduction
There are several classifications based on thyroid ultrasound for selecting suspected malignant thyroid nodules. In 2017 the European Thyroid Association developed a new and simple European Thyroid Imaging and Reporting Data System (EU-TIRADS), which classifies the risk of malignancy of thyroid nodules in adults to the following categories: benign, low-, intermediate-, and high-risk.
Objective
To evaluate the accuracy of the EU-TIRADS for detecting malignant thyroid nodules.
Methods
A retrospective study of 213 patients (335 nodules) who underwent thyroid surgery at our ENT department, from 2013 to 2021. Histological results were correlated to the ultrasound findings.
Results
Our study included 193 women and 20 men. The mean age was 46,8 years. The percentage of each EU-TIRADS class was: EU-TIRADS 2 = 12,8 %, EU-TIRADS 3 = 43,9 %, EU-TIRADS 4 = 7,2 % and EU-TIRADS 5 = 36,2%. Thyroid cancer was noted in 14,6% and 85,4% of the cases had benign nodules. The risk of malignancy was: EU-TIRADS 2 = 4,6 %, EU-TIRADS 3 = 6,1 %, EU-TIRADS 4 = 8,3 % and EU- TIRADS 5 = 80,09 %. Correlation of histological results with preoperative ultrasound findings showed a sensitivity of 77,55%, a specificity of 62,95% with positive and negative predictive values of 26,21% and 94,21% respectively.
Conclusion
To conclude, EU-TIRADS is a simple tool in assessing the malignancy of thyroid nodules, which demonstrates a good clinical correlation with histological results. Because of its good sensitivity it can be used in selecting nodules with a high risk of cancer.

Anasarca state with exceptional localization revealing a deep hypothyroidism

Chaymaa Alami Hassani[1], Ayoub Idrissi[2], Abainou Lahousssaine[3], Sanae Elhadri[3], Azzelarab Meftah[3,4] & Hicham Baizri[3,4]
[1]CHU SOUSS MASSA AGADIR/Faculty of Medicine and Pharmacy Ibn Zohr Agadir, Department of Endocrinology Diabetology and Metabolic Diseases, Agadir, Morocco; [2]Military Hospital Avicenne Marrakech, Department of Endocrinology Diabetology and Metabolic Diseases, Marrakech, Morocco; [3]Military Hospital Avicenne Marrakech, Department of Endocrinology Diabetology and Metabolic Diseases, Marrakech, Morocco; [4]Faculty of Medicine and Pharmacy - CADI AYYAD University Marrakech, Department of Endocrinology Diabetology and Metabolic Diseases, Marrakech, Morocco

Introduction
Hypothyroidism-related anasarca is due to the capillary permeability disorders associated with hypothyroidism. It is a rare mode of revelation especially when associated with ascites, which is an exceptional localization. We report the case of a deep hypothyroidism revealed by an ascites of great abundance.
Observation
Our patient is 73 years old with a history of 2 daughters followed for Hashimoto's thyroiditis. He consults for abdominal distension associated with hoarseness, hypoacusis and constipation evolving for 3 months.. Clinical examination revealed cutaneous-mucosal infiltration, dry scaly skin and abundant ascites with positive flot sign without collateral venous circulation. The diagnosis of Hashimoto's thyroiditis was retained in view of an elevated TSHus at 150 Uui/ml; a low LT4 at 2.48 pmol/l; very positive anti thyroperoxidase antibodies $>$ 1000 UI/ml and an appearance of thyroiditis on cervical ultrasound. The ascites fluid study showed a sterile exudative fluid without malignant cells with a negative GeneXpert tuberculosis. The transthoracic echocardiography showed a pericardial effusion slide and the thoraco-abdomino-pelvic CT scan did not reveal any tumor focus apart from a large ascites and a small bilateral pleurisy. Hormone replacement therapy was started progressively at a dose of 75 µg/dl of L-thyroxine allowing the progressive disappearance of ascites and signs of hypo metabolism.
Conclusion
Exudative ascites remains a rare location of myxedematous hypothyroidism. Our case underlines the importance of F-T4 and TSH assay in the etiological assessment of ascites of undetermined cause and particularly in elderly subjects. This allows to avoid useless explorations which can, in rare cases, lead to the death of the patient in a myxedematous coma.

Rare case of Graves' disease resistant to methimazole: a case report

Zahra Ismail[1], Sana Rafi[2], Ghizlane El Mghari[2] & Nawal El Ansari[2]
[1]Mohamed VI University Hospital Center, Department of Endocrinology, Diabetes and Metabolic Disease, Marrakech, Morocco; [2]CHU Mohamed VI, Department of Endocrinology, Diabetes and Metabolic Disease, Marrakech, Morocco

Introduction
The treatment of Graves' disease is represented principally by anti-thyroid drugs, radioiodine ablation or thyroidectomy. Methimazole is the most used drug for the initial treatment. It is rare to encounter patients with resistant hyperthyroidism despite high doses of MMI.
Case presentation
A 41-year-old woman was referred to our unit for resistant thyrotoxicosis. She had a confirmed Graves' disease with positive serum Trab. Whilst her MMI dose had been increased to 60 mg/day, in adjunction with prednisone therapy (70 mg/day), her serum free thyroxin concentration was too high to be measured ($>$ 100 pmol/l). No adverse effects were noted. The patient did not show any symptoms or signs of gastrointestinal or liver disease, and had good drug compliance. Additional therapy with inorganic iodine (Lugol solution 10 drops 3 times /day) was initiated and she underwent a therapeutic plasma exchange. After 10 days, the patient's serum free thyroxin concentration normalized, and total thyroidectomy was then performed.
Discussion
It is rarely reported that cases of Graves' disease show no response to a very high dose of MMI and corticosteroid therapy. By preventing the iodination of tyrosine residues in thyroglobulin by thyroid peroxidase, MMI inhibits thyroid hormone synthesis. A previous clinical study showed that a high dose of MMI (120 mg/day) reduces thyroid hormone concentration more rapidly than standard doses of MMI in patients with hyperthyroidism. However, such a high dose of MMI may increase the risks of severe adverse effects. Therefore, we decide to maintain the MMI dose of 60 mg/day for our patient. Although previous cases of Graves' disease with resistance to antithyoid drugs has been reported, the underlying mechanisms remain unclear. Inorganic iodine inhibits the release of thyroid hormone from the thyroid gland, and corticosteroids work by suppressing the conversion of T4 to T3 in peripheral tissues. The Japan Thyroid Association and the Japan Endocrine Society recommended strategy is combination of MMI with corticosteroid and inorganic iodine in preparation for a thyroidectomy.
Conclusion
We reported a rare case of Graves' disease that was resistant to MMI. Combination therapy of MMI with corticosteroid, inorganic iodine and therapeutic plasma exchanges may represent a therapeutic option for the preoperative preparation.

Alemtuzumab-Induced Autoimmune Thyroid Dysfunction. A review of two cases

Pablo Lois Chicharro, Ane Miren Azcutia Uribe Echevarria, Pablo Ferreira-Ocampo, Sandra Carolina Doejo Marciales, Solange Fabiola Barra Malig, Remy Edward Astuñague Condori & Francisca Almodóvar Ruiz
Hospital Universitario Fundación Alcorcón, Endocrinología y Nutricion, Alcorcón, Spain

Introduction
Alemtuzumab is an humanized monoclonal antibody used for treatment of Relapsing remitting Multiple Sclerosis (RRMS). One of its main adverse effects is thyroid dysfunction, being a fluctuating hypothyroidism the most frequent presentation. Sometimes this thyroid disturbance is so significant that it might lead to alemtuzumab withdrawal. We present two Clinical cases of hyperthyroidism secondary to alemtuzumab with different clinical courses.
Case 1
53-year-old woman with RRMS **under** treatment with alemtuzumab (1 cycle received in 2019). She was referred by the Neurology Department due to thyroid disturbance (TSH 0.2 mcU/ml) prior to starting a new cycle. Laboratory tests showed previous normal TSH values but with positive autoimmunity (TgAb and TPOAb). She was asymptomatic so clinical monitoring was decided. The patient experienced progressive clinical and analytical development of severe hyperthyroidism in the follow-up, so antithyroid drugs (ATD) were **prescribed**. The study was completed with an ultrasonography and radionuclide scintigraphy, which showed diffuse hypercaptant goiter; and antibodies (TRAb positive). ATD was prescribed, and she was progressively improving. After that, the patient developed several relapses after lowering the dose. For this reason, we considered treatment with radioiodine, which was effective.
Case report 2:
43-year-old woman with RRMS since 2019, **under** treatment with alemtuzumab and autoimmune thyroid disease since 2013, with normal function. Two months after the start of treatment with alemtuzumab, she consulted about severe hyperthyroidism. The study consisted of an ultrasonography and radionuclide scintigraphy, which showed diffuse hypercaptant goiter; and antibodies (TRAb positive). The patient presented spontaneous evolution to severe hypothyroidism two months later. We started substitution treatment, and during follow-up, the patient presented two relapses of hyperthyroidism, which was resolved after discontinuation of replacement therapy. Currently, the patient is followed and checked every six months showing thyroid stability.
Conclusions
Alemtuzumab, an effective disease-modifying drug therapy for relapsing-remitting multiple sclerosis, frequently causes autoimmune thyroid dysfunction in a significant proportion of patients. Graves' disease and Hashimoto's thyroiditis can have similar clinical presentations. In alemtuzumab-induced autoimmune thyroid dysfunction, additional challenges are posed by spontaneous, bidirectional switching between hyperthyroidism and hypothyroidism. Guidelines recommend monitoring thyroid function pre-treatment and every three months for four years post-treatment.

A systematic review and meta-analysis on the associations of maternal iodine status and supplementation with thyroid function during postpartum

Pantea Nazeri[1], Elizabeth N. Pearce[2], Nahid Farrokhzad[3], Fatemeh Baghalha[4] & Mamak Shariat[3]
[1]Breastfeeding Research Center, Family Health Research Institute, Tehran University of Medical Sciences, Tehran, Iran; [2]Section of Endocrinology, Diabetes and Nutrition, Boston University Chobanian & Avedisian School of Medicine, Boston, United States; [3]Maternal, Fetal and Neonatal Research Center, Family Health Research Institute, Tehran University of Medical Sciences, Tehran, Iran; [4]Imam Hossein Hospital, Shahid Beheshti University of Medical Sciences, Tehran, Iran

Background
Iodine deficiency and excess are well-recognized risk factors for thyroid dysfunction. This systematic reveiw and meta-analysis was designed, for the first time, to explore whether maternal iodine status or supplementation is associated with postpartum thyroid function.
Methods
Electronic databases, including the MEDLINE/PubMed, Web of Science, Embase, and Scopus were searched between January 1923 and December 2021 to identify relevant studies. We assessed the quality of studies using the Newcastle-Ottawa scale. The pooled mean thyroid stimulating hormone (TSH), free thyroxin (fT4), and thyroxin (T4) concentrations and 95% confidence intervals (CIs) were estimated based on maternal iodine status. Iodine status was defined based on median values <100 and ≥ 100 µg/l for urinary iodine concentration (UIC) or breast milk iodine concentration (BMIC) during postpartum. We used a fixed/random effect model based on the absence/presence of heterogeneity. A narrative synthesis of the data was performed for iodine supplementation.
Results
Of the 2175 studies were identified, 18 were eligible for inclusion in the meta-analysis. Thyroid hormones in women who had UIC $\geq$ 100 µg/l were higher than those of women with UIC <100 µg/l during the postpartum period. The pooled values [95% CI] for TSH, fT4, and T4 concentrations in iodine-sufficient women were 1.31 [1.09, 1.53] mIU/l, 14.26 [13.86, 14.66] pmol/l, and 91.97 [88.61, 95.33] nmol/l, respectively; whereas the corresponding values in iodine-deficient women were 1.00 [0.84, 1.16] mIU/l, 12.26 [10.49, 14.03] pmol/l, and 79.80 [59.53, 100.07] nmol/l, respectively. However, none of these differences was significant. The concentration of thyroid hormones in women with BMIC <100 µg/l and ≥ 100 µg/l were within the normal range. Iodine supplementation was administered from 1 week to 9 months postpartum as supplements doses from 75 to 300 µg oral iodine daily ($n=3$) or a single 400 mg dose of iodized oil ($n=1$). In none of these, significant differences in thyroid parameters of postpartum women between the iodine-supplemented and control groups were observed.
Conclusion
Findings of the present systematic review and meta-analysis showed no effects of iodine status or supplementation on thyroid hormones in postpartum women. Further investigations are still needed to explore the effects of different degrees of iodine deficiency as well as iodine excess on different maternal thyroid parameters during postpartum and effects on thyroid function in breastfed offspring.

Frequency of Coeliac Disease in Children with Chronic Autoimmune Thyroiditis

Oksana Khyzhnyak[1], Olga Oleksyk[2] & Roman Nikolaiev[1]
[1]V. Danilevsky' Institute of Endocrine Pathology Problems, Clinical Endocrinology, Kharkiv, Ukraine; [2]A. Novak' Transcarpathian Clinical Regional Hospital, Endocrinology, Uzhgorod, Ukraine

Introduction
Chronic autoimmune thyroid disease (ATD) or Hashimoto thyroiditis (HT) is one of the main thyroid diseases in pediatric age. HT characterized by the production of anti-thyroid antibodies, by an infiltration of autoreactive B and T lymphocytes into the thyroid parenchyma and by alterations in thyroid function. Coeliac disease (CD) is a systemic autoimmune disease caused by gluten ingestion in genetically predisposed subjects. At presents with a pathognomonic enteropathy, a variety of clinical manifestations, positivity for specific antibodies, positivity for typical haplotypes HLA DQ2/DQ8. The close relationship between celiac disease and glandular autoimmunity can be largely explained by sharing of a common genetic background. Haplotypes HLA B8 and DR3 occur with increased frequency in adults and children with CD, as well as in ATD. Modern international recommendations recommend screening for CD in children with already diagnosed ATD.
The aim
of this study was to investigate the incidence of celiac disease in children with ATD.
Methods
65 children with ATD aged 7-17 years (57 girls, 8 boys) were examined. We studied the level of TSH, free T4, antibodies to thyroperoxidase (Anti-TPO), antibodies to thyroglobulin (Anti-TG) gliadin immunoglobulin G (Anti-IgG Gl), anti-tissue transglutaminase (Anti-IgG TGT), ultrasound of the thyroid gland (US ThG). Diagnosis of autoimmune thyroiditis was made if Anti-TPO >35 IU/ml or Anti-TG >20 IU/ml. Diagnosis of CD was made according recommendation from the European Society for the Study of Coeliac Disease (ESsCD) (2019).
Results
Among the children with ATD 32.3% ($n=21$) were diagnosed with hypothyroidism, the patients received levothyroxine replacement therapy and were in a state of medical euthyroidism at the time of inclusion in the study. CD was detected in 10.8% ($n=7$, all girls) of the patients. The mean age (12.5 $\pm$ 1.6 yrs) at the diagnosis of HT was significantly lower in patients with higher levels Anti-TPO (432.2 $\pm$ 23.8 IU/ml) and Anti-TG (86.6 $\pm$ 12.5 IU/ml). After prescribing a gluten-free diet for 6 months to children with a positive level of Anti-IgG TGT, patients showed a statistically significant decrease in the level of Anti-TPO and in 3 patients (280.4 $\pm$ 18.2 IU/ml) and decrease the dose of levothyroxine by an average of 30%.
Conclusion
Frequency of CD in children with ATD was 10.8%. Gluten-free diet for 6 months has some effect on improving and maintaining euthyroid status of CD patients and decreased anti-thyroid antibodies.

Factors associated with elevated liver enzymes in patients with uncontrolled hyperthyroidism

Meriem Yazidi, Ibtissem Oueslati, Nadia Khessairi, Kammoun Elyes, Fatma Chaker & Melika Chihaoui
University of Tunis El Manar, Faculty of Medicine of Tunis, La Rabta Hospital, Endocrinology, Tunis, Tunisia

Liver dysfunction is common in patients with hyperthyroidism. The underlying mechanisms remain unclear. Predictors of liver dysfunction and recovery are controversial. The aim of this study was to assess the prevalence of elevated liver enzymes in patients with uncontrolled hyperthyroidism and to identify its predictive factors.
Methods
This is a retrospective study conducted in 131 patients with hyperthyroidism admitted in the endocrinology department of La Rabta Hospital (Tunisia) between January 2009 and December 2018. Patients with subclinical hyperthyroidism and those with controlled thyroid function under treatment were not included. Liver enzymes: Aspartate aminotransferase (AST) and alanine aminotransferase (ALT) were measured in all the patients at admission. Clinical and biological data were reviewed to identify factors associated with elevated liver enzymes (AST and/or ALT) using univariate and multivariate analysis.
Results
The mean patient age was 44.1 $\pm$ 16.9 years. They were 52 men (39.7%) and 79 women (60.3%). Hyperthyroidism was related to Graves' disease in 74.8% of cases. The mean AST level was 25.6 $\pm$ 18.4 UI/l (normal range: 5-34). It was elevated in 16.0% of patients. The mean ALT level was 28.8 $\pm$ 22.5 UI/l (normal range: 6-55). It was elevated in 8.4% of patients. Elevated liver enzymes (AST and/or ALT) have been observed in 18.3% of cases. FT4 levels were significantly higher in patients with elevated liver enzymes (6.0 $\pm$ 4.2 vs 4.3 $\pm$ 2.1 ng/dl, $P=0.006$). FT4 higher than 4 times normal range was associated with elevated liver enzymes (41.7% vs 19.6%, $P=0.02$, OR [95%CI] = 2.9 [1.2-7.4]). Age, gender, smoking status, BMI, etiology of hyperthyroidism, and anti-TSH receptor antibody levels were not associated with elevated liver enzymes. After adjustment for age and gender, FT4 level higher than 4 times the normal range remains an independent parameter associated with elevated liver enzymes ($P=0,05$; ORa [95%CI] = 2.5 [1.0-6.7]).
Conclusion
Elevated liver enzymes are common in hyperthyroidism. The biological severity of hyperthyroidism seems to be the main predictive factor of this liver dysfunction.

The role of PTEN methylation level changes in papillary thyroid carcinoma diagnosis and prognosis

Mintaute Kazlauskiene[1], Kristina Zukauskaite[2,3], Raimonda Klimaitė[1,4], Aistė Kondrotienė[1,4], Dalia Daukšienė[1], Birute Zilaitiene[1,4], Rasa Sabaliauskaite[2,3] & Albertas Dauksa[5]
[1]Lithuanian University of Health Sciences, Institute of Endocrinology, Lithuania; [2]National Cancer Institute, Laboratory of Genetic Diagnostic, Vilnius, Lithuania; [3]Vilnius University Life Sciences Centre, Institute of Biosciences, Vilnius, Lithuania; [4]Hospital of Lithuanian University of Health Sciences Kaunas Clinics, Department of Endocrinology, Kaunas, Lithuania; [5]Lithuanian University of Health Sciences, Institute of Digestive Research, Kaunas, Lithuania

Introduction
Papillary thyroid cancer (PTC) is the most common type of thyroid cancer (85%–90%). Today Fine needle aspiration biopsy (FNAB) is the diagnostic tool for the evaluation of thyroid nodules because of its accuracy and cost-effectiveness, but FNAB also has limitations, as it is quite challenging to take a biopsy from a small thyroid nodule moreover FNAB diagnosis is doubtful in up to 20% of cases. Therefore, non-invasive biomarkers of PTC are needed.
Aim of the study
To evaluate methylation level changes of the PTEN gene in FFPE tissue samples and peripheral blood plasma samples of PTC patients before and after surgery.
Methods
The study included 50 FFPE tissue samples from 25 patients and 68 patients plasma samples with a histologically confirmed diagnosis of PTC. Peripheral blood samples were collected before surgery and 4-6 weeks after surgery. Methylation level changes of the PTEN gene were analysed in plasma and FFPE tissue samples by quantitative methylation-sensitive polymerase chain reaction.
Results
Paired sample analysis showed statistically higher PTEN methylation levels in FFPE tumor tissue samples compared to non-cancerous tissue samples ($P=$ 0,016). Plasma PTEN methylation levels were compared before and after PTC surgery. Significantly lower levels of PTEN methylation were found in samples collected after surgery compared to samples collected before surgery ($P=$ 0,031).
Conclusion
PTEN methylation level changes may be a promising minimal invasive biomarker in predicting PTC prognosis and diagnosing PTC.

Bone metastases of differentiated thyroid cancer: characteristics and prognostic factors in a multicenter series

Ana Piñar Gutiérrez[1], Ana R. Romero-Lluch[1], Suset Dueñas Disotuar[1], Irene De Lara-Rodriguez[1], Maria Angeles Galvez Moreno[2], Tomas Martin Hernandez[3], Jorge Garcia Aleman[4], Guillermo Martínez-de Pinillos[5], Carolina Sánchez-Malo[6] & Elena Navarro[1]
[1]Virgen del Rocío University Hospital, Sevilla, Spain; [2]Hospital Universitario Reina Sofia, Córdoba, Spain; [3]Hospital Universitario Virgen Macarena, Sevilla, Spain; [4]Hospital Universitario Virgen de la Victoria, Málaga, Spain; [5]Hospital Universitario Nuestra Señora de Valme, Sevilla, Spain; [6]Hospital of Jaen, Jaén, Spain

Objective
To describe the characteristics, survival and prognostic factors of a cohort of patients with bone metastases (BM) of differentiated thyroid carcinoma (DTC).
Methods
Multicenter retrospective observational study. Patients diagnosed with DTC and BM between 1980-2021 were included. A Cox regression was performed to study prognostic factors for 5- and 10-year survival. Kaplan-Meier and log-rank tests were performed for survival analysis and comparison between groups.
Results
$n=63$. Follow-up = 35(15-68)months. 30(48.4%) presented with BM at the initial DTC evaluation. 38(60.3%) had papillary variant. 32(50.8%) presented multiple BM. The most frequent location was the spine (60.3%). Other metastases were present in 77.8%, mainly pulmonary (69.8%). 54(85.9%) received treatment with I131, with BM uptake in 31(49.2%). 25(39.7%) received treatment with multikinase inhibitors. 34(54%) presented skeletal related events. 34(54%) died. 5- and 10-year survival was 42.4% and 20.4% respectively. Significant prognostic factors in multivariate analysis were the presence of N1 (HR 2.916 (95% CI 1.013-8.391);$P=0.047$) and treatment with I131 (HR 0.214 (95% CI 0.069-0.665);$P=0.008$) at 5 years; and the presence of other metastases (HR 6.844 (95% CI 1.017-46.05);$P=0.048$) and treatment with I131 (HR 0.23 (95% CI 0.058-0.913);$P=0.037$) at 10 years.
Conclusions
Our study reflects the management of patients with BM of DTC in real clinical practice in several centers in southern Spain. The use of antiresorptive drugs was lower than recommended based on current evidence on their preventive role in SRE. Overall survival at 5 and 10 years was lower in patients who were not treated with I131, had nodal involvement and/or had other metastases.

The role of thyroid peroxidase antibodies on the risk of thyroid cancer: a systematic review and meta-analysis of surgical cohort studies

Dimitra Bantouna[1], Ioannis Zoupas[2], Juan C Jaume[3], Shanawaz Imam[3], Evaggelos Karvounis[4], Sarantis Livadas[5,6], Panagiotis Anagnostis[7] & Rodis Paparodis[3,8]
[1]Private Practice, Patras, Greece; [2]National and Kapodistrian University of Athens, Medical School, Athens, Greece; [3]University of Toledo College of Medicine and Life Sciences, Center for Diabetes and Endocrine Research, Toledo, OH, United States; [4]Euroclinic Hospital, Endocrine Surgery Center of Excellence, Athens, Greece; [5]Athens Medical Center, Endocrinology, Diabetes and Metabolism, Athens, Greece; [6]Endocrinology, Diabetes and Metabolism Clinics, Private Practice, Athens, Greece; [7]Medical School, Aristotle University of Thessaloniki, First Department of Obstetrics and Gynecology, Thessaloniki, Greece; [8]Endocrinology, Diabetes and Metabolism Clinics, Private Practice, Patras, Greece

Introduction
Hashimoto's thyroiditis raises the risk for thyroid cancer (TC) in surgical series, but the role of thyroid peroxidase antibodies (TPO) remains controversial in that regard. We designed the present study to evaluate the effect of preoperative TPO titers in the risk of DTC.
Methods
A comprehensive search was conducted in PubMed, CENTRAand Scopus databases in November 2021 for the terms "thyroid cancer" and "TPO" or "peroxidase antibodies". We characterized the differential risk found in patients with high titers of TPO (TPO+), as compared to those with low or undetectable titers (TPO-) with regard to TC. Data are expressed as odds ratio (OR) with 95% confidence interval (CI).
Results
We retrieved and reviewed 408 records; 22 retrospective cohort studies (2006-2021) from 7 countries and $n=30,077$ subjects, fulfilled the eligibility criteria: 15 studies in East Asia with $n=24,096$ subjects and 7 studies in the Western world with $n=5981$ subjects (19.9%)]. These comprised $n=17,374$ subjects with benign disease and $n=12,703$ with TC. The reference used for TPO+ was 23.6 ± 18.8 (Range 5.1-50.0 IU/ml); $n=6,105$ patients were TPO+ and $n=22,882$ were TPO-. TC was present in $n=2,817$ TPO+ patients (46,14%) and $n=9,122$ TPO- patients (39,87%), RR 1.31 (1.24 - 1.39, $P<0.0001$). A high titer of TPO was associated with increased risk for DTC in Asian cohorts, [OR 1.21 (1.13-1.29, $P<0.0001$)] and Western world alike, [OR 1.91 (1.66-2.21), $P<0.0001$]; That risk was statistically significantly higher in the Western world cohorts as compared to east Asia cohorts OR 1.65 (1.44-1.89), $P<0.0001$.
Conclusions
Thyroid peroxidase antibodies are an integral part of Hashimoto's thyroiditis, which is a well characterized risk factor for thyroid cancer and seem to increase that risk as well. That effect seems significantly higher in the Western world, as compared to the East Asia region. Further studies are needed to characterize the effects of the immune response, with regard to thyroid cancer risk.

Benign and Malignant Thyroglossal Duct Cyst Remnants: Systematic Review and Case Series of 1842 Surgical Cases

Ioannis Zoupas[1], Juan C Jaume[2], Sarantis Livadas[3,4], Evaggelos Karvounis[5], Dimitra Bantouna[6], Shanawaz Imam[2] & Rodis Paparodis[7,8]
[1]National and Kapodistrian University of Athens, Medical School, Athens, Greece; [2]University of Toledo College of Medicine and Life Sciences, Center for Diabetes and Endocrine Research, Toledo, OH, United States; [3]Athens Medical Center, Endocrinology, Diabetes and Metabolism, Athens, Greece; [4]Endocrinology, Diabetes and Metabolism Clinics, Private Practice, Athens, Greece; [5]Euroclinic Hospital, Endocrine Surgery Center of Excellence, Athens, Greece; [6]Private Practice, Patras, Greece; [7]University of Toledo College of Medicine and Life Sciences, Center for Diabetes and

Endocrine Research, Patras, Greece; [8]Endocrinology, Diabetes and Metabolism Clinics, Private Practice, Patras, Greece

Introduction
Thyroglossal duct (TGD) carcinoma is an uncommon entity, diagnosed in patients undergoing evaluation of the neck for midline swelling, or incidentally after removal of a TGD cyst. Despite the presence of multiple publications on the topic, no systematic characterization of these tumors has been performed to date.
Methods
We performed a systematic search for the term "Thyroglossal duct" in Pubmed, Embase and Cochrane databases on December 1, 2021 and retrieved 1229 records. We excluded articles other than case reports or case series, and those written in languages other than English, Italian, French or Spanish.
Results
We incorporated data from 366 manuscripts, comprising 1202 patients operated for TGD disease. Out of these, $n=550$ cancers were identified, consisting of $n=475$ (86.4%) Papillary carcinomas (PTC), $n=8$ Follicular carcinomas (FTC) (1.5%), $n=5$ Hürthle cell carcinomas (HCC) (0.9%), $n=27$ Squamous cell carcinomas (SCC) (4.9%), $n=2$ poorly differentiated/anaplastic thyroid carcinomas (ATC) (0.4%), $n=1$ Adeno-SCC (0.18%), $n=1$ Adenocarcinoma (0.18%), $n=12$ synchronous PTC/FTC (2.2%), $n=1$ synchronous PTC/SCC (0.18%) and $n=18$ of unclear histological diagnosis (4.75%). $n=173$ patients were males and $n=273$ were females; gender was not available in $n=104$ cases. Mean cancer size was 1.3 ± 1.3 cm (range 0.01-7.0 cm); 49.6% were microcarcinomas (<1 cm). Lymph node involvement was present in $n=62/243$ (25.3%). Distant metastasis was present in $n=4$ patients (0.7%).
Conclusions
TGD remnant cancers include various tumors, with histology and features of aggressive behavior similar to what we see in thyroid cancer cases. More research is needed to better understand the mechanisms of tumorigenesis in the TGD.

Hashimoto's encephalopathy: a case report

Faten Haj Kacem Akid[1], Raida Ben Salah[2], Siddiqa Soomauroo[1], Abdel Mouhaymen Missaoui[1], Sarra Chouaib[1], Fatma Mnif[1], Faten Frikha[2], Zouheir Bahloul[2] & Mohamed Abid[1]
[1]Hedi Chaker University Hospital, Department of Endocrinology, Sfax, Tunisia; [2]Hedi Chaker University Hospital, Department of Internal Medicine, Sfax, Tunisia

Introduction
Hashimoto's encephalopathy (HE) is characterised by the combination of clinical signs of encephalitis and autoimmune thyroiditis with elevated levels of antithyroid antibodies (ATA). It is a rare condition and its etiopathogenesis is still poorly understood.
Observation
we present a 33-year-old female patient who was hospitalized for gait disorders. The diagnosis of a chronic cerebellar syndrome related to Hashimoto's encephalitis was retained in view of an elevated TSH level and positive ATA, but the patient was clinically euthyroid. A series of investigations was performed: a cervical ultrasound scan showing a diffuse multi-micronodular goiter. A cerebral magnetic resonance imaging showed a cerebellar atrophy without focal or confluent white matter hyperintensities. A lumbar puncture was performed, showing no hyperproteinorrachia or pleocytosis. The electroencephalogram was normal. Other causes such as tumoural, toxic, malformative and degenerative were ruled out.
Discussion/Conclusion
HE is a rare entity, which was first described in 1966. It is characterised by aspecific neurological and/or psychiatric symptoms. Biologically, it is associated with an increase in ATA in the serum and sometimes in the cerebrospinal fluid of affected patients. The pathogenesis of HE is unknown. The role of ATA is a matter of debate. Indeed, several studies have shown that anti-thyroperoxidase antibodies have a high prevalence in asymptomatic individuals. This entity is usually very sensitive to corticosteroid therapy. It is a diagnosis by exclusion.

Thyroid pathology in patients with familial adenomatous polyposis

Joaquin de Carlos[1], Lucia Zabalza[2], Maria Rosario Aznarez[2], Ana Irigaray[2] & Emma Anda[2]
[1]Hospital de Zumárraga, Zumarraga, Spain; [2]Hospital Universitario de Navarra, Pamplona, Spain

Introduction
Familial Adenomatous Polyposis (FAP) syndrome is an autosomal dominant disorder associated with a high risk of multiple intestinal and extraintestinal cancers. They develop hundreds or thousands of adenomas in the rectum and colon during the second decade of life that. If they are not identified and treated, almost all patients develop colorectal cancer (CRC) and die by the age of 40-50 years. Thyroid carcinoma is a FAP manifestation with an unknown reported higher risk with an approximate prevalence of 1-2%. We sought to define the prevalence of t thyroid pathology, defined as autoimmunity, nodularity, and carcinoma.
Materials and methods
Prospective study, selecting 17 living patients diagnosed and registered with APC mutations under follow-up from the Digestive Department of the Hospital Universitario de Navarra (HUN) with current or past follow-up in the Endocrinology Department. Radiological tests, clinical, and analytical variables were analyzed.
Results
The study population included 12 men (64.7%) and 5 women (35.3%), with a mean age of 47 years. The median age at diagnosis of FAP was 28 years, with a mean follow-up time of 16 years. All patients underwent thyroid ultrasound examination and blood tests with the determination of thyroid autoimmunity. The prevalence of nodular pathology was 58.8% (10/17), of which 7 had single nodules and 3 had multinodular goiters. Of the 10 patients with nodular pathology, 5 had nodules >1 cm (29.4% of the total sample). Of these, 4 had indications for cytologic study. The result of the cytologic study was Bethesda II in 3 cases and Bethesda IV in one, so surgical treatment was necessary. The anatomopathological study was follicular adenoma. No malignancy was found in the sample. The overall prevalence of autoimmunity is 31.25% (5/16). Of the 5 patients with thyroid autoimmunity: 2 present thyroid peroxidase antibodies (40%), 2 thyroglobulin antibodies (40%), and 1 patient both (20%).
Conclusion
The prevalence of thyroid nodularity in the sample of patients with FAP is above that described in the general population. Probably the small number of patients in the sample has conditioned the non-detection of thyroid carcinoma.

Thyroid calcifications: tragedy or stability

Yuriy Aleksandrov[1] & Lubov Timofeeva[2]
[1]Yaroslavl State Medical University, Surgery, Yaroslavl, Russia; [2]FSBEI HE «I. N. Ulianov Chuvash State University», Cheboksary, Russia

Thyroid calcifications are a difficult problem to interpret. The deposition of calcium salt crystals often indicates profound morphological changes, cell death, their rearrangement and dedifferentiation. The calcifications are not guaranteed markers of any process. There is also no data on the effect calcifications on the development of a process in the thyroid. The analysis of 67 thyroid nodules, in wich calcifications were detected during ultrasound. Macrocalcifications were detected in 44 cases. They were ring-shaped, lumpy, amorphous, and had an acoustic shadow, the density of which depended on the sizes of the calcifications. Macrocalcifications were clearly detected during clinical examination and surgery in 35 patients. In this cases the biopsy was difficult, since calcifications was an obstacle to the needle, and the acoustic shadow does not allow registering the position of the needle tip. The 13 patients with coarse calcifications had a wide acoustic shadow covering a large volume of the nodules, which did not allow to determine their sizes and the echostructure of the central part. Microcalcifications were detected in 19 cases. The results of the biopsy: 47 patients had thyroid tumors (39 – cancer, 8 – adenomas), 20 – nodular colloidal goiter. Factor analysis revealed that in the group with macrocalcifications, tumor were detected in 59,1%, colloidal goiter in 36,4%. In the group with microcalcifications, tumors were detected in 89,5%, and colloidal goiter in 10,5%. The analysis also found that the detection by ultrasound of a combination of signs of nodules such as hypoechogenicity, blurred contours and "height more than width" (TI-RADS4-5) with a high probability indicates of a tumor and the need for biopsy. The detection of macrocalcifications, a liquid component, Halo rim, and reduced peripheral blood flow in the nodules is more typical for colloidal goiter. However, the presence of calcifications causes high rigidity of such nodules during elastography, which translates these cases into the TI-RADS4 group, in which a biopsy is absolutely indicated. In the group of tumors, macrocalcifications were detected in 55,3%, and microcalcifications in 36,2%. In colloidal goiter, macrocalcifications were detected in 80,0%, and microcalcificatoins in 10,0%. It was also found that the presence of calcifications does not affect the functional

activity of the thyroid. Based on this, we can say that the presence of microcalcifications, along with reduced echogenicity and fuzzy contours of the nodules, is one of the key signs of a thyroid tumor. Colloidal goiter is more characterized by ring-shaped and lumpy macrocalcifications.

Paraneoplastic Hyperthyroidism in an Adult with Choriocarcinoma – A Case Report

Isabel Inácio[1], Sara Santos[1], Paulo Dias Silva[2], Nuno Gonçalves[3], Joaquina Maurício[4], Ricardo Teixeira Pinto[4], Ana Vaz Ferreira[4], Raquel Calheiros[1], Pedro Souteiro[1], Joana Oliveira[1], Ana P Santos[1] & Isabel Torres[1]

[1]Portuguese Institute of Oncology of Porto, Endocrinology, Porto, Portugal; [2]Portuguese Institute of Oncology of Porto, Clinical Pathology, Porto, Portugal; [2]Portuguese Institute of Oncology of Porto, Clinical Pathology, Porto, Portugal; [4]Portuguese Institute of Oncology of Porto, Oncology, Porto, Portugal

Introduction

Hyperthyroidism is an endocrine condition with multiple causes. Paraneoplastic hyperthyroidism due to marked overproduction of human chorionic gonadotropin (hCG) by choriocarcinoma is a rare diagnosis, which results from the homology of the alpha subunit of hCG to TSH.

Clinical case

A 33-year-old man, with a history of cryptorchidism and orchidopexy in infancy and a euthyroid thyroid nodule, presented with nausea, constipation, and abdominal pain. Computed tomography showed a retroperitoneal mass with 90x77x72 mm and multiple bilateral pulmonary nodules. Laboratory data revealed pancytopenia with neutropenia and hCG levels of 144,690 (<2.5) mUI/ml, and testicular ultrasound was normal. He was admitted with a presumptive diagnosis of extragonadal choriocarcinoma with pulmonary metastases and was started on chemotherapy and corticotherapy. Approximately a week later, the patient presented with respiratory insufficiency and hemoptoic cough likely in the context of haemorrhage from the pulmonary metastasis. He was admitted to the intensive care unit for ventilatory support, requiring an increase in corticotherapy dose. On the ninth day of chemotherapy, laboratory data showed maximum hCG levels of 590,399 mUI/ml. Due to the thyroid function compatible with hyperthyroidism [FT4 7.77 (0.80-1.67) ng/dl, FT3 18.5 (2.00-4.40) pg/mand TSH <0.005 (0.270-4.200) uUI/ml], the treatment with methimazole was started. Later results showed negative anti-TSH receptor, anti-thyroid peroxidase and anti-thyroglobulin antibodies. The patient continued treatment, with a favorable response: on the twenty-first day of chemotherapy, hCG levels dropped to 25,656 mUI/ml, pancytopenia and neutropenia improved, and thyroid function showed FT4 of 2.47 ng/dl and FT3 2.58 pg/ml. Approximately 3 months later, the patient is still on chemotherapy and methimazole, with improved thyroid function [FT4 1.20 (0.80-1.67) ng/dl, FT3 3.15 (2.00-4.40) pg/ml and TSH <0.215 (0.270-4.200) uUI/ml] and significantly lower hCG levels [58.9 (<2.5) mUI/ml].

Conclusion

The treatment of paraneoplastic hyperthyroidism due to hCG is directed against the tumor, however antithyroid medication is a useful adjunctive therapy in a presence of frank and prolonged hyperthyroidism. Chemotherapy, in an initial phase, can cause an even more marked increase in hCG levels, as seen in this case. Since symptoms of hyperthyroidism overlap with those of metastatic disease, is important to evaluate thyroid function in addition to the hCG value.

Malignancy rates for Bethesda III and IV thyroid nodules in a tertiary referral hospital

Noemí Jiménez López[1], Álvaro Mauricio Chávez Villegas[1], Gonzalo Allo Miguel[1], Irune Blanco Urbaneja[1], Francisco Javier García Alonso[2] & Miguel León Sanz[1]

[1]University Hospital October 12, Endocrinology and Metabolism, Madrid, Spain; [2]Rio Hortega University Hospital, Valladolid, Spain

Background

Thyroid nodules are one of the most common clinical entities in Endocrinology practice. Fine needle aspiration (FNA) and the 2017 Bethesda System for Reporting Thyroid Cytopathology have been proved to be an effective tool to identify malignancy risk and guide surgical decision-making. However, thyroid nodules classified as Bethesda (BTH) III and IV remain a challenge, considering the varying risk of malignancy (ROM) found in different papers. The aim of this study is to determine the ROM in BTH III and IV nodules, and its possible correlation with several demographic factors.

Material and methods

Single-centre, retrospective study. Between March 2020 and August 2022, 61 patients with a FNA initially categorized as BTH III or IV underwent thyroid surgery (total or hemi-thyroidectomy). Data included demographic characteristics, FNA cytology result, presence of multinodular goitre (MNG) or solitary nodule (SN), type of thyroidectomy and pathologic diagnosis. Our ROM calculations were compared to the median ROM described in the BTH 2017 Statistics. A p-value less than 0.05 was considered statistically significant.

Results

48 (78.6%) female and 13 (21.12%) male patients were included in the study. Mean age was 57.3+/-14 years. 5 (8.33%) patients had family history of thyroid disease. 58.33% of the patients had been diagnosed with SN and 43.33% with MNG. 39 FNA reports were compatible with BTH III and 22 with IV. Thyroid cancer cases in the BTH IV group were 40.9%. Surprisingly, this value was higher in the BTH III group (53.8%). ROM calculated in our study was significantly higher than the one proposed in the BTH system report (53.8% vs 18%, IC 95% $P<.001$). There was no significant difference in the ROM for BTH IV. BTH III was significantly correlated with the diagnosis of papillary carcinoma ($P<0,05$), but not with the follicular type. No statistical significance was found between ROM and sex, age, family history of thyroid cancer or presence of SN or MNG.

Conclusions

The obtained ROM in Bethesda category III thyroid nodules in this study is significantly higher than the initially suggested by the Bethesda 2017 consensus. It is comparable to other international cohorts previously reported, but in our study thyroid cancer rates were higher in the BTH III group than in the BTH IV one. Ours is one of the first studies describing these data. Our findings suggest that we might be underestimating the potential for malignancy related to Bethesda III thyroid nodules.

The Reactive Oxygen Species Level of Blood Monocytes in Patients with Graves' Disease After Radioiodine Therapy

Daria Fomina[1], Sergey A. Dogadin[1,2], Andrey Savchenko[3,4], Margarita Dudina[1,2] & Ivan Gvozdev[4]

[1]Krasnoyarsk State Medical University, Hospital Therapy and Immunology, Krasnoyarsk, Russia; [2]Krasnoyarsk Regional Clinical Hospital, Endocrinology, Krasnoyarsk, Russia; [3]Krasnoyarsk State Medical University, Physiology, Krasnoyarsk, Russia; [4]Federal Research Center «Krasnoyarsk Science Center» of the Siberian Branch of the Russian Academy of Sciences, Scientific Research Institute of medical problems of the North, Laboratory of Molecular and Cell Physiology and Pathology, Krasnoyarsk, Russia

Background

Increased production of reactive oxygen species (ROS) and oxidative stress play a significant role in the initiation and persistence of the autoimmune process in Graves' disease (GD)

Aim

To study the ROS level of peripheral blood monocytes in patients with GD after radioactive iodine (RAI).

Materials and Methods

The study included 48 patients with a confirmed diagnosis of GD, from 18 to 65 years (mean 46.42 ± 15.26 years). The hormonal status and functional activity of blood monocytes in patients were studied on the day of RAI and 1, 3 and 6 months after RAI. To measure ROS, spontaneous luminol- and lucigenin-dependent luminescence, luminescence induced by zymosan, were determined using the chemiluminescence method with a BLM-3607 analyzer (MedBioTeh, Krasnoyarsk). The rate of reaction development, the maximum level of ROS, the total ROS were determined.

Results

Before RAI the thyroid status of patients corresponds to subclinical thyrotoxicosis that developed when thyrostatic therapy was canceled: TSH 0.08 mU/l (0.01; 0.45), free T4 17.49 pmol/l (12.88; 21.44), free T3 5.28 pmol/l (4.32; 7.38), 12.80 IU/l (5.77; 26.58). Monitoring of patients reveals normalization of TSH levels, a decrease in free fractions of thyroid hormones. The level of TRAb decreased 6 month after RAI – 1.48 IU/l (0.86; 2.91). A decrease in all parameters of lucigenin-dependent spontaneous chemiluminescence in patients with GD compared to the control was revealed: the time to maximum (Tmax) ($P<0,001$), the maximum luminescence level (Imax) ($P=0,038$) and the total ROS (S) were reduced ($P=0,011$). Differences were determined for all points of observation. There were no statistically differences between the control and patients with GD before RAI in the parameters of luminol-

dependent chemiluminescence of monocytes. After RAI decrease in parameters was found when comparing the controls and patients 1, 3 and 6 months after therapy: in luminol-dependent spontaneous chemiluminescence S was reduced ($P=0,009$, $P=0,018$, $P=0,033$, resp.), in chemiluminescence of the induced by zymosan, Imax ($P=0,005$, $P=0,022$, $P=0,019$ resp.) and S were reduced ($P=0,008$, $P=0,017$, $P=0,019$ resp.).
Conclusion
Decrease in the level of initial and induced primary ROS and the total ROS production in blood monocytes of patients with GD before RAI, compared to the control was revealed, that may be a sign of immunomodulatory and restrictive effects of thiamazole, despite the development of subclinical hyperthyroidism. After RAI, the level of primary and secondary ROS of monocytes decreases, that indicates the immunosuppressive effect of RAI and inhibition of autoimmune process.

Long-term observation of thyroid immunity - Experience in a single institution of northeast Japan

Takao Kunori & Hiroshi Yoshida
Iwaki-City Medical Center, Surgery, Iwaki, Japan

Background
Abnormal thyroid autoimmunity is often experienced in thyroid clinic. Some of them are associated with hyperthyroidism (HY) or chronic thyoiditis (Hashimoto, HA). The abnormality, however, is observed not only in HY or HA, but nodular goiter (NOD), and seems to be associated with various factors; age, visiting periods, residence, ABO blood type or others. We analyzed long-term (more than 16 years) data of patients who live in northeast Japan, if there is any characteristics in thyroid immunity.
Patients and methods
6,578 patients (2007-2022), age 54 ± 16 (3-96); female 83.7%), were examined. Observation period: 7.4 ± 7.1 years (median 5). Nodular goiter was 1,442(solid), cyst(513). HY was 577 and HA was 409. Hormonal assay for Tg, anti-thyroglobulin (aTg), thyroid peroxidase antibody (TPO), anti-TSH receptor antibody (TSH-R) and thyroid stimulating antibody (TS), were performed at their visits. Clinical diagnosis was confirmed by ultrasonography(US) and, if necessary, by fine needle aspiration (FNA); classified 0-5(cancer). Signifiance was determined by Kai2 test or student-t test; $P< 0.05$ significant.
Results
1) Correlation analysis: TPO was correlated with aTg, TSH-R, TS. Negative correlation was found with AGE, and positive correlation with ABO blood type ($A<B<O<AB$; $A=30\%$, $AB=58\%$). aTg was correlated with TPO, but not with TSH-R and TS. TPO positive rate decrease with age (78% in 20-29 years old to16% in 60- years old). 2) Changes of autoimmunity during observation years: TPO positive patients showed decreasing of aTg negative rate with years (46% to 3%), whearas aTg positive patients showed increasing of TPO positive rate (82% to 91%). TSH-R and TS in HY patients showed decreasing with period, but remained positive in 60% of patients through observation period. 3) Autoimmunity in disease: Positive (aTg and TPO) rate in NOD was 29% in solid nodules and 23% in cyst. Positive rate was 86% in HY and 98% in HA. 4) Residece: There was significant difference in local communities; TPO positive rate was 34% (city area) to 45%(fisher man's area).
Conclusion
These data suggest that autoimmunity may reflect patients' life style and genetic back ground. Moreover the immunity seemed long-lasting response in most patients of this area.

Zenker diverticulum: an uncommon finding during ultrasound examination of the neck area

Elena Chobankova[1], Boyan Nonchev[1,2] & Antoaneta Argatska[2]
[1]Kaspela University Hospital, Endocrinology Department, Plovdiv, Bulgaria; [2]Medical University of Plovdiv, Endocrinology Department, Plovdiv, Bulgaria

Introduction
Ultrasound examination is the preferred imaging technique for thyroid morphology assessment. Sometimes neck sonography reveals extra-thyroidal pathological formations which may be a cause for diagnostic predicaments. The Zenker diverticulum is a type of esophageal diverticulum, located in a natural area of weakness on the posterior pharyngeal wall. It appears as a structure in close proximity to the left thyroid lobe and can be in some cases misinterpreted as a thyroid, parathyroid or a lymph nodule.
Case report 1
A 42-year old female complaining of cough and dysphagia was referred for a fine-needle aspiration biopsy due to a suspicious finding in the left thyroid lobe. A rounded isoechoic formation with micro-echogenic foci, smooth margins and a thin hypoechoic rim was visualized on the posterior surface of the left thyroid lobe. The finding was suspicious of an esophageal diverticulum. The patient had undergone gastroscopy 3 years earlier and diagnosed with chronic gastritis. The cytological result verified lack of malignancy. Based on ultrasound and clinical suspicion the patient was referred for another endoscopy where a Zenker diverticulum was confirmed.
Case report 2
A 47-year old woman was referred for clinical assessment regarding a lump in the left neck area and dysphagia. She had no comorbidities. During the ultrasound examination a large mass behind the left thyroid lobe and partially behind the right one was visualized. The formation resembled an esophageal enlargement. She was referred to a gastroenterologist and further diagnosed with achalasia.
Discussion and conclusion
The Zenker diverticulum, being in close proximity to the thyroid gland, can in some cases be a cause for misinterpretation. The sonographic appearance of these formations can mimic thyroid nodules. Despite this fact, there are several characteristics, which can be helpful for distinguishing an esophageal diverticulum from thyroid nodules. The typical localization on the posterior surface of the left lobe, the thin hypoechoic rim and the dynamics of the formation when the patient is asked to swallow suggest an esophageal diverticulum, especially when these features are combined. Although not the modality of choice, the ultrasound examination can be of significant importance in discovering esophageal diverticula in the neck area.

Covid- associated subacute thyroiditis

Veranika Lobashova[1] & Yuliya Dydyshka[2]
[1]Republic Center of Medical Rehabilitation and Balneotherapy, Endocrinologic, Minsk, Belarus; [2]Belarusian State Medical University, Endocrinologic, Minsk, Belarus

Objectives
The number of reported cases COVID-19 associated subacute thyroiditis (ST) in literature is small thus peculiarities of its clinical features remain the subject of interest. The aim of the review is to share our experience of COVID-19 associated ST.
Materials and Methods
We describe 5 cases of COVID-19 associated ST. SARS-CoV-2 diagnosis was based on the presence of its typical symptoms and real-time polymerase chain reaction on nasopharyngeal swab or by positivity of specific IgG.
Results
ST manifested in 15-28 days after COVID-19. General symptomatology (asthenia and malaise) was recorded in all cases. Neck pain and subfebrile temperature presented in 60% cases, one patient described some discomfort in neck but without pain. Thyroid function tests showed mild thyrotoxicosis in three patients (60%) and two patients were euthyroid (40% cases). The median ESR was 28 (18-36). Thyroid ultrasound showed the typical characteristics (hypoechogenic areas with reduced vascularization) in 100 % cases. Steroid therapy with methylprednisolone was the administered in all case. The euthyroid patient with neck discomfort received non-steroidal anti-inflammatory agents firstly, but after 7-12 days they both represented the negative dynamic and treatment with steroids was initiated. The median dose of methylprednisolone was 24 mg. One of the patient had relapse of the process after steroid withdrawal and needed to be cured repeatedly. The time of active cure with glucocorticoids lasted from 3 to 12 month.
Conclusion
Available literature suggests that forms COVID -19 associated ST are mild and sometimes do not require specific treatment. Our experience showed that the disease had more covert clinical symptoms but long period of duration.

Phenotypic and genetic features of familial thyroid dyshormonogenesis in the Tunisian population

Faten Haj Kacem Akid, Abdel Mouhaymen Missaoui, Siddiqa Soomauroo, Younes Ayadi, Nabila Rekik Majdoub, Mouna Mnif & Mohamed Abid
Hedi Chaker Hospital, Department of Endocrinology, Sfax, Tunisia

Objective
To describe the phenotypic and molecular characteristics of familial thyroid dyshormonogenesis (FTDH) in the Tunisian population.
Patients and Methods
A retrospective descriptive study including two related (R and K) with high consanguinity whose members are carriers of FTDH. Biological and genetic screening was proposed for all consenting members.
Results
FTDH was identified in 11 patients (8 girls, 3 boys) with a mean age of 4 years and 3 months (range: 1 month-17 years). The family screening revealed 10 other members with hypothyroidism not related to FTDH. At diagnosis, 63.6% of the patients were clinically hypothyroid vs 36.4% with apparent euthyroidism who were diagnosed through the family survey. Mental retardation was detectable in 4 children. Three patients also had sensorineural deafness. Three patients had a homogeneous goiter. Mean TSH and T4 were 24.19 mIU/l and 4.73 pmol/l, respectively. The antithyroid antibodies positivity rate was 18.2%. Substitution therapy (mean dose = 125 mg/d) resulted in euthyroidism in all patients. After a mean follow-up of 11.88 years, three patients required thyroidectomy for compressive and/or nodular goiter. Molecular analysis revealed a single mutation (c.875 C> T) (p.S292F) in the TPO gene with recessive inheritance.
Discussion
FTDH is responsible for 15-20% of congenital hypothyroidism cases that can lead to severe neurosensory complications. In the Tunisian population, the TPO gene mutations are the most frequent and would be amplified by a founder effect in certain regions with high rates of consanguinity and endogamy.

Hypothyroidism: A challenging condition

Anna Hawkins, Nancy Enriques, Edel Casey, Bonnie Grant, Raj Tanday, Usman Shah & Khash Nikookam
Barking, Havering and Redbridge University Hospitals NHS Trust, Diabetes & Endocrinology, United Kingdom

Introduction
Hypothyroidism can present in a variety of ways, from unexpected abnormal blood results in seemingly asymptomatic patients to those with a multitude of debilitating symptoms. Levothyroxine dose titration is a challenge often faced by physicians. We identified 8 difficult cases which following MDT discussion underwent the Thyroxine Absorption Test (TAT) to gain further clarification (Walker *et al.* 2013).
Aim
To identify if the issue is absorption, patient compliance with medication or true thyroid hormone resistance.
Method
Notes and results of 8 patients with various underlying aetiologies of hypothyroidism (table 1) were retrospectively reviewed over 20 months. All patients were female, age ranging from 27-63 years (mean and median 41.6 and 55.5 years respectively). BMI range of 33-41 kg/m2 (mean 36.8 kg/m2). At the first consultation, 6 patients were on levothyroxine and 2 were on combination levothyroxine and triliothyronine. Triliothyronine was stopped 2 weeks prior to the TAT. As per TAT protocol, thyroxine dose was calculated at 1.6 mg/kg/day x 7 which equated to a range of 1000-1200 mg weekly (mean of 1075 mg). Blood tests were subsequently carried out over 6 hours and 4, 6 and 24 weeks with levothyroxine dose adjusted accordingly.
Conclusion
Patient compliance, rather than absorption, was identified as the main challenge. Thyroid hormone resistance was not identified in this cohort. All patients had a reference range FT4 at some point, either during the TAT or following a period of supervised weekly dosing. General improvements in wellbeing was reported but sample size was insufficient for statistical analysis. Psychological support could potentially benefit this group of patients to improve insight into their condition and thus further impact their wellbeing.

Table 1

Assessment of quality of life indicators of operated and non-operated children with primary hyperparathyroidism in the observed aspect at different times

Nazira Rikhsieva
Tashkent Pediatric Medical Institute, Tashkent, Uzbekistan

Aim
To study tne quality of life of children with primary hyperparathyroidism (PHPT).
Material and methods
90 children with suspected PHPT were examined according to anamnesis, outpatient cards and surgical logs. The children were aged from 3 to 15 years old, who were treated in stationary conditions, and then were observed by us on an outpatient basis. 50 of them were treated surgically (1st group), 40 (2nd group) refused surgery for various reasons and received antiresorptive therapy. Complaints, objective, endocrinological condition of all patients were assessed. The preliminary diagnosis was made on the basis of the obtained clinical data, confirmed by laboratory and instrumental studies. To assess QoL, we used questionnaire of Pas and SF-36. The duration of the study ranged from 1-3-6 months to 1 year in the early postoperative period and 5-10-15 years in the long-term period.
Results
Quality of life indicators in patients with PHPT are significantly lower than in the control group, to a greater extent due to pain, general health, social functioning and vitality ($P < 0.05$). Thus, in patients with PHPT before surgery, a significant violation of both the physical and mental components of the quality of life was established. Further, in the 1st group of patients with surgical treatment, in dynamics after 3 and 6 months, all QoL indicators according to SF-36 were significantly closer to the control group in all domains. In the 2nd group of patients with conservative treatment in dynamics after 3, 6, 12 months and 10 years, all QoL indicators according to SF-36 remained significantly lower than the control group in all domains and did not change significantly. Thus, according to our studies of QoL in patients with PHPT of the compared groups, successful surgical treatment with normalization of the level of parathyroid metabolism contributes to a significant improvement in the quality of life of patients with PHPT of the 1st group already in the early stages after surgery and has a lasting effect in the long-term follow-up period.
Conclusions
The results obtained demonstrate the positive effect of surgical treatment from the patient's point of view and confirm the feasibility of assessing the quality of life both at the decision-making stage when choosing a surgical approach and as part of a comprehensive assessment of the effectiveness of therapy in determining the degree of recovery of various aspects of functioning in patients after surgery.

Tuberculous lymphadenitis mimicking nodal metastasis in papillary thyroid carcinoma

Houas Jihene[1], Ben Arfi Taissir[1], Ghammam Monia[1], Kechiche Jawaher[1], El Omri Malika[1], Bellakhder Mouna[1], Hasni El Abed Yosra[2], Meherzi Abir[1], Kermani Wassim[1] & Abdelkefi Mohamed[1]
[1]ENT Department and Neck Surgery of Farhat Hached Hospital, Sousse, Tunisia; [2]Endocrinology Department Farhat Hached Hospital, Sousse, Tunisia

Introduction
The tuberculous lymphadenitis is the most common form of extra-pulmonary tuberculosis. The association with thyroid cancer is rare and can mislead the physician with the lymphadenopathy being considered as metastatic. In an endemic region for tuberculosis such as Tunisia, an adequate preoperative evaluation is crucial to distinguish these two entities and provide the patient with the appropriate treatment.
Material and methods
2 cases of a lymph node tuberculosis associated with a papillary thyroid carcinoma treated in our ENT department.
Patient 1
Is about a 37-year-old patient with no significant pathological history who consulted for left cervical lymphadenopathy that has been evolving for 2 months with a recent weight loss of 5 kg. The clinical examination objectified a lymphadenopathy of the III left territory and a right thyroid nodule. The patient underwent right lobo-isthmectomy with an extemporaneous examination identifying a papillary thyroid carcinoma, hence a thyroid totalization with a central lymph nodes dissection. An additional functional left lymph node dissection identified a lymph node tuberculosis. The definitive pathological examination concluded to a 1.5 cm papillary carcinoma of the right lobe of the thyroid with no lymph node metastasis in the central lymph nodes dissection, and tuberculous lymphadenitis in the left functional lymph node dissection. The patient is currently in complete remission after postoperative radiation therapy and anti-tuberculosis treatment. The current follow-goes up to six years with no metastasis.
Patient 2
Is about a 62-year-old diabetic patient who consulted for a right thyroid nodule. During his right lobo-isthmectomy, the extemporaneous examination identified a papillary carcinoma, hence the totalization of the thyroid with a central lymph nodes dissection. The definitive pathological examination concluded to a papillary carcinoma with no lymph node metastasis but rather a lymph node tuberculosis in the central lymph node dissection. The patient received anti tuberculosis treatment for 6 months and a radioactive iodine treatment and is now doing well. The current follow-up goes up to four years.
Conclusion
In the presence of metastatic cervical lymphadenopathy, and even in the presence of suggestive signs such as necrosis and calcifications, in patients in which a papillary thyroid carcinoma is suspected, a tuberculous lymphadenopathy should be considered as a differential diagnosis and should be carefully researched preoperatively in order to limit surgical complications.

Vesicular thyroid carcinoma with retropharyngeal node metastasis: case report

Houas Jihene[1], Lazid Sarra[1], Ghammam Monia[1], BelHadj Miled Heyfa[1], El Omri Malika[1], Bellakhdher Mouna[1], Hasni El Abed Yosra[2], Meherzi abir[1], Kermani Wassim[1] & Abdelkefi Mohamed[1]
[1]ENT Department and Neck Surgery of Farhat Hached Hospital, Sousse, Tunisia; [2]Endocrinology Department Farhat Hached Hospital, Sousse, Tunisia

Purpose
Retropharyngeal lymph nodes metastases from differentiated thyroid carcinoma are extremely rare. The objective of this study was to describe our experience in the management of a vesicular thyroid carcinoma with RPMs.
Case report
We report a case of 60 years old female patient who presented a thyroid goiter with pressure symptoms as well as dysphagia. Initial Serum thyroid stimulating hormone (TSH) rate was normal. The ultrasound thyroid showed a multinodular goiter without any malignancy sign. The patient underwent a total thyroidectomy for compressive symptoms. The final anatomophathological examination had concluded to a vesicular carcinoma of the right thyroid (T3 N0 M0) with a very low extension beyond the thyroid. Radioactive iodine therapy were performed to complete treatment. Six month follow up, the patient presented metastatic cervical lymph nodes in the upper jugular nodes (IIA, IIB) with internal jugular vein thrombosis. We performed a Modified radical neck dissection involving the internal jugular vein. During follow-up, an increased serum thyroglobulin rate was noted although appropriate radioactive iodine therapy. Clinical examination and ultrasonograpgy were unremarkable. A neck and chest CT scan revealed a large right mass of 4 cm in the retropharyngeal space, suggesting a retro-pharyngeal node metastasis with a bone metastasis at the rib. Dramatically, the patient passed away one month after.
Conclusion
Retropharyngeal nodes metastases from differentiated thyroid are rare, although it should be considered at the follow-up of the disease. Because these metastases will be missed by routine ultrasonography of the neck, periodic CT scan or MRI is recommended for follow-up.

Role and expression of miRNAs (miRNA 149_5p, miRNA-548c-3p, miRNA 3619-3p) in Papillary thyroid cancer progression and metastasis

Ramesh Bangaraiahgari[1], Rajesh Bangaraiahgari[2], Ramakanth Bhargav Panchangam[3], Udaya kumar Neelagiri[4], Srinivas Vudathala[5], Rajkiran Reddy Banala[6] & Chakrapani Bangaraiahgari[7]
[1]Arundathi Institute of Medical Sciences, Biochemistry, Hyderabad, India; [2]Arundathi Institute of Medical Sciences, Anatomy, Hyderabad, India; [3]Bhargav Endocare Hospital, Endocrine and Metabolic Surgery, Andhra pradesh, India; [4]Arundathi Institute of Medical Sciences, Pediatrics, Hyderabad, India; [5]Arundathi Institute of Medical Sciences, CRL, Hyderabad, India; [6]Sunshine Hospital, CRL, Hyderabad, India; [7]Chakri Neuro Hospital, Neurology, Nizamabad, India

Objective
Papillary thyroid carcinoma (PTC) is themalignantcancer with altered microRNA (miR) changes. miR149-5p and miR-548c-3p participates in multiple processes of tumor development, progression, tumor suppression. Whereas miR-3619-3p plays role to promote cell migration and invasion in PTC. However, the role of miR149, miR-548c-3p, and miR-3619-3p in PTC and the underlying mechanisms remain undefined. Therefore, the present study is aimed to quantify therelative expression of these 3 miR's in tissues and whole blood of PTCpatients to understand the underlying mechanism in metastasis and reoccurrence.
Materials and Methods
miR149, miR-548c-3p, and miR-3619-3pexpression was analyzed in PTC tissue and whole blood by Real-Time quantitative Polymerase Chain Reaction.
Results
Our results indicated that miR-149-5p and miR-548c3p was downregulated and simultaneously, the miR-3619-3p expression was found to be upregulated in the tissues and whole blood of PTC patients. Moreover, downregulation ofmiR-149-5p and miR-548c-3p will help in cell viability, colony formation, cell migration, invasion capacity, upregulation of N-cadherin and vimentin genesin both PTC and whole blood samples. A negative correlation was determined betweenmiR's (miR-149-5p and miR-548c-3p) and miR-3619-3p, hypoxia-inducible factor (HIF) 1α or vascular endothelial growth factor (VEGF) levels, indicating that miR149-5p and miR548c-3p inhibited tumor progression by suppressing the HIF1α-mediated VEGF signalling pathway.
Conclusions
Higher expression miR149-5p and miR-548c-3p could suppress PTC progression by inhibiting the HIF1α-mediated VEGF signalling pathway.

Fungal necrotizing otitis externa in diabetic patients

Mohamed Masmoudi, Chaima Zitouni, Wadii Thabet, Ezer Chebil, Mehdi Hasnaoui & Khelifa Mighri
Taher Sfar Hospital, ENT Department, Mahdia, Tunisia

Introduction
Pseudomonal infection is the most common cause of necrotizing otitis externa (NOE), which typically affects elderly diabetic patients. Fungi are a rare cause of this disease. Fungal NOE can be life-threatening if not recognized and treated promptly.

Objective
The aim of this study is to describe the epidemiology, clinical features, management and evolution after treatment of diabetic patients with fungal NOE.
Methods
This is a retrospective study about 17 diabetic patients diagnosed with fungal otitis externa between 1992 and 2022.
Results
This study is about 11 males and 6 females. The average age of the patients was 69 years (51 – 81 years). All of them had diabetes. Five of them, had terminal chronic renal failure. The symptoms included: otalgia and otorrhea in all cases and facial palsy in 4 cases. Fungi isolated from samples were: Candida albicans (4 cases), Candida glabrata (2 cases), Candida tropicalis (1 case) and Aspergillus flavus (10 cas). There was a case of a simultaneous bacterial infection. CT-scan showed lysis: in the temporal bone (all cases), the carotid canal (1 case), the facial nerve canal (1 case) and the jugular bulb (1 case). One patient had thrombosis in the intrapetrous carotid artery and the internal jugular vein. An extension to the parapharyngeal space was found in 3 cases. An extension to the temporo-mandibular joint was found in 5 cases. Treatment included maintaining euglycemic blood glucose levels and anti-fungal medicines (Fluconazole in 4 cases and Voriconazole in the other cases) for the average of 96 days. After treatment, 13 patients were free of disease, 1 patient had brain ischemia and 3 patient presented with recurrence.
Conclusion
Fungal NOE are known to be more aggressive than bacterial NOE. Aggressive disease, lack of response of NOE to antibacterial drugs or progression despite the use of these drugs should raise the suspicion of a fungal etiology of NOE. The current guidelines are lacking in terms of antifungal of choice and optimum duration of treatment.

Surgical Management of Thyroid Differentiated Microcarcinomas

Sirine Ayedi[1], Souha Kallel[1], Faten Haj Kacem Akid[2], Mariem Ben Ayed[1], Hamdi Frikha[2], Mohamed Abid[2] & Ilhem Charfeddine[1]
[1]Habib Bourguiba Hospital, Department of Otolaryngology (ENT) Head and Neck Surgery, Sfax, Tunisia; [2]Hedi Chaker University Hospital, Department of Endocrinology, Sfa, Tunisia

Background
The management of differentiated microcarcinomas of the thyroid (DMCT) is controversial, and ranges from simple active surveillance to total thyroidectomy with bilateral lymph node dissection and post operative adjuvant therapy. Our purpose was to determine prognostic factors to guide the surgery of DMCT.
Methods
This was a retrospective study conducted from January 2000 to December 2017, involving 122 patients with DMCT who were treated surgically, at the ear nose throat and head and neck surgery and the nuclear medicine departments.
Results
In our population (sex ratio = 0.13), the average age was 46 (range 18 to 84). During the first time of surgery, the extent of the procedure was based on ultrasound and extemporaneous examination results: a non-total thyroidectomy was performed in 10 patients (8%), a total thyroidectomy in 108 patients (89%), and a completion thyroidectomy in 4 patients (3%). The dissection of bilateral central lymph nodes (CLN) was done in 46 patients (38%), of ipsilateral CLN in 2 patients (1.5%), and of bilateral CLN et lateral lymph nodes in 10 patients (8%). After definitive histological examination, a surgical complement was performed in 12 patients (9.8%). At definitive histology examination, a typical thyroid papillary microcarcinoma was observed in 60 patients (49%), a vesicular type of thyroid papillary microcarcinoma in 52 patients (43%), and a thyroid vesicular microcarcinoma in 10 patients (8%). Multifocality was observed in 34 patients (27.9%), an extra-thyroidal extension in 2 patients (1.6%), with a mean tumor size 5.8mm. Histological lymph node involvement was observed in 24 patients (36.4%) among the 66 patients who underwent lymph node dissection. A therapy by I131 was indicated in 100 patients (82%). A complete remission was noted in 76 patients (62.3%). Regional lymph node recurrence was detected in 4 patients (3.2%). No cases of distant metastases or deaths have been reported. The analytical study showed that tumor size and multifocality were statistically significant risk factors for occult lymph node involvement.
Conclusion
The "active surveillance" is retained by several authors as the attitude of choice in case of DMCT without risk factors for locoregional evolution. In the absence of such conditions, surgical treatment remains the gold standard.

EP986

Thyroid hormone replacement during Ramadan fasting is a real challenge to hypothyroid patients. A systematic review and meta-analysis

Eslam Mohammed Rabea, Mohamed Mohamed Belal, Asmaa Reda Youssef, Nessreen Awaad Elalaky, Hany Baker & Muhammed Adel Muhammed Quaisy
Alexandria Faculty of Medicine, Alexandria University, Alexandria, Egypt

Background
Ramadan is the religious month in which Muslims fast from pre-dawn (suhoor) until sunset (iftar), abstaining from all kinds of food, and liquid. The major change in meal times may be challenging for hypothyroid patients on levothyroxine because levothyroxine has a narrow therapeutic index and should be taken on an empty stomach.
Objective
We aim to compare pre- and post-Ramadan Thyroid function tests of hypothyroid patients taking levothyroxine and to determine the best timing of levothyroxine intake during Ramadan.
Methods
We searched PubMed, Scopus, WOS, Google Scholar, Ovid, Science Direct, Clinical trials.gov, and Cochrane Library for studies published in English investigating the effect of Ramadan fasting on thyroid functions in hypothyroid patients on levothyroxine, and/or comparing different time points of the drug intake. Assessed outcomes were TSH change, Free T4 change, number of patients above reference range of TSH. Subgroups of different time points (Pre-Iftar, Post-Iftar, and Pre-Suhoor) were analyzed separately. The analysis was done by RevMan software. The National Institutes of Health (NIH) quality assessment tools were used according to the study designs.
Results
Twelve studies; 3 RCTs, and 9 observational studies were eligible. All studies compared the same group before and after Ramadan (pre-post study). Ramadan fasting is associated with a statistically significant increase in TSH (MD= -1.07, CI 95% [-1.46, -0.67], $P< 0.00001$). However, no difference was found as regards the number of patients with TSH above the reference range (RR= 0.66, [0.41, 1.08], $P= 0.1$). Also, It didn't reflect on an increase in FT4 (MD= 0.01, [-0.03, 0.06], $P= 0.59$). Our analysis showed that taking the drug at pre-iftar, or post-iftar significantly increases TSH after Ramadan ($P= 0.009$, and 0.01 respectively). Taking the drug before suhoor (0.5 to 1 hour) showed no significant difference (MD= -0.72, [-2.25, 0.81], $P= 0.36$), but the heterogeneity between the studies makes the significance inconclusive.
Conclusion
TSH increases significantly after Ramadan. Choosing an optimal timing is still a challenge, but our analysis suggests that taking the drug before suhoor meal by one hour is the best option. More high quality research is warranted to break this controversy.

Risk factors for postoperative complications in total thyroidectomy

Moncef Sellami[1], Mohamed Amine Chaabouni[1], Ines Kharrat[1], Faten Haj Kacem Akid[2], Bouthaina Hammami[1], Mohamed Abid[2] & Ilhem Charfeddine[1]
[1]Habib Bourguiba University Hospital, Department of Otorhinolaryngology, Head and Neck Surgery, Sfax, Tunisia; [2]Hedi Chaker University Hospital, Department of Endocrinology, Sfax, Tunisia

Introduction
Thyroidectomy is a quite common procedure. Major postoperative complications of total thyroidectomy, including recurrent laryngeal nerve injur and hypocalcemia are not infrequent. The purpose of this study was to evaluate the incidence and risk factors of postoperative complications after total thyroidectomy.
Methods
We retrospectively included patients who underwent total thyroidectomy over a period of 6 years. Hypocalcemia was defined as a blood calcium level that was strictly below 2 mmol/l and considered definitive after more than 6 months of vitamin-calcium treatment. Recurrent nerve palsy that persists beyond 12 months was defined as permanent.
Results
This study included 372 patients (87.4% female), of whom 117 underwent central neck dissection. The mean age was 48 years. Histopathological examination revealed one to two resected parathyroid glands in 63 patients (16.9%). Hypocalcemia was transient in 116 cases (31.2%) and permanent in 22 cases (5.9%). We observed 43 cases of recurrent nerve palsy (11.6%) of which 39 were

transient (10.5%) and 4 were definitive (1.1%), 1 case of hematoma (0.3%), 4 cases of cervical abscesses (1.1%), 5 cases of lymphorrhea (1.3%) and 7 cases of keloid scarring (1.9%). On univariate analysis, the risk factors of transient hypocalcemia were parathyroid autotransplantation ($P=$ 0.018), parathyroid gland in the surgical specimen ($P=$ 0.001). Transient and permanent hypocalcemia were significantly associated with longer operative time, central neck dissection and cancer on histopathological examination. Male ($P=$ 0.007), smoking ($P=$ 0.013), and Graves' disease ($P=$ 0.042) were significantly associated with definitive recurrent nerve palsy. On multivariate analysis, the presence of parathyroid gland in the surgical specimen was the risk factor for transient hypocalcemia (OR: 2.09) and Graves' disease for definitive recurrent nerve palsy(OR: 670).
Conclusion
Complications of total thyroidectomy occur in specific circumstances. Involuntary parathyroidectomy and Graves' disease were independent risk factors for transient hypocalcemia and definitive recurrent nerve palsy respectively. Given these risk factors, preventive procedures can be considered to minimize the morbidity of this surgery.

Evaluation of the adverse effects of antithyroid drugs in the treatment of Graves' disease

Sawsen Nouira, Taieb Ach, Asma Ben Abdelkarim & Molka Chadli Chaieb
Hospital Farhat Hached, Endocrinology, Sousse, Tunisia

Introduction
Antithyroid drugs (ATD) are usually the first-line treatment for Graves' disease (GD). It represents an effective treatment with good compliance. This therapeutic modality can be the cause of adverse effects including hematological, cutaneous and hepatic complications. The aim of our study is to evaluate the efficacy of ATD as well as its tolerance in patients with GD.
Methods
It is a retrospective study that included 76 patients, with GD, followed in our department and treated with ATD for at least 2 years. Patients who received ATD to prepare them for radical treatment were eliminated. Remission was defined as the appearance of biological euthyroidism maintained after discontinuation of ATD.
Results
Our study included 29 males (38.2%) and 47 females (61.8%) with a mean age of 33.82 years (8-66 years), The mean duration of treatment was 28.73 months (0.5 - 230 months). Remission was observed in 33 patients (43.4%), with a mean duration of 24.8 months (8-72 months). Relapse was observed in 22 patients (28.9%), 7 cases at the time of degression; 29 cases or 87.8% of the cases having achieved remission; and one case after transition to hypothyroidism despite discontinuation of thyroxine treatment, most likely in the context of Hashitoxicosis. Side effects were observed in 16 patients: one case of agranulocytosis occurring 2 weeks after the Introduction of Basdene*, 6 cases of digestive disorders such as vomiting, 2 cases of hepatic cytolysis, 4 cases of ANCA-positive rash, one case of acute pancreatitis stage A with negative etiological investigation and an improvement upon discontinuation of Basdene*. We noted a case of rapidly progressive ANCA-positive glomerulonephritis in a 50-year-old woman, who presented with hematuria. We also noted a case of segmental and focal hyalinosis in a 15-year-old girl with Graves' disease since the age of 5 and a history of ANCA vasculitis at the age of 7-year-old.
Conclusion
Our results confirm that the rate of durable remission on ATD is relatively low. The possibility of the occurrence of ANCA vasculitis and the potential severity of these vasculitis require special attention to systemic symptoms (rash, hematuria, proteinuria) and the search for ANCA in the presence of such manifestations.

EP989

Immunological and ultrasound characteristics of different forms of postpartum thyroid dysfunction

Antoaneta Argatska & Boyan Nonchev
Medical University Plovdiv, Endocrinology, Bulgaria

Objective
To assess the immunological and ultrasound (US) characteristic of hypothyroidism and thyrotoxicosis developing during the postpartum period.
Patients and methods
66 women with postpartum thyroid dysfunction (PPTD) (30 with hypothyroidism and 36 with thyrotoxicosis) without history of previous thyroid disorder were included. TRAb positive women were excluded from the study. Clinical evaluation was done, TSH, FT4, FT3, TPOAb, TgAb were measured, ultrasound examination of the thyroid gland was performed.
Results
Women who developed hypothyroidism were of similar age compared to women with thyrotoxicosis (29.83 $\pm$ 4.13 vs 29.72 $\pm$ 4.07 years, $P=0.913$). Women with hypothyroidism had significantly higher frequency of TPOAb positivity ($P=0.038$) compared with those with postpartum thyrotoxicosis. No differences in the presence of TgAb were found. On US examination hypothyroid women had larger thyroid volume ($P=0.029$) and higher grade of thyroid hypoechogenicity ($P=0.004$) compared to women who presented with thyrotoxicosis. In TPOAb positive hypothyroid women the levels of antibodies showed positive correlation with TSH ($P=0.030$) and negative relation with FT4 values ($P=0.028$). In TPOAb positive women with postpartum thyrotoxicosis TPOAb levels had positive correlation with thyroid volume ($P=0.004$), but not with hormonal parameters. In TPOAb negative thyrotoxic women however there was significant positive correlation between thyroid volume and FT4 ($r=0.627$, $P=0.029$) and FT3 ($r=0.822$, $P=0.001$) levels suggesting different stimulatory immune effects.
Conclusion
Hypothyroidism as an initial presentation of PPTD is characterized by more pronounced immunological and ultrasound abnormalities than postpartum thyrotoxicosis resulting in a relatively high risk of permanent thyroid dysfunction. In women with a history of PPTD regular follow up is justified.

EP990

Relationship between thyroid function and metabolic parameters in healthy premenopausal women

Antoaneta Argatska[1], Boyan Nonchev[1,2] & Elena Chobankova[2]
[1]Medical University Plovdiv, Endocrinology, Bulgaria; [2]Kaspela University Hospital Plovdiv, Clinic of Endocrinology, Bulgaria

Objective
To investigate the prevalence and the relation between metabolic syndrome components and TSH values below and above 2.5 mIU/l in euthyroid premenopausal women.
Material and methods
446 women of mean age 30.98 $\pm$ 9.3 (18-51 years) with no history of diabetes or lipid-lowering medications were included in the study. Standard oral glucose tolerance test with insulin measurement was performed, TSH, total cholesterol, HDL, triglycerides were measured, LDL and BMI were calculated. All women had TSH within reference range (0.4-4.2 mIU/l) with no significant medical conditions.
Results
266 women had TSH $<$ 2.5 mIU/l (group 1), while 180 had TSH $\geq$ 2.5 mIU/l (group 2) with no differences between mean age (30.8 $\pm$ 8.9 vs 31.3 $\pm$ 9.9 years, $P=0.554$). Group 2 women had higher frequency of overweight or obesity (OR = 1.553, $P=0.039$), elevated triglycerides (OR = 2.290, $P=0.002$), HOMA index higher than 2.5 (OR = 1.804, $P=0.003$) compared to group 1. Moreover, the levels of total cholesterol (5.03 $\pm$ 1.01 vs 4.82 $\pm$ 0.97 mmol/l, $P=0.036$) and LDL (3.17 $\pm$ 0.91 vs 2.99 $\pm$ 0.84 mmol/l, $P=0.027$) were higher in women with TSH $\geq$ 2.5 mIU/l than in those with TSH $<$ 2.5 mIU/l. After adjustment for age and BMI TSH levels showed weak positive correlations with total cholesterol and LDL cholesterol.
Conclusion
The results of the study confirm the association between thyroid hormones and the components of metabolic syndrome. Even high-normal TSH values in these young otherwise healthy women may lead to increased risk of obesity, insulin resistance and dyslipidemia.

Impact of L-thyroxine intake schedule on therapeutic balance during the month of Ramadan in patients followed for hypothyroidism

Nezha Raki, Nassim Essabah Haraj, Siham El Aziz & Asma Chadli
UHC Ibn Rochd, Endocrinology, Diabétology, Nutrition and Metabolic, Casablanca, Morocco

Introduction
Hypothyroidism is a chronic pathology, which can have several etiologies and which requires long-term treatment. The modification of meal times during the month of Ramadan which can modify the absorption of L-thyroxine, knowing that it interferes with the taking of meals.
Purpose of the study
Assess the impact of L-thyroxine intake schedule on the therapeutic balance during Ramadan in patients with hypothyroidism.
Materials and methods
This is a prospective study that included all patients followed for hypothyroidism on levothyroxine, including patients followed in thyroid carcinoma consultation, having consulted during the pre-Ramadan 2022 period. All the patients included were in euthyroidism before Ramadan or within the TSH objective for patients operated on for thyroid carcinoma. We divided the patients into three groups according to the schedule for taking the treatment (before Shour, before Ftour and without a fixed schedule) and we evaluated the impact on TSHus 6 weeks after the end of the month of Ramadan. We assessed therapeutic compliance based on the Morisky questionnaire.
Results
We collected 177 patients. The average age is 49.8 years with a female predominance of 67.8%. Peripheral hypothyroidism was present in 64 patients (36.5% of cases) while hypothyroidism secondary to total thyroidectomy was present in 113 patients, i.e. 63.5% of cases including 43 thyroidectomized patients for thyroid carcinoma. During the month of Ramadan, therapeutic compliance was good in 81% of cases, average in 11% and poor in 8% of cases. Among our patients, 55% took the treatment before the fasting meal and 43% took it before the dawn meal and 2% did not have a fixed intake schedule. Post-Ramadan, 83% of patients remained in euthyroidism or within the TSH objective in those followed for carcinoma, 8% in hyperthyroidism and 9% in hypothyroidism with no significant correlation between the first two groups.
Conclusion
The change in the schedule for taking L-thyroxine during the month of Ramadan can affect the hormonal balance as observed in our study, hence the importance of monitoring and specific therapeutic education of patients.

The Prevalence of Thyrothyropin Receptor, Cytotoxic T Lymphocyte Antigen-4 and Interleukin-1 Receptor Antagonist Polymorphisms in The Group of Hashimoto Thyroiditis in Turkish Community and their Relationship with Clinical Parameters

Lamia Şeker Can[1], Onur Elbasan[2], Can Ilgin[3], Duygu Yaşar Şirin[4], Rıfat Bircan[4] & Hulya Gozu[5]
[1]Esenyurt State Hospital Necmi Kadioglu, İnternal Medicine, İstanbul, Turkey; [2]Sinop Atatürk Devlet Hastanesi, Endocrinology, Sinop, Turkey; [3]T C Saglik Bakanligi Istanbul Egitim ve Arastirma Hastanesi, Radiation Oncology, İstanbul, Turkey; [4]Tekirdağ Namık Kemal Üniversitesi, Molecular Biology and Genetics, Tekirdağ, Turkey; [5]Marmara University Pendik Research and Education Hospital, Endocrinology, İstanbul, Turkey

Aim
Hashimoto Thyroiditis (HT); is the most common form of hpothyroidism in iodine-sufficient regions. Both genes and and environmental factors are involved in the immunopathological process of HT. Our aim in this study is to determine the prevalence of Thyrothropin Receptor (TSHR), Cytotoxic T Lypmhocyte Antigen-4 (CTLA-4) and Interleukin-1 Receptor Antagonist (IL-1RN) gene polymorphisms associated with HT in Turkish population and the relationship of genotype characteristics with phenotype.
Method
Patients with HT between the ages of 18-75 and healthy controls were included in this prospectively designed study. Clinical symptoms, iodine status according to the age of 6-15 and last city of residence asked in questionnaire and thyroid ultrasonography (USG) were performed in the participants. Peripheral blood was collected from participants for genetic analysis.
Results
The mean age of 244 patients (220 females,24 males) participating in the study was 40.84 years (min-max:18-75); The average age of 107 controls (91 females,16 males) is 38.37 years (min-max:19-65). In the 6-15 age range, the iodine adequacy of the cities where the patients live was found to be significantly higher than the control group (59.46%vs.41.00%; $P=0.002$). Except for dry skin ($P=0.167$) and weight gain ($P=0.968$), hypothyroidism symptoms and signs were significantly correlated with the disease in the Hashimoto group ($P< 0.05$). All controls were euthyroid. On the other hand 56.97% of the patients were euthyroid, 26% were subclinical hypothyroid, 11.07% were overt hypothyroid and 5.33% were hyperthyroid ($P=<0.001$). No difference was found between the patient and control groups in terms of thyroid volumes in thyroid USG ($P=0.506$). There was no significant difference in TSHR, CTLA-4, IL-1RN polymorphism distributions between HT patients and controls ($P> 0.05$). No association was also found between genotype and clinical parameters of patients with HT except the incidence of hypertension in TSHR GC polymorphism in patients is significant compared to CC and GG ($P=0.007$); The rate of hypertension was higher in IL1RN A3A3 and A2A2 polymorphisms in patients ($P=0.031$) and the incidence of HL was found to be higher in A3A3 and A1A1 polymorphisms ($P=0.003$).
Conclusions
The development of HT is multifactorial. In our study, it has been shown that TSHR, CTLA-4 and IL-1RN do not create a significant predisposition to HT. However, it should be taken into consideration that factors such as the diversity of polymorphisms, ethnic differences and the number of patients may affect the results and studies should be evaluated accordingly.

Thyroidectomy as a treatment of graves' disease in children

Mohamed Masmoudi, Chaima Zitouni, Wadii Thabet, Ezer Chebil, Mehdi Hasnaoui & Khelifa Mighri
Taher Sfar Hospital, ENT Department, Mahdia, Tunisia

Introduction
Graves' disease (GD) accounts for 10%-15% of thyroid disorders in children and adolescents.
Material and Methods
We report the clinical, therapeutic aspects and long-term results of 9 children (< 18 years) who had for Graves' disease, from 2000 to 2021.
Results
The mean age at diagnosis was 15,8 years [9 – 18 years]. Our study included 3 boys and 6 girls. One patient had coeliac disease. The surgery was conducted because of failed 2-year medical therapy in 5 cases and compressive goiter in 4 cases. Total thyroidectomy was performed in all cases. The postoperative course was complicated by transient hypocalcemia in one case. After an average follow-up of 5 years, all patients had control of the disease clinical manifestations including Graves' ophthalmopathy and biological euthyroidism.
Conclusion
The use of antithyroid drugs as the initial treatment option in Graves' disease is well accepted. An average two years remission is achieved in about 30% of children. Otherwise, radio-iodine therapy and surgery are considered as treatment options. Compared to surgery, radioiodine therapy can increase the risk of cancer and cause worsening of Graves' opthalmopathy, especially in children. Therefore, surgery may be a better option.

Resistance to thyroid hormone alpha: a case report

Greta Griciūnaitė[1], Marius Šukys[2] & Milda Danelienė[1]
[1]Department of Endocrinology, Academy of Medicine, Lithuanian University of Health Sciences, Kaunas, Lithuania; [2]Department of Genetics and Molecular Medicine, Academy of Medicine, Lithuanian University of Health Sciences, Kaunas, Lithuania

Introduction
Resistance to thyroid hormones (RTH) is a rare syndrome. This condition is caused by gene mutations of thyroid hormone receptors (THR). There are two

types of genes that code THR: THR alpha (THRA) and THR beta (THRB). The RTH alpha is associated with mutations in the THRA gene and is less common than RTH beta [1]. It is challenging to identify patients with RTH alpha because usually they only have mildly abnormal (or even normal) thyroid hormone levels and the severity of clinical features may depend on localization of the particular mutation in THRA [1].

Clinical case

A 38 year-old female patient was admitted to our outpatient clinic with symptoms of mild hypothyroidism (obesity, weakness, constipations, lethargy). 10 years ago she was diagnosed with hypothyroidism (FT4 0.69 ng/dl (normal: 0.8-1.9 ng/dl), TSH 1.89 mlU/ml (normal: 0.4-4.0 mlU/ml)) and levothyroxine (L-T4) was prescribed. Currently the patient was using L-T4 75 mg per day. Phenotypic features of the patient showed short stature (height 161 cm), obesity (BMI 40.12 kg/m^2), coarse facial features, skin tags and puffy hands. The laboratory tests showed low TSH, normal FT4 and high FT3. The ultrasound of the thyroid gland showed no changes. Autoimmune thyroid diseases were excluded. Simultaneously the patient was consulted by a geneticist due to neurological disorders (ataxia, speech disorders, epilepsy). For this, next generation sequencing was performed, incidental findings showed a heterozygous THRA mutation NM_199334.5:c.871G > A. The variant was interpreted as likely pathogenic (as there were no records in GnomAD and very few reports in literature with the same interpretation) [1]. The diagnosis of autosomal dominant hypothyroidism due to THRA mutation was confirmed and the treatment with L-T4 was continued. Subsequently, the same mutation variant was verified for the patients' mother and brother.

Conclusion

Although the mutation of THRA gene causes hypothyroidism, the clinical features are mostly mild and the disease is often left undiagnosed or is diagnosed in adulthood as it was in our case. We recommend that RTH should be suspected for every patient that has unusual clinical and laboratory test changes of thyroid function.

Calcitonin Measurement in Needle Washout Fluid After Fine Needle Aspiration As a Complementary Diagnostic Test in Medullary Thyroid Carcinoma

Pavle Puzigaca[1], Manuel J Caballero Segura[1], José Ignacio Fernández Peña[1], Eyvee Arturo Cuellar Llocl la[1], Joaquín Bobillo Lobato[2] & Guillermo Martínez de Pinillos Gordillo[1]

[1]University Hospital Virgen de Valme, Endocrinology and Nutrition, Seville, Spain; [2]University Hospital Virgen de Valme, Clinical Biochemistry, Seville, Spain

Introduction

The diagnostic accuracy of fine needle aspiration (FNA) in case of medullary thyroid cancer (MTC) has been less studied than in other thyroid cancers. The complementary measurement of calcitonin in the needle washout fluid after FNA (FNA-Ct) could improve the usefulness of this technique.

Materials and Methods

Description of two cases of patients with thyroid nodules suspicious for MTC in whom FNA-Ct was measured as a complementary diagnostic method.

Results

CASE 1: a 53-year-old man who was referred to our Endocrinology department due to a 1.3 cm right thyroid nodule and a 6 cm left thyroid nodule, with elevated CEA in laboratory tests (11.7 ng/ml). The additional blood calcitonin measurement was also elevated (91.3 pg/ml). FNA was performed on both nodules as well as FNA-Ct measurement. The cytology of the right nodule was categorized as Bethesda III with undetectable FNA-Ct and that of the left nodule was Bethesda V with FNA-Ct of 240 pg/ml (2.6 times more elevated than in blood). Total thyroidectomy with central lymphadenectomy was performed and the histological result was MTC in the left nodule and follicular variant of papillary carcinoma in the right nodule. CASE 2: a 79-year-old woman with a history of rectal adenocarcinoma and chronic kidney disease stage IV who presented a progressive elevation of CEA in laboratory tests, hypermetabolic uptake in the left thyroid lobe on FDG-PET, that corresponded to 1.2 cm nodule. The blood calcitonin measurement was also elevated (332 pg/ml). FNA was performed and the cytological result was categorized as Bethesda III. However, FNA-Ct was 800,000 pg/ml (2409 times more elevated than in blood). Total thyroidectomy with central lymphadenectomy was performed, confirming the diagnosis of MTC in the left nodule.

Conclusions

Although there are no obvious cut-off points, the FNA-Ct measurement showed values in both cases higher than blood levels, reinforcing the diagnostic suspicion of MTC and helping to decide on a more appropriate surgical approach. In neither case had cytology been reported as suggestive of CMT.

A case report: non-germinal center type diffuse large B-cell lymphoma in thyroid

Ruta Kriksciuniene[1], Gabija Siusaite[2] & Raimonda Klimaite[3,4]

[1]Endocrinology Diagnostic and Treatment Center "Hormodernus", Endocrinology, Kaunas, Lithuania; [2]Lithuanian University of Health Sciences, Kaunas, Lithuania; [3]Hospital of Lithuanian University of Health Sciences, Kauno Klinikos, Endocrinology, Kaunas, Lithuania; [4]Institute of Endocrinology, Medical Academy, Lithuanian University of Health Sciences, Kaunas, Kaunas, Lithuania

Introduction

The diffuse large B-cell lymphoma (DLBCL) is known as one of the most common lymphoma worldwide with the prevalence of 25 % of all of non-Hodgkin lymphoma cases [1], but it is very rearly observed in thyroid. Around 30 % of Clinical cases of the DLBCL appear from extranodal organs, the prognosis depends on the site of origin [2].

Case

A 18-year-old man was admitted to endocrinologist, complaining with a palpable nodule in the front neck for about 2 months. Patient has never been diagnosed with any thyroid disease before.

Diagnostic tests: Laboratory tests: Euthyroid chronic autoimmune thyroiditis was diagnosed TSH 2.3 (normal range 0.4-3.6) IU/l, FT4 12.2 (9.0-21.07) pmol/l, FT3 5.9 (3.34-5.1) pmol/l, ATPO 823 (0-3.2) kIU/l).

Thyroid ultrasound A hypoechoic, ill-defined margin, calcificated nodule was visible in the left lobe of the thyroid gland (EU-TIRADS 5).

Microscopic examination A core needle biopsy of the left thyroid lobe identified diffuse large B-cell non-germinal center lymphoma as diffused lymphoid infiltration of mitotically active cells with large irregular-contoured *nuclei* and sparse cytoplasm with positive *LCA immunolabeling* and negative MyoD1.

PET/CT scan

A 3.3 x 6.2 x 7.3 cm of polysegmental, *FDG - accumulating* lymphoma mass was observed in the left lobe of the thyroid gland. There were no visible metabolically active lymph nodes, infiltrative changes in the lungs and pathological foci in the bones.

Treatment

Treatment consisting of immunotherapy with Rituximab and immunochemotherapy with regimen R-CHOP was initiated. Patient received Filgrastim and Prednisolone for neutropenia prophylaxis. No complications have been observed.

Conclusion

The prevalence of lymphoma in thyroid is very rear, still the early diagnosis and specific treatment is crucial for proper management of the disease, as non-germinal center type large B-cell lymphoma is usually associated with a higher mortality rate compared to germinal center large B-cell lymphoma [3].

Levothyroxine liquid oral substitution as a treatment of refractory hypothyroidism due to gastrointestinal malabsorption

Yasmine Mouelhi, Ibtissem Oueslati, Faten Cherchir, Asma Ben Hamida, Meriem Yazidi & Melika Chihaoui
La Rabta University Hospital, Department of Endocrinology, Tunis, Tunisia

Introduction
Primary hypothyroidism is a common condition. Its treatment is simple and consists of daily levothyroxine intake. Cases with refractory hypothyroidism despite high doses of levothyroxine were reported. Herein, we report the case of a patient with refractory hypothyroidism secondary to gastrointestinal malabsorption that was improved by L-thyroxine liquid oral substitution.
Observation
A 49-year-old woman was admitted for refractory hypothyroidism. Her past medical history included Graves 'disease treated with radioiodine therapy, asthma, and vitamin d deficiency. The patient was treated with levothyroxine 200 µg/day (2.63 µg/kg/day) with good compliance and regular intake. She presented with persistent symptoms of hypothyroidism and a TSH level of 72 mIU/l (nr: 0.35-4.95). A levothyroxine absorption test was performed by oral administration of 300 µg of levothyroxine (3 solid tablets of 100 µg each). The LT4 absorption rate was 25%, consistent with the diagnosis of malabsorption. A second absorption test was carried out by a concomitant oral administration of 300 µg of levothyroxine and 1 g of vitamin C. The LT4 absorption rate was 3 %. Sublingual administration of levothyroxine was not associated with the increase of FT4. Etiological investigations showed negative celiac disease serology and Helicobacter pylori (HP) gastritis. HP infection was treated but symptoms of hypothyroidism and elevated TSH persisted. The levothyroxine dose was progressively adjusted from 200 µg to 400 µg once a day. Biological tests showed a TSH level of 92.4 mIU/l and a FT4 level lower than 0.42 ng/dl (nr: 0.7-1.5). The patient was put on L-thyroxine in liquid form at a dose of 80 drops per day. Two weeks later, she presented with clinical improvement with a normal FT4 level at 1.14 ng/dl.
Conclusion
Refractory hypothyroidism has a significant impact on patients. It can be caused by several conditions such as poor compliance with levothyroxine therapy, drug interferences, and malabsorption syndrome. Liquid formulations tend to have a better effect on patients with gastritis or those receiving proton pump inhibitors. This is thought to be due to increased dissolution and absorption.

Recurrence of Graves disease after 30 years

Kadiri Chaimae & Lachkar Hassan
Hospital Cheikh Zaid, Endocrinology, Rabat, Morocco

Introduction
Graves' disease is an autoimmune disease of the thyroid that manifests as hyperthyroidism, homogeneous goiter and sometimes ophthalmopathy. Medical treatment with synthetic antithyroid drugs restores clinical and biological euthyroidism. However, an apparently successful treatment can be followed by relapse in 40% of cases. We report the case of a patient who presented with a recurrence of Graves' disease after 30 years of remission.
Observation
This is a 62-year-old patient, followed for Graves' disease since the age of 30, treated with carbimazole for 2 years and then obtaining remission with clinical and biological euthyroidism. She presented for consultation for thyrotoxicosis with tachycardia, thermophobia, hand tremors and proptosis. Clinical examination found a homogeneous stage III goiter. The biological evaluation confirms the peripheral hyperthyroidism with a TSH slowed down to 0 mIU/ml and elevated T4L. Thyroid scintigraphy found hyperfixing goiter suggestive of Graves' disease. The patient received treatment with iodine 131 radiation therapy at a dose of 20 mci. It is then supplemented by LT4 with favorable evolution.
Conclusion
The evolution of Graves' disease treated medically remains difficult to predict requiring long-term monitoring given the high risk of recurrence even after several years of remission as the case of our patient.

The relationship between TSHR methylation level and clinicopathological factors in papillary thyroid cancer

Raimonda Klimaite[1,2,3], Mintautė Kazokaitė[2,3], Aistė Kondrotienė[1,2,3], Dalia Dauksiene[3], Birute Zilaitiene[1,2,3] & Albertas Dauksa[2,4]
[1]Department of Endocrinology, Hospital of Lithuanian University of Health Sciences, Kauno klinikos, Kaunas, Lithuania; [2]Lithuanian University of Health Sciences, Kaunas, Lithuania; [3]Institute of Endocrinology, Medical Academy, Lithuanian University of Health Sciences, Kaunas, Kaunas, Lithuania; [4]Institute of Digestive Research, Medical Academy, Faculty of Medicine, Lithuanian University of Health Sciences, Kaunas

Introduction
Papillary thyroid carcinoma (PTC) is the most common thyroid cancer type. It carries a good prognosis. However, approximately ten percent of cases may present with metastatic disease at initial presentation. Fine needle aspiration biopsy cytology is still the gold standard for diagnosing PTC, but there is a technical limitation. That's why minimally invasive diagnostic test is the subject of research in nowadays.
Our objective
We aimed to explore the *TSHR* methylation level in PTC patient's plasma samples and to compare with clinicopathological factors.
Methods
Study included 68 patients with a histologically confirmed diagnosis of PTC treated at Hospital of Lithuanian University of Health Sciences, Kaunas clinics 2020 - 2021. Peripheral blood samples were collected from patients. DNA methylation level changes of *TSHR* were analyzed by quantitative methylation-sensitive polymerase chain reaction. The total tumor size was calculated as the sum of the diameters of all tumors in PTC multifocal cases. Statistical analyses were performed using SPSS 22.0 software (SPSS Inc., Chicago, IL, USA). The results were considered statistically significant at $P < 0.05$.
Results
Average age at diagnosis was 48.19 $\pm$ 14.9 years, there were 8 male patients (11.8%) and 60 female patients (88.2%). We observed that *TSHR* concentration were significantly higher in PTC with greater tumor size (>2 cm) compared to lower (≤ 2 cm) tumor size ($P < 0.001$), lymph node metastasis ($P = 0.01$), lymphovascular invasion ($P = 0.02$), multifocality ($P = 0.013$). A weak positive correlation between the concentration of *TSHR* with the total size of PTC tumors was found ($P = 0.09$, $r = 0.315$). However, there was no correlation between demographic characteristics and histopathological subtypes of PTC.
Conclusion
This study analyzed associations between TSHR promoter methylation level and PTC clinicopathologic features. Our results indicate that TSHR promoter methylation may be useful parameter in assessing disease progression. Further studies are also warranted to expand upon our findings.

Papillary thyroid carcinoma and Graves' disease: a case report

Houas Jihene[1], Ben Arfi Taissir[1], Ghammam Monia[1], Lazid Sarra[1], El omri Malika[1], Bellakhdher Mouna[1], Hasni El Abed Yosra[2], Meherzi Abir[1], Kermani Wassim[1] & Abdelkefi Mohamed[1]
[1]ENT Department and Neck Surgery of Farhat Hached Hospital, Sousse, Tunisia, [2]Endocrinology Department Farhat Hached Hospital, Sousse, Tunisia

Introduction:
The occurrence of a thyroid cancer on Graves' disease is rare (0.3 to 16.6%). Most often than not, the type found is a papillary carcinoma and is discovered incidentally. Finding a thyroid nodule within the goiter must always raise suspicion of malignancy.
Material and methods
We report the case of a patient followed for Grave's disease in whom a fortuitous association with differentiated thyroid cancer was discovered on a pathological examination.
Observation
A 51-year-old patient with no significant pathological history was hospitalized for an anterior cervical swelling, associated with clinical signs of hyperthyroidism, meanwhile no signs of compression were found. Physical examination revealed an enlarged thyroid with a 2.5 cm right nodule. The lymph node areas were free. The hormonal assessment revealed a profile of a peripheral hyperthyroidism. The cervical ultrasound revealed a multinodular goiter with thyroid nodules classified EUTIRADS 5 on the right side and EUTIRADS 3 on the left side. A thyroid scan showed bilateral l hypo fixing foci. The treatment was initially based on the administration of synthetic anti-thyroid drugs. The evolution was marked by partial improvement of the clinical and biological hyperthyroidism. The patient underwent a right lobo-isthmectomy with an extemporaneous examination that identified a papillary carcinoma of the thyroid, hence the thyroid totalization with a central lymph nodes dissection. Histological examination revealed a 23 mm papillary carcinoma of the right lobe with one metastatic lymph node alongside with a remodeled thyroid parenchyma compatible with Graves' disease. A complementary radiation therapy (3 courses of 100 mCi) was instituted. The evolution was favorable with no signs of recurrence nor extension. The current follow-up goes up to 6 years.
Conclusion
Diagnosing a patient with Graves' disease should never later on blind the physician on a possible association with a thyroid cancer. The subsequent management is similar to that of differentiated thyroid cancers and the prognosis is usually good enough.

Revealing Distant Metastasis of Differentiated Thyroid Carcinoma: About 4 Cases

Houas Jihene[1], BelHadjMiled Heyda[1], Ghammam Monia[1], Lazid Sarra[1], El Omri Malika[1], Bellakhdher Mouna[1], Hasni El Abed Yosra[2], Meherzi Abir[1], Kermani wassim[1] & Abdelkefi Mohamed[1]
[1]ENT Department and Neck Surgery of Farhat Hached Hospital, Sousse, Tunisia, [2]Endocrinology Department Farhat Hached Hospital, Sousse, Tunisia

Introduction:
Distant metastases of thyroid tumors are rare. They are mainly of pulmonary (10-15%), bone (9%) and brain (<1%) location. These metastases are more frequent with vesicular (20%) than papillary (3.5%) histological type carcinoma. The aim of our work is to document the clinical and radiological aspects as well as the therapeutic modalities of these entities.
Materials and methods
We report 4 cases of distant metastasis that revealed a differentiated thyroid carcinoma: two cases of pulmonary localization and two cases of bone localization collected at our department of otorhinolaryngology and cervicofacial surgery.
Observations (pulmonary metastasis)
These are two women aged 38 and 45 years who consulted for respiratory symptomatology without palpable thyroid nodules, with the finding of a micronodular miliary on standard chest radiography. A whole-body 131 iodine scan and a chest CT scan were also performed for the second patient, confirming the metastatic nature of the lung involvement. The diagnosis was confirmed on lung biopsy for both patients. Total thyroidectomy with bilateral functional dissection was performed in both cases confirming the presence of multifocal papillary carcinoma. A complement by iratherapy allowed to sterilize the sites in one of the two patients after 6 years, and to decrease the pulmonary iodine fixation for the other patient after 6 months.
Observation (bone metastasis)
This is a 55-year-old woman and a 60-year-old man who consulted for low back pain with motor deficit related to lumbosacral osteolysis and ductal invasion for the woman and neck pain for the man. The biopsy concluded to a metastasis of a vesicular carcinoma of the thyroid in both cases. Further imaging showed multinodular thyroid involvement without adenopathy in both cases. The female patient underwent decompressive radiotherapy. Both patients underwent total thyroidectomy associated with bilateral central curage. The histological examination had confirmed the vesicular type for the female patient and the papillary type for the male patient.
Conclusion
Visceral metastases of differentiated thyroid carcinoma have no clinical or radiological specificity. The metastatic potential remains independent of the size of the thyroid nodule. These metastases are more frequent with the vesicular histological type and have a more reserved prognosis. The presence of a single metastasis should prompt treatment with a carcinological aim.

Safety and Efficacy of Radiofrequency Ablation of Thyroid Nodules. Our Experience With A Cohort of 43 Patients

Blanca Bernaldo Madrid[1], Sara Mera Carreiro[1], Patricia Espinosa De Los Monteros[1], Fernando Hernández Olmeda[1], Laura Avila Anton[1], Noelia Sánchez-Maroto García[1], Salomé Merino[1], Celia Lopez Nevado[2], Mario Pazos Guerra[1] & Maria Cristina Familiar Casado[1]
[1]Hospital Clinico Universitario San Carlos, Madrid, Spain, [2]Hospital Central de La Defensa Gómez Ulla, Madrid, Spain

Introduction
The majority of current guidelines recommend surgery for benign solid nodules with pressure symptoms or a significant growth. Currently, minimal invasive techniques have emerged such as radiofrequency ablation (RF) which achieve significant volume decrease and many cases, the improvement or disappearance of pressure symptoms.
Results
We describe the efficacy and safety of one single-session of RF in our centre performed in thyroid nodules from 43 patients (8 men) with a mean age of 58,6 ± 13 years. Only nodules with a minimum follow-up of 6 months were included (range 6 months to a maximum of 2 years in 28 cases). Half of the patients had a multinodular goiter and only 3 patients were on previous treatment with antithyroid drugs. Mean plasma thyroid hormone levels were 1.75 ± 1.13 mU/l for TSH 8.7 ± 1.34 pg/ml for T4. The mean nodular volume was 21.6 ± 13.4 ml before the procedure. The indications for RF included: pressure symptoms in 37.2% of patients, nodule growth in 48.8% and both criterion in 14% of cases in patients who refused surgery. After RF, transient minor complications (local pain, bleeding) were registered in 46,8% of cases and one patient presented a major complication consisting in a nodule rupture which resolved spontaneously. During the follow-up, mean volume decreased significantly since the first month (14.1 ± 10.7 ml) achieving a value of 9.9 ± 9.1 ml at the 3rd month; 8.35 ± 7.95 ml at the 6th month; 8.5 ± 8.9 ml at the first-year y 7.7 ± 9,6 ml at the 2nd year. The percentage of ablation success (defined as decrease >50% nodular basal volume) also increased progressively: 25,6% ($n=42$) at the first month, 53,5% ($n=40$) at month 3 and 60,5% ($n=39$) at month 6. Pressure symptoms disappeared in all but one patient. Surgery was needed in 7 cases (16,2%), in half of the cases due to RF failure and subsequent nodule growth.
Conclusion
RF is a safe and effective alternative to surgery in patients with pressure symptoms or significant nodule thyroid growth.

Association Between Metabolic Syndrome Components and Urinary Iodine Concentration

Volodymyr Pankiv[1] & Ivan Pankiv[2]
[1]Ukrainian Research and Practical Centre of Endocrine Surgery, Preventive Endocrinology, Kyiv, Ukraine, [2]Bukovinian State Medical Univetsity, Clinical Immunology, Allergology and Endocrinology, Chernivtsi, Ukraine

Iodine is important in both thyroid function and human metabolism. The roles of iodine intake on the metabolic syndrome (MetS) etiology remain controversial.

The aim of this study
Was to investigate the relationship between iodine status and MetS and its components. 371 subjects aged ≥20 years were included.
Materials and methods
The presence of MetS was defined according to the Adult Treatment Panel (ATP) III criteria. The prevalence of MetS and its components were calculated based on the level of urinary iodine concentrations (UICs) using the chi-square method. To further explore whether prevalence was associated with UIC, quadratic and UIC-stratified logistic regression models were used.
Results
As UIC changed, the prevalence of MetS presented as a U-shaped curve, showing a lower prevalence of 18.3% at the UIC level of 150-200 μg/l, whereas the prevalence at the UIC level of below 100 μg/l was 32.6%. After adjusting for age, gender and other confounding factors, iodine status of 150-200 μg/l was a protective factor for MetS [OR = 0.674, 95%CI (0.709-0.932)]. UIC level < 100μg/l was a risk factor for hypertension.
Conclusions
Urinary iodine concentrations in adults are U-shaped associated with MetS and its components. A UIC level of 150-200 μg/l was beneficial to hypertension, hyperglycemia and hypertriglyceridemia. The beneficial effect disappeared when iodine was deficiency (<100μg/l).

EP1005

Relationship between TSH and metabolic parameters in overweight and obese premenopausal euthyroid women with autoimmune thyroiditis on levothyroxine treatment and healthy women

Boyan Nonchev[1,2], Antoaneta Argatska[1] & Elena Chobankova[2]
[1]Medical University Plovdiv, Endocrinology, Bulgaria, [2]Kaspela University Hospital Plovdiv, Clinic of Endocrinology, Bulgaria

Objective
To investigate the relationship between serum thyroid stimulating hormone (TSH) and free thyroxine (FT4) and body mass index (BMI), blood glucose, serum lipids and liver in overweight and obese euthyroid healthy premenopausal women and euthyroid women with autoimmune thyroiditis on levothyroxine replacement therapy.
Patients and methods
The study includes 34 premenopausal women with autoimmune hypothyroidism on stable levothyroxine dose and 129 aged-matched healthy premenopausal women. All women had TSH within reference range (0.4-4.2 mIU/l) and were overweight or obese (BMI 25-40 kg/m^2) without pre-existing diabetes. Fasting blood glucose, ASAT, ALAT, total cholesterol, HDL, triglycerides were measured and LDL was calculated.
Results
Women on levothyroxine had higher levels of TSH (2.55±1.02 vs 2.02±0.89 mIU/l, *P*0.009) and FT4 (11.58±1.63 vs 10.80±1.36 pmol/l, *P*0.007) compared to healthy controls. No differences between BMI and the investigated laboratory parameters were found between treated and healthy women. In women with treated hypothyroidism no correlations between TSH and BMI, blood glucose, lipids and liver enzymes were established. FT4 showed significant negative relation with total (r=-0.547, *P*0.001) and LDL cholesterol (r=-0.553, *P*0;001). In euthyroid control group positive correlation between TSH and BMI was found (r=0.291, *P*0.001). FT4 levels did not affect the investigated parameters.
Conclusion
Obesity, blood glucose and lipids are not associated with TSH levels within the target range in premenopausal women with autoimmune thyroiditis on replacement therapy. In healthy women TSH variations within reference range are associated with higher BMI but do not have significant influence on features associated with high risk of metabolic syndrome.

EP1006

Severe symptomatic hypercalcaemia associated with thymic hyperplasia and mediastinal lymphadenopathy secondary to Graves' Disease

Samuel Audet, Jana Bujanova & Erisa Ito, Adam Watson
Southampton General Hospital, Southampton, United Kingdom

Background
Hypercalcaemia of hyperthyroidism via increased bone turnover is not uncommon, however it is usually mild and asymptomatic. Corrected calcium (cCa) concentrations ≥ 3.0mmol/l are seen rarely and tend to be associated with high TSH receptor antibodies concentration. Some of the less well-known effects include thymic hyperplasia (TH) and lymphadenopathy. TH is explained by thyroid hormone acting on thyrotropin receptors in thymic tissue to increase proliferation of thymic epithelial cells and thymic medullary lymphoid follicles. Thyroxine can also have a direct effect on lymph tissue causing lymphadenopathy, splenomegaly and lymphocytosis. Importantly, thymic hyperplasia and lymphadenopathy secondary to thyrotoxicosis are benign and reversible with treatment of hyperthyroidism.
Clinical Case
We present a case of a 79-year-old lady, who was admitted acutely to the Emergency Department with symptomatic hypercalcaemia manifesting as confusion, word-finding difficulty, anorexia and worsening lethargy over a period of 12 weeks. cCa on admission was 3.19 mmol/l (2.2-2.6 mmol/l), ALP 173 U/l (30-130 U/l), PTH was normal at 2.0pmol/l (1.8-6.8 pmol/l). Confusion screen revealed hyperthyroidism with free T4 49.2pmol/l (7.7- 15.1 pmol/l), TSH < 0.01mu/l (0.34-5.6 mu/l). Low magnesium was also noted 0.38mmol/l (0.70-1.0 mmol/l). CT scan to screen for malignancy detected an enlarged thymus with calcifications and mediastinal lymphadenopathy. No malignancy was detected. An enlarged thymus was also noted on scan 5 years prior. Global heterogenous enhancement of the liver and spleen likely perfusional in nature was noted and was attributed to thyrotoxic state. Thyroid stimulating immunoglobulins returned strongly positive at 32.6IU/L (<0.1), confirming Graves' Disease without associated goitre or thyroid eye disease. She was managed with intravenous pamidronate, fluids and started on carbimazole. She developed transient hypocalcaemia (cCa 2.05 mmol/l) and hypophosphatemia on days 8 – 11 post pamidronate reflecting hungry bone syndrome due to rapid cessation of bone resorption. Her calcium normalised by day 11 post pamidronate and was maintained in range with normalisation of thyroid function. Endobronchial ultrasound and lymph node sampling and interval scan was offered to further investigate the lymphadenopathy, but were declined by the patient.
Discussion
This case highlights the importance of thyroid function testing when investigating and managing hypercalcaemia as well as the relationship between thyrotoxicosis, increased organ perfusion and thymic hyperplasia, which is most often benign and reversible with appropriate management of the underlying thyrotoxicosis. While our patient declined lymph node biopsy, her lymphadenopathy was clinically consistent with her thyrotoxicosis in the absence of any other apparent sinister cause and red flags.

EP1007

Graves' orbitopathy and pretibial myxoedema developed years after thyroidectomy

Ann Kobaidze[1], Ilona Tserediani[2], Nino Tedoradze[1] & Meri Davitadze[3]
[1]V. Iverieli Endocrinology, Metabology, Dietology Center "ENMEDIC", Georgia, [2]Medical Center VIvamedi, Georgia, [3]Clinic NeoLab, Georgia

Background
Graves' orbitopathy (GO), also known as thyroid eye disease, is an autoimmune condition and is one of the main extrathyroidal manifestations of Graves' disease. GO is relatively rare and usually accompanies the onset or develops soon after the Graves' disease. We present a case of GO that developed 18 years later from total thyroidectomy.
Case report
A 64-year-old men presented at the ophthalmology clinic with one-month history of gradual bilateral vision impairment with inability to walk independently, exophthalmos, pain in the eyes, swelling of eyelids, and excessive tearing. From past medical history, 18 years ago, patient underwent a subtotal thyroidectomy due to Graves' disease. 4 years following surgery, his vision started to deteriorate; however, he has not seen a specialist or done any investigations. 4 years ago, he was diagnosed with cataract in both eyes and underwent surgery. Patient was smoker (30 cigarettes/day), BMI = 21 kg/m2. His only regular medication was for hypertension. Physical examination revealed the presence of pretibial myxoedema on both legs and thyroid acropathy. Ophthalmological examination revealed swelling of periorbital tissue, eyelid retraction, and exophthalmos of both eyes. Clinical activity score (CAS) was 6. Moderate-to-severe and active GO was diagnosed. Laboratory tests were consistent with overt hypothyroidism (TSH = 29μIU/ml, FT4 = 0.56ng/dl) and positive TSH receptor antibody (TRAB) titter (7.11U/l). Cerebral and orbital CT scan was also done, which revealed an infiltration of the orbital fat and enlargement of the extraocular muscles. Neck ultrasound revealed 3 nodules in the thyroid bed. FNA cytology of the dominant nodule (33x26x10mm) was performed, which showed follicular neoplasia. Patient was started on 50 mg levothyroxine, he quitted smoking, and a pulse-therapy with methylprednisolone (cumulative dose 4.5 g) was done. After 12

weeks of pulse-therapy, repeated ophthalmological examination revealed moderate and inactive GO, vision significantly improved, pretibial myxoedema completely resolved, patient's quality of life also significantly improved. Biochemically, he was euthyroid and TRAB decreased to 4.63U/l. Thyroid remnant surgery was recommended, but patient refused to undergo the surgery.
Conclusions
Although GO usually presents soon after the onset of Graves' disease, late presentation can also occur, even after long-standing thyroidectomy. Raising awareness among both patients and clinicians in terms of diagnosing GO in time can reduce the severity of complications and ensure better quality of life for such patients.

Monitoring thyroid function test in patients with growth hormone deficiency, receiving growth hormone replacement therapy

Taha Asaad[1] & Akam Saeed[2]
[1]University of Slemani/College of Medicine, Medicine, Sulaimania, Iraq, [2]Sulaimani Cardiac Center, Cath Lab, Slemani, Iraq

Introduction
Interaction of growth hormone system with Hypothalamic pituitary axis can be complicated, and the effect of GH treatment on thyroid function is still not completely clear. GH has inhibitory effect on conversion of T4 to reverse T3, while enhancing extrathyroidal conversion of T4 to T3.
Objective
To assess thyroid function test in patients with growth hormone deficiency, receiving growth hormone replacement therapy in Slemani, Kurdistan region of Iraq.
Methodology
A prospective follow up study carried out in Endocrine and Diabetic Center in Slemani from October 2014 to October 2015, on a convenient sample of 54 patients with growth hormone deficiency. The patients were followed up to check thyroid function tests (TSH, T3 and T4) at the end of 1, 3, 6, 9 months of GH replacement therapy.
Results
Mean age of studied patients was 14 ± 3.4 years and males were more than females. There was a significant increase in TSH level after 6 months of treatment with GH ($P = 0.02$). No significant differences were observed in T3 level after 9 months of GH treatment ($P = 0.9$). A significant decrease in T4 level was observed after 9 months treatment with GH ($P = 0.03$).
Conclusions
Thyroid hormone T4 of patients with growth hormone deficiency declined while thyroid stimulating hormones increased after growth hormone replacement therapy.

50 Shades of Graves'

Philip Newland-Jones[1,2], Jana Bujanova[2], Nemia Pilobello[2], Diane Bray[2] & Alicja Knysak[2]
[1]University of Southampton, Faculty of Medicine, Southampton, United Kingdom, [2]University Hospital Southampton NHS Foundation Trust, Diabetes & Endocrinology, Southampton, United Kingdom

Introduction:
We present a series of 10 cases of GD presenting with seemingly unrelated symptoms with limited features of thyrotoxicosis, where control of thyroid function tests (TFTs) led to complete normalisation of presenting symptoms. In all cases patients were shown to have Graves disease with thyroid antibodies.
Case series review:
1. 82F with symptomatic hypercalcaemia and thymic hyperplasia on CT. Calcium normalised with standard therapy and remained within range with normalisation of TFTs. Hyperthyroidism could cause hypercalcaemia due to increased osteoclastic activity.
2. 37F with visual blurring due to bilateral papilloedema. Brain MRI excluded tumour and lumbar puncture excluded idiopathic intracranial hypertension. No thyroid eye disease or orbitopathy on MRI. TFTs and papilloedema improved spontaneously, where papilloedema mimicking brain tumour 'pseudotumor cerebri' has been reported with GD.
3. 32M with severe headaches and photophobia. MRI head and venogram confirmed extensive cerebral venous sinus thrombosis. Enlarged thymus and splenomegaly on CT. Thymic hyperplasia and splenomegaly resolved with carbimazole. 4. 51F debilitating headaches with features of increased intracranial pressure. CT head excluded space occupying lesion. Symptoms resolved fully with normalisation of TFTs with carbimazole.
5. 67F with symptoms of parkinsonism. Started carbimazole and Sinemet with symptomatic improvement. Sinemet withdrawn after normalisation of TFTs, with symptoms returning slightly. Case suggests dual pathology (GD + PD), with symptom improvement through normalisation of TFTs. Thyroid hormones can increase dopamine catabolism or alter dopamine receptors' sensitivity.
6. 50F with generalized pruritic urticaria refractory to antihistamines and topical steroids. Rash responded promptly to anti-thyroid treatment. Urticaria possibly due to raised IgE with GD, concurrent chronic idiopathic urticaria (CIU) and rash exacerbation by skin hyperperfusion in thyrotoxicosis.
7. 36F with leg oedema, breathlessness, splenomegaly and renomegaly. Organomegaly and symptoms resolved with control of TFTs.
8. 28F with acute manic psychotic episode requiring sectioning. Commenced risperidone and propylthiouracil with improvement in manic symptoms.
9. 39M with one month history of painful gynaecomastia, fully resolving within 2 months of normalisation of TFTs. Gynaecomastia could present with GD due to raised estradiol concentrations and increased aromatisation of testosterone to oestradiol.
10. 33F with increased abdominal swelling and pain from a large ovarian tumour. Histology revealed struma ovarii. Ovarian struma possibly grew due to TSH receptor stimulation with TRAb similarly to cervical goitre in GD.
Discussion
Variability of GD presentation highlights complex interactions between thyroid hormones, autoimmunity, genetics and biochemical processes, highlighting the need to consider TFT's in a wide range of presenting complaints.

Locoregional and distant recurrences of papillary thyroid carcinoma : A case series of 12 patients

Sanaa Bammou, Zineb Ait Si Ali, Sana Rafi, Ghizlane El Mghari & Nawal El Ansari
Mohamed VI University Hospital Center, Department of Endocrinology, Diabetology, Metabolic Diseases Nutrition, Marrakesh, Morocco

Introduction
Patients with PTC usually have excellent outcomes with appropriate therapy, while up to 30% of patients present with aggressive disease, including patients with locoregional recurrence and distant metastasis.
The aim
Of this study is to analyze the characteristics of patients with papillary carcinoma of the thyroid with locoregional and distant recurrences.
Résults
We included 12 cases of locoregional and distant recurrence of papillary thyroid carcinoma. 10 of our patients are female and 2 are male with a sex ratio of 1/5. The majority of our female patients are younger than 55 years. The initial surgical treatment consisted of lobo-isthmectomy in one patient, total thyroidectomy in 9 of our patients and thyroidectomy with lymph node dissection in 2 cases. Five of our patients had a tumor size greater than 4 cm, in 3 cases the tumor size was between 2.1 cm and 4 cm, and in 4 patients it was less than 2 cm. In our series we noted multifocality in only one patient. Capsular invasion was observed in 6 patients, representing half of the cases. As for the aggressive histological type, we noted only one case of a patient with the oncocytic variant of papillary carcinoma on anatomical-pathological study. Two of our patients had lymph node metastasis in the cervical region at the time of diagnosis. None of our patients had distant metastasis at the time of diagnosis. In one case the ATA risk stratification of recurrence was in favor of a low recurrence risk. In 3 patients the risk of recurrence was intermediate and in 8 cases the risk of recurrence was high. All our patients received radioiodine therapy, 6 patients had received a single cure of radioiodine therapy, 4 patients had received two cures, only one patient had received 3 cures and one patient had received 4 cures of radioiodine therapy. Only one patient had received 2 lines of targeted therapy: sorafenib and sunitinib. Eight patients had locoregional lymph node recurrence alone, one patient had lymph node and lung metastasis, one case had lymph node and bone recurrence in the right sacroiliac joint. One case had a bone metastasis in the tibia. One case had pulmonary and bone metastases in the femur. During the follow-up period, none of our patients died.
Conclusions
Papillary thyroid carcinoma is an indolent disease, but cases having certain characteristics are likely to show recurrence and even become life-threatening.

Echographic characteristics of thyroid cancers in the Regional Hospital of Malaga

Virginia Soria Utrilla, Viyey Kishore Doulatram Gamgaram & Stella González Romero
Hospital Regional Universitario de Málaga, Endocrinology and Nutrition, Málaga, Spain

Introduction
Thyroid cancer is the most common endocrine malignancy, and its incidence is increasing worldwide.
Objective
Our aim is to look at the prevalence of ultrasound features and FNA findings of nodules in patients operated on for thyroid cancer in our hospital.
Material and methods
Cross-sectional observational study of patients operated on for thyroid cancer at the Regional University Hospital between 2018-2021, we collected data on the ultrasound characteristics of the nodules and their classification according to the ultrasound risk scales: ATA and ACR-TIRADS. The analysis has been carried out using the JAMOVI program.
Results
88 patients were included: 60 women and 28 men, mean age: 50.8 years (range 14-86 years), mean TSH 2.47 (SD 2.98), mean diameter of nodules: 25.8mm (SD 15.5), 87.1% are solid and 12.9% solid-cystic, 30.6% have microcalcifications and are ill-defined, borders are irregular in 39.5%, higher than wide in 14.1%. According to the ACR-TIRADS classification: II:1.2%, III:17.6%, IV:28.2% and V:47.1%, according to ATA classification: very low suspicion:1.2%, low suspicion:23.5%, intermediate suspicion:28.2% and high suspicion:47.1%. There is concordance between both echographic risk scales in 77 of the 85 patients (statistically significant correlation $P < 0.05$).
Conclusions
Both the ACR TI-RADS and the ATA risk stratification systems provide a clinically feasible thyroid malignant risk classification, with high thyroid nodule malignant risk diagnostic efficacy.

Papillary microcarcinoma: Diagnosis, treatment and outcomes

Mohamed Masmoudi, Chaima Zitouni, Wadii Thabet, Ezer Chebil, Mehdi Hasnaoui & Khelifa Mighri
Taher Sfar Hospital, ENT Department, Mahdia, Tunisia

Introduction
Papillary microcarcinoma (PMC), is defined as papillary carcinoma of the thyroid that is less than 10 mm in diameter.
Objective
The purpose of this study is to describe the diagnosis, treatment and outcomes of papillary thyroid microcarcinoma.
Material and Methods
This is a retrospective study including 55 cases of papillary thyroid microcarcinoma treated at our department, from 2000 to 2021.
Results
Our study included 8 men and 47 women. The mean age was 48 years (24-73 years). Three patients had hypothyroidism, 1 patient had hyperthyroidism and 2 patients had a history of loboisthmectomy for benign nodules. No personal history of cervical radiation therapy or family history of thyroid cancer have been noted. The average consultation delay was 14 months. The circumstances of discovery were: lateral cervical lymph node metastases in 5 cases, incidentally discovered by histological examination of the thyroidectomy specimens in 51 cases and ultrasound-guided fine-needle aspiration in 4 cases. The surgical procedure towards the gland was total thyroidectomy in 47 cases, loboisthmectomy in 6 cases and lobectomy in 2 cases (totalization). Central lymph node dissection was performed in 42 cases and 5 patients had lateral lymph node dissection. The postoperative course was complicated by: lymphorrea in 1 case, hematoma in 1 case, transient hypocalcaemia in 5 cases, transient Recurrent Laryngeal Nerve Palsy in 3 cases. The mean size of microcarcinomas was 5 mm (1-10 mm). Microcarcinoma was multifocal in 16 cases, non-encapsulated in 28 cases and with extra thyroid extension in 12 cases. Fifteen patients had central lymph node metastasis and lateral lymph node involvement was noted in 5 cases. None of the patients had distant metastasis. Radioactive iodine has been indicated in 42 cases with a dose ranging from 100 mCi to 400 mCi. Thyroid hormone suppression was indicated in all cases. After a mean follow up of 3 years and 6 months, 2 patients presented a recurrence. Five patients were lost to follow-up.
Conclusion
The incidence of papillary thyroid microcarcinoma is increasing due to the extensive use of ultrasound-guided fine-needle aspiration cytology. However, there is no consensus in the management of the disease.

Ectopic Cervical Thymic Hyperplasia In A Patient Treated For Hodgkin Lymphoma

Souha Kallel[1], Faten Haj Kacem Akid[2], Imen Achour[1], Yousef Hbaieb[1], Rim Kallel[3], Hamdi Frikha[2], Mohamed Abid[2] & Ilhem Charfeddine[1]
[1]Habib Bourguiba Hospital, Department of Otolaryngology (ENT) Head and Neck Surgery, Sfax, Tunisia, [2]Hedi Chaker Hospital, Department of Endocrinology, Sfax, Tunisia, [3]Habib Bourguiba Hospital, Department of Pathology, Sfax, Tunisia

Background:
True thymic hyperplasia results from stressful situations such as chemotherapy. It commonly presents as an anterior mediastinal mass; cervical location is exceptional. The aim of this work is to illustrate a case of an incidental ectopic cervical thymic hyperplasia in a patient treated for Hodgkin lymphoma.
Case reprt
Here we report a case of a cervical true thymic hyperplasia in a 12-year-old girl who had a Hodgkin lymphoma treated by radiotherapy and chemotherapy. She was referred to our department for a left cervical mass. The PET scan showed a hypermetabolic adenopathy. Mediastinal MRI was unremarkable. The patient underwent resection of the cervical mass under general anesthesia. Pathological examination confirmed the diagnosis of a true thymic hyperplasia.
Conclusion
Residual ectopic tissue may persist during its migration to its final position in the anterior mediastinum. True thymic hyperplasia may result from chemotherapy for lymphoma in the pediatric population. However, its presence in the cervical region is exceptional. Histological examination is necessary for diagnosis if imaging techniques are unable to rule out malignancy.

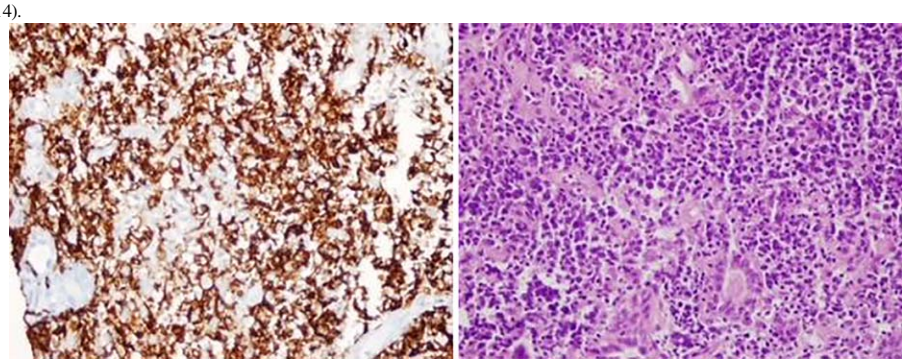
EP1014

A patient with thyroid lymphoma diagnosed during follow-up with benign thyroid nodule

Cigdem Birinci, Hülya Coskun, Özge Ücüncü, Cüneyt Bilginer, Ozlem Kanburoglu Meletli, Mustafa Kocak & Irfan Nuhoglu
Karadeniz Technical Univercity Faculty of Medicine, Endocrinology and Metabolism, Trabzon, Turkey

Objectives
Primary thyroid lymphoma constitutes 0.5-5% of all thyroid malignancies. Its incidence is two per million persons. Patients usually present with rapidly growing masses in the thyroid their sixth-seventh decades. The disease is frequently accompanied by chronic Hashimoto's thyroiditis. Most tumors are B-cell derived non-Hodgkin's lymphoma.
Case report
An 84-year-old male patient presented with a palpable swelling in the neck. Ultrasonography revealed heterogeneous hypoechoic thyroid parenchyma (thyroiditis?), a 17x7 mm hyperechoic solid nodule in the right thyroid lobe, 22x9 mm lymph nodes in the right jigular chain. Thyroid antibodies were positive and laboratory tests revealed that the patient was euthyroid. Thyroid fine needle aspiration(FNA) biopsy was performed. The right lobe nodule and lymph node were found to be benign. The patient, who was followed up with benign troid nodule, presented again 6 months later with complaints of rapidly growing mass in the neck, shortness of breath, 10 kg weight loss in the last 1 month and fever. Ultrasonography revealed hypoechoic lesions diffusely infiltrating the parenchyma. Hyperechoic patchy areas and echogenic septa were observed in both lobes except infiltrating areas. Lymphadenopathies of 11x13 mm in the right cervical region and 12x6 mm in the left cervical region were observed. A core needle biopsy (CNB) was performed for definitive diagnosis of suspicious lymph node and thyroid gland and reported as compatible with disseminated large B-cell lymphoma.

Patology: (Abstract EP1014).



Ultrasound: (Abstract EP1014).

Discussion
Thyroid lymphomas are an exceptional finding in patients with thyroid nodules. Given the rarity of this disease, making a prompt diagnosis can be challenging. For instance, FNA cytology, which is the first-line diagnostic test that is performed in patients with thyroid nodules, is often not diagnostic in cases of thyroid lymphomas, with subsequent delay of the start of therapy as occured in our patient. It has been argued that in cases suspicious of thyroid lymphomas, CNB could help to reduce diagnostic surgery and, most importantly, to obtain earlier the diagnosis necessary to start life-saving treatment with multiagent chemotherapy.
Conclusions
We presented this case because it suggests that thyroid FNA biopsy, which is the most commonly used method for troid nodule evaluation, may be insufficient in the diagnosis of thyroid lymphoma. Even if the fine needle aspiration biopsy result is benign, patients should be closely monitored and should be evaluated by CNB or open biopsy when there is high clinical suspicion of malignancy.

What are we going to do with Bethesda IV nodes in future? Do we need molecular testing for all of them?

Arseny Semenov[1], Dmitry Buzanakov[1], Roman Chernikov[1], Iliya Sleptsov[1], Viktor Makarin[1], Anna Uspenskaya[1], Nataliya Timofeeva[1], Nataliya Gorskaya[1], Sergey Vorobyev[2], Konstantin Novokshonov[1], Yuliya Karelina[1], Igor Chinchuk[1], Elisey Fedorov[1], Dina Rebrova[1], Iliya Sablin[1], Anna Zolotukho[1], Svetlana Alekseeva[1], Kseniya Gerasimova[1], Alexander Puskaruk[1], Nataliia Levchenko[3] & Shamil Shihmagomedov[1]
[1]SPbU Hospital, Endocrine Surgery, Sankt-Peterburg, Russia, [2]National Center for Clinical Morphological Diagnostics, Sankt-Peterburg, Russia, [3]SPBU, Medical Faculty, Saint Petersburg, Russia

Background
Bethesda IV is the most common indication for thyroid surgery. As histological verification is the only 100% certain method of confirming malignancy, surgery remains the gold standard for FN treatment. Most cases of FN malignancy are variants of papillary thyroid cancer that require active surveillance alone in nodules sized less than 2 cm.
Materials
A continuous cohort of 4399 patients who underwent surgery at SPbU_Hospital in the years 2020-2021 with Bethesda IV cytology obtained by FNAB with MG staining.
Results
In 1296 (29,5%) patients malignant thyroid nodules were identified by final histological examination. However, in 406 of those patients (31,3%) malignancy was found in non-punctured minor nodules. Of 980 cases of FN found to be malignant 46% were NIFTP or minimally invasive follicular thyroid cancer and only in 185 (8,8%) cases invasion of at least the nodules' capsule was reported. 39 cases involved an invasion of the gland's capsule (4%). 29 (3,6%) cases had vascular invasion or were suspicious for vascular invasion. 3066 patients had nodules of $\leq$2 cm. Of those patients 578 had malignant nodules (18,9%). In 262 patients (45,3%) the nodules were identified as NIFTP or minimally invasive follicular thyroid cancer. However, the risk of finding cancer with aggressive features in nodules of 2 cm or less was only 0,9%, as compared to 6,4% in nodules $>$2 cm. OR$=$7,4 The risk of finding aggressive cancer in any nodule sized $\leq$2 cm was 0,16%, while that in larger nodules was 1,5%. Most of the malignant nodules were found to be variants of thyroid cancer meeting the criteria for active surveillance. We performed ROC analysis to establish cut off size of FN and the risk of missing an aggressive thyroid cancer (AUC$=$0.84). Cut off nodule diameter of 3 cm showed a sensitivity of 0.8 (0.64 - 0.92), and a specificity of 0.79 (0.78 - 0.81) for the risk of aggressive cancer. For 2 cm sensitivity was 0.84 (0.68 - 0.96), while specificity was 0.6 (0.59 - 0.62). NPV was 0.9984 (0.9971 - 0.9994) for the 3 cm diameter and 0.9983 (0.9966 - 0.9996) for the 2 cm diameter.
Conclusion
It seems that patients with nodules of $\leq$2 cm can safely avoid surgery until the nodules grow in size even if no genetic test is performed. This may also be true for nodules of $\leq$3 cm, should the surveillance criteria for papillary thyroid cancer be expanded.

Hematological changes in patients with Graves disease

Farida Saidova[1], Jale Aslanova[1], Leyli Akhmedova[2] & Oruc Shahsuvarov[1]
[1]Scientific Center of Surgery after M.A. Topchubashov, Endocrine Surgery, Baku, Azerbaijan, [2]Azerbaijan State Advanced Training Institute for Doctors after A. Aliyev, Central Scientific Research Laborator, Baku, Azerbaijan

The aim of the study is to identify the frequency of occurrence of various morphological types and various degrees of severity of anemia in patients with Graves disease(GD).
Material and methods
The data of the case histories of 157 patients operated on for GD in 2012 were analyzed. When assessing hematological parameters, two groups were identified: Group 1 - patients with GD with mild anemia ($n=$ 98), age 39.4 $\pm$ 1, 4, men - 41 (41.8%), women - 57 (58.2%) and group 2 - patients with GD with moderate anemia ($n=$ 59), age 41.1 $\pm$ 1.7, men - 11 (18.6%), women - 48 (81.4%). In the clinical analysis of blood, hemoglobin, hematocrit, erythrocyte count and erythrocyte indices MCV, MCH, MCHC were determined.
Results
Microcytic type of anemia was observed more often with moderate severity of anemia (89.8%), and normocytic type of anemia was detected more often with mild anemia (12.2%). Hypochromic and normochromic types of anemia were detected with the same frequency in mild and moderate anemia (hypochromic in 94.9%, normochromic in 5.1%,)
Conclusion
GD is characterized by a high incidence of anemia, more often of mild severity (62.4%), microcytic (88.5%) and hypochromic (94.9%), due to iron deficiency.

Achalasia associated with Grave's disease: case report

Faiza Bensmaine[1], Lynda Beloucif[1], Jean-Marc Guglielmi[1], Camille Botella[1], Régis Quittelier[1] & Guillausseau Pierre Jean[2]
[1]Hôpital Rives de Seine de Neuilly sur Seine, Médecine Polyvalente, Neuilly sur Seine, France, [2]Hôpital Lariboisières, Médecine Interne, Paris, France

Rationale
Grave's disease (GD) is the most common subtype of autoimmune hyperthyroidism, which can manifest with a variety of extrathyroidal clinical syndromes such as ophthalmopathy, pretibial myxedema (dermopathy), acropathy, cardiomyopathy, and encephalopathy. In very rare instances, GD can also be diagnosed following severe gastrointestinal symptoms such as dysphagia, heartburn, nausea and vomiting. We hereby describe a rare case of GD with digestive symptoms which were later diagnosed as achalasia.
Case presentation
A 26 years old Portuguese woman presented thyrotoxicosis at 2 months of pregnancy. Anti-thyroid stimulating hormone receptor antibody (TSI) was present, and she was diagnosed as GD. Anti-thyroid medication was chosen as the initial treatment for Grave's disease. However, this treatment failed to normalize free triiodothyronine (FT3), free thyroxine (FT4) and thyroid stimulation hormone (TSH). Throughout pregnancy and three months after delivery, patient had sensation of 'burning' in the anterior cervical region, which extended to the epigastric region. She reported feeling the worst in the morning after waking up noticing an improvement following the ingestion of refrigerated liquids. Daily post prandial vomiting (10 times) became more frequent, with important weight loss (from 76 to 56 kg in the three months after delivery), progressive dysphagia, and global lethargy. No exophtalmus or skin changes were present. Thyroid gland was painless and normal in size. Laboratory assessment showed low serum TSH ($<$ 0,01 mUI/l) and increased both serum FT3 (27,3 pmol/l) and FT4 (63 pmol/l). TSI was still present (4,2 IU/l). A computed tomography scan of the chest and an upper digestive endoscopy were carried out, considering predominant dysphagy-related symptoms, suggestive of esophageal achalasia involving the lower esophageal sphincter. In relation to the significant weight loss, an endoscopic esophageal dilatation was performed in order to improve nutritional status and allow antithyroid drugs treatment to pass through stomach. After dilatation and treatment with anti-thyroid medication, symptoms resolved. Patient recovered her body weight remarkably (56 to a current 64 in one month). FT4, FT3 and TSH normalized after one month of therapy.
Conclusion
We present here a rare case of GD associated with achalasia diagnosed one year after the initial treatment for GD. In case of gastrointestinal symptoms such as dysphagia and vomiting in GD, physicians need to be aware of the possible diagnostic of achalasia as delay in the diagnosis could possibly result in potential harm and/or unnecessary interventions.

EP1018

Possibilities and priority of ultrasound in thyroid lesions covid-19

Yuriy Aleksandrov[1], Vasiliy Semikov[2], Lubov Timofeeva[3] & Elena Yanovskaya[4]
[1]Yaroslavl State Medical University, Surgery, Yaroslavl, Russia, [2]I.M. Sechenov First Moscow State Medical University, Moscow, Russia, [3]FSBEI HE «I. N. Ulianov Chuvash State University», Cheboksary, Russia, [4]Yaroslavl State Medical University, Yaroslavl, Russia

Scientists have studied the direct effect of Civi19 on the pancreas and thyroid gland, in particular, on the development of subacute thyroiditis de Quervian. Our study describes 9 cases of subacute thyroiditis associated with coronavirus infection. Three patients had a mild form of covid19 (positive PCR test result). Subacute thyroiditis was one of the components of multiple organ lesions. Patients had typical manifestations of thyroiditis neck pain, cough, signs of hyperthyroidism. Palpation of the neck revealed local soreness and thickening in the thyroid gland. Laboratory parameters corresponded to the activity of the process (ESR -28,17,35 (respectively), CRP -9,13, 17 (respectively), Ig M level: 4,2, 3,8 and 5,9 (respectively). The main method of examination was ultrasound (separate hypoechoic heterogeneous areas in the thyroid without clear contours). In 4 patients with covid19 of moderate severity, subacute thyroiditis was detected at the rehabilitation stage (all had a negative PCR test, Ig M – 2.2; 1.4; 2.3 and 1.7 (respectively), IgG -34, 121, 231 and 33 (respectively)). It is possible that the disease began at the peak of coronavirus infection. Clinical and laboratory indicators did not indicate a generalized infectious process. The thyroid gland lesions were revealed on the basis of complaints (neck pain) and a specific ultrasound picture (characteristic heterogeneity, hypoechoic zones without clear boundaries with uneven contours according to the type of geographical map with changes in blood flow activity depending on the phase of the process). Two patients with subacute thyroiditis occurred 4 and 5 months after covid19. Before the appearance of subacute thyroiditis, patients had no other viral diseases. The PCR test at the time of treatment was negative. The clinical picture corresponded to subacute thyroiditis: neck pain during swallowing and movement, subfebrility. According to ultrasound dates, there were extensive hypoechoic hypovascular zones in the thyroid with indistinct uneven contours and pronounced hyperplasia of the cervical lymph nodes). Laboratory studies revealed elevated levels of ESR and CRP, titers Ig G -233 and 76 (respectively), Ig M -0.7 and 1.1 (respectively).
Conclusion
Subacute thyroiditis associated with Covid19 can develop into various phases of viral disease. In the diagnosis of thyroiditis associated with covid19, the main diagnostic marker is ultrasound, which requires an assessment of the clinical status. Clinical and laboratory parameters are labile and depend on the stage of the disease. Therefore, all patients with covid19 should undergo thyroid ultrasound at the stages of treatment in order to exclude thyroid damage.

Complications related to necrotizing otitis externa among patients with diabetes

Mohamed Masmoudi, Chaima Zitouni, Wadii Thabet, Ezer Chebil, Mehdi Hasnaoui & Khelifa Mighri
Taher Sfar Hospital, ENT Department, Mahdia, Tunisia

Introduction
Necrotizing otitis externa is an invasive infection of the external auditory canal and skull base, which typically occurs in older adult patients with diabetes mellitus.
Objective
The purpose of this work is to describe the complications related to necrotizing otitis externa among patients with diabetes.
Methods
This is a retrospective study including 10 diabetic patients with complicated necrotizing otitis externa treated in our ENT department.
Results
Our study included 4 men and 6 women. The mean age was 64 years ranging from 58 to 71 years. The average duration of diabetes follow-up was 10 years. All patients have received oral and local antibiotics before hospitalization. Symptoms were made of otalgia in all patients and otorrhea in 6 patients. Headache and temporo-mandibular joint pain were reported in 2 cases. Fever was observed in 4 patients. Four patients noted ipsilateral facial palsy. Stenosis of external auditory canal was observed in all patients. Pseudomonas Aeruginosa was isolated in 9 cases and Candidada Albicans in one case. CT-scan confirmed the diagnosis of necrotizing otitis externa in all cases. It also showed: an extension to parapharyngeal space in 2 cases, an extension to the rhinopharynx in one case, temporomandibular arthritis in 2 cases, lysis of the skull base in one case, lysis of the facial canal in 2 cases, sigmoid sinus thrombosis in one case and jugular vein thrombosis in 2 cases. MRI was performed in 2 cases showing the extension to parapharyngeal space and to the rhinopharynx. Diabetic control worsened with the onset of the infection in all cases. Nine patients received intravenous anti-pseudomonal medications. Antifungal therapy was conducted in one case. One patient had drainage of the retropharyngeal abscess. Symptoms disappeared in 8 cases and 2 patients had facial palsy as a sequel.
Conclusion
Necrotizing otitis externa is characterized by its aggressive behavior and its difficulty of management, especially among diabetic patients. Early diagnosis, adequate control of diabetes in association with early antibiotic therapy can reduce the morbidity and mortality of this disease.

EP1020

Case report: Methimazole-induced eosinophilic pleural effusion in a patient recently diagnosed with Graves' disease

Noemí Jiménez López, Gonzalo Allo Miguel, Irune Blanco Urbaneja, Álvaro Mauricio Chávez Villegas, Guillermo Martínez Diaz-Guerra & Miguel León Sanz
University Hospital October 12, Endocrinology and Metabolism, Madrid, Spain

Background
Thionamides are a class of drugs used to control thyrotoxicosis. A wide range of systemic adverse effects have been described, including agranulocytosis, rash, fever, arthralgia, hepatitis and even drug-induced lupus. Besides, there are some uncommon events related to their use, such as pleural effusion (only eight cases have been previously reported). We report a case of methimazole-induced eosinophilic pleural effusion.
Case
Our patient is a 77-year-old female diagnosed with Graves' disease on august 2022, one month after SARS-CoV-2 infection. She started treatment with methimazole 30 mg daily right after the diagnosis. 4 weeks after starting thionamides, the patient developed severe dyspnoea, tachycardia and chest pain, even though thyroid hormones were within normal limits. Chest X-Ray showed extensive right-sided pleural effusion without mediastinal deviation. Blood test showed elevated C-reactive protein and eosinophilia. Thoracentesis result showed exudative fluid with eosinophilia (27% eosinophils); cytology and adenosine deaminase were negative, as well as the result of multiple pleural fluid cultures. She was admitted to our hospital. Blood cultures, IGRA, and autoinmunity tests (antinuclear antibodies, antineutrophil cytoplasmic antibody and antimyeloperoxidase) were performed, all of them came back negative. Total body CT scan didńt show suggestive signs of neoplastic disease. Due to her age and comorbidities, she was not a candidate for pleural biopsy, so our patient was discharged after complete resolution of the pleural effusion, which required three evacuating thoracenteses procedures. Patient kept on using carbimazole. Two months after hospital discharge, we suspected that carbimazole was the potential cause of her pleural effusion, so the drug was discontinued. She was then referred to radio-iodine ablation with subsequent total resolution of the thyrotoxicosis. One month later, chest X-ray showed complete resolution of the pleural effusion without new recurrence.
Conclusion
Although the temporal relationship between the carbimazole use and the development of the effusion was clear, and the most common causes for pleural effusion were excluded, discontinuation of carbimazole was delayed and as a result the patient suffered from several recurrences of the effusion. This case highlights the relevance of keeping in mind the potential adverse events related to the use of anti-thyroid drugs. Some of them, although rare, are associated with severe and even life-threatening consequences. In these cases, definitive treatment alternatives to control the thyrotoxicosis are mandatory to avoid uncontrolled thyroid disease.

EP1021

A case of acute adrenal insufficiency revealing thyrotoxicosis

Boubaker Fadia, Mariem Souissi, Houcem Elomma Mrabet, Malek Belkhiri, Zantour Baha, Najoua Lassoued, Alaya Wafa & Sfar Mohamed Habib
Taher Sfar University Hospital, The Endocrinology Department of the Taher Sfar University Hospital of Mahdia, Mahdia, Tunisia

Introduction
The coexistence of hyperthyroidism and adrenal insufficiency in the same individual is a rare clinical condition.A total of 20 cases has been reported in the literature [1]. These two conditions may have the same clinical manifestations such as weight loss, asthenia, and digestive disorders and each one may mask the other. We describe the case of a patient presenting to the emergency department with acute adrenal insufficiency in whom associated hyperthyroidism was discovered.
Case report
A 69-year-old woman presented to the emergency department with asthenia, abdominal pain, vomiting, and a rapidly worsening neurological state leading to mental confusion. In her history, we note a diabetes evolving for 10 years in stop of treatment. T e examination noted an altered general condition with significant weight loss, dehydration without associated hemodynamic or respiratory failure. The presence of exophthalmos and a moderate vascular goiter was noticed. There was no melanoderma. Cardiac tracing revealed atrial fibrillation. The biology showed a venous blood glucose of 8.7 mmol/l, a natremia of 125 mmol/l, a hyperkalemia of 6.29 mmol/l, a renal insufficiency with creatinine of 136 µmol with hyperuremia of 62 mmol/l. So, a cortisolaemia and a TSH were requested and the patient had an emergency hemodialysis session and was put on corticosteroids by intravenous route with clinical and biological improvement. Results of cortisolaemia were of 17.47ug/l and the diagnosis of adrenal insufficiency was retained. TSH was requested, which was reduced to 0.001 mIU/l (0.3-5.6) with an increased FT4 to 64.31pmol/l (7.8-14.8). Anti-TPO antibodies were strongly positive at 602 IU/ml. The patient was transferred to our endocrinology department. The patient was put on synthetic antithyroid drugs, betablockers and oral hydrocortisone therapy.
Discussion
This case illustrates the precipitation of an acute adrenal insufficiency crisis by an unrecognized thyrotoxicosis condition. This can be explained by the fact that thyroid hormones accelerate cortisol metabolism [2]. Thyrotoxicosis increases metabolic demands and induces a state of stress which results in an increased need for cortisol which cannot be procured in case of adrenal insufficiency [2].
Conclusion
It is crucial to consider the diagnosis of adrenal insufficiency in renal insufficiency patients. It is also predijuciable to consider the diagnosis of thyrotoxicosis in some patients having adrenal insufficiency, selected by a well-conducted examination.

Exogenous biotin interference in streptavidin-biotin immunoassays: Interpret results with caution

Rachael Innes[1], Jacqueline McGuire[2] & Babu Mukhopadhyay[1]
[1]University Hospital Hairmyres, Diabetes and Endocrinology, East Kilbride, United Kingdom, [2]University Hospital Hairmyres, Clinical Biochemistry, East Kilbride, United Kingdom

A 52-year-old patient with a history of secondary progressive multiple sclerosis was referred to our endocrine vetting service with deranged thyroid function tests (TFTs). Medicines reconciliation demonstrated that the patient was currently on regular fampridine and carbamazepine only. TFTs checked in the community revealed a free T4 of 65.8pmol/l (12.0-22.0pmol/l) with a TSH of 2.03mU/l (0.27-4.20mU/l) and a free T3 of 5pmol/l (3.1-6.8pmol/l). 25-OH vitamin D and vitamin B12 were raised above the reference range, prompting a discussion of whether this patient was taking any over the counter medications. It became apparent that they were taking regular multi-vitamin supplements containing vitamin B7 (biotin) which is known to interfere with the Roche immunoassay. With regards to competitive assays such as free T4, excess biotin competes with the antibody in the reagent for binding sites on streptavidin, causing falsely elevated results. TFTs were subsequently sent to a laboratory in a neighbouring health board and were analysed using the Abbott immunoassay and results returned euthyroid with a free T4 of 13.5pmol/l (9.0-21.0pmol/l) and TSH 2.56mU/l (0.3-5.0mU/l). Biotin is a water-soluble B-complex vitamin that has an important role in metabolism and cell-turnover, and is commonly found in multi-vitamins and dietary supplements. Most multi-vitamins will contain between 40-62.5 mg of biotin, greater than the recommended daily intake of 30 mg. The majority of adults will meet their daily requirements through diet alone, in foods such as eggs, dairy products, vegetables and meat. There have been studies recommending higher biotin doses for patients with demyelinating neurological conditions such as multiple sclerosis. Unfortunately, it is not known what daily dose of biotin our patient was receiving. This case highlights the importance of interpreting deranged thyroid function tests with caution, particularly when the patient is asymptomatic, as was the case here. Similar cases have resulted in patients receiving unnecessary treatment with carbimazole which risks potentially severe side effects. After discussion with our senior biochemists, this assay interference is well documented within the laboratory setting, but is less well known clinically. At the time of writing this case report, Roche are currently working on assays without this interference and we eagerly await the results of this patient's thyroid function when assessed via the updated assay.

Association of Basedow and primary biliary cholangitis : a case report

Asmae El Hafiani, Iraqi Hinde, Mohamedelhassan Gharbi, Rifai Kaoutar, Karimi Meryem & Toulali Fatima
Ibn Sina University Hospital, Endocrinology, Rabat, Morocco

Introduction
Primary biliary cholangitis (PBC) is a rare chronic cholestatic liver disease, which is most likely of autoimmune origin. It is often associated with other autoimmune diseases, although it is rarely seen with Basedow.
Observation
We report the case of a 38 years old patient, chronic smoker, who presents clinical and biological hyperthyroidism related to Basedow, treated with synthetic antithyroid

drugs for years with poor compliance and notion of discontinuation of treatment. He was admitted to our department for rapid preparation for radical treatment. The clinical examination showed a patient with alteration of the general state, tachycardic, with frank icterus of cholestatic appearance evolving since 2 months, presence of exophthalmos, and perception of a homogeneous goiter at cervical palpation. In front of the frank icterus, a hepatic assessment was carried out showing a hepatic cytolysis, a hepatic cholestasis and a hepatocellular insufficiency. Abdominal ultrasound was unremarkable. Viral serologies were negative. A liver biopsy was performed, showing a PBC, an esogastro-duodenal fibroscopy was performed, which did not show the presence of esophageal varices. An autoimmune workup was performed to look for associated autoimmune hepatitis, as part of the overlap syndrome is ongoing. For his hepatic problem, the patient was treated with ursodesoxycholic acid with slight improvement of the hepatic balance. Then received a rapid preparation with lugol, bblocker and corticosteroid therapy, and had a total thyroidectomy. The post-operative course was complicated by severe bleeding and hepato-cellular failure, resulting in the patient's death.

Discussion and conclusion

Work has been done to determine the prevalence of autoimmune diseases associated with PBC and to assess their impact on the prognosis of this disease. These diseases were dominated by autoimmune hepatitis and Hashimoto's thyroiditis. The association with Basedow was very rare. PBC is often associated with other autoimmune diseases, which should be routinely screened. Conversely, the search for PBC in patients with other autoimmune diseases is necessary in order to initiate treatment at early stages, thus improving the patient's prognosis.

Assessment of sleep quality in patients with well-controlled primary hypothyroidism

Sahar Abidi, Ibtissem Oueslati, Asma Ben Hamida, Meriem Yazidi & Melika Chihaoui

La Rabta University Hospital, Department of Endocrinology, Tunis, Tunisia

Introduction

Poorly-controlled hypothyroidism is frequently associated with sleep disorders such as impaired sleep quality and obstructive sleep apnea. The aim of this study was to evaluate the sleep quality in patients with well-controlled primary hypothyroidism.

Methods

This was a single-center, cross-sectional study including 50 patients with well-controlled primary hypothyroidism (TSH level within the normal range: 0.35-4.94 mIU/l) for at least one year. Sleep quality was assessed using the Pittsburgh Sleep Quality Index (PSQI). Sleep disturbance was defined by a score greater than 5.

Results

The study included 45 women and 5 men with a mean age of 55 $\pm$ 12.5 years. Hypothyroidism was secondary to Hashimoto's thyroiditis, thyroidectomy, and radioactive iodine treatment in 70%, 16%, and 8% of cases, respectively. Its median duration was 10.4 years. Mean sleep duration was 7.3 $\pm$ 1.8 hours/day, with no significant difference between women and men. The mean PSQI score was 7.6 $\pm$ 4. This score was not correlated with TSH level and levothyroxine dose. Sleep disorders were diagnosed in 34 patients (68%). Seventy-four percent of patients had daytime sleepiness.

Conclusion

Sleep disturbances are common even in patients with well-controlled hypothyroidism. Screening and adequate management of these disorders would improve the quality of life of patients with primary hypothyroidism.

Clinical Significance of Basal and Stimulated Calcitonin Levels in A Case with Obesity Under Liraglutide Treatment

Taner Bayraktaroğlu, Doğancan Yilmaz, Sakin Tekin & Ömercan Topaloğlu

Zonguldak Bülent Ecevit Üniversitesi, Department of Endocrinology and Metabolism, Zonguldak, Turkey

Background:

Liraglutide is a long-acting GLP-1 receptor (GLP-1R) agonist. GLP-1R is highly expressed in C-cells hyperplasia and in medullary thyroid cancer. We aimed to evaluate calcitonin levels stimulated by calcium test and possible development of C-cell hyperplasia during Liraglutide therapy in a case with obesity.

Case Report

A 50-year-old woman was referred to endocrinology policlinic with complaints of increased appetite and weight gain. There were no history and familial history about thyroidal diseases. In phsical examination, his wieght 92,7 kg, weight 171 cm, body mass index 31,7 kg/m2, waist circumferences 112 cm, blood pressures 114/92 mmHg and pulse rate 76 per minute were detected. The findings of the other systems were unremarkable. For the treatment of obesity, medical nutrition therapy, behavior change therapy and increased physical activity were started. Liraglutide was started when appetite control and weight loss were not sufficient. In third months, basal calcitonin level was 13.6 pg/ml (normal range, $<$ 5 pg/ml), peak calcitonin value was 69.5 pg/ml during calcium stimulation test Thyroid function tests were in normal range, and sonographical evaluation of thyroid gland was shown normal. Liraglutid therapy were stopped because of possible C-cell hyperplasia. The patient was followed up with medical nutrition therapy, behavioral therapy and increased physical activity.

Discussion

Liraglutide leads to variations in both basal calcitonin and stimulated calcitonin. According to our case, the findings suggest the possible induction of the C cells and thus C-cell hyperplasia.

Keywords

Calcitonin, GLP-1R, Liraglutide, obesity

A rare diagnosis of lateral Neck Mass

Houas Jihene[1,2], Ben Arfi Taissir[2], Ghammam Monia[2], BelHadjMiled Heyfa[2], El Omri Malika[2], Bellakhdher Mouna[2], Hasni El Abed Yosra[3], Meherzi Abir[2], Kermani Wassim[2] & Abdelkefi Mohamed[2]

[1]ENT and Cervicofacial Surgery Department Farhat Hached Hospital University, Sousse, Tunisia, [2]ENT Department and Neck Surgery of Farhat Hached Hospital, Sousse, Tunisia, [3]Endocrinology Department Farhat Hached Hospital, Sousse, Tunisia

Introduction

Ectopic thyroid is characterized by thyroid tissue in a location other than anterior to the upper tracheal rings. The estimated incidence of thyroid ectopia is approximately 1/100,000. The most frequent locations are along the midline from the base of the tongue (90%) to the mediastinum. Ectopic thyroid tissue in the lateral neck is rare. We present a case of an ectopic thyroid gland with an atypical presentation as a lateral neck mass.

Case presentation

A 45 year old woman, with no significant past medical history, who presented with complaints of a painless lateral neck mass for the past 1 year exhibiting rapid progression since the past 3 months. There was no dysphagia, dyspnea or hoarseness of voice. Physical exam was notable for a painless, mobile, 3.5 cm mass, right supraclavicular, rubbery that was not fixed to the overlying skin. There was no cervical lymphadenopathy noted in the left neck or beyond the apparent right supraclavicular neck mass. The thyroid was normal. The neck ultrasound was performed revealing an anechoic liquid mass with a honeycomb structure that was well limited, measuring 42mm and hypervascular on color Doppler. The thyroid bed was scanned and it showed a normal thyroid gland. The CT scan of the neck was in favor of cystic lymphangioma. Her laboratory tests were normal. The mass was surgically removed. The extemporaneous examination of the specimen was benign. The definitive pathological examination indicated a benign thyroid tissue with no evidence of malignancy. Immunohistochemical staining showed the expression of TTF1, Thyroglobulin, Cytokeratin19 yet no expression of Galectin3. The diagnosis of Ectopic thyroid tissue was confirmed.

Conclusion

The presence of thyroid ectopia can create a complicated clinical scenario but can be elucidated through the use of basic radiographic and histologic analyses. Conservative management remains a legitimate option for many patients, with surgical intervention reserved for severe symptoms or malignancy.

Complications of hypothyroidism: a series of 67 cases

Faten Haj Kacem Akid[1], Raida Ben Salah[2], Siddiqa Soomauroo[1], Abdel Mouhaymen Missaoui[1], Sarra Chouaib[1], Mouna Mnif[1], Sameh Marzouk[2], Zouheir Bahloul[2] & Mohamed Abid[1]

[1]Hedi Chaker University Hospital, Department of Endocrinology, Sfax, Tunisia, [2]Hedi Chaker University Hospital, Department of Internal Medicine, Sfax, Tunisia

Introduction
Hypothyroidism is a consequence of thyroid hormone deficiency which may be of peripheral or central origin. If hypothyroidism is left untreated, the symptoms progress and lead to life-threatening complications.
Patients and method
Retrospective study of 67 patients with primary hypothyroidism. We determined the different complications associated with hypothyroidism.
Results
We collected 67 patients with overt hypothyroidism. The mean age was 38.76 years. There were 57 women and 10 men. Hashimoto's thyroiditis was the retained etiology in all patients. The mean TSH level was 48.12µUI/l. The mean FT4 level was 7.07 pmol/l. Anti-thyroperoxidase antibodies and anti-thyroglobulin antibodies were positive in 62 and 41 patients respectively. Sixteen patients had complications. The most frequent complications were anaemia and dyslipidaemia in 11 patients each, followed by neuromuscular complications in 8 patients such as myopathy, muscle induration and Hashimoto's encephalitis. Other complications were cardiovascular such as pericarditis in 2 patients, sleep apnea syndrome in one patient and myxedema coma in one patient.
Discussion/Conclusion
Hypothyroidism is the most common endocrine disorder. The complications can be minor or major. Untreated hypothyroidism leads to serious consequences such as myxedema coma which is rare but life-threatening. Treatment is based on L-thyroxine replacement therapy.

Graves' disease and autoimmune bullous dermatosis

Faten Haj Kacem Akid[1], Raida Ben Salah[2], Siddiqa Soomauroo[1], Abdel Mouhaymen Missaoui[1], Sarra Chouaib[1], Sameh Marzouk[2], Nadia Charfi[1], Zouheir Bahloul[2] & Mohamed Abid[1]
[1]Hedi Chaker University Hospital, Department of Endocrinology, Sfax, Tunisia, [2]Hedi Chaker University Hospital, Department of Internal Medicine, Sfax, Tunisia

Introduction
Autoimmune bullous dermatoses (ABD) represent a heterogeneous group of AIDs that target different epidermal or subepidermal proteins of the skin and/or mucous membranes. As with any autoimmune disease (AID), it may be associated with other AIDs. We report a case of ABD associated with Graves' disease (GD).
Observation
The ABD was a pemphigus vulgaris (PV) that was diagnosed at the age of 25 years in our patient and she was treated with corticosteroid therapy. After 19 years, in the course of the disease, she developed hyperthyroidism. clinical examination revealed a firm goiter and bilateral exophthalmos. Anti-thyroid antibodies (ATA) were positive as well as TSH receptor antibodies. The diagnosis of GD was retained and she was managed with radioactive iodine therapy with a good clinical course and obtaining biological hypothyroidism after 6 months. our patient also benefited from an HLA typing test which showed : HLA_AB:A1, A white, B17, B40(BW4,BW6).
Discussion/Conclusion
Pemphigus is a rare condition, usually affecting patients aged 50-60 years. Pemphigus vulgaris is the most common form (80% of cases). The association of pemphigus with other AIDs has long been reported and can affect up to 25% of patients. The most frequently reported AITs in association with pemphigus are autoimmune thyroid disease (AITD), rheumatoid arthritis, myasthenia and systemic lupus erythematosus. A higher prevalence of ATAs in patients with pemphigus vulgaris compared to healthy subjects is described (2.5% vs 1.2%). Hashimoto's thyroiditis is the AITD most associated with pemphigus vulgaris according to the literature.

PENDRED syndrome with ectopic thyroid : about a delayed diagnosis

Chtioui Sara, Ait Si Ali Zineb, Sana Rafi, El Mghari Ghizlane & El Ansari Nawal
Mohammed VI University Hospital Center, Department of Endocrinology, Diabetes, Metabolic Diseases and Nutrition, Marrakech, Morocco

Pendred syndrome, an autosomal recessive disorder, is the most common syndromal form of hearing loss and involves abnormalities of the cochlea, varying degrees of sensorineural hearing loss and diffuse thyroid enlargement/goiter. We describe a case of a delayed diagnosis of Pendred syndrome. The patient is a 30 years female who had a history of total thyroidectomy 13 years ago. And presented when aged 30 with a cervical abscess of ectopic thyroid under the submaxillary gland. The patient had a hearing loss from the early childhood and she had a 27 year old sister who present the same history of deafness and goiter. It is important to determine an early diagnosis of Pendred syndrome; however, reducing the rate of missed diagnoses and misdiagnoses requires further investigation, thus, it is essential for clinicians to improve their understanding of Pendred syndrome. Hypothyroidism in Pendred syndrome can be–although rarely–present from birth and therefore diagnosed by neonatal screening. We highlight to the general physician the classical features of this syndrome that would aid early diagnosis.
Key-words
goiter, sensorineural deafness, thyroid hormone, Pendred syndrome

Primary Thyroid Lymphoma: Clinical Course vs High Suvmax in Fdg-Pet

Mariana Lopes-Pinto[1], David Aparício[2], Ema Paula Ricca Lacerda Nobre M Caetano[1], Maria Dolores López-Presa[3] & Maria Joao Bugalho[1]
[1]Centro Hospitalar Universitário Lisboa Norte, Endocrinology, Diabetes and Metabolism, Lisbon, Portugal, [2]Centro Hospitalar Universitário Lisboa Norte, General Surgery Department, Lisbon, Portugal, [3]Centro Hospitalar Universitário Lisboa Norte, Pathological Anatomy Department, Lisbon, Portugal

Introduction
Primary thyroid lymphomas (PTL) account for 5% of all thyroid malignancies. Treatment and prognosis depend on tumor subtype. Contrasting with diffuse large B-cell lymphomas (DLBCL), that have an aggressive clinical course and higher maximum standardized uptake value (SUVmax) in Fluorine-18-fluorodeoxyglucose positron emission tomography (FDG-PET), thyroid extranodal marginal zone B-cell lymphomas of mucosa-associated lymphoid tissue (MALT) usually show an indolent course, lower SUVmax and do not require multimodal treatment. Accurate histological classification remains crucial in PTL approach.
Aim
Raise awareness for the possibility of high captation of FDG in Thyroid MALT Lymphoma (Tml) by presenting a case of TML with SUVmax of 21 in FDG-PET.
Case
A 66-year-old woman presented to the endocrine clinic due to cervical enlargement, dysphagia for solids and dyspnea with thorax anteflexion for the last four months. She denied any other symptoms. A large asymmetric multinodular diving goiter with right tracheal deviation had been firstly documented three years before. Clinically she had thyroid enlargement, multiple palpable nodules, and developed Pemberton sign. Laboratory findings included euthyroid Hashimoto Thyroiditis. Ultrasound guided fine needle aspiration (FNA) cytology of the dominant nodule (EUTIRADS-5) suggested Non-Hodgkin B Lymphoma. Two core biopsies revealed chronic lymphocytic thyroiditis with abundant B cells, suggesting PTL, which was confirmed by clonality analysis. FDG-PET revealed intense uptake exclusively in the thyroid with SUVmax of 21. Considering Ann Harbor staging IE-localized disease, and compressive symptoms, a diagnostic and potentially therapeutic total thyroidectomy was performed, with subsequent symptoms resolution and TML histologic diagnosis.
Discussion and Conclusion
PTL approach relies on accurate tumor classification. In this case, the chronic thyroiditis substract supported TML diagnosis, while the clinical course with recent compressive symptoms and SUVmax of 21 raised discomfort in postponing medical treatment in case it was a DLBCL, or TML with recent B-cells transformation, urging the need for final diagnosis. Total thyroidectomy proved to be both diagnostic and therapeutic. The clinical evolution and higher than expected SUVmax challenged final TML diagnosis.

Combination of recurrent thyroid artery embolization and sorafenib treatment in the management of inoperable papillary thyroid cancer

Damla Köksalan[1], İsa Çam[2], Berrin Cetinarslan[1], Zeynep Canturk[1], Alev Selek[1], Emre Gezer[1], Mehmet Sözen[1] & Ozlem Alkan[1]

[1]Kocaeli University Faculty of Medicine, Endocrinology and Metabolism, Kocaeli, Turkey, [2]Kocaeli University Faculty of Medicine, Interventional Radiology, Kocaeli, Turkey

Introduction
Thyroid papillary cancer is a solid organ malignancy that can be cured mostly by surgical and radioactive iodine(RAI) therapy. Metastatic disease state and radioactive iodine resistance have led to new treatment searches. In recent years, sorafenib, a tyrosine kinase inhibitor, has been used as a first-line treatment in thyroid papillary cancers that cannot be cured by surgery or radioactive iodine treatment. In addition, the use of thermal ablation and transarterial embolization in the curative or palliative treatment of patients who cannot undergo surgery is becoming increasingly common.
Case Report
A 76-year-old male patient was admitted 2 years ago with a swelling and bleeding wound on his right neck. The biopsy was concluded as papillary thyroid cancer. Right lateral neck dissection + total thyroidectomy was performed to the patient. Since the patient's fistulized mass to the skin invaded the right common carotid artery, the mass was incompletely removed, and then a total of 350 mCi RAI was given in the follow-ups. The patient, who was evaluated in the council for reoperation due to open wound, without distant organ metastasis, was considered inoperable. Right inferior thyroid artery embolization(TAE) was planned for palliation for the patient who had continuous bleeding from his open wound and needed 8-10 dressing changes per day and monthly erythrocyte suspension replacement. In the neck computed tomography was taken 2 months later, a volumetric decrease of 82% was observed, and the amount of bleeding of the patient decreased. The patient was started on sorafenib 2x400 mg, but the dose was reduced to 1x400 mg due to the side effect of thrombocytopenia. In the first year of the follow-up, due to the increase in the amount of bleeding from the wound and the need for erythrocyte suspension, neck computed tomography angiography was performed again, and right superior thyroid artery embolization for palliation was performed 2 more times at 9-month intervals. The follow-up and sorafenib treatment of the patient whose bleeding amount is reduced continues.
Conclusion
TKI's increase the progression-free survival of patients with inoperable and radioactive iodine treatment-resistant thyroid papillary cancer cases. Transarterial embolization reduces the mass size by reducing mass blood supply and can be used as a curative or palliative treatment option.

Thyroid cancer yield in patients with Graves' disease

Souha Kallel[1], Faten Haj Kacem Akid[2], Imen Achour[1], Slim Charfi[3], Hamdi Frikha[2], Mohamed Abid[2] & Ilhem Charfeddine[1]
[1]Habib Bourguiba Hospital, Department of Otolaryngology (ENT) Head and Neck Surgery, Sfax, Tunisia, [2]Hedi Chaker Hospital, Department of Endocrinology, Sfax, Tunisia, [3]Habib Bourguiba Hospital, Department of Pathology, Sfax, Tunisia

Background
Thyroid nodules found in patients with Graves' disease have a higher likelihood of being malignant. Management of these association is controversial.
Objectives
To discuss clinical and therapeutic features of this association.
Materials and methods
We report three cases of thyroid cancer occurring in Graves' disease, treated surgically at our department.
Results
There were three patients, aged respectively 19, 20 and 49 years, addressed for surgical management of a Graves' disease resistant to medical treatment. The exam found Homogeneous goitre in all cases, firm and hard nodules in two cases. scintigraphy showed cold nodules and ultrasound suspected malignancy in only one case. *Histopathological* examination concludes to a papillary carcinoma in all cases (from 0,5 to 2,5 cm) including one with Extra thyroid invasion and Metastatic central lymph adenopathy. All patients received a total thyroidectomy and *Radioactive iodine therapy*. One patient had central and lateral neck dissection. *Evolution* was a complete remission in all cases.
Conclusion
Prevalence of thyroid cancer in Graves' patients is 0.4% to 10%. It is explained by the stimulating action of the anti TSH antibodies on adenylcyclase. The characteristics of this association are: higher incidence of papillary carcinoma and multi focality, extra thyroid invasion, lymph node metastasis, loco regional and distant recurrence. Ultrasonography should be used routinely to detect any associated nodule. Fine needle aspiration has an important place in the monitoring of these nodules. Total thyroidectomy with histopathological study is indicated at the slightest sign of malignancy.

Association of papillary and medullary thyroid carcinoma in multiple endocrine neoplasia type 2a

Boutheina Mohamed Ali, Mariem Cheikh, Moctar Mohamed, Kaoutar Rifai, Iraqi Hinde & Mohamedelhassan Gharbi
Ibn Sina Hospital, Endocrinology, Rabat, Morocco

Introduction
The association of papillary carcinoma with medullary thyroid carcinoma may in rare cases be found in some members of families with multiple endocrine neoplasia type 2a (MEN 2a).
Case Report
A 38-year-old patient with a family history of papillary thyroid carcinoma (PTC), operated for multinodular goiter classified Tirads 4 by total thyroidectomy, the anatomopathological examination concluded to a lobar medullary thyroid carcinoma (MTC) of 20mm and an isthmic PTC of 5mm. Calcitonin was not measured preoperatively and was negative postoperatively. The patient was put on LT4 suppression treatement. The genetic study showed a mutation in exon 10 of the RET gene in favor of MEN 2a. The search for other components of MEN 2a revealed a pheochromocytoma of the left adrenal gland, the patient was referred for surgery and a family genetic study was requested.
Discussion
PTC may be associated with sporadic CMT or CMT in patients with MEN 2a with RET proto-oncogene mutation. In MEN 2a, some germline RET mutations have oncogenic activity on thyroid follicular cells. Nevertheless, this activity remains modest and occurs in specific circumstances explaining the rare occurrence of PTC in this context. This observation underlines the importance of calcitonin determination before surgery in case of thyroid nodules to avoid inappropriate therapeutic management

Papillary Thyroid Cancer is also more common in The Iodine Deficiency area: Evaluation of 2748 Patients

Mustafa Koçak[1], Gülşah Erbölükbaş[2], İrfan Nuhoğlu[1], Ahmet Suat Demir[3] & Halil Önder Ersöz[4]
[1]Karadeniz Technical University Faculty of Medicine, Endocrinology, Trabzon, Turkey, [2]Akçaabat Haçkalı Baba Government Hospital, Internal Medicine, Trabzon, Turkey, [3]Kırklareli Training and Research Hospital, Endocrinology, [4]Karadeniz Technical University Faculty of Medicine (retired), Endocrinology, Trabzon, Turkey

Thyroid cancer is the most common malignancy of the endocrine system. Papillary thyroid cancer is the most common thyroid malignancy worldwide and has a good prognosis. The prevalence of follicular thyroid cancer in endemic iodine deficiency regions is higher than in regions without iodine deficiency. However, it has been observed that the incidence of follicular thyroid cancer decreases and the incidence of papillary thyroid cancer increases after iodine prophylaxis. The Our study, 2748 patients (2201 females, 547 males) admitted to the Endocrinology Department of Faculty of Medicine/Karadeniz Technical University between January 1993 and June 2018 were diagnosed as thyroid cancer pathologically. In this study, papillary thyroid cancer was the most

common type of thyroid cancer in Trabzon, endemic iodine deficiency region. It was observed that the incidence of thyroid cancer tended to decline after peaking in 2012 according to the years of diagnosis. Of these cases, 2201 (80.1%) were female and 547 (19.9%) were male. Female cases were observed 4 times more. The age range of the cases was 18-89 and the mean age at diagnosis was 48.14 ± 12.5. The mean age of the female cases was 47.5 ± 12.8, and the mean age of the male cases was 51.3 ± 11.9. It was observed that female cases were diagnosed at a younger age than males and it was found to be statistically significant ($P < 0.001$), (Table 9). The cases diagnosed with thyroid cancer histopathologically were divided into 7 diagnostic groups. 1) 2571 Papillary Thyroid Cancer (PTC), 2) 97 Follicular Thyroid Cancer (FTC), 3) 45 Medullary Thyroid Cancer (MTC), 4) 16 Anaplastic thyroid cancer (ATC), 5) 7 Hurthle cell cancer (HTC), 6) 11 Mixed type thyroid cancer (MixedTC) and 7) 1 poorly differentiated carcinoma group (poorly differentiatedTC) (Table 1). PTC was evaluated as two main groups; Those with tumor size less than ≤10 mm were called papillary microcarcinoma. The distribution of 2542 PTC cases with tumor size in our study; 1238 (48.7%) papillary microcarcinoma, 1304 (51.3%) >1 cm PTC. 83.4% (1032/1238) of cases with papillary microcarcinoma were female, 16.6% (206/1238) were male, 78.3% (1021/1304) of cases with PTC > 1 cm were female, % 21.7 (283/1304) of them are male.

PaulescuInst N. Paulescu, Bucharest, Romania

The coexistence of Graves disease (GD) and thyroid carcinoma used to be considered uncommon, but association between the two is being progressively acknowledged.
Case report
We present the case of a 69-year-old woman with a 10 year history of GD who was referred to our clinic for fatigue, sweating, palpable cervical mass and weight loss. She was treated only in the previous 5 months with block and replace therapy. Laboratory workup at admission showed suppressed TSH (0.0003 µUI/ml), high levels of FT4 (31.08 pmol/l) and T3 (>600 ng/dl), positive TRAb (30.85 UI/l). Thyroid ultrasound revealed a multinodular goiter with two hypoechoic macronodules in the right lobe and isthmus classified as TIRADS 4. Technetium-99m scintigraphy showed multinodular goiter with a cold nodule over the right lobe and fine-needle aspiration citology smears of the isthmic nodule were suggestive of follicular carcinoma oncocytic type. High doses of methimazole (40 mg/day) were required to lower thyroid hormone levels preop, but TSH remained suppressed. Total thyroidectomy along with lateral neck lymph node dissection were performed. Pathology yielded a diagnosis of background of GD with invasive PTC in the isthmic nodule with poorly differentiated areas and metastasis in a right lateral lymph node - pT4bpN1bST4G2R1LV1. Postoperative follow-up revealed high titers of thyroglobulin (>500 ng/ml) and antithyroglobulin antibodies (461.3 UI/ml) with a suppressed TSH off levothyroxine; cervical ultrasound demonstrated a small paratracheal remnant of thyroid tissue and nonspecific lymph nodes laterocervical bilateral. Whole body radioiodine scan after Thyrogen showed significant iodine uptake in the thyroid bed and retrosternally and additional ^{131}I accumulation for both lungs. Patient received 100 mCi ^{131} with a drop in thyroglobulin level. Genetic profiling is pending.
Discussion
Genomic profiling allows personalisation of thyroid cancer therapy based on molecular information. A multi-step model of progression from well to poorly differentiated carcinoma has been proposed which includes 2 types of molecular events comprising 'early' events such as RAS and BRAF mutations and late 'events' as TERT and TP53 mutations. In this case we expect to find 'early' driver events like RAS/BRAF mutations which are the most prevalent in poorly differentiated cancer.
Conclusion
This case outlines the importance of further assessment for underlying malignancy when a nodular thyroid is present on the background of GD and genetic profiling of such malignant nodules to guide second stage therapy in the event of progressive disease after standard therapies.

To analyze the data of relatives of first-degree patients operated on for medullary thyroid cancer (MTC), we analyzed the anamnestic data of the database of patients with MTC, formed on the basis of the cancer registry of the Republic of Belarus and medical records of the Republican Thyroid Tumor Center. Further examination of relatives is also performed on the basis of the Republican Center for Thyroid Tumors.
The aim
of the study was to create a database of first-degree relatives of patients operated on for medullary thyroid cancer with identified mutations in the RET proto-oncogene.
Materials and methods
An electronic database was created in the Excel far entering the results of demographic, clinical, morphological, instrumental, laboratory and molecular genetic studies. Rows correspond to each of the study subjects. The columns correspond to the features indicated in the description of the study design.
Results and discussion
The group included 76 (30 men and 47 women, the median age was 43 years) first-degree relatives of patients operated on for MTC, mutations in the RET proto-oncogene were detected in 35 people. The distribution of participants by region varied from 20.0% to 35.0%. A survey, collecting an anamnesis, a clinical examination data with measurement of blood pressure, ultrasound of the thyroid gland of regional lymph nodes was performed. Nodular pathology of the thyroid gland was detected in 58 patients, hyperplasia of the cervical lymph nodes in 62 patients, a combination of nodular goiter and cervical lymphadenopathy was registered in 49 people. Puncture-aspiration biopsy of the thyroid gland (and LU) was performed in 45 patients; the results were benign. In individuals with nodular pathology of uncertain malignancy potential were used calcitonin stimulation test. Taking into account the hereditary factor and with elevated levels of calcitonin, preventive thyroidectomy was performed in 5 cases. Data for hyperplasia of the parathyroid glands were detected in 7 patients, further additional examination was carried out in case of suspected diagnosis of hyperparathyroidism. Computed tomography was performed in 9 patients; data for tumor pathology were not established.
Conclusions
An increase in the level of basal calcitonin and parathyroid hormone was noted in relatives of first-degree patients operated on for MTC with a mutation in the RET proto-oncogene, but without statistical significance of differences ($P = 0.067$ and $P0.120$, respectively). Currently, further analysis and systematization of the results of examinations is being carried out, including the results of molecular genetic testing.

Coexistence of thyroid carcinoma and graves' disease: report of two cases

Manal Azriouil, Ikrame Qasdi, Ikram Amira, Kaoutar Rifai, Iraqi Hinde & Mohamedelhassan Gharbi
Ibn Sina University Hospital, Endocrinology, Rabat, Morocco

Introduction
Graves' disease (GD) is a common autoimmune thyroid disease. The association between GD and thyroid carcinoma (TC) remains controversial. We describe two patients presenting this association.
Case report
Case 1 a 46 years old woman with clinical history of type 2 diabetes, she was diagnosed with Graves' disease and multiple nodules were found in her enlarged thyroid gland by ultrasonography. The patient underwent total thyroidectomy after the achievement of euthyroïdism by medical treatment. Histopathological study demonstrated a papillary thyroid carcinoma without capsular invasion. Case 2 a 36 years old woman, with no known past medical history, the diagnosis of GD was based on the findings of biological hyperthyroidism, thyroid gland enlargement and the presence of TSH receptor antibodies. Total thyroidectomy was performed for methimazole-induced agranulocytosis. Histopathological study demonstrated an 8 mm follicular thyroid carcinoma with massive vascular invasion.
Discussion
GD is treated with antithyroid drugs, radionuclide therapies, and surgery. The common surgical indications for GD include non-responsiveness to medical or radio-ablative therapies, a large goiter with compressive symptoms, and worsening of ophthalmopathy. Several studies have demonstrated both an increased incidence of follicular thyroid cancer in surgical treated Graves' disease patients, with rates varying from as low as 1% to as high as 9% of cases. The mechanisms responsible for the increased thyroid cancer incidence in patients with GD remains to be elucidated. It is thought that thyroid stimulating antibodies may be responsible for this increase. Regarding TC prognosis in GD, it is controversial with some studies showing that GD does not affect TC prognosis and some studies suggesting that GD may be associated with a worse outcome only if cancer is $\geq$ 1 cm.
Conclusion
In conclusion, a careful evaluation for patients with GD is essential, in order to check the development of possible incidental TC, even if they are nodule free, and total thyroidectomy should be the treatment of choice for Graves' disease in the presence of nodules.

Intrathyroidal Parathyroid Cysts

Souha Kallel[1], Ines Kharrat[1], Faten Haj Kacem Akid[2], Wadii Thabet[1], Hamdi Frikha[2], Mohamed Abid[2] & Ilhem Charfeddine[1]
[1]Habib Bourguiba Hospital, Department of Otolaryngology (ENT) Head and Neck Surgery, Sfax, Tunisia, [2]Hedi Chaker University Hospital, Department of Endocrinology, Sfax, Tunisia

Objective
Our aim is to describe the epidemiological, clinical and paraclinical features of intrathyroidal parathyroid cysts (PCs).
Materiel and Methods
We report 2 cases of intrathyroidal PC treated in our ENT department.
Results
We report 2 cases of non-functioning intrathyroidal PCs: 2 women (22 and 45 years old). They were referred to our department for anterior neck mass lasting for an average of 13 months. They had no compressive symptoms. Physical exam showed a soft, non-tender and well-limited anterior neck mass moving on swallowing. The mean size of the swellings was 3,5 cm. Ultrasonography of the neck revealed a right cystic thyroid nodule in the 2 cases. The mean size of the nodules was 42 mm. The serum TSH level was normal in all cases. The patients underwent right lobo-isthmectomy. Intra-operative examination suggested a benign cystic thyroid nodule. Post-operative histological exam confirmed the diagnosis of intrathyroidal PC. After an average follow-up of 3 years, no recurrence was noted.
Conclusion
Parathyroid cyst is a very rare entity. Ectopic sites are more uncommon. Intrathyroidal location is an exceptional ectopic location. To the best of our knowledge, eight intrathyroidal PC cases have been reported in the literature. They are often incidentally discovered in the histological exam after surgery.

Oculomotor paralysis and diabetes: what is the link?

Widad Douali, Fatima Zahra El Jaafari, Sana Rafi, Ghizlane El Mghari & Nawal El Ansari
CHU Mohamed VI, Marrakech, Department of Endocrinology, Diabetology, Metabolic Diseases and Nutrition, Marrakech, Morocco

Introduction
Oculomotor palsies in diabetes are focal mononeuropathies. It is a diabetic neurological complication, relatively rare. The oculomotor nerves affected are mainly the external oculomotor nerve (VI), the common oculomotor nerve (III), and more rarely, the pathetic nerve (IV). We report the case of a type 2 diabetic patient in whom the diagnosis of oculomotor palsy was retained.
Observation
This is a 65-year-old diabetic patient, 4 years old, poorly followed under metformin and sulfonamide, was admitted for sudden onset ptosis associated with diplopia. Clinical examination: unilateral left ptosis, workup: hba1c at 7.5%; etiological workup: negative, ophthalmological examination and cerebral angiography: normal, therefore the diagnosis of common oculomotor palsy secondary to diabetic neuropathy was retained.
Discussion-Conclusion
Diabetes mellitus is the first cause of neuropathy in the world. Non-retinal diabetic complications including oculomotor damage represent 1 to 3% of the ocular manifestations of diabetes. It should be considered in any diabetic presenting with unexplained visual disorders. Its evolution is favorable in a few weeks, but recurrence on the same side or on the contralateral side is possible

Hashitoxicosis : a case report

Brahimi Hanane[1], Amira Bouchenna[2], Lamara-Mohamed Sara[1] & Ouldkablia Samia[1]
[1]Central Army Hospital, Algiers [El Djazaïr], Algeria, [2]Central Army Hospital, Algiers, Algeria

Introduction
Autoimmune thyroid diseases are frequent and very polymorphic pathologies. The same person can successively present with different manifestations. Graves' disease and Hashimoto's thyroiditis seem to be able to coexist. The name "Hashitoxicosis" has been suggested in this case, characterized by the sequential association, whatever the order, of hyper- and hypothyroidism. We report in this work, the case of a patient treated for autoimmune hypothyroidism and who subsequently presented with Graves' disease.
Observation
Aged 38, our patient presented at the age of 33 with autoimmune hypothyroidism and she was put on Levothyroxine for a period of 4 years. Considering her falling TSH levels at each quarterly check-up, we had to stop the replacement opotherapy, a few months later, another TSH level came back down to 0.001 µui/ml with an FT4 of 22 pmol/ml, and an FT3 at 8 pmol/l, with an autoimmunity assessment in favour of Graves' disease with a TSI level $>$ 40 ui/l and TPO antibodies $>$453 ui/l. The thyroid ultrasound revealed a thyroid of normal volume with heterogeneous echogenicity, without Doppler hyperaemia, completed by a thyroid scintigraphy that returned in favour of diffuse toxic goiter, suggesting Graves' disease. The patient was put on Antithyroid drugs.
Conclusion
The close relationship of these two forms of autoimmune thyroid disease explains the possible transition from one to the other, with successive phases of hyper-, eu- and hypothyroidism, linked to alterations of the balance between the various classes of antibodies.

EP1041

A 3rd degree atrioventricular block revealing hypothyroidism: a case report

Widad Douali, Fatima Zahra El Jaafari, Sana Rafi, Nawal El Ansari & Ghizlane El Mghari
CHU Mohamed VI, Marrakech, Department of Endocrinology, Diabetology, Metabolic Diseases and Nutrition, Marrakech, Morocco

Introduction
Hypothyroidism is a rare cause of atrioventricular block. We report the case of an 85 year old patient admitted with a 3rd degree AVB and in whom the biological work-up had objectified a hypothyroidism.

Observation
85-year-old patient, followed for thyreopathy for 20 years on LT4: 100 ug/d, Diabetic for 2 years on premixed regimen: 08-00-12 ui ;HTA for 5 years on amlodipine 5 mg/d presented to the emergency room for syncope. No signs of hypothyroidism, on clinical examination:Patient infiltrated;Hypertensive; bradycardic; polypneic; bilateral IMO, soft white, taking the cup reaching mid-leg; normal thyroid, on workup:CBC: hyperleukocytosis;TSH 9.22 ECG : Complete BAV Management was based on: increasing the dose of LT4 by 6.25 ug/d after cardiovascular evaluation; For diabetes: the patient was put on Lantus:10 ui 22h and rapid insulin according to capillary blood glucose
Discussion
The pathophysiology of atrioventricular block in hypothyroidism is not clear on the molecular level, the different clinical manifestations observed in hypothyroidism-associated cardiopathy can be explained by the genomic and non-genomic effects of thyroid hormones on cardiomyocytes
Conclusion
Evaluation of thyroid status is mandatory before any cardiac rhythm or conduction disorder

DOI: 10.1530/endoabs.90.EP1041

Navigating the differential diagnosis of thyrotropinoma and resistance to thyroid hormones

Cristina Niculaide, Theodor Mustata[1,2], Carmen Sorina Martin[1,2] & Simona Fica[1,2]
[1]Elias Emergency University Hospital, Endocrinology, Bucharest, Romania, [2]Carol Davila University of Medicine and Pharmacy, Endocrinology, Bucharest, Romania

Introduction
Syndrome of inappropriate secretion of thyrotropin (SITSH) is a rare condition characterized by uninhibited serum TSH in the presence of high thyroid hormones, usually caused by TSH secreting adenoma or resistance to thyroid hormones (RTH). Differential diagnosis between the two is often challenging due to their overlapping features.
Case report
We present the case of a 50-year-old postmenopausal woman with a history of -myocardial infarction in 2013, with angioplasty and 4 stent coronary placement. The patient was referred to our clinic for the evaluation of abnormal thyroid function tests (TSH = 3.25 µIU/ml RR = 0.3-3.6, FT4 = 30.2 pmol/l RR 9-24, FT3 = 11.8 pmol/l RR 3.1-6.8). The patient had no family history of thyroid disorders and a personal history showing a consistent pattern of a normal or elevated TSH level accompanied by elevated levels of thyroid hormones, which persisted despite the treatment with thiamazole 10 mg per day between 2017-2020. Clinically, the patient was euthyroid except for tachycardia, which was managed with metoprolol 300 mg per day. Our laboratory results confirmed inappropriate secretion of TSH (TSH = 4.07 µIU/ml RR = 0.3-3.6, FT4 = 1.73 ng/dl RR 0.7-1.48, TT4 = 15.37 µg/dl RR 4.8-11.7, TT3 = 244 ng/dl RR 76.3-220.8), normal pituitary function tests, negative anti-thyroid autoantibodies and thyroid ultrasound showed an unremarkable multinodular goiter. Due to anxiety the patient refused pituitary MRI, therefore screening CT scan was performed as an alternative diagnostic tool. It revealed an enlarged sella turcica (25/14/19mm) and a 18/11 mm pituitary tumor. Given the ischemic heart disease T3 suppression test was considered to be contraindicated. Furthermore, TRH is not available in our country. Alpha glycoprotein subunit levels were elevated (α-GSU = 1.89IU/l RR for postmenopausal women < 1.3). We decided to escalate the thiamazole dose to 20 mg per day and to reassess the patient in 4 weeks adding SHBG, a short-term somatostatin analog test, genetic screening for RTH and psychological counseling in order to obtain a MRI contrast enhanced pituitary scan.
Conclusions
The diagnosis of SITSH can be difficult to establish due to the low prevalence, insufficient awareness or experience of diagnosis or treatment, and unavailability of highly accurate diagnostic tests. This case was challenging due to the patient's ischemic heart condition, lack of access to certain diagnostic tools and the patient's refusal to undergo MRI examination. It is also important to remember that TSH-omas are very rare tumors, while pituitary incidentalomas are common. Therefore, a high level of suspicion and a thorough differential diagnosis algorithm are imperative.

The current state of the problem of thyroid pathology in iodine-deficient regions of the Russia

Maria Isaeva[1], Ekaterina Troshina[1], Evgeniia Kolpakova[1], Natalia Makolina[1], Nadezhda Platonova[2], Maria Galieva[2], Ludmila Pronina[2], Larisa Nikankina[2] & Zamira Zuraeva[2]
[1]Endocrinology Research Center, Institute of Clinical Endocrinology, Moscow, Russia, [2]Endocrinology Research Center, Moscow, Russia

Introduction
Interaction between genetic and environmental factors is the foundation of the pathogenesis of autoimmune thyroiditis (AIT). One of the important factors is iodine supply. Iodine deficiency is the main cause of goiter, dysfunction of the thyroid gland, disorders of mental and physical development. Main solution of that problem is the iodine salt consumption. It can decrease iodine deficiency, but the RF doesn't have general programs of salt iodization and has a lot of regions with low iodine supply.
Materials and Methods
The study was conducted in 3 districts of the Tula region (TR) ($n = 286$), 4 districts of the Chechen Republic (CR) ($n = 302$). The volume of the study was 588 adult people (over 18 years old). Examinations by an endocrinologist with taking anamnesis of life, evaluating anthropometric parameters, palpation of the thyroid gland. Participants of the study had thyroid ultrasound, analysis of venous blood for TSH, free fractions of T4, T3, antibodies to thyroid peroxidase (AT-TPO). The study is supported by the Russian Science Foundation, Grant No.22-15-00135.
Results
According to the results of the study, the prevalence of thyroid pathology is 81.79% in the CR, 42.66% in the TR. 19.9% participants in the TR, 27.15% in the CR have an elevated titer of AT-TPO in the blood serum. 19.9% participants in the TR, 21.2% in the CR have ultrasound signs of autoimmune thyroid changes. Prevalence of hypothyroidism due to AIT is 16.4% in the structure of the general thyroid pathology in the TR; there are 13.36% in the CR. 21% participants with hypothyroidism in the TR, 15% in the CR have the gland hypertrophy. The frequency of nodular goiter according to thyroid ultrasound is 95% in the general thyroid diseases in the TR, 83% in the CR, the combination of nodular goiter and AIT is 0.35% in the TR, 7.3% in the CR.
Conclusion
The TR and the CR are confirmed iodine-deficient regions. The obtained data on the prevalence of thyroid pathology and nodular goiter is higher than the data of official statistics (21.3% and 42% in the TR; 27% and 73.8% in the CR, FSSS, 2021). The obtained data reflect the problem of the high prevalence of thyroid pathology, including iodine deficiency thyroid diseases, in the whole area of the RF, in the absence of mass iodine prophylaxis at the state level. The data formed the basis for the creation of regional programs for the prevention of iodine deficiency.

Wernicke's encephalopathy complicating hyperemesis gravidarum associated with hashitoxicosis: Rare association

Zineb Ait Si Ali, Jaddi Oussama, Sana Rafi, Ghizlane El Mghari & Nawal El Ansari
Centre Hospitalo-Universitaire Mohammed VI Marrakech, Department of Endocrinology, Diabetology, Metabolic Diseases and Nutrition, Marrakech, Morocco

Introduction
Wernicke's encephalopathy is a rare neurological disorder initially described in alcohol-dependent and malnourished patients. It is characterised by confusion, ataxia and nystagmus. It is caused by thiamine deficiency. We report the case of a patient with hyperemesis gravidarum and hashitoxicosis complicated by Wernicke's encephalopathy
Observation
A 22 year old patient, 1G0P, without any particular pathological history, was admitted to the intensive care unit with incoercible vomiting that had been evolving for one and a half months during a pregnancy estimated at 12 weeks' gestation, complicated by hydroelectrolytic disorders, in particular hypokalemia at 1.9 mmol/l and hyponatremia at 124 mmol/l. The clinical examination revealed confusion and dysarthria, the patient presented tachycardia at 128 bpm, normal blood pressure at 120/74 mmhg, no exophthalmos, her thyroid was palpable and not enlarged. The initial work-up showed liver cytolysis with ASAT and ALAT levels 4 times normal. Peripheral hyperthyroidism with TSHus < 0.005 µui/ml, T4l: 68 pmol/l. Cervical ultrasound showed a normal sized, homogeneous,

normo-vascularized thyroid. Anti-TPO antibodies were positive, while anti-R-TSH antibodies were negative. Brain MRI confirmed the diagnosis of Wernicke's encephalopathy. Treatment consisted of immediate thiamine administration, correction of fluid and electrolyte disorders, anti-emetic medication, and plasmapheresis for her hyperthyroidism. The clinical evolution was favourable with a normalisation of the ionogram and thyroid function tests.
Discussion
Wernicke's encephalopathy is an acute condition caused by severe deficiency of thiamine, which is an essential cofactor in many biochemical pathways in the brain. The overall incidence rate of Wernicke's encephalopathy is 0.04-0.13%. Hyperemesis gravidarum is an uncommon cause of Wernicke's encephalopathy. Hyperthyroidism is a hypermetabolic state in which thiamine utilisation is increased. This condition may precipitate Wernicke's encephalopathy in patients with reduced thiamine stores. Wernicke's encephalopathy due to hyperemesis gravidarum and hyperthyroidism is rare and difficult to diagnose. Its gold standard treatment is urgent thiamine substitution, allowing resolution of symptoms within hours to days depending on the severity of the disease.
Conclusion
Wernicke's encephalopathy is a potentially reversible disease if diagnosed and treated in time. Hyperthyroidism in patients with hyperemesis gravidarum may precipitate the onset of Wernicke's encephalopathy.

EP1045

Myxoedema Coma, Life Threatening with Multiple Exacerbating Factors, Presenting with Bradycardia and Hypoglycaemia, Rare Interesting Experience with Bizarre Hormonal Imbalances

Mohammed Alfahal[1], Maria Omer[2], Omer Abdalla[3], Gideon Mlawa[4] & Mustafa Taha[3]
[1]London North West University Healthcare NHS Trust, London, United Kingdom, [2]Royal Liverpool University Hospital, United Kingdom, [3]National Ribat University, Internal Medicine, Khartoum, Sudan, [4]Queen's Hospital, Acute Medicine, Endocrinology, Romford, United Kingdom, [5]University of Khartoum, Khartoum, Sudan

A 91-year-old lady presented with bradycardia 'HR ~36, she was alert and conscious initially. Soon after the initial assessment, she was found unresponsive; with blood glucose of 0.8 mmol/l; bradyapnoec; BP 151/59; GCS 5/15; temp '32.8℃'. She was aroused after resuscitation with intravenous Dextrose, GCS 15/15 with an element of confusion, the temperature did not exceed 34.9℃ despite active warming. The patient looked in a low mood, barely audible, with bilateral reactive constricted pupils and hyporeflexia. The face was velvety and dry. She has hypothyroidism, AF on amiodarone, osteoporosis and multiple joint replacements. ECG showed atrial fibrillation with a slow ventricular response, low amplitude waves and QTc (469ms).
Initial investigation
Normal T4 and elevated TSH. INR 1.4 (on warfarin). Elevated creatinine. K+6.3; Na+ 123 mmol/l. Diagnosis of myxoedema coma was based on refractory hypothermia, AF with slow ventricular response, wide pulse pressure, hyporeflexia and hypoglycaemia with partial response to IV glucose. Liothyronine (T3) 80 mg-IV administered one hour after hydrocortisone 200 mg IV. Six hours after T3 administration, the core temperature increased to 36.6℃, the heart rate went up to 80 before settling at 60 bpm, QTc shortened to a normal range (410ms) and the patient regained consciousness and was communicating clearly.
Discussion
Myxedema coma reported in patients with undiagnosed hypothyroidism (1) and patients on levothyroxine as in amiodarone-induced myxedema coma (2) In this case it was multifactorial with amiodarone being a chief trigger. Omeprazole could be a contributory factor (3). Amiodaron inhibit conversion of T4 to T3 (5). With short half-life of the T3 in comparison to T4 and the very long half-life of amiodarone, serum-free T3 levels expected to decline soon with a single dose of Liothyronine - even after stopping the amiodarone. Causes of hyponatremia other than severe hypothyroidism was considered (4). Hyponatraemia, hyperkalaemia and hypoglyceamia indicate possible hypo-adrenal state
Conclusion
The threshold to suspect myxoedema coma should be lower in patients with a background of hypothyroidism; on amiodarone or with the following (bradycardia/bradypnea/hypothermia/hypoglycaemia) Heart rate, core body temperature, level of consciousness and respiratory rate are good parameters of response to thyroxine. When Amiodarone triggers myxoedema coma, continued T3 therapy with low doses may give better results than T4 therapy as the amiodarone effect on T4 conversion continues for a long time after discontinuation of therapy. Many factors should be considered to determine the correct dose of IV Liothyronine including age, weight, cardiovascular risk factors and metabolic demands.

A fatal case of myxedema coma

Imane Boubagura, Sana Rafi, Ghizlane El Mghari & Nawal El Ansari
Department of Endocrinology, Diabetology and Metabolic Diseases, University Hospital of Marrakech, Marrakech, Morocco

Introduction and Backgrounds
Myxedema coma is a severe life threatening form of decompensated hypothyroidism which is associated with a high mortality rate. Infections and discontinuation of thyroid supplements are the major precipitating factors. It's characterized by a decreased mental status, hypothermia, bradycardia, hypotension, and hypoventilation. Very few cases of Myxedema coma have been reported till date, actual prevalence is unclear with the estimated incidence rate of 0.22 cases per million people per year. The purpose of the present article is to describe a fatal case of myxedema coma in an elderly woman occurring in the context of immunodeficiency.
Case Presentation
A 61-year-old woman with a past medical history of hypertension, type 2 diabetes, end-stage renal failure, miliary tuberculosis with pulmonary and peritoneal involvement under anti-bacillary treatment, autoimmune thyroiditis with discontinuation of L-thyroxine since 2 months. She was admitted to the emergency department for altered mental status. At admission her vital signs revealed a blood pressure of 20/70 mmHg, bradycardia at 54 bpm, hypothermia at 35 °C. The patient presented with dry depilated skin, vitiligo and generalized myxedema, the Glasgow Coma Scale was 10/15. The patient was transferred to the intensive care unit. The initial laboratory evaluation revealed the normochromic normocytic anemia and absence of electrolyte disturbances, Thyroid function was altered with thyroidstimulating hormone (TSH) of 100 mU/l and free thyroxin (T4) of 3.9 pmol/dl and free (T3) of 1.6 pmol/l. Diagnosis of myxedema coma was made and medical treatment was started. The patient was warmed gradually and oxygen was supplied via a mask. levothyroxin 300 µg was given via a nasogastric tube on third day after admission. The patient's clinical condition has not improved and she died 3 days later.
Discussion
Myxedema coma is an extreme manifestation in patients with untreated hypothyroidism. The diagnosis could be delayed because diagnostic laboratory data may not be available in a timely manner during emergency presentation. Our patient was also reported to have delayed diagnostic despite she was presented with all-common features of Myxedema coma, because she has other medical history as miliary tuberculosis and end-stage renal failure that make the first diagnostic suspected of a decreased mental status secondary to hyper uremia or central nervous system tuberculosis.
Conclusion
Myxedema coma is a lethal endocrine emergency. Thyroid hormone measurement allows the diagnosis. Protocols with rapid intravenous administration of high doses of thyroid hormones, together with warming and mechanical ventilation, may improve the prognosis.

Thyroidectomy in Graves' disease

Mohamed Masmoudi, Chaima Zitouni, Wadii Thabet, Ezer Chebil, Mehdi Hasnaoui & Khelifa Mighri
Taher Sfar Hospital, ENT Department, Mahdia, Tunisia

Introduction
Graves' disease is an immune system disorder that results in the overproduction of thyroid hormones. Treatment include: anti-thyroid medications, beta blockers, radioiodine therapy and surgery.
Objective
The aim of our study is to describe the role of surgery in the treatment of Graves' disease.
Patients and methods
We conducted a retrospective study including 40 patients who underwent surgery for Graves' disease in our department between 1996 and 2022.
Results
Our series included 30 women and 10 men, aged between 11 years and 63 years. All of the patients had hyperthyroidism. Thirty-eight patients had a goiter. A vascular thrill was perceived in 4 patients. Twelve patients had Graves' orbitopathy. All of the patients were treated with anti-thyroid drugs and β blockers. The average duration of medical treatment was 18 months. No patient was treated with radioiodine therapy. Indications for surgery were: failed medical therapy after 2 years of treatment (29 cases), a compressive goiter (4 cases), concomitant suspicious thyroid nodules (4 cases), side effects of antithyroid drugs (2 cases) and pregnancy (1 case). All of the patients had a total thyroidectomy. Seven patients developed postoperative complications such as transient hypocalcemia (6 cases) and recurrent laryngeal nerve palsy (1 case). No case of recurrent disease was noted.

Conclusion
Antithyroid drugs are used as initial treatment in Graves' disease. If remission is not achieved, radio-iodine therapy and surgery are considered as treatment options. Compared to surgery, radioiodine therapy can increase the risk of cancer and cause worsening of Graves' opthalmopathy, especially in children. Therefore, surgery may be a better option.

Hashimoto's thyroiditis associated with alopecia

Faten Haj Kacem Akid[1], Raida Ben Salah[2], Siddiqa Soomauroo[1], Abdel Mouhaymen Missaoui[1], Sarra Chouaib[1], Faten Frikha[2], Nabila Rekik Majdoub[1], Zouheir Bahloul[2] & Mohamed Abid[1]
[1]Hedi Chaker University Hospital, Department of Endocrinology, Sfax, Tunisia, [2]Hedi Chaker University Hospital, Department of Internal Medicine, Sfax, Tunisia

Introduction
Alopecia is an autoimmune disease (AID) affecting the hair follicles. Alopecia can become generalised and affect all hairy areas (universal alopecia). As with any AID, it may be associated with other AIDs. We report 2 cases of the association of alopecia with autoimmune thyroid disease (AITD).
Observation
The subjects were a man and a woman aged 48 and 54 years respectively. They presented with hypothyroidism. Hashimoto's thyroiditis (HT) was diagnosed and they were treated with L-thyroxine susbtituion therapy with favourable outcome. The thyroid disease was preceded since 24 years by an alopecia universalis, which appeared at the age of 23 years in the case of the man. In the other patient, this hypothyroidism was preceded by 2 other AIDs: alopecia universalis and vitiligo.
Discussion/Conclusion
Alopecia is a common condition with a significant psychosocial impact. It is a non-scarring alopecia, occurring most commonly in patches. The diagnosis is made clinically and does not require any further investigation in the absence of any particular symptoms. Alopecia can be associated with other AIDs, in particular thyroiditis, vitiligo and scleroderma. One study estimated the frequency of AITD in patients with alopecia to be 12.7%. Hypothyroidism was present in 92% of cases. It was found that alopecia in AITDs was most often severe, total or universal. Significantly higher levels of anti-thyroperoxidase antibodies and anti-thyroglobulins antibodies were found in the severe forms of alopecia.

Myopathy in hyperthyroidism : a retrospective analysis of 6 cases

Faten Haj Kacem Akid, Wafa Belabed, Abdel Mouhaymen Missaoui, Mouna Elleuch, Fatma Mnif, Nabila Mejdoub & Mohamed Abid
Hedi Chaker University Hospital, Department of Endocrinology and Diabetology, Sfax, Tunisia

Background and aim:
Hyperthyroidism status can be complicated by polymorphic neuromuscular manifestations sometimes revealing. In the majority of cases, these disorders regress during the transition to euthyroidism. We report in this work 6 observations illustrating the neuromuscular manifestations seen in hyperthyroidism.
Observations
We report two cases of chronic myopathy: a man and a woman aged 47 and 55 years respectively, hospitalized for hyperthyroidism associated to generalized amyotrophy with functional impotence. The EMG confirmed the muscular damage. Thyrotoxic periodic paralysis was noted in 2 patients, a man and a woman, aged 27 and 34 years respectively. They presented with spontaneously resolving paralytic attacks predominantly in the lower limbs lasting 3 to 24 hours and associated with thyrotoxicosis and hypokalemia. The fifth and sixth patients had peripheral polyneuropathy associated with thyrotoxicosis. They were a 39-year-old woman and a 45-year-old man. The woman presented with parasthesia of the extremities and gait disorders. The man presented with flaccid paraparesis. The electrophysiological study showed neurogenic damage in both cases. Graves' disease was the cause of hyperthyroidism in 5 cases. Hashimoto's disease was incriminated in the remaining case.
Discussion
In all of these cases, early treatment led to a dramatic improvement in neuromuscular symptoms. The pathophysiological mechanisms of these disorders remain difficult to elucidate and require more advanced studies on larger cohorts of patients

Nodular Dystrophy Revealing an Ectopic Thyroid : About A Case

Yousra Settai, Nassim Essabah Haraj, Siham El Aziz & Asma Chadli
UHC Ibn Rochd, Endocrinology, Diabetology, Nutrition and Metabolic, Casablanca, Morocco

Introduction
Thyroid ectopia is a rare pathology linked to a migration defect of the thyroid gland during its embryonic development. It is most often asymptomatic, but can be revealed by dysthyroidism, or a cervical or thoracic mass. We report the case of an ectopic thyroid revealed by a mediastinal mass.
Observation
61-year-old patient, with no particular history, followed for a plunging multi-hetero-nodular goiter which cervical ultrasound showed an enlarged thyroid, whose largest nodule was on right lobe measuring 12 x 18 x 29 mm classified EUTIRADS 3, and the most pejorative on left lobe measuring 11 x 16 x 22 mm classified EUTIRADS 5. Cervicomediastinal CT showed an anterior mediastinal mass with CT characteristics similar to those of the thyroid parenchyma. The patient underwent a total thyroidectomy with resection of the mediastinal mass. The anatomo-pathological examination noticed a multinodular thyroid dystrophy, and on the mediastinal mass a dystrophic thyroid nodule, without signs of malignancy.
Conclusion
Pathological changes that affect normal ectopic thyroid can occur in ectopic tissue. Hence the importance of long-term clinical and biological monitoring and possible fine needle biopsy of ectopic thyroid tissue.

Neutropenia secondary to synthetic antithyroid drugs: about 5 cases including one case of agranulocytosis

Nezha Raki, Nassim Essabah Haraj, Siham El Aziz & Asma Chadli
UHC Ibn Rochd, Endocrinology, Diabétology, Nutrition and Metabolic, Casablanca, Morocco

Introduction
Hematological toxicity is the main risk of synthetic antithyroid drugs (ATS); the major form is acute agranulocytosis requiring adequate and urgent management. The literature concerning neutropenia and agranulocytosis under ATS is relatively poor, based on rare studies, with often small numbers of patients, and most often concerning American or Japanese populations treated.
Purpose of the study:
Report our experience in the endocrinology and metabolic diseases department of the CHU IBN ROCHD in Casablanca, through 5 cases of neutropenia secondary to ATS.
Method
Descriptive retrospective study including patients followed in the endocrinology department of the CHU Ibn Rochd in Casablanca, for hyperthyroidism who presented with neutropenia secondary to ATS during the period 2021–2022.
Results
All our cases were female with an average age of 43 years (24-63 years), two patients (40%) had multi hetero nodular goiter and three patients (60%) were followed for Graves' disease. Concerning the ATS, all the patients were under carbimazole with an average dose of 22 mg/day (10-30). Only one patient presented with a fever of 39.6°C and erythematous throat with agranulocytosis, while the other four patients had no signs of infection with neutropenia ranging from 580 to 1300/mm3 discovered as part of the monitoring report. Discontinuation of ATS was recommended in all cases with oral corticosteroid therapy (prednisolone at an average dose of 40 mg/d) with three patients who were initially on a bolus of solumedrol. The use of a broad-spectrum antibiotic therapy was envisaged in two patients and that of hematopoietic growth factors in a single patient. The evolution was favorable in four cases with neutropenia (80%) with normalization of PNN and regression of signs of hyperthyroidism, while the patient with agranulocytosis had died in intensive care.
Conclusion
The seriousness of the severe neutropenia and especially of the agranulocytosis which can be observed under ATS, justifies good patient education as well as close monitoring of the blood count, in particular during the first two months of treatment.

Two rare cases of Riedel's thyroiditis

Andreia Martins Fernandes[1], Ana Rita Elvas[1], Joana Couto[1], Raquel G. Martins[1], Jacinta Santos[1], Teresa Martins[1] & Fernando Rodrigues[1]
[1]Portuguese Institute of Oncology of Coimbra, Endocrinology, Coimbra, Portugal

Introduction
Riedel's thyroiditis (RT) is a rare chronic inflammatory disease characterized by a dense fibrosis that replaces normal thyroid parenchyma. The most common manifestation is a stony hard thyroid mass, commonly associated with compressive symptoms. Histological confirmation is essential for diagnosis and the main differential diagnosis is the anaplastic thyroid cancer. The management is challenging and there is no agreed standard treatment, since only a few cases have been described.
Clinical Case
Case 1: A 46-year-old woman presented with a 2-month history of painless anterior neck mass and dysphonia. Neck examination revealed a hard and painful thyroid mass. Blood tests showed subclinical hyperthyroidism and positive thyroglobulin antibodies (TgAbs). Ultrasound showed a 39 mm solid, hypoechoic and heterogeneous nodule with poorly defined margins. There was no cervical lymphadenopathy. Tc99m *scintigraphy* revealed a cold nodule. Fine-needle aspiration biopsy (FNAB) was non-diagnostic. The patient underwent total thyroidectomy, requiring postoperative emergency tracheostomy. Laryngoscopy revealed bilateral vocal cord paralysis. The histological study was compatible with RT. The tracheostomy was closed 8 weeks after surgery. Prednisolone 40 mg and, posteriorly, tamoxifen 20 mg were started with symptomatic relief. Both medications were tapered off. Currently, 7 years after diagnosis, the patient is asymptomatic.
Case 2 A 67-year-old woman with thyroid nodular disease was proposed for right hemithyroidectomy. Intraoperatively, a hard mass adhering to the trachea and right carotid artery was found, making resection impossible. Therefore, a intraoperative biopsy was performed to establish histological diagnosis. Histopathology was consistent with RT and the patient was referred to Endocrinology consultation. She had no compressive symptoms and physical examination revealed a 5 cm stony hard thyroid mass. There was no cervical lymphadenopathy. Blood tests showed hypothyroidism and positive TgAbs. Ultrasound showed a 52 mm solid, hypoechogenic and heterogeneous mass in the right thyroid lobe. A FNAB was performed with a non-diagnostic result. A neck CT confirmed a voluminous solid mass in the right lobe without cleavage planes with cervical vessels and trachea. Given the clinical stability and absence of symptoms, it was decided to maintain active surveillance. After 5 years of follow-up, the patient remains asymptomatic and the thyroid mass is stable on ultrasound.
Conclusion
Although malignancy is more frequent, in patients presenting with a hard thyroid mass RT should be considered as differential diagnosis. Our cases highlight the challenges inthe diagnosis and management of this rare disease and the importance of taking an individualized approach.

Tuberculosis of the thyroid gland: a case study

Bessaid Khadidja[1], Mouna Mezoued[2] & Malha Azzouz[2]
[1]Bologhine Ibn Ziri, Endocrinology Department, El Hammamet, Algeria, [2]Bologhine Ibn Ziri, El Hammamet, Algeria

Introduction
Thyroid tuberculosis is a rare entity even in countries like Algeria where tuberculosis is endemic.
Observation
We report the case of a 40-year-old woman, with a history of hypertension and severe renal failure, consulting for recent cervical swelling evolving in a context of asthenia, nocturnal fever and weight loss. The clinical examination found a compressive goitre. The biological assessment objectified a primary hypothyroidism and an inflammatory syndrome. Cervical ultrasound revealed a poorly circumscribed strongly hypoechoic area in the left thyroid lobe associated with multiple left cervical adenopathies. The diagnosis of thyroid lymphoma was evoked, the patient benefited from several inconclusive fine needle punctures. Biopsies of the thyroid gland and adenopathies were performed; the histological examination objectified epithelioid granulomas with caseous necrosis.
Discussion
Tuberculosis of the thyroid gland accounts for 0.1-0.4% of all localizations. It mainly affects young adults with a preponderance of the female sex. The clinical picture is not specific. It is most often a basicervical tumefaction of progressive installation accompanied by satellite adenopathies and general signs suggesting cancer in first intention. Thyrotoxicosis or hypothyroidism may exceptionally be observed. The appearance on cervical ultrasound is not specific. Most often, cytopuncture is not contributory. Histological examination confirms the diagnosis. The treatment of thyroid tuberculosis is medico-surgical. Our patient was put on anti-tuberculosis treatment and she was designated for surgical management.

Jougerot sjogreen syndrom revealing autoimmun hypothyroidism

Neima Hassan, Sanaa Bammou, Sana Rafi, Ghizlane El Mghari & Nawal El Ansari
Mohamed VI University Hospital Center, Department of Endocrinology, Diabetology, Metabolic Diseases Nutrition, Marrakesh, Morocco

Introduction
Jougerot –sjogreen syndrom is an auto-immune exocrinopathy secondary to the interaction between a favorable ground and environmental factors that can lead to the disease. Thyroiditis can precede sjogreen's syndrom or follow it, just as the two diagnoses can be made at the same time.
Case report
46-year-old female patient, type 2 diabetic on oral antidiabetic 2g/d, followed for sjogreen jougerot syndrom retained in the face of occulo-buccal dry syndrom, cervicothoracic pain, schirmer test positive salivary gland biopsy under corticosteroid therapy. On questionning, the patient reported inflammatory polyarthralgia associated with chronic constipation and asthenia. Objective physical examination morbid obesity with BMI = 44 kg/cm^2, palpable thyroid increased in size. On the balance sheets TSH = 6.7uui/l, T4 = 11pmol/l on the cervical ultrasound : homogenous thyroid, with regular contours, normo vascularized on the doppler seat at the left mid-lobe level hypoechogen formations formations measuring 12.6*7.3mm classified Eu-tirads 3, at the left lower lobe level hypoechogen formations measuring 9*7mm Eu-tirads 2with positive anti-TPO antibodies. The patient was put on levothyrox 75ug/d.
Discussion
Jougerot-sjogreen syndrom is a dysregulation of the immune system by B cell hyperactivation. It is probably the systemic autoimmun disease most frequently associated with autoimmun thyroiditis with an estimated prevalence of 20%. The strong association between the presence of thyroid antibodies for patients with autoimmun hypothyroidism with jougerot syndrom. The association does not seem to result from a disease caused by the other, but results from the appearance of entities to which a context genetically predisposes the subjects, such as patients with HLA DRW3 and HLAB8 haplotypes.
Conclusion
The jougerot sjogreen syndrom and auto-immun thyroiditis their association reflects the presence of a common genetic ground on which are added environmental factors which are added environmental factors which determine the clinical aspects. Regular assessment of thyroid function is necessary in any patient with jougerot sjogreen syndrom.

Transient hypothyroidism post radioiodine therapy

Ghada Sabbagh[1], Hamza Elfekih[1,2], Ghachem Aycha[1], Ghada Saad[1,2], Fatma Barkallah[1], Ach Taieb[1,2], Yosra Hasni[1,2] & Molka Chadli Chaieb[1,2]
[1]Farhat Hached Hospital, Endocrinology, Sousse, Tunisia, [2]Faculty of Medicine Ibn Al Jazzar, University of Sousse, Endocrinology, Sousse, Tunisia

Introduction
Grave's disease is an autoimmune disorder and is considered the most common cause of hyperthyroidism. Its treatment options include medical therapy, radioactive iodine (RAI), and surgery. RAI is commonly employed for Grave's disease regarding its efficiency and safety. Definitive hypothyroidism is the main goal of RAI and is typically achieved within the first 3 to 6 months of therapy. Transient hypothyroidism and recurrence of hyperthyroidism after RAI might occur in some patients. We herein describe 2 cases of transient hypothyroidism following RAI.
Observations
Case 1 is a 67-year-old patient with a history of hyperthyroidism revealed by cardiothyreosis (atrial fibrillation and heart failure) 20 years ago with levels of TSH < 0.05 mUI/l. TSH receptor antibodies were positive confirming the

diagnosis of Grave's disease. He received RAI after 2 months of methimazole. Six months later he developed hypothyroidism requiring thyroxine supplementation. During the follow up, he presented low TSH levels although dose tapering, leading to the discontinuation of thyroxine after 8 years of supplementation. He remained euthyroid for 7 months then redeveloped hypothyroidism. Case 2 is a 52-year-old patient with type 1 diabetes mellitus. Grave's disease was revealed by weight loss and a goiter. His initial TSH was suppressed He was treated by RAI he was hypothyroid post RAI and was put on thyroxin supplementation until he started in a 3 year time presenting with persistently low TSH levels despite lessening the doses, we decided not to follow through with treatment and the patient remained euthyroid despite a 4 year period of treatment withhold

Discussion

Transient hypothyroidism post RAI should be thought of after radioiodine therapy when patients present with a lessened daily needs of thyroxin. It leads to a variably lasting period of euthyroidism necessitating further monitoring of TSH levels.

Conclusion

Grave's disease incidence is growing worldwide. RAI being the most common treatment for either complicated or recurrent cases or within patient's preference. Transient hypothyroidism post radioiodine should be taken into account and further studies are needed to confirm it, describe what might be its causes and predicting factors.

EP1056

Association of Crohn's disease and Hashimoto's thyroiditis : a case report

Khaoula Gorgi, Abderrahman Tadaloui, Sanae Chakdoufi, Yassine Errahali & Ahmed Anas Guerboub
Mohammed V Military Training Hospital, Endocrinology, Rabat, Morocco

Introduction

Crohn's disease is a chronic inflammatory bowel disease, most commonly affecting the terminal ileum and colon. In the other hand, Hashimoto's thyroiditis is a chronic autoimmune inflammation of the thyroid gland. The association between the 2 diseases is rare. We report the observation of a patient with this association.

Observation

A 23-year-old female patient who consulted for persistent diarrhea, rectorrhagia, abdominal pain, bradycardia and asthenia. A workup was ordered in favor of hashimoto's autoimmune hypothyroidism with TSH at 12 (normal value: 0.4-3.78 IU/ml), free T4 at 0.4 (normal value: 0.7-1.48 ng/dl), anti-thyroperoxidase antibody at 200 IU/ml (normal value: $<$0.1 IU/ml). The cervical ultrasound was in favor of thyroiditis. The patient was put on Lthyroxine supplementation; concomitantly, the patient benefited from a colonoscopy and biopsy which anatomopathological examination was in favor of the diagnosis of Crohn's disease.

Discussion and conclusion

The coexistence of Crohn's disease and Hashimoto's thyroiditis is rare. This relationship has been explained by the coexistence of genetic and immunological factors. Several studies have shown that the immune response is polyclonal in both diseases. At present, there is no clear explanation for the coexistence of autoimmune thyroid disease and Crohn's disease, a random coexistence remains possible but the increasing accumulation of reported cases requires further analysis to clarify the etiology of these associations.

Diagnostic performance of fine needle aspiration biopsy in the diagnosis of medullary thyroid carcinoma

Khelil Nour El Houda
Faculty of Medicine - Tlemcen Hospital, Endocrinology, Tlemcen, Algeria

Medullary thyroid cancer (MTC)is a very polymorphic tumour, it remains difficult to diagnose, especially in cytology. The MTC is characterized by a polymotphic cell population, the amyloid stroma is found in 43 to 81% of cases. In this retro and prospective study carried out over 5 years, we included 45 lesions (8 nodules, 35 lymph nodes and 2 cervical masses) these lesions were punctured and the cytological results were compared with the definitive histology. On cytology, 13 lesions (29%) were benign, 14 lesions (31%) were malignant and 18 lesions (40%) were MTCs. After surgery, the definitive histology confirms the MTC in 32 lesions (5 nodules, 25 lymph nodes and 2 cervical masses). For the remaining 13 lesions, 9 were true negatives and 4 were follicular carcinomas of the thyroid. Finally, fine needle aspiration biopsy has a sensitivity of 53.12% and a specificity of 92.3% for the diagnosis of MTC. It is a good diagnostic tool for follicular carcinoma but less so for the diagnosis of MTC.

DOI: 10.1530/endoabs.90.EP1057

EP1058

Lymph node metastasis in medullary carcinoma of the thyroid gland

Mohamed Masmoudi, Chaima Zitouni, Wadii Thabet, Ezer Chebil, Mehdi Hasnaoui & Khelifa Mighri
Taher Sfar Hospital, ENT Department, Mahdia, Tunisia

Introduction

Medullary thyroid carcinoma (MTC) is a neuroendocrine malignancy of the thyroid C cells. Metastatic spread commonly occurs to cervical lymph nodes.

Methods

This is a retrospective study including 8 cases of medullary carcinoma of the thyroid gland between 2000 and 2020.

Results

The sex-ratio (M/F) was 0.125. The mean age of our patients was 55.87 years. No personal or family history of multiple endocrine neoplasm was found. Symptoms included: a cervical mass in all cases, dyspnea in 2 cases and a flush syndrome in 2 cases. On physical exam, a level 2 lymph node was palpated in 3 cases. On ultrasound, thyroid nodules were classified as EU-TIRADS 4 or 5 nodules with lymph node showing malignant features in 4 cases. Fine-needle aspiration was performed in 3 cases and did not suggest the diagnosis of a MTC. Surgery included: total thyroidectomy with central lymph node dissection in 1 case, central and lateral lymph node dissection in 7 cases. It was bilateral in 3 cases. Extemporaneous exam suggested MCT in one case. All patients had lymph node metastases. The tumor mean size was 57mm, multifocal in 1 case, with extra-thyroidal extension in 1 case. There was no evidence of distant metastasis on CT-scan in all cases. There was also no evidence of hyperpathyroidism or pheochromocytoma. Six patients had radiotherapy. There was 1 case of lymph node recurrence and 2 cases of distant recurrences (lung and bone metastases).

Conclusion

In MTC, Surgery is the best treatment option. Patients with MTC should receive lateral lymph node dissection especially when calcitonin levels are elevated, even in the absence of lymph node metastasis on clinical exam and imaging.

EP1059

An unexpected discovery of MEN 2B Syndrome in an adolescent - a case report

Tiberiu Manole[1], Larisa Buduluca[2], Sorina Schipor[3], Andrei Muresan[3] & Iuliana Gherlan[1]
[1]C I Parhon National Institute of Endocrinology, Pediatric Endocrinology, Bucharest, Romania, [2]C I Parhon National Institute of Endocrinology, Radiology, Bucharest, Romania, [3]C I Parhon National Institute of Endocrinology, Scientific Research Laboratory, Bucharest, Romania

Introduction

Multiple Endocrine Neoplasia Syndrome 2B (MEN 2B) is a very rare genetic disorder which affects the thyroid and the adrenal glands, the development of mucosal neuromas and the general appearance of the patient's body. Therefore, we can encounter Medullary Thyroid Carcinomas (MTC), adrenal sympathetic paragangliomas (or Pheochromocytomas) and habitus Marfanoid. The disease represents a challenge for every clinician, especially if it occurs in a child.

Methods

Clinical exam, Blood work, CT scan, genetic testing, pathology exam.

Case report

We present the case of a 12-year-old girl who came in the Pediatric Endocrinology Department with a right thyroid solid mass, for which she was admitted. Upon clinical examination, the patient was thin and tall, with flexible joints, suggesting Marfanoid habitus and also mucosal neuromas were found in the oral cavity, with normal blood pressure, no palpitations, no sweating. No significant family history was discovered. Thus, MEN 2B syndrome was a possible diagnosis. The general blood work and thyroid function were normal, calcitonin was 1100 times over the upper normal limit, while serum PTH and urinary metanephrines and normetanephrines in the 24 h sample urine were within normal range. We also performed a thyroid ultrasonography which revealed 2 hypoechoic nodules in each thyroid lobe, with macrocalcifications. We

performed a CT scan which showed the 2 nodules, with no lymphatic nodes suggesting metastases. The patient underwent a total thyroidectomy with bilateral cervical lymph node dissection. The pathology report came back positive for MTC in both nodules, with no extension to the lymph nodes, confirming our diagnosis of MEN 2B. The next step was genetic testing from the patient's blood to identify if she had the germinal mutation of the RET gene, which came back positive for the p.Met918Thr in exon 16. Obviously, we had to test the patient's parents and brother and there were all negative for the mutation.
Discussions
The patient was brought to us because of a thyroid nodule which turned out to be a MEN 2B syndrome with bilateral MTC, mucosal neuromas and Marfanoid habitus, without the implication of the adrenal glands, with a de novo mutation of the RET gene. The fact that it was discovered in a child makes it even more rare.
Conclusions
MEN 2B Syndrome is a very rare genetic disorder in the general population, making it even more unexpected to be found in the case of a child.

DOI: 10.1530/endoabs.90.EP1059

EP1060

Test for determination of stimulated calcitonin level

Tatiana Leonova[1], Victor Kondratovich[2], Alexandra Sosedkova[1], Alla Shepelkevich[3] & Yuliya Dydyshka[3]
[1]Minsk City Clinical Cancer Center, Oncological Consultative and Diagnostic Department of Thyroid Pathology, Minsk, Belarus, [2]Minsk City Clinical Cancer Center, Minsk, Belarus, [3]Belarusian State Medical University, Endocrinology Department, Minsk, Belarus

Assessment of basal calcitonin as the main marker of medullary thyroid cancer (MTC) was introduced into routine practice in the Republic of Belarus more than 10 years ago. A number of laboratory and clinical factors can influence the result of this parameter determination. Equally important is the gender, age, weight, the deviation of the serum calcium level, certain medications.
The aim
Of the study was to develop and implement of stimulated calcitonin test to solve the problem of low specificity of basal calcitonin test for MTC diagnosis.
Materials and methods
The test protocol includes 1) determination of basal calcitonin level in the serum - blood sampling before the administration of calcium gluconate; 2) determination of the stimulated calcitonin level in the serum - blood sampling in 2 and 5 minutes after intravenous administration of a 10% solution of calcium gluconate. Tubes with blood must be immediately placed on ice, as calcitonin decomposes at room temperature. It is recommended the estimated dose of a 10% solution of calcium gluconate is indicated in terms of elemental calcium and is 2.0-2.5 mg/kg. The maximum allowable dose (all patients weighing more than 70 kg) is 20 ml of a 10% calcium gluconate solution. The drug is administered intravenously slowly over at least 30 seconds. In this case, the patient must be in a horizontal position.
Results and discussion
In the Republic of Belarus stimulated calcitonin test was carried out in 2017 in the consultative and diagnostic department of thyroid pathology of the Republican Center for Thyroid Tumors. Within the framework of the project, the test was carried out in 50 patients, preventive thyroidectomy was performed in 20, the systematization and analysis of the results continues. Possible adverse reactions during the test are a feeling of heat, a decrease in blood pressure, heart rhythm disturbances, fainting, cardiac arrest. Contraindications to the test are hypercalcemia and the simultaneous intake of cardiac glycosides.
Conclusions
Thus, the introduction and conduct of a calcitonin stimulated test showed its effectiveness for the differential diagnosis of nodular thyroid pathology (primary diagnosis of MTC in patients with nodal pathology of uncertain malignancy potential, taking into account the hereditary factor and with elevated levels of calcitonin); to verify the progression of the tumor process in patients with MTC (detection of early biochemical recurrence). This method can confirm a stable remission of the disease and allow women with MTC to plan pregnancy.

EP1061

Prolonged Survival in Follicular Thyroid Cancer with Bone Metastasis

Francisca de Brito Marques, Francisco Simões de Carvalho, Joana Lima Ferreira & Ana Paula Marques
Pedro Hispano Hospital, Matosinhos Local Health Unit, Endocrinology, Matosinhos, Portugal

Introduction
Follicular thyroid cancer (FTC) accounts for 12% of differentiated thyroid cancers (DTC). It is frequently complicated by bone metastasis (BM), which impact quality of life (QOL) and decreases the 10-year survival rate to 13-21%.
Case Report
A 53-year-old woman followed at the Pain Clinic for over 10 years for lower back pain, had been operated three years before due to lumbar disc herniation. Pain relapsed one year after surgery and was resistant to analgesics. On physical examination (2010) a right thyroid mass and lower-extremity hypoesthesia were noted. Spine CT scan documented a 60x98 mm lytic mass at left pelvis and sacrum. Core biopsy revealed FTC with positivity for thyroglobulin (Tg) and TTF1. Thyroid ultrasound showed a bulky right thyroid nodule and suspicious right laterocervical lymph nodes. Laboratory tests revealed normal thyroid function, Tg 30334 ng/ml and negative TgAtbs. Thoracic CT documented pulmonary micrometastasis. Total thyroidectomy with cervical lymphadenectomy was performed. Histopathology showed a 7 cm widely invasive FTC with extra-thyroidal extension and lymph node metastases. Six weeks post-surgery Tg was 74560 ng/ml (TSH 8.9 uUI/ml). Within five years, she received four radioactive iodine (RAI) treatments with post-RAI scans demonstrating 131-I avid metastasis. After the second RAI, Tg dropped to 513 ng/ml, but TgAtb became positive. A debulking surgery with sacrum stabilization was also performed. Lenvatinib (LVT) was started seven years after diagnosis, due to imaging and biochemical evidence of metastatic progression, despite suppressive levothyroxine therapy and cumulative 131-I 29.7 Gbq. The dosage was reduced from 24 to 20 mg/day due to diarrhea. Arterial hypertension and anorexia developed and were pharmacologically controlled. She had good clinical and biochemical response (Tg decreased and stabilized; TgAtbs decreased and became negative). Thoraco-abdominal CT and spine MRI showed no significant signs of progression. Lumbar pain was controlled with opioids. After 1.5 years since LVT, there was pulmonary metastasis progression, despite biochemical stability. After an additional two years since LVT, she had substantial biochemical progression (last Tg level 41059 ng/ml in OCT-2022) and persistent vertebral pain. Significant BM progression was documented on 18-F-FDG PET and CT scans, the latter also revealing pulmonary disease progression. Tumor RET status was negative. The initiation of cabozantinib is under consideration.
Discussion
We describe a case of FTC with BM at presentation, with prolonged survival, currently 13 years. Although mostly not curative, a multimodal therapeutic approach should be employed by experienced teams to improve patienťs QOL and survival.

EP1062

Papillary carcinoma of the thyroid in Basedow disease : case report

Meherzi A, Jemli S, Laabidi E, El Omri M, Bellakhdher M, Kermani W & Abdelkefi M
ENT and Neck Surgery Department Farhat Hached Hospital, Sousse, Tunisia

Introduction
The occurrence of Basedow disease does not eliminate the possibility of an associated thyroid cancer. Thyroid carcinoma in Basedow disease is particularly rare (1 to 2%). Most often, it is a papillary carcinoma. This is most often a chance discovery. We report a case of a papillary carcinoma in a Basedow disease taken care of in our department.
Case Report
This was a 39-year-old hypertensive diabetic woman followed in endocrinology for Basedow' disease under medical treatment, referred to our department for management of an anterior basal cervical swelling rapidly increasing in size. anterior cervical swelling of 6 cm of MA associated with multiple supracentimetric left jugular carotid adenopathy as well as bilateral proptosis. The rest of the ENT examination was without abnormalities. Cervical ultrasound showed a multinodular thyroid goiter with an upper left nodule classified EUTIRADS V associated with bilateral lymphadenopathy, especially at the level of bilateral IIb and IIA chains with a 'thyroid-like' appearance. The patient had a total thyroidectomy associated with bilateral recurrent mediated dissection and left functional dissection. The frozen section examination found a carcinoma papillary lymphadenopathy and metastatic papillary carcinoma. Definitive anatomy pathology examination confirmed the diagnosis of multifocal and bilateral papillary carcinoma with a crossing of the capsule associated with lymph node metastasis at the level of the adenopathy of the recurrent and lateral mediastinal dissection. The patient was referred to IRAtherapy, she received 100 Mci of radioactive iodine with white cartography with good evolution without recurrence after one year of follow-up.

Conclusion
According to data from the literature, the incidence of thyroid cancer in Basdewo disease is rare (0.1 – 9.8%). The histological type is a papillary carcinoma in most cases.
• The subsequent management is similar to that of differentiated thyroid cancers, namely isotopic ablation at I131 and a braking treatment with L-thyroxine.

EP1063

Parkinson's disease associated to Hashimoto's thyroiditis

Zineb Ait Si Ali, Ahmed Boukhalfa, Sana Rafi, Ghizlane El Mghari & Nawal El Ansari
Centre Hospitalo-Universitaire Mohammed VI Marrakech, Department of Endocrinology, Diabetology, Metabolic Diseases and Nutrition, Marrakech, Morocco

Introduction
Parkinson's disease (PD) is one of the most common neurodegenerative disorders characterized by bradykinesia, tremor, rigidity and postural instability as well as neurocognitive impairment and depression. Studies found a significant association between thyroid dysfunction and an increased risk of PD. We report the case of a patient treated for PD who had also Hashimoto's thyroiditis, and we discuss the association of thyroid dysfunction with risk of PD.
Case report
Female patient, aged 52 years. Followed for 2 and a half years for Parkinson's disease, clinically retained for bradykinesia, rigidity, tremor, treated with L-Dopa Benserazide and trihexyphenidyl hydrochloride. She presented weight loss, palpitations and intermittent diarrhea. The clinical examination noted a goiter and normal heart rate to 70 bpm. Thyroid function tests showed hyperthyroidism TSH us $<$ 0.01 uUl/ml, fT4: 51.9 pmol/I, fT3: 13.9 pmol/I. Anti-thyroid antibodies measurement indicated positive anti-tpo Ab to 663.5 IU/l and negative anti-TSH receptor Ab. Thyroid ultrasound examination revealed typical image of Hashimotós thyroiditis. The diagnosis of Hashitoxicosis was retained. In one month follow-up, fT4 level decreased to 34 pmol/l. Follow-up with biological monitoring is planned for the diagnosis and management of hypothyroidism stage.
Discussion
There is a correlation between thyroid function and PD, but the mechanism is not completely clear. Patients with thyroid dysfunction have an increased risk of developing PD. Oxidative stress is one of the chief contributing factors to dopaminergic neuron loss and PD progression. Both hyperthyroidism and hypothyroidism are related to oxidative stress and cellular damage. Patients with autoimmune diseases, such as Hashimoto's thyroiditis, Graves disease, amyotrophic lateral sclerosis, multiple sclerosis, and rheumatoid myalgia, had an additional 33% risk of PD. Besides the direct effects of thyroid hormone on dopaminergic neuron and skeletal muscle function and shared genetic risk, the association may be driven by autoimmunity; autoimmune response and neuroinflammation may play a role in the pathogenesis of PD. In addition, studies have suggested that presence of thyroid auto antibodies (anti-thyroid peroxidase and antithyroglobulin) are associated with neurodegenerative disorders such as multiple system atrophy and cerebellar degeneration. However, it's unknown whether and how thyroid autoantibodies affect the dopaminergic neurons and risk of PD.
Conclusion
Many studies have shown that there is a correlation between thyroid dysfunction and PD, but the mechanism is incompletely clear. Further investigations should be conducted to provide clear evidence and to identify the mechanism responsible for this association.

EP1064

Case of Subacute Thyroiditis after receiving the SARS-CoV-2 vaccine and the Covid-19 infection 6 months later in the same patient

Natia Vashakmadze[1,2,3]
[1]Israeli-Georgian Medical Research Centre "Healthycore", Department of Endocrinology, Tbilisi, Georgia, [2]David Tvildiani Medical University, T'bilisi, Georgia, [3]Ilia State University, Tbilisi, Georgia

A 43-year-old woman received the CoronaVac COVID-19 vaccine produced by Sinovac Biotech in September 2021. 1 month after the last dose of vaccine (10/2022), she developed pain in her right neck, palpitations, and fever. Laboratory studies revealed severe thyrotoxicosis (TSH - 0.1 mIU/ml, high FT4) and increased ESR - 59 mm/h; Ultrasound showed an asymmetric thyroid due to enlargement of the hypervascular right lobe. The left lobe was intact. She was diagnosed with subacute thyroiditis developed after CoronaVac vaccine and was treated with steroids for 3 months. She had an immediate improvement after the first dose of the methylprednisolone. After this episode, thyroid function tests were checked regularly and were normal. In January 2022 the patient tested positive for COVID-19. In April 2022, she developed pain in the left side of her neck, fever, and palpitations. The left lobe of the thyroid gland was painful on palpation, the right lobe was painless. Thyroid ultrasound revealed an increase in the left lobe compared to the previous report: $3.8 \rightarrow 8.5$ cm^3, thyroid was heterogeneous, with inflammatory infiltration areas. TSH done 2 weeks ago showed the presence of subclinical hypothyroidism (TSH - 5.8 mIU/ml). CBC showed anemia, an increase in ESR of 62 mm/h and elevation of CRP. TFT were re-evaluated: TSH - 0.11 mIU/l, FT4 and FT3 were high normal. Thyroid scintigraphy showed absence of uptake in both lobes - 0%. Based on performed investigations, the patient was diagnosed with subacute thyroiditis, this time after a covid infection. She was given NSAIDs and propranolol, but the pain in her neck worsened, it was extremely difficult for her to swallow even liquids, and any touch on her neck was very painful. The fever was persistent despite the use of NSAIDs. Due to the deterioration of the clinical picture, despite taking ibuprofen 1200 mg per day, methylprednisolone 32 mg was prescribed with appropriate gastroprotection and potassium supplementation. Again, immediately after the first dose of the steroid, the patient felt a marked improvement, she was prescribed methylprednisolone at a dose of 32 mg for 1 month, and then down titrated according to laboratory data and clinical picture, and discontinued in July 2022. Since then, her thyroid function tests have been normal and she feels well. Besides the thyrotoxic phase of subacute thyroiditis, laboratory testing revealed vitamin D deficiency, vitamin B12 deficiency, and iron deficiency. The patient was prescribed the supplements for the aforementioned deficiencies.

Diagnosis and management of a thyrotoxicosis storm on unknown hyperthyroidism

Brahimi Hanane, Fetouci Somia, Amira Bouchenna & Ouldkablia Samia
Central Army Hospital, Algiers [El Djazaïr], Algeria

Introduction
In the spectrum of endocrine emergencies, thyroid storm is one of the most critical complications. Recognition and appropriate management of life-threatening thyrotoxicosis is vital to prevent the high morbidity and mortality that may accompany this disorder. The incidence of thyroid storm has been noted to be less than 10% of patients hospitalized for thyrotoxicosis; however, the mortality rate secondary to thyroid storm ranges from 20 to 30%. We report in this work, the case of a patient with unknown Grave disease, who had a thyreotoxicosis storm after cholestectomy.
Observation
52-year-old patient, 20 days before his thyrotoxicosis storm, our patient presented with acute pancreatitis on vesicular lithiasis, which required the realization of a cholecystectomy, our patient did not show any clinical sign of thyrotoxicosis before surgery, but the occurrence of a hypertensive peak, tachycardia at 147 beats/min and significant dyspnea, a thyroid assessment was carried out, returning in favour of hyperthyroidism with a TSH level $<$ 0.01µui/ml and an FT4 level: 69 pmol/l, the electrocardiogram found an atrial fibrillation, the diagnosis of a thyroid storm was retained on clinical and biological criteria (scored at 50 according to the Wartofsky score) and the patient was transferred to an intensive care unit, where he received appropriate management. Subsequently, our patient received radical treatment for his hyperthyroidism.
Conclusion
Thyrotoxicosis and thyroid storm represent a critical diagnostic and therapeutic challenge to the clinician. Recognition of life-threatening thyrotoxicosis and prompt use of medications aimed at halting the thyrotoxic process at every level is essential to successful management. A set of therapeutic weapons exist: the treatment aimed at stopping synthesis of new hormone within the thyroid gland, halting the release of stored thyroid hormones from the thyroid gland, preventing conversion of T4 to T3, and providing systemic support of the patient. All of which can stop the thyroid storm and save the patient from critical complications. Once this transition occurs, definitive therapy of thyrotoxicosis can be planned.

Ectopic thymus discovered during thyroid surgery

Mohamed Masmoudi, Chaima Zitouni, Wadii Thabet, Ezer Chebil, Mehdi Hasnaoui & Khelifa Mighri
Taher Sfar Hospital, ENT Department, Mahdia, Tunisia

Introduction
The thymus is a primary lymphoid organ and the initial site for development of T cell immunological function. It originates high in the neck in early fetal life and reaches its definitive location in the mediastinum after a process of descent, generally leaving no trace behind. Occasionally, during this descent, remnants of thymic tissue can be implanted along the cervical pathway, later appearing as a cervical mass.
Case Report
This is a case of a 39-woman undergoing surgery for a left thyroid nodule. During surgery, a yellowish mass located behind the lower pole of the left thyroid lobe was discovered. The mass was not removed. A biopsy was performed. On histologic examination, it corresponded to a thymic tissue.
Conclusion
The third and fourth pouches are responsible for the development of the parathyroid glands, the thymus, and a portion of the thyroid gland. Ectopic parathyroid tissue can be found anywhere along their pathway of descent. However ectopic thymus is rarer and is usually found at the mediastinum. The diagnosis of ectopic thymus is difficult and can be misleading, it should be suspected in case of yellowish tissue located posteriorly to the thyroid gland. If ectopic thymus is suspected, frozen section biopsy should be performed. If the diagnosis is confirmed, the mass should not be excised unless it is causing dyspnea or dysphagia.

Hepatic Encephalopathy Complicating Graves 'disease: A Case Report

Benlafqih Maryame, Ahmed Boukhalfa, Sana Rafi, Ghizlane El Mghari & Nawal El Ansari
Arrazi Hospital, Faculty of Medicine and Pharmacy of Marrakech, Mohammed VI University Hospital, Endocrinology, Marrakech, Morocco

Introduction
Hepatic encephalopathy is a neuropsychological syndrome complicating a chronic liver disease (cirrhosis), rarely acute (fulminant hepatitis). We report the case of a patient with Graves' disease who suddenly presented with hepatic encephalopathy.
Case Report
S.B., a 48-year-old woman followed for Graves' disease treated with antithyroid drugs and also presenting vitiligo, was admitted to our facility for a relapse of Graves' disease with major hyperthyroidism (TSH < 0.05 and T4l: 100 pmol) and cholestatic jaundice. The patient benefited from a plasmapheresis session and the evolution was characterized by a picture of hepatic encephalopathy made of behavioral disorders and biochemically, low prothrombin, low albumin, and major cholestasis.
Discussion
The pathophysiology of hepatic dysfunction in hyperthyroidism is multifactorial; it can be secondary to hyperthyroidism or associated with autoimmune liver disease, especially primary biliary cirrhosis and autoimmune hepatitis. In our patient, given the autoimmune context, especially vitiligo, and Graves' disease, it is very likely a non-known liver pathology, either primary biliary cirrhosis or autoimmune hepatitis, complicated by hepatic encephalopathy.
Conclusion
Graves' disease can be associated with several autoimmune disorders, including liver involvement. Screening for these disorders is important as they can affect the patient's prognosis.

EP1068

A treasure hunt! An unusual presentation of benign thyroid tissue as cervical masses

Geethika Thota[1,2,3] & Hongxiu Luo[1]
[1]Saint Peter's University Hospital, New Brunswick, United States, [2]Saint Peter's University Hospital Emergency Room, New Brunswick, United States, [3]Saint Peters University Hospital, Internal Medicine, New Brunswick, United States

Introduction
Cervical masses in a patient with thyroid nodules raise the possibility of thyroid cancer with nodal metastases. Our case highlights the possibility of the rare presentation of benign thyroid tissue as a lateral neck mass in a patient with a previous history of thyroid surgery.
Case Description
A 66-year-old women with a past surgical history of partial left lobectomy for unclear reasons 30 years ago was referred by the surgeon for evaluation of thyroid nodules. She reported noticing palpable neck masses but didn't report associated heat/cold intolerance, palpitations, diarrhea, tremor, fatigue, skin/hair /sleep /weight/appetite changes. No associated neck pain, dysphagia, fever, URTI, or vaccination. No obstructive symptoms. No recent Biotin, herbal or over-the-counter remedies. No previous similar complaints, no family history of thyroid disorders. No radiation exposure and is postmenopausal. Vitals normal, BMI 22.7 Physical examination is significant for two right-sided rubbery, non-tender, mobile masses in right upper neck, palpable right thyroid nodules. The biochemical evaluation revealed normal CBC and CMP. -TSH 1.33IU/ml, FT4 1.06ng/dl -Thyroid US: two thyroid nodules 20x19x13mm,9x8x7mm and several small nodules in the right lobe and one Right mid jugular chain lymph node -US Neck mapping: R level III mid jugular: three lymph nodes measuring 4-5 mm, no fatty hila, other levels, and left side are normal -Lymph node Excisions of two right cervical lymph nodes showed fragments of benign thyroid tissue; no lymphoma, however, flow cytometry couldn't be performed due to lack of significant lymphoid population. -Thyroseq molecular test from the lymph nodes samples obtained was negative for genetic mutation -Repeat Thyroid US-Stable thyroid nodules -Repeat TFT after 2 months, TSH 2.180IU/ml, FT4 1.00ng/dl remained clinically, biochemically euthyroid.
Discussion
Ectopic thyroid tissue (ETT) is a rare phenomenon and usually occurs along the normal path of thyroid descent. There have been reports of thyroid tissue found in places such as the abdominal organs, pelvis, axilla, and thoracic cavity. It is, however, rare to find thyroid tissue within lateral neck masses. When thyroid tissue is found in a cervical lymph node, the suspicion of nodal metastasis of differentiated carcinoma of the thyroid should be high. In our case, FNAB of thyroid nodules, excision biopsy of lymph nodes, and a Thyrosequence molecular test were negative for malignancy. Our hypothesis is that in our patient with a previous history of thyroid surgery, the seeding of cells from thyroid tissue may be the possible mechanism

Thyroid pathology and hypofertility

Raida Ben Salah[1], Faten Hadjkacem[2], Seddiqa Somauroo[2], Mohamed Abid[2] & Zouhir Bahloul[1]
[1]Sfax University, Internal Medicine, Sfax, Tunisia, [2]Sfax University, Endocrinology, Sfax, Tunisia

Introduction
Thyroid pathology is common in women of reproductive age. Evaluation of thyroid function is classically recommended in cases of recurrent abortion. The presence of dysthyroidism or antithyroid antibodies increases the risk of abortion. We report two observations of hypofertility related to thyroid pathology and discuss the therapeutic course.
Case 1
A 33 year old woman was referred for etiological investigation of recurrent abortion. She presented 3 successive abortions at 6, 8 and 12 weeks of amenorrhea respectively. The etiological investigation concluded to a Hashimoto's thyroiditis with FT4: 11.1 m IU/l and TSH: 13.46 m IU/l and strongly positive anti TPO antibodies. The diagnosis of latent hypothyroidism was retained. The patient was able to carry a pregnancy to term with a healthy baby under hormone replacement therapy.
Case report 2
A 35-year-old woman was referred for etiologic investigation of recurrent abortion. She had two in-utero fetal deaths at 12 weeks and 30 weeks of amenorrhea respectively. The thyroid workup was normal but the anti TPO antibodies were strongly positive. In the absence of a therapeutic consensus on how to deal with repeated abortions associated with positive antithyroid antibodies, our approach was to abstain with monitoring of the thyroid balance. The evolution was marked by the subsequent occurrence of two abortions and a patent hypothyroidism requiring hormone replacement. Hypofertility was attributed to a purely gynecological cause.
Discussion
Hypothyroidism is recognized as a cause of hypofertility. Several mechanisms have been put forward to explain the dys- or anovulation related to this pathology; these are essentially hyperprolactinemia, disturbance of sex steroids, etc. If not substituted, hypothyroidism exposes the patient to miscarriage, and fetal death in utero. Regarding thyroid antibody positivity in clinically euthyroid women, the majority of studies have found that the miscarriage rate is doubled in these women compared to women without antibodies. The hypothesis is that the presence of anti-thyroid antibodies reflects a

more generalized activation of the immune system. In this context, several studies report a decrease in the percentage of spontaneous miscarriages and preterm deliveries during treatment with immunoglobulins and levothyroxine in euthyroid women with anti-TPO antibodies.
Conclusion
The management of hypothyroidism during pregnancy is currently well codified, allowing the prevention of spontaneous miscarriage as shown in the first observation. However, the management of thyroid antibody positivity in clinically euthyroid women is still not consensual and the imputability of these antibodies remains to be demonstrated on large cohorts.

A Case of Myxoedema Coma Presenting as Suspected Angioedema with Confusion

Hayre Jatinder[1,1,2], Lubna Etbinah[1], Ayan Mohamed[1], Bashir Mahamud[1], Karen Tam[1], Ahmed Mohammed[1], Khash Nikookam[1], Mohammed Mohammed[1] & Gideon Mlawa[1]
[1]BHURT, Romford, United Kingdom, [2]BHURT, London, United Kingdom

Background
Myxoedema coma although uncommon can be life-threatening in patients who are poorly compliant with levothyroxine replacement. Some of the precipitating factors include intercurrent respiratory infection, use of sedatives, and electrolyte imbalance such as hyponatremia(Wiersinga 2018). A 73-year-old man presented to the Hospital with face and tongue swelling, shortness of breath, and type 2 respiratory failure. His past medical history includes hypothyroidism, Obstructive sleep apnea syndrome (OSA), venous leg ulcers, Type 2 diabetes, prostate problems, and Atrial fibrillation. His current medications on table 2 below He initially received a CI esterase inhibitor for suspected angioedema and had some improvement in the Accident and Emergency Resuscitation room was transferred to the intensive care unit and intubated due to agitation and concerns about maintaining his airway. His blood test showed severe hypothyroidism likely due to poor compliance. He was treated with iv liothyronine(T3) and iv hydrocortisone. He was also treated for congestive cardiac failure. Chest X-ray showed bilateral pleural effusion. He developed hospital-acquired pneumonia for which he received iv antibiotics. His confusion improved with the improving thyroid function test table 1 below. He was discharged home on levothyroxine after prolonged hospital admission.
Discussion
Severe hypothyroidism presenting as myxoedema can lead to fatal outcomes. The mortality rate is around 30-60% (Wall, C 2000), and therefore early clinical diagnosis and timely treatment are important to ensure patient recovery and desired outcomes. The clinical manifestation of myxoedema coma is variable. Some of the clinical presentations include confusion, altered level of consciousness, hypothermia tiredness, generalized swelling, and constipation. The presented case had some of the above-mentioned clinical features and the swelling on his face and enlarged tongue were treated as suspected angioedema
Conclusion
Myxoedema coma is both a medical and an endocrine emergency. Early treatment using Liothyronine is important to get desired and better outcome for the patient. Ruling out Addisonian crisis and correcting hypothermia, hypotension, and other electrolytes imbalance contributes positively to patient care(Wiersinga 2018)

Transverse Myelitis and Covid-19 Disease in A Patient with Hashimoto's Thyroiditis

Lambros Athanassiou[1], Panagiotis Athanassiou[2], Pavlos Tsakiridis[2], Sofia Nikolakopoulou[3], Dimitra Mathiou[4], Maria Nikolidaki[4] & Kostoglou Athanasiou Ifigenia[5]
[1]Asclepeion Hospital, Voula, Department of Rheumatology, Athens, Greece, [2]St. Paul's Hospital, Department of Rheumatology, Thessaloniki, Greece, [3]Asclepeion Hospital, Voula, Covid-19 Department, Athens, Greece, [4]European University Cyprus, Nicosia, Cyprus, [5]Asclepeion Hospital, Voula, Department of Endocrinology, Athens, Greece

Introduction
The SARS-CoV-2 virus has caused the recent pandemic. Most affected patients have gone through a rather mild disease. However, some of the patients have gone through a severe illness requiring admission to an acute care unit. Some survived while others succumbed to the disease. In some patients the SARS-CoV-2 infection was characterized by neurological manifestations. One of these is transverse myelitis thought to be caused either by the virus itself as the SARS-CoV-2 virus may be neuroinvasive or by an autoimmune reaction due to molecular mimicry between the viral and host proteins.
Aim
The aim was to describe the case of a male patient with Hashimoto's thyroiditis who developed transverse myelitis in the course of COVID-19 illness.
Case description
The case of a 52 year-old male patient is described. The patient presented with Hashitoxicosis approximately 15 years ago at the age of 37 years. TSH was 0.01 μIU/ml, anti-Tg and anti-TPO antibodies were positive, while a thyroid ultrasonogram revealed loss of homogeneity of the thyroid parenchyma. Unimazole was administered. During the course of the disease the patient developed hypothyroidism and thyroxine was administered. Approximately a year ago he presented with COVID-19 disease and a rather severe illness. The patient was admitted to a COVID-19 department. During hospitalization he started to feel numbness in the lower extremities and subsequently the lower extremities were paralyzed. Transverse myelitis was diagnosed and prednisolone was administered. Over the course of two months prednisolone was tapered and the patient improved. During the course of a year the patient improved substantially and is now in a program of rehabilitation. He is able to walk independently without the use of walking aids.
Conclusions
Transverse myelitis in the course of COVID-19 disease has been described. The disease may be due to the virus itself, as it may be neuroinvasive or to an autoimmune reaction due to molecular mimicry, i.e. due to the homology of amino acid sequences of the viral proteins to human amino acid sequences. Thus, an immune reaction to the SARS-CoV-2 virus leads to an immune reaction to proteins of the human host and the development of clinical autoimmune disease. The SARS-CoV-2 virus is neuroinvasive and may have led to the development of transverse myelitis. Alternatively, the SARS-CoV-2 virus may be a virus which leads to autoimmunity and may have led to an autoimmune reaction in a vulnerable host, as the patient described herein.

EP1072

Unusual Warthin-like variant of papillary thyroid carcinoma associated with Hashimoto's thyroiditis

Susana Mallea-Gil[1], Maria de los Angeles Sosa[1], Marcela Bachella[2], Yamila Sanchez[1], Bibiana Coca[1], Maria Marta Aparicio[1], Silvina Sankowicz[1] & Carolina Ballarino[1]
[1]Hospital Militar Central, Endocrinology, Buenos Aires, Argentina, [2]Hospital Militar Central, Pathology, Buenos Aires, Argentina

Warthin-like variant of papillary thyroid carcinoma is a rare histologic variant of PTC; they resemble Warthin tumor of salivary gland, frequently associated with lymphocytic thyroiditis. There is scarce literature available regarding this tumor.
Clinical case
In August 2019 a 51-year-old female patient sought consult because she complained of constant pain in the anterior surface of the neck. Medical background: arterial hypertension, she had no history of family thyroid illnesses. On examination, she had a 2 cm painless nodule in the left thyroid lobe, with no lymph nodes. Ultrasonography: right lobe was measuring 45x20x21mm with multiple spongiform nodules, the largest: 16x9 mm; left lobe: 51x20x25 mm with a 19x17x17mm hypoechogenic nodule, with irregular margins, microcalcifications and minimal vascularization. In November 2019 ultrasound-guided FNA: nodule in right lobe: Bethesda II, nodule in left lobe: Bethesda VI: scattered cells and groups of cells with nuclear overlapping, elongated cells, anisokaryosis, 1-2 prominent nucleoli, intranuclear cytoplasmatic inclusions. There were two probable diagnoses: medullary thyroid carcinoma vs. an infrequent variant of papillary carcinoma. Hormonal laboratory: normal TSH, FT4 and calcitotin, negative TPO and antithyroglobulin antibodies. In January 2020 a total thyroidectomy and lymph nodes removal of region VI was performed. Pathology report: unifocal Warthin-like variant of papillary carcinoma of 0.7x0.7 cm, without lymphatic emboli, perineural and extra-thyroid invasion, lymphocytic thyroiditis in the remaining tissue. Region VI lymph nodes: 1/7 positive micrometastasis of papillary carcinoma (<2 mm) without capsular invasion.

Intermediate risk of recurrence, TNM: T1b, N1a, Mx. Under levothyroxine treatment: TSH 0.15 mUI/ml, thyroglobulin (TG) 0.04 ug/dl and negative antithyroglobulin antibody. Because of COVID-19 pandemic, treatment with 100 mCi radioiodine could be performed in October 2020 under recombinant TSH; whole body scan (WBS): positive in thyroid lodge and in the right region of the neck. Six months later, a neck ultrasonography showed a 11 mm adenopathy with cortical irregularity in III cervical region; a FNA was negative for neoplastic cells and thyroglobulin measurement in the needle washout after FNA was <0.1 ug/dl. In more than 3 years of follow-up, the patient had negative WBS, cervical ultrasonography and normal levels of thyroglobulin.
Conclusion
We presented a patient with a rare variant of papillary thyroid carcinoma associated with Hashimoto's thyroiditis with negative serum thyroid antibodies. The patient had excellent response to the treatments in more than 3 years of follow-up. We need a longer follow-up to define the real risk of this type of thyroid cancer.

Tuberculous lymphadenitis with the appearance of thyroid carcinoma metastasis

Hatice Sebile Dökmetaş[1], Esma Eren[2], Kadriye Karahangil[3], Ayşenur Akkoyun[2], Meriç Dökmetaş[2], Onur Şahin[2] & Hikmet Zeynep Ağaoğlu[2]
[1]Istanbul Medipol University, Endocrinology, Istanbul, Turkey, [2]Istanbul Medipol University, Internal Medicine, Istanbul, Turkey, [3]Istanbul Medipol University, Infectious Diseases, Istanbul, Turkey

Tuberculosis (TB) is a disease that affects all organs and progresses with a wide variety of clinical manifestations. Cases of extrapulmonary tuberculosis (EPTB) are particularly difficult to diagnose because of its atypical course.
Case
A 32-year-old female patient was evaluated in our clinic with the complaint of localized swelling in both supraclavicular regions (ScR) for one and a half months. There were no fevers, cough, or weight loss symptoms present. Ultrasonography showed approximately 6x6 mm calcified nodule in the left thyroid lobe and lymphadenopathy (LAP) of 3.2x2.4 cm in the left supraclavicular region (ScR) and 2.1x2 cm in the right ScR. A clinical diagnosis of metastasis of thyroid carcinoma or lymphoma were considered. In her family history, it was learned that her mother had TB and received treatment for 6 months. Hemoglobin 9.5 g/dl (11.7-15.5), the white blood cell count was 5,100 uL (4,4-11,3), erythrocyte sedimentation rate (ESR) was raised 1st hour 43 mm ($<$ 20), c-reactive protein of 8.2 mg/dl (<5). The results were negative for hepatitis markers, human immunodeficiency virus, toxoplasmosis, brucellosis and syphilis. Quantiferon-tb gold test was negative. Fine needle aspiration (FNA) cytology to the left thyroid lobe and left supraclavicular lymph nodes (ScLN) revealed epithelioid cells and necrotic material forming granulomas and lymphocytes. Thyroid nodule aspiration report: Atypia of undetermined significance. The real-time polymerase chain reaction (RT-PCR) test and Ziehl-Neelsen staining of the biopsy sample taken from the lesions in ScR were negative. No TB compatible lesion was found on computed tomography scan of the lung. Considering the pathology result and family history, tuberculous lymphadenitis was considered and 4-antituberculosis treatment was started. In the presence of palpable lymphadenopathy in countries where TB is common, TB should be considered in the etiology. TB affecting primarily ScLN is uncommon. In absence of systemic signs and symptoms, as in our case, it can be difficult to diagnose TB.

Squamous cell carcinoma of the larynx associated with thyroid carcinoma: a case report

Loubna Guissi, Khaoula Gorgi, Lamya Echchad, Kaoutar Rifai, Hinde Iraqi & Mohamed Elhassan Gharbi
Ibn Sina University Hospital, Department of Endocrinology and Diabetology, Rabat, Morocco

Introduction
The discovery of thyroid cancer during surgery for another malignant disease of the upper aerodigestive tract is rare. We report the case of a man presenting squamous cell carcinoma (SCC) of the larynx associated with papillary thyroid carcinoma (PTC).
Case presentation
A 68-year-old patient with history of cigarette smoking underwent total laryngectomy for laryngeal cancer associated with subglottic extension. Hemithyroidectomy on the lesion side was performed. On histology, SCC of the larynx and PTC were documented. Continuing to total thyroidectomy was decided secondarily and the other thyroid lobe was hyperplastic without signs of malignancy. The patient then received external radiotherapy as adjuvant therapy to surgery for his squamous cell carcinoma.
Discussion/Conclusion
Thyroid carcinoma found incidentally during treatment of SCC of the larynx is a rare event with very few cases reported in the literature. It is most often an incidental histological finding. The prognosis depends on the squamous carcinoma which therapeutic management is established. There is no well-coded management for combined thyroid and laryngeal cancers. In our patient, totalization surgery and external radiotherapy were performed as the only complement therapeutics. This was justified by the absence of poor prognostic factors for papillary thyroid carcinoma.

A vesicular carcinoma of the thyroid on Graves' disease: a rare association

Chaymaa Alami Hassani[1], Ayoub Idrissi[2], Abainou Lahousssaine[2], Sanae Elhadri[2], Azzelarab Meftah[2,3] & Hicham Baizri[3,4]
[1]CHU SOUSS MASSA AGADIR/Faculty of Medicine and Pharmacy Ibn Zohr Agadir, Department of Endocrinology Diabetology and Metabolic Diseases, Agadir, Morocco, [2]Military Hospital Avicenne Marrakech, Department of Endocrinology Diabetology and Metabolic Diseases, Marrakech, Morocco, [3]Faculty of Medicine and Pharmacy - CADI AYYAD University Marrakech, Marrakech, Morocco, [2]Military Hospital Avicenne Marrakech, Department of Endocrinology Diabetology and Metabolic Diseases, Marrakech, Morocco

Introduction
The occurrence of vesicular carcinoma in Graves' disease is exceptional. It is most often a papillary carcinoma rarely vesicular. We report the case of a vesicular carcinoma discovered at the anatomopathological study of a total thyroidectomy in a patient followed for Graves' disease.
Observation
This is a 61-year-old female patient with type 2 diabetes, on SGLT2 inhibitor. There isn't any family history of thyroid cancer or exposure to radiation in the cervico-thoracic region. Consulted for pelvic girdle myopathy with thyrotoxicosis. The biological assessment showed a TSH of 00 uUI/ml, an LT4 elevated twice the normal value, positive anti TSH receptor antibodies at 21 IU/l, and on ultrasound a thyroiditis appearance with a left lower lobar nodule 3 of 20.4*24.3*22 mm classified EUTIRADS 3 and a right lower lobar nodule of 10.2*6.3 mm classified EUTIRADS 3. Thyroid scintigraphy showed an aspect in favour of Graves' disease associated with a hypo-captant left lower lobar nodule. The patient received synthetic antithyroid drugs until euthyroidism was obtained, then she underwent a total thyroidectomy.. Histology concluded to a vesicular micro carcinoma of the thyroid of 7mm in diameter with capsular breakthrough and without vascular emboli. The patient did not receive iodine 131, simple monitoring with L-thyroxine inhibitor treatment were indicated.
Conclusion
The association of Graves' disease and vesicular carcinoma remains rare but the discovery of a thyroid nodule during surveillance or even at diagnosis constitutes a predictive element requiring a careful search for malignancy as illustrated by our clinical case.

Papillay microcarcinoma in patient with graves' disease

Mohamed Masmoudi, Chaima Zitouni, Wadii Thabet, Ezer Chebil, Mehdi Hasnaoui & Khelifa Mighri
Taher Sfar Hospital, ENT Department, Mahdia, Tunisia

Introduction
Patients with Graves' disease are at a 2.5 times higher risk of developing thyroid cancer than the general population.

Objective
We report here a case of a papillary microcarcinoma discovered in patient with graves' disease.
Case report
This report is about a 51-year-old woman treated with anti-thyroid drugs and β blockers for Graves' disease. Cervical ultrasound found an enlarged, hypervascular thyroid gland with a 10 mm nodule classified EUTIRADS 5. Indications for surgery were: failed medical therapy after 3 years of treatment and concomitant suspicious thyroid nodule. The patient underwent total thyroidectomy. Intraoperative examination suggested a papillary thyroid carcinoma. A central neck dissection was performed. Histologic exam confirmed the diagnosis of papillary thyroid carcinoma associated with Graves' disease. The patient underwent ablative radioiodine therapy. After 9 years of follow-up, she had no recurrence.
Conclusion
Over 85% of thyroid cancer in patients with GD was papillary thyroid carcinoma, although other histologic types including follicular, medullary, and anaplastic carcinoma could be found in some studies. Patients with GD tend to have microcarcinomas Thyroid USG can identify more thyroid nodules or cancers in patients with GD, compared with palpation or radioactive iodine scintigraphy.

surprise or evil hidden behind a toxic thyroid nodule: about a case

Malak Riznat, Hajar Srifi, Rifai Kaoutar, Hind Iraqui & Gharbi Mohamed Hassan
Hopital Avicenne, Service Endocrinologie, Rabat, Morocco

Introduction
Thyroid TB is rare even in endemic countries, and diagnosis is often delayed by atypical presentation and clinical latency. Rarely, if ever, does a tumor and infection form in the same thyroid nodule We report the case of a subject who was followed for a hot nodule and who was found to be both thyroid tuberculosis and tumor damage.
Observation
This is a 59 year old patient vaccinated against BCG, with no histrory of pulmonary or extrapulmonary tuberculosis, followed by atrial fibrillation on anticoagulant therapy. Treated for a few months for hyperthyroidism on a toxic hot nodule confirmed by radionuclide imaging. After laboratory euthyroidism was achieved with synthetic antithyroid medicinal products, the patient underwent a total thyroidectomy. The definitive pathological examination had noted epiteloid and gigantocellular follicles with the presence of caseous necrosis, concluding with thyroid tuberculosis; as well as the presence within the same nodule of an oncocyte tumor with a potential of uncertain malignancy. The clinical and paraclinical examination did not reveal any other site of tuberculosis, thus being a primary thyroid disease The patient was placed on anti-bacillary treatment for a period of 6 months
Discussion
The hot nodule, unlike the cold nodule, is generally a benign nodule with a low risk of malignant degeneration, this risk is far from being zero and approved by many authors but the coexistence within the latter of tuberculosis and a tumor is rare, even exceptional. Tuberculosis associated with a thyroid tumor is rare but can be common in immunocompromised patients. In the literature, several cases of a combination of tuberculosis and thyroid tumor have been reported. The causal relationship was demonstrated by a meta-analysis between pulmonary tuberculosis and lung cancer with a 74% risk of progressing to lung cancer after diagnosis of pulmonary tuberculosis. So far no studies have been performed that can demonstrate the same causal relationship for thyroid tuberculosis and neoplastic risk, although the relationship appears to be consistent.

Clinical case: I131 resistant follicular thyroid carcinoma

Gabija Siusaite[1], Beata Kairyte[1], Raimonda Klimaite[1,2,3] & Birute Zilaitiene[1,2,3]
[1]Lithuanian University of Health Sciences, Kaunas, Lithuania, [2]Department of Endocrinology, Hospital of Lithuanian University of Health Sciences, Kauno Klinikos, Kaunas, Lithuania, [3]Institute of Endocrinology, Medical Academy, Lithuanian University of Health Sciences, Kaunas, Lithuania

Introduction
Follicular thyroid carcinoma (FTC) is the second most common thyroid tumor and accounts for about 5-10 % of all thyroid cancers. As FTC often retains the ability to concentrate radioactive iodine (I^{131}), tumor may be responsive to I^{131} therapy. However, about 60-70 % of all metastatic thyroid cancers are resistant to I^{131} and has a poor prognosis with 10-year survival rate of 10 % and the average life expectancy 3-5 years after diagnosis.
Case
A 64-year-old man was admitted to the Hospital of Lithuanian University of Health Sciences Kaunas Clinics for thyroidectomy due to thyroid follicular carcinoma pT3NxMx. Levothyroxine replacement therapy and I^{131} therapy were indicated. Four years later, patient was diagnosed with follicular thyroid carcinoma metastasis to the right III rib and S2-3 vertebra. Surgical treatment and I^{131} therapy were ineffective. After a few years, bone pain intensified, but ultrasonography (US) and computer tomography (CT) denied the possibility of relapse so the treatment with Denosumab was started. One year later, CT revealed a pathological lymph node between the right kidney and v. cava inferior - stereotactic radiation therapy was performed to the pathological lymph node. Patient complained about numbness in the buttocks, anal fissure, neck lump and weight loss.
Diagnostic tests
Chest, abdomen and pelvic organs CT: Pathological lymph node had increased up to 1,6 cm between the right kidney and v. cava inferior. A 6,7 cm solid mass was observed in the sacrum.
Thyroid US
A 2,2 x 1,3 x 2,6 cm of hypoechoic, non-homogeneous tissue with microcalcinates in the post-operative area was observed. There were no pathological lymph nodes in the neck.
Microscopic examination:
Biopsy of sacral solid mass identified follicular thyroid carcinoma metastasis. Fine needle aspiration biopsy of the neck lump revealed Hurthle cell neoplasia.
Treatment
Systemic treatment with Lenvatinib was initiated. A positive effect is observed after V courses of Lenvatinib, sacral and neck tumor masses have decreased. Lenvatinib has caused transient skin lesions and mild gastrointestinal disorders, treatment is continued.
Conclusion
Resistance to I^{131} is usually associated with higher mortality rate so that precise multiple imaging tests of the targeted organs with possible metastasis and molecular testing are important for appropriate management of the disease.

Evaluation and treatment of cardiovascular risk factors in patients with adrenal insufficiency

Anja Wasmuth[1], Iris van de Loo[2], Julia Domberg[3], Catharina Bullmann[4] & Birgit Harbeck[1,4]
[1]University Medical Center Hamburg-Eppendorf, Hamburg, Germany, III. Department of Medicine, Hamburg, Germany, [2]Practice Endocrinology Bremen, Bremen, Germany, [3]Practice Am alten Handelshafen – Internal Medicine, Diabetology und Endokrinology, Leer, Germany, [4]MVZ Amedes Experts, Endocrinology, Hamburg, Germany, Hamburg, Germany

Introduction
Patients with adrenal insufficiency (AI) are known to have a higher cardiovascular risk (CVR) than the normal population. In particular arteriosclerosis, coronary heart disease, arterial hypertension, hyperlipoproteinemia as well as metabolic disturbances contribute to the increased morbidity and mortality. Aim of this study was to evaluate known cardiovascular risk factors as well as the quality of care by the treating physicians.
Material and Methods
To this end a questionnaire evaluating cardiovascular risk factors was handed out to all participating AI patients. In addition, we screened all medical records for CVR factors and documented the treatment initiated. Statistical analysis was performed by SPSS.
Results
In total, 363 AI patients were included in the study. 294 of these patients were found to have one or more cardiovascular risk factors. Although 51 patients suffered from diabetes mellitus, 2/3 still had increased HbA1c values. With respect to hyperlipoproteinemia, only 1/3 of the AI patients reached values in the normal range ($n=31$). 105 patients were diagnosed with arterial hypertension, of these 26 patients still showed increased values in the outpatient setting. The data shows that 51 patients have a diagnosis of Diabetes mellitus and 30 of them still have high HbA1c values. Furthermore, of the 85 patients with hyperlipoproteinemia only 31 have the blood fat in the normal range and 38 still have high values. For 16 not all of the blood fat values existed. Of 105 patients with hypertension, 44 still have a higher blood pressure.
Conclusion
Our study demonstrates (1) the increased CVR risk in patients with AI, leading to increased morbidity and mortality, (2) AI patients are inadequately monitored and

treated for CVR factors, thus having a higher risk of suffering from a cardiovascular event, (3) treating physicians should be aware of this risk to minimize complications where possible

Gitelman syndrome, a rare disease: case report

Teodora Dumitru[1], Cristina Preda[1,2], Andreea Rosu[1], Nada Akad[1], Miruna Anisia[1], Letitia Leustean[1,2] & Maria Christina Ungureanu[1,2]
[1]Emergency University Hospital 'Saint Spiridon', Endocrinology, Iasi, Romania, [2]"Gr. T. Popa" University of Medicine and Pharmacy, Endocrinology, Iasi, Romania

Introduction
Gitelman syndrome(GS) is a salt-wasting tubulopathy characterized by renal potassium wasting, hypokalemia, metabolic alkalosis, hypomagnesemia, hypocalciuria and hyperreninemic hyperaldosteronism. It is caused by the mutation of genes encoding sodium chloride (NCCT) and magnesium transporters in the thiazide-sensitive segments of the distal nephron (SLC12A3 and TRMP6 gene). GS is a rare autosomal recessive disease with a prevalence of only 25 cases per one million population.
Case report
A 23-year-old girl diagnosed with Hashimoto thyroiditis with hypothyroidism, polycystic ovarian syndrome, short stature due to SGA (2000 g at 38 wks, twin pregnancy), treated with recombinant GH during childhood, presented for paresthesias of the hands, nausea, dizziness, and acne. Her clinical features were short stature (T = 154 cm) and low BMI (15.61 kg/mp). The biological assessment revealed persistent hypokalemia ($<$ 2.9 mmol/l), hypomagnesemia ($<$1.34 mg/dl), hypochloremia with a normal sodium and bicarbonate level, normocalcemia (9.13 mg/dl) with hypocalciuria (43 mg/24 h). Hormonal profile: normal thyroid function tests with levothyroxine replacement, hyperreninemic (281 uUI/ml, normal values: 2.8-39), hyperaldosteronism (35.2 ng/dl, normal values 1.76-23.2). The hepatic and renal functions were normal; she was also normoglycemic. The suspicion for Gitelman Syndrome was confirmed by the genetic testing, which showed heterozygosity for SCL12A3 gene mutation. Due to the absence of symptoms, her potassium and magnesium serum levels were not assessed periodically during childhood, and the diagnosis was raised at about 16 years. Her twin sister has average stature and no potassium or magnesium imbalance. Supplementation with oral potassium chloride of two grams per day and oral magnesium chloride 500 mg per day was started but with a slow improvement of biological parameters. Spironolactone treatment does not ameliorate potassium levels as in others hypopotasemia disorders but was mentained due to associated acne.
Discussion
Gitelman syndrome is a condition that may remain asymptomatic or present with mild or nonspecific symptoms. Phenotypic variability and potential severity are also seen in genetically confirmed GS patients, but many patients are not tested, with genetic testing that is not widely available and expensive. The primary differential diagnosis of GS is with Bartter syndrome, especially type III. Treatment is symptomatic and life-long to prevent cardiac arrhythmias and dehydration; it includes supplementation with potassium chloride (with better absorption) and magnesium replacement (organic salts are preferred). Magnesium replacement should be considered first because the repletion of magnesium will facilitate potassium repletion.

Cushing Syndrome Due To Acth-Secreting Pheochromocytoma: A Case Report

Laura Ruiz Arnal, Leire Perez Garcia, Leire Agea Diaz, Maria Vega Blanco, Clara Rosario Fuentes Gomez, Sheila Gonzalez Gonzalez, Aitor Galarza Montes, Octavio Perez Alonso, Leire Garaizabal Azkue & Mikel Gonzalez Fernandez
Araba University Hospital, Gasteiz, Spain

Introduction
The most frequent causes of ACTH-dependent Cushing's syndrome are of pituitary origin and, less frequently, due to ectopic secretion of bronchial carcinoid, small cell lung cancer, and neuroendocrine tumors; it is rarely caused by an ACTH-producing pheochromocytoma.
Methodology
We present a case of a 44-year-old female with a history of poorly controlled type 2 diabetes, hypertension, and long-standing obesity with no genetic predisposition or typical Cushingoid features who was initially admitted due to edema in both legs and hyperglycemic decompensation. On arrival, analysis showed she presented hypokalemia and hyperglycemia, in addition to clinical hypertension that was difficult to control and altered behavior without history of previous psychiatric pathology. After a full-body CT scan incidentally revealed suprarenal damage, we began a radiological study. Adrenal CT scans showed a 4 $\times$ 3.5 cm right adrenal nodule and MR imaging of the pituitary did not reveal an adenoma.
Results
After starting pharmacological treatment with ketoconazole, the subject continued to have severe symptoms of hypercortisolism. Therefore, etomidate was administered to inhibit corticosteroid synthesis, alpha blockade was used in the preoperative preparation, and right adrenalectomy surgery was performed. The anatomic pathology results were intermediate risk, moderately differentiated pheochromocytoma (according to GAPP risk stratification). The patient subsequently evolved favorably, with the high levels of cortisol, ACTH, and metanephrine initially found in her urine decreasing to normal levels.
Conclusions
Although this is an extraordinary case, a full examination must be completed anytime a suprarenal nodule is found, as it may be the result of a ACTH-secreting pheochromocytoma and quick diagnosis and treatment are crucial.

Biochemical tests

Plasma levels	24-h urinary measurement
Basal cortisol 114.6 μg/dl (4.0 - 20.0)	Cortisol excretion 25199 μg/dl (0 – 134)
ACTH 215 μg/dl (7-62)	Normetanephrine 1145 μg/24h (0 – 444)
	Metanephrine 756 μg/24h (0 – 341)
	Epinephrine 32 μg/24h (0-18)
	Norepinephrine 262 μg/24h (0-7)

Pheochromocytoma presenting with multi-system crisis during endoscopic procedure: a case report

Sidelya Ecem Yigit[1], Iffet Beril Gokmen[1], Yildiz Okuturlar[1], Ozlem Celik[2], Fadil Havas[3], Yavuz Bekmezci[4], Erman Aytac[5] & Ali Tekin[6]
[1]Acibadem University School of Medicine, Internal Medicine, Istanbul, Turkey, [2]Acibadem University School of Medicine, Endocrinology and Metabolism Diseases, Istanbul, Turkey, [3]Acibadem University Atakent Hospital, Intensive Care Unit, Istanbul, Turkey, [4]Acibadem University Atakent Hospital, Neurology, Istanbul, Turkey, [5]Acibadem University School of Medicine, General Surgery, Istanbul, Turkey, [6]Acibadem University Atakent Hospital, Urology, Istanbul, Turkey

A 45-year-old female patient with diagnosis of hypertension was admitted to Acibadem University Hospital for colonoscopy due to perianal abscess and rectovaginal fistula. She had been diagnosed with hypertension for 7 years and had been using 3 different classes of antihypertensive drugs. Intermittent hypertensive attacks and hospitalization for myocarditis history was documented. During anesthesia induction for colonoscopy her condition acutely worsened and she became hemodynamically unstable. She developed acute respiratory distress and was transferred to the intensive care unit. On physical examination, she was conscious, tachypneic, hypoxic and had wheezing under 15 lt/min oxygen support. Vital signs were; heart rate:150 bpm, respiratory rate: 32/minute, blood pressure:140/70 mmHg. Bilateral diffuse widespread infiltrates were seen in the chest radiography. Echocardiography demonstrated 30% ejection fraction. Blood gasses analysis revealed severe metabolic acidosis and hypoxia. She was put on non-invasive mechanical ventilation support. Arterial hypoxia persisted hence she was intubated. Due to insufficient response to diuretic therapy and multiorgan dysfunction syndrome she was put on continuous veno-venous hemodiafiltration (CVVHDF) and arteriovenous extracorporeal membrane oxygenation (ECMO) respectively. After 6 days of ECMO support, ejection fraction increased to 40%. Considering her clinical findings being suggestive of pheochromocytoma, radiologic and laboratory tests were ordered. Abdominal computed tomography (CT) revealed an 86x76 mm sized left adrenal mass. Levels of plasma metanephrines (179.5 pg/ml) (reference $<$90 pg/ml) and plasma normetanephrine ($>$4800 pg/ml) (reference $<$200 pg/ml) were determined. Gallium-68 DOTATATE PET/CT imaging revealed increased uptake on the mass (SUVmax: 43). Preoperative antihypertensive preparation was done with doxazosin and metoprolol. Then she underwent left adrenalectomy, splenectomy, left nephrectomy and cholecystectomy. Postoperative pathology confirmed diagnosis of pheochromocytoma. During weaning from mechanical ventilation, it was discovered that she developed polyneuropathy. EMG results were compatible with critical illness neuro-myopathy. Intravenous immunoglobulin (IVIG) therapy for 5 days was given. Plasma metanephrine levels returned to normal level post-operative 2 weeks later and she didn't need any antihypertensive drugs.

The patient was subsequently discharged, and has remained stable 1st year follow-up.

Abdominal extraadrenal paraganglioma: review of the literature and report of 3 cases

Maria Jose Vallejo Herrera[1], Veronica Vallejo Herrera[2], María Cruz Almaraz Almaraz[1] & Felix Serrano Puche[2]
[1]Hospital Regional De Malaga, Endocrinology, Malaga, Spain, [2]Hospital Regional De Malaga, Radiology, Malaga, Spain

Extraadrenal paraganglioma is a rare tumor. The clinical and pathological findings of patients with abdominal localization paragangliomas (perihepatic, paraaortic, interaortocaval and retroperitoneal) are described. Its characteristics and diagnostic imaging are analyzed, as well as its therapeutic management. Between January 2021 and January 2022, 3 patients with extra-adrenal paragangliomas were diagnosed, all of them women. The age of our patients was 26, 57 and 67 years. The location of these tumors was at the para-aortic, inter-aortocaval, retrocaval and perihepatic level; one of the cases also presented cervical paragangliomas, with a size of the lesions ranging from 13 to 30 mm. We reviewed the clinical data. In all cases, the paragangliomas were detected as an incidental finding in imaging tests performed for another reason, although re-examining the predominant symptoms were tinnitus, sweating, tremor and headache, only one of the cases presenting hypertensive crises. One patient presented with concomitant bilateral adrenal hyperplasia/adenomas, with incomplete dexamethasone braking, but with normal ACTH and cortisol, probable hypercortisolism (Cushing's syndrome). Metanephrine levels in 24-hour urine and catecholamines in blood were estimated in all cases, with elevated levels in one of the cases (coinciding with the hypertensive patient), with normal levels in the rest. The lesions were initially detected by computed tomography and a study was completed with 113I-MIBG scintigraphy and DOPA PET-CT in all of them. In addition, a genetic study was requested in all patients (kif-1b, MAX, NF1, PRKAR1A, RET, SDHA, Af2,B,C,D, TME127, VHL) with negative results. All cases were evaluated by Endocrinology, with a prescription of premedication with Doxazocin prior to surgery. All but one patient underwent surgical treatment. The case associated with carotid glomus is pending evaluation by surgery for excision. The preoperative diagnosis of non-functioning abdominal paragangliomas is difficult, although they should be suspected in patients with hypertension or compatible symptoms. The 3 reported cases were found in the usual locations: paraaortic, interaortocaval, retrocaval, and perihepatic. All the patients except one had multiple tumors at the abdominal level, in addition to carotid glomus in one of the cases. Resection is the treatment of choice with prior initiation of alpha-blocker medication. These patients should follow a multi-disciplinary approach.

Primary adrenal lymphomas, a race against time

Oumayma Zarrouk, Sana Abid, Yassmine Abdelkafi, Ines Bayar, Ekram Hajji, Bilel Ben Amor, Hanene Sayadi, Héla Marmouch & Inès Khochteli
University Hospital of Monastir, Endocrinology and Internal Medicine Department, Monastir, Tunisia

Introduction
Primary adrenal lymphomas (PAL) are extremely rare and constitute 0.5% of all adrenal tumors. The number of cases described is approximately 70 cases [1] and It is bilaterally manifested in approximately 70% of cases [2]. The diagnosis is made on histological features, as there is no specific symptoms. Treatement is based on chemotherapy and prognosis is usually poor. We report two cases of bilateral PAL.
Cases
First case: A 63-year-old woman, admitted for exploration of a bilateral adrenal mass discovered on CT-Scan requested after a 3 week history of asthenia, weight loss, vomiting and abdominal pain. Her medical history comprised hypertension and and stroke. Clinical examination revealed no signs of hypersecretion. Biology showed elevated lactate deshydrogenase(362 UI/l) and β-2 microglobulin levels (4.97 mg/l). On imaging, there was large adrenal masses measuring 7 cm on the right and 9 cm on the left side with 32UH of spontaneous density and signs of vascular infiltration. CT-guided biopsy concluded on diffuse large B-cell lymphoma. Chemotherapy treatment was decided, unfortunately, the patient died before starting treatement.
Second case
A 52-year-old man, with a medical history of diabetes mellitus, was admitted for exploration of a deterioration of general condition. Adrenal insufficiency was confirmed by low cortisol level and required hydrocortisone replacement therapy. β-2 microglobulin level was elevated (3.34 mg/l). Abdominal CT-scan revealed 2 adrenal masses measuring 7 cm on the right and 3 cm on the left side with a spontaneous density of 35UH infiltrating the stomach greater curvature, the pancreas tail and The upper pole of the left spleen. The biopsy had shown a Diffuse large B-cell lymphoma. Chemotherapy was decided and patient is still receiving courses.
Conclusion
The prognosis of PAL is usually poor, it grows progressively throughout the adrenal glands. Thus early diagnosis and treatment is the key to saving patients.

A case of Primary pigmented nodular adrenocortical disease in a young woman with arterial hypertension

Valentina Morelli[1], Vittoria Favero[2], Irene Campi[3], Fabiana Guizzardi[2], Carmen Aresta[4] & Luca Persani[3]
[1]Istituto Auxologico Italiano, IRCCS, Unit for Bone Metabolism Diseases and Diabetes, Milan, Italy, [2]Department of Biotechnology and Translational Medicine, University of Milan, Milan, Italy, [3]Department of Endocrine and Metabolic Diseases & Lab of Endocrine and Metabolic Research, IRCCS, Istituto Auxologico Italiano, Italy

Primary pigmented nodular adrenocortical disease (PPNAD) is a rare form of ACTH-independent Cushing's syndrome (CS). Approximately 30% of patients with PPNAD are sporadic cases and the other are familial. We describe a case of a patient affected by PPNAD presenting with isolated arterial hypertension. A 19-year-old black female patient was referred to the Endocrinology Unit in september-2021 due to severe arterial hypertension and fatigue. Previous clinical history was unremarkable and physical examination did not reveal typical signs of hypercortisolism. The echocardiogram revealed mild cardiac hypertrophy and antihypertensive treatment was started, but the subsequent laboratory tests revealed: normal potassium levels, increased midnight salivary cortisol levels (MSC 10-8.9-10.1 nmol/l n.v. <2.8), increased cortisol levels after both 1 mg and 8 mg dexamethasone suppression test (15 mg/dl, 20.1 mg/dl respectively), low plasma ACTH levels (1.5 ng/l; n.v.: 8-50) and increased urinary free cortisol excretion (81.5 mg/24h n.v. <43), with aldosterone and renin levels within normal ranges. Computed tomography (december-2021), showed a slight enlargement of the left adrenal gland with a 8 mm nodule however, adrenal scintigraphy documented the presence of a bilateral (131)I-norcholesterol, uptake. ACTH-independent CS was diagnosed and treatment with metyrapone was started (750 mg) in order to achieve disease control before surgery. Unfortunately, after a few weeks, the patient complained hypoadrenal symptoms as abdominal pain, nausea, and fatigue worsening even in the presence of normal morning cortisol levels, and the treatment was discontinued. The patient underwent left-sided laparoscopic adrenalectomy (october-2022). Histopathological examination confirmed typical features of PPNAD (multiple cortical solid black nodules of 0.4–2.5 mm). Perioperative hydrocortisone therapy was performed and replacement treatment with cortisone acetate was started before hospital discharge. At the last visit, three months after surgery, adrenal insufficiency was confirmed (morning basal cortisol 8 mg/dl with cortisol peak after Synacthen test 12 mg/dl), ACTH levels were still suppressed, and so were androgens and MSC (1.3 nmol/l). However, blood pressure control was still scarce and antihypertensive treatment was maintained. An extensive follow-up has been scheduled due to the high risk of recurrence. Genetic testing revealed a rare heterozygous missense PDE8B germline mutation, c.219G>C (p.Glu73Asp), inherited from her father who is normotensive and presents normal cortisol levels after 1 mg dexamethasone suppression test.

EP1086

Hyponatremia and its prevalence in the outpatient setting

Vanessa Messer[1], Denise Köster[2] & Birgit Harbeck[3]
[1]University Hamburg-Eppendorf, Hamburg-Eppendorf, Germany, [2]Institute of Medical Biometry and Epidemiology, University Medical Center

Hamburg-Eppendorf, Hamburg-Eppendorf, Germany, [3]Department of Medicine III., University of Hamburg, Hamburg-Eppendorf, Germany

Introduction
Hyponatremia is the most common electrolyte disorder and it affects approximately 5% of adults and 35% of hospitalized patients. Diagnostic and/or therapeutic challenge is given. It is defined by a serum sodium concentration of less than 136 mmol/l. Symptoms of hyponatremia range from mild and nonspecific to severe and life-threatening. Hyponatremia is classified as mild, moderate and severe and may be acute or chronic. Mortality and morbidity are significantly increased in patients with hyponatremia.
Material and Methods
About 46.700 medical records between Augusts 2012 and 2022 were screened in an outpatient endocrine department. In 136 cases hyponatremia was found with an overall prevalence of 0.3%. Due to missing data, 40 patients had to be excluded from statistical analysis. Patients were analyzed with respect to age, sex, BMI, pre-existing conditions, medication, type and degree of hyponatremia and random finding of hyponatremia. Symptoms, therapy and serum sodium levels before and after treatment were assessed. To evaluate the prevalence of hyponatremia in the outpatient setting and identify specific risk factors.
Results
Females (79.2%) were more affected than males. Afflicted patients had a mean age of 71 years. With respect to severity, 19.7 % of patients had mild, 43.9% moderate and 36.4% severe hyponatremia. 97% of patients complained symptoms like nausea, vomiting, fatigue and dizziness. 59.1% of patients were diagnosed with SIADH with 6.1% also having a post op SIADH. In 25.8% cases the origin could not be clarified in the course of the disease. Hypervolemic or hypovolemic hyponatremia was found in 9% of the patients. Regarding known risk factors such as diuretic use, previous cardiological disease or nephrological preconditions we found no notable differences compared to patients without hyponatremia. Although women are more likely to develop hyponatremia, gender did not seem to play a role in the severity of the disease. The presence of incidental finding probably had an influence on the degree of hyponatremia. Conventional treatment (drinking restriction, adaptation of the medication schedule, modification of diuretics and/or tolvaptan therapy) led to a meaningful improvement in 74% of patients.
Conclusion
The number of outpatient cases was noticeably lower than the average number of hospitalized patients. However, in almost 25% of the affected patients, the origin could not be found. Guidelines and therapies used in the hospital also showed a noticeable improvement in this patient group. We hypothesize, that quick treatment may reduce the mortality and morbidity of outpatients.

EP1087

Unusual case of iatrogenic adrenal insufficiency related to corticosteroid eye drop usage

Manjusha Rathi
Sandwell and West Birmingham Hospital, Endocrinology, Birmingham, United Kingdom

Corticosteroids have been widely used within the management of wide spectrum of conditions. It is well known that long-term use of exogenous glucocorticoids leads to the suppression of the hypothalamic– pituitary–adrenal axis. Even a 5-day course of oral high-dose steroid therapy can cause adrenal suppression. Similarly, high-dose steroid therapy - administered intranasally, inhaled or applied topically to skin can cause adrenal suppression. Depending on administration form, the percentage of patients with adrenal insufficiency varied from 52.2% for intra-articular corticosteroids to 4.2% for nasal corticosteroids. Hence topical route is preferred over oral or parenteral route and administered for shortest possible duration. It is extremely unusual to develop adrenal insufficiency with corticosteroid eye drop usage. In fact, a study specifically designed to establish whether hypothalamic-pituitary-adrenal axis suppression is possible secondary to long-term topical ophthalmic corticosteroid use in patients undergone penetrating keratoplasty (PKP) found no evidence that using continuous long-term corticosteroid eye drops after PKP experienced adrenal suppression. I present a young boy, born with Bilateral Peter's anomaly, a condition is characterized by central, paracentral, or complete corneal opacity as well as Bilateral congenital glaucoma. He was treated glaucoma tube implant surgery, Bilateral penetrating keratoplasties (full thickness corneal transplants) followed by Dexamethasone 0.1% eye drops twice a day to prevent rejection. By age 9 yrs, he displayed Cushingoid features and possibility of adrenal insufficiency was raised. Hence dexamethasone eye drops were withheld for 1 week. In the interim, Parents were educated regarding possibility of developing adrenal crisis and provided with emergency hydrocortisone supply. One week later, short synacthen test was arranged which revealed Serum Cortisol of < 10 nmol/l at at 0,30 and 60 minutes. His ACTH $<$ 5 (ref 7.2 – 63.3 ng/l) and Adrenal Antibody was negative. Since then further assessment of hypothalamic–pituitary–adrenal axis have consistently revealed complete adrenal suppression. He continues to require dexamethasone eyes drops to treat his ophthalmic condition and is treated with hydrocortisone replacement therapy to treat his adrenal insufficiency.
Learning points
• Long-term use of glucocorticoids leads to the suppression of the hypothalamic–pituitary–adrenal axis which is known as glucocorticoid-induced or iatrogenic adrenal insufficiency.
• Possibility of iatrogenic Adrenal insufficiency should be considered in the differential diagnosis in all patients receiving long term corticosteroid therapy in any form. A thorough clinical as well medication history is of paramount importance in suspecting as well as arriving at the correct diagnosis.

EP1088

Unconventional 21 hydroxylase block revealed by high blood pressure : about a case

Malak Riznat, Mohamed Malad, Hajar Srifi & Guerboub Ahmed Anas
Mohamed V Military Training Hospital, Rabat, Morocco

Introduction
Enzyme block is a rare disorder that can be discovered at birth by a severe, life-threatening disorder or in a more attenuated form in adulthood by a clinical picture of hyperandrogenism most often. The enzyme block most commonly suspected in high blood pressure is 11 B OH blockWe report the case of a young patient who was diagnosed with 21 hydroxylase enzyme block by secondary hypertension testing.
Observation
This is a 32 year old patient without any notion of familial hypertension or salt loss syndrome in the family, followed for hypertension for 8 years, i.e the age of 24 years on dual therapy and whose evolution was marked by hypokalaemia motivating an exploration in the sens of secondary high blood pressure. Endoctrine investigations revealed an adrenal mass of 3.5 cm, density >10 and a wach or relative 34% and without associated hyperplasia. The secretary balance related to the dosage of FLU, DOC, SDHA, SRAA as well as the DM strictly normal income. In addition, the patient is monitored for primary infertility with the use of IVF without conclusive results and in whom the examination does not find any manifest clinical biological androgenism. In this sense, the dosage of 17progestogen hydroxy is raised to 8 ng/ml as well as del4A raised to 1.6 ng/ml thus diagnosing late 21 hydroxylase enzyme block.
Discussion
21 hydroxylase block is the most common form and accounts for 80% of enzyme blocks, and diagnosis is usually made by measuring 17 progestogen hydroxy in the morning in the follicular phase with the progestogen test for amenorrhea. A value greather than 5 ng/ml makes it possible to make the diagnosis, which can be confirmed by the synacthene test with a valur required at 10 ng/ml in order to be able to confirm the latter. Treatment is with frenzator doses of hydrocortisone.
Conclusion
Late 21 hydroxylase enzyme block may be found in the less suggestive table, but should always be considered in the presence of primary or secondary infertility even in the absence of hyperandrogenism.

Influence of muscle mass and strength on bone mineralization with consideration of sclerostin concentration

Martyna Patalong-Wójcik, Elżbieta Sowińska-Przepiera, Kinga Malczyk-Matysiak, Aleksandra Myszka, Agnieszka Janiec & Anhelli Syrenicz
Pomeranian Medical University, Department of Endocrinology, Metabolic Diseases and Internal Diseases, Szczecin, Poland

Introduction
Osteoporosis is a disease characterized by a decreased bone strength, as a result of increased bone porosity and impaired mineralization. According to the mechanostat theory, loads generated by the muscle mass and muscle strength, stimulate bone reconstruction.
Aim of the study
In our study, we investigated whether muscle strength and mass exert a significant effect on bone mineral density in young adult women. We also tested whether sclerostin concentration can be used as an indicator in the assessment of bone mineralization.

Methods
The study included 111 patients with transient menstrual disorders, in whom organic causes were excluded. The subjects had their anthropometric measurements taken, along with a laboratory analysis of hormonal status. Metabolic activity of osteocytes was assessed by serum sclerostin concentration, using an enzyme-linked immunosorbent assay (ELISA). Whole body and lumbar spine bone mineral density (BMD) as well as body composition (fat mass- FM, lean body mass – LBM, visceral fat -VF) were assessed by dual-energy X-ray absorptiometry (DXA). Muscle strength was assessed by measuring handgrip strength using a hand dynamometer.
Results
There was a significant positive correlation of left and right handgrip strength and all parameters expressing bone mineralization. Lumbar spine (L1-L4) BMD was also positively associated with the body mass components: fat mass, lean body mass and their ratio (FLR). In contrast, sclerostin levels in this study did not differ between groups with normal and reduced bone mineral density.
Conclusions
Assessment of muscle strength may be an indicator of decreased bone mineral density in young adult women. However, the utility of sclerostin in the clinical assessment of bone mineralization has not been demonstrated.

Systematic review of cardiovascular morbidity and mortality associated with primary hyperparathyroidism; does early surgical intervention improve the outcome?

Fatima Azad[1] & Muhammad Siddique Arif[2]
[1]Portsmouth Hospitals University NHS Trust, United Kingdom, [2]University Hospital Sussex, Chichester, United Kingdom

Introduction
Primary hyperparathyroidism is associated with numerous cardiovascular complications including hypertension, left ventricular hypertrophy and calcification of cardiac valves. However, guidelines from expert panels and NICE have not included cardiovascular complications as an indication of parathyroidectomy. This literature review will be focused on benefits of parathyroidectomy on cardiovascular complications of primary hyperparathyroidism.
Methodology
Literature search done through use of search engines goggle scholar, PubMed, Cochrane database, Medline and EmBase using PRISMA model. Initial database search revealed 79 studies. After applying exclusion and inclusion criterion, 43 studies were finalized for systemic review.
Results
Amongst the cardiovascular complications of 1HPT hypertension and LVH are most investigated in literature and evidence is relatively strong for hypertension and LVH compared to other cardiovascular complications. Evidence is relatively weak for coronary artery disease, serum lipid profile, endothelial vasodilatory dysfunction, calcification of cardiac valves, occurrence of cardiovascular events and cardiovascular mortality.
Conclusion
Although evidence for beneficial effects of parathyroidectomy on HTN and LVH is relatively strong, lack of well-designed multicenter randomized control trial seems to be the main obstacle for inclusion of this as part of parathyroidectomy criterion. However, there is a rationale on basis of evidence available to include Hypertension and LVH as possible indications. Consideration should be given for inclusion of echocardiogram at baseline and follow up of 1HPT patients managed conservatively.

Surgical treatment for Primary hyperparathyroidism in ederly patient

Yolanda Zambrano Huerta, Maria Elena Jerez Arzola & Ricardo Moya Medina
Molina Orosa Hospital, Endocrinology and Nutrition, Arrecife, Spain

Introduction
Primary hyperparathyroidism (PHPT) is the third most common endocrine disease, the incidence is greater in women (ratio 3-4:1) and the prevalence increases with age (1). Surgery is the only curative treatment and usually in elderly patients there is a delay or are not considered for parathyroidectomy due to perceived high operative risk or postoperative complications (2)
Clinical Case
A 84 year-old female patient was under treatment with Cinacalcet since the diagnosis of PHPT four years ago, at the beginning she was not considered for surgery due to her age and comorbidities (kidney disease, prefrailty stage). In the last year patient suffered a worsening of cognitive decline, affecting medication compliance and water intake, being admitted at the hospital with hypercalcemia of 16 mg/dl with neurological and kidney function impairment, after the administration of intravenous hydration, zoledronic acid and calcitonin, calcium levels went to normal. Surgery was done after outweigh benefits over the risks. The ultrasound and scintigraphy localized the parathyroid adenoma superior to the right thyroid lobe, intraoperative PTH levels decreased in more than 50% resulting in normal PTH and calcium levels, and the anatomy pathology confirmed adenoma. Although the patient was able to get discharged she had prolonged stay in hospital as consequence of nosocomial pneumonia and urinary tract infection.
Conclusion
Albeit there is risk for any procedure and an inverse association for parathyroidectomy in older patients (3), data have shown that surgery is safe in the elderly, improves the symptoms and quality of life (4). So surgery should not be ruled out as complications can come from that decision particularly in a patient with no adherence to medical treatment and improvement was not expected without parathyroidectomy.

EP1092

Parathyroid Carcinoma – an uncommon endocrine malignancy

Olivia Jones, Parez Namiq & Sing Sim
Royal Sussex County Hospital, Brighton, United Kingdom

Case history
A 62-year-old male presented with generalised weakness, decreased oral intake, increased lethargy and polydipsia. He had a background of type 2 diabetes, hypercholesterolemia, and was a heavy smoker. No family history of parathyroid disease, other disorders causing hypercalcaemia or other endocrine tumours.
Investigations
Initial blood results showed severe hypercalcaemia adjusted calcium 3.87mmol/l (2.2 - 2.55mmol/l), significantly raised PTH 61.8pmol/l (1.6 - 6.9pmol/l), normal serum phosphate, normal renal function with vitamin D of 77nmol/l He had not reported previous fractures or history of renal calculi. Localisation studies with neck ultrasound did not localise a parathyroid adenoma but showed a left thyroid spongiform nodule (U2). Subsequent Technetium99m (99mTc)-sestaMIBI-99 scan demonstrated a functional parathyroid adenoma in the upper left part of the thyroid.

Results and treatment
Due to multiple episodes of severe hypercalcaemia, he required frequent hospital admissions for intravenous fluids and intravenous bisphosphonates. He was temporarily started on Cinacalcet which was uptitrated to 90 mg four times daily to manage his hypercalcaemia whilst awaiting definitive management. Two months following his initial presentation he underwent parathyroid surgery, due to suspicion of carcinoma intra-operatively, he underwent a hemithyroidectomy. Histology report confirmed a 30 mm parathyroid carcinoma, GATA3 positive. Proliferation index indicated by MIB1 was less than 5% with no infiltration into the thyroid, or local lymph nodes. There was no evidence of metastasis on subsequent CT scan of chest, abdomen and pelvis. PTH and calcium normalised with no hypocalcaemia post operatively and resolution of initial presenting symptoms.
Conclusion:
Parathyroid carcinoma is an extremely rare disease accounting for less than 1% of primary hyperparathyroidism. This case demonstrates the challenge of pre-operative diagnosis due to the difficulty in distinguishing from benign disease, owing to the absence of reliable diagnostic criteria and initial presentation can be similar. It is essential to consider the diagnosis of parathyroid carcinoma in cases of severe hypercalcaemia with marked rise in PTH (often over 5 times the upper limit of the normal range). Unlike benign causes of hyperparathyroidism, parathyroid carcinoma has an equal prevalence in males and females, with a lower average age of diagnosis and is more likely to have concomitant renal and skeletal involvement. Most cases are sporadic however rarely it can occur in those with familial hyperparathyroidism. Further elucidation of the molecular pathogenesis of parathyroid carcinomas will enhance our understanding of this rare entity

EP1093

Spontaneous remission of primary hyperparathyroidism postpartum

Apostolia Lamprinou, Damianos Tsitlakidis & Rainer Gutekunst
Endokrinologikum Stuttgart, Endocrinology, Stuttgart, Germany

Introduction
Primary hyperparathyroidism is a disorder, characterized by autonomous overproduction of parathormone resulting in hypercalcemia. The main cause is a parathyroid adenoma. Less common etiologies are parathyroid hyperplasia and carcinoma. Primary hyperparathyroidism during pregnancy is rare and the management could be challenging. Maternal and fetal/neonatal complications occur in more than 50% of the cases.
Patient
We report about a 38-year-old female, who was referred with hypercalcemia for further evaluation. The patient suffered from rheumatoid arthritis treated with prednisolone 2.5 mg/d. She reported no symptoms. Parathormone 12.1 pmol/l (1.6-6.9), albumin adjusted calcium (AAC) 2.59 mmol/l (2.1-2.55), phosphate 0.87 mmol/l (0.8-1.45), calciuria 9.7 mmol/d ($<$6.2), 25-OH-Vitamin D3 46.8 nmol/l (50-150) and 1.25-OH Vitamin D3 207 pmol/l (47.8-190) showed primary hyperparathyroidism. Ultrasound revealed no enlarged glands. Pregnancy occurred while under investigation. During pregnancy ACC remained stable at 2.7 mmol/l and parathormone at the upper normal range by 6.7 pmol/l. Repeated neck ultrasound during the second trimester was non diagnostic. No maternal or fetal complications occurred. Labor started spontaneous at 43 weeks. One month postpartum the biochemical markers were normalized. Six months after delivery secondary hyperparathyroidism due to vitamin D deficiency was shown.
Conclusion
Spontaneous resolution of primary hyperparathyroidism is rare, but is reported after infarction or hemorrhage of small parathyroid adenomas.

Introduction
Diabetic foot infection imposes a significant burden and is a major cause of non-traumatic limb amputation. Antibiotic therapy plays a crucial role in the management these patients. In our institution, empirical antibiotic therapy is tailored to the presence of risk factors for multidrug-resistant microorganisms. For patients without risk factors, empirical intravenous amoxicillin-clavulanate at a dose 2.2 g every 8h is used. For patients with risk factors such as previous hospitalization or antibiotic therapy in the last 3 months, or hemodialysis, empirical intravenous vancomycin and piperacillin-tazobactam (P/T) at a dose of 4.5 g every 6 hours is recommended.
Objective
To assess the adequacy of empirical antibiotic therapy recommended in our protocol in relation to microbial isolates.
Methods
We conducted a retrospective cohort study that included patients who were hospitalized for neuropathic diabetic foot infection on a tertiary refferal hospital between January 2020 and December 2022. Tissue specimens (biopsy or aspiration of purulent exudate) were aseptically collected from the ulcer for culture. Demographic, clinical, and microbiological data were collected.
Results
Fifty-one patients were enrolled in this cohort, 69% of whom were male, with a mean age of 58.9 ± 11.9 years, and 73% of whom had type 2 diabetes mellitus. Two-thirds of cases were classified as PEDIS 3, and one-third as PEDIS 4. Sixty-one percent of patients had risk factors for multidrug-resistance. A total of 108 microorganisms were identified (an average of 2.7 pathogens per patient). *S. aureus* was the most frequently identified pathogen (20%), and *P. aeruginosa* was the most frequent Gram-negative bacteria (10%). Fourteen percent of S. aureus and 58% of coagulase-negative *Staphylococcus* were methicillin-resistant, and 35% of *Enterobacterales* were resistant to P/T. All *P. aeruginosa* were sensitive to P/T. Overall, by applying our treatment guidelines, antibiotic coverage of the identified pathogens was achieved in 75% of cases (84% in patients with risk factors, and 60% in patients without risk factors
Conclusion
Not initiating broad-spectrum antibiotic therapy in all cases reduces the risk of antibiotic resistance emergence (at the possible expense of a lower percentage of initial empirical coverage in patients without risk factors for multirrestance). To avoid compromising patient outcomes, it is essential to collect samples for culture as early as possible. Our study highlights the high adequacy of empirical antibiotic therapy protocols that take into consideration risk factors for multidrug-resistant microorganisms, which ultimately improves the outcomes of these patients.

Subtypes of gestational diabetes based on indices of insulin sensitivity and insulin secretion

Andrea Fernández Valero[1], Teresa María Linares Pineda[1], Fuensanta Lima Rubio[1], Maria Molina Vega[1], Carolina Gutierrez Repiso[1], Nerea Peña Montero[1], María Suárez Arana[2], Ana María Fernández Ramos[1], Francisco J Tinahones[1], María José Picón César[1] & Sonsoles Morcilo[1]

[1]Hospital Virgen de la Victoria, Endocrinology and Nutrition, Málaga, Spain, [2]Hospital Regional Universitario de Málaga, Ginecology and Obstetrics, Málaga, Spain

Objectives
Some authors have defined subtypes within gestational diabetes (GD) based on the calculation, from glucose and insulin levels during oral glucose overload (OGTT), of indices of insulin sensitivity (Matsuda) and insulin secretion (Stumvoll). Powe *et al* [1] found that 30% of women with GD had predominantly low insulin secretion, 51% low insulin sensitivity and 18% both (mixed). The aim of this work is to analyze the correlation of these indices with other known parameters of insulin sensitivity and insulin secretion and the definition of GD subtypes in our population.
Material and Methods
We calculated the Matsuda and Stumvoll indices (at 120 minutes), from the data of 68 100 g OGTT for the diagnosis of GD (both basal, 1-hour, 2-hour and 3-hour glucose and insulin were determined) and correlated them with HOMA and C-peptide. Based on the 25th percentile of these indices in the non-GD population, we established cut-off points and defined the 29 GD patients as having predominantly low insulin sensitivity (Matsuda < 25th percentile), predominantly low insulin secretion (Stumvoll < 25th percentile), both, or neither.
Results
We found that both the Matsuda and Stumvoll indices correlated significantly inversely with HOMA and C-peptide, as well as with each other directly, both in the general population and in women with GD (Table 1).
Conclusion
Both the Stumvoll index and, mainly, the Matsuda index correlate well with HOMA, which is more widely used and easier to calculate. Contrary to that previously described by Powe *et al* [1], in our population the mixed GD group predominates, with a similar percentage of women with a predominance of low insulin secretion and a much lower percentage with a predominance of low insulin sensitivity.
1. Powe CE, Allard C, Battista MC, Doyon M, Bouchard L, Ecker JL, Perron P, Florez JC, Thadhani R, Hivert MF. Heterogeneous Contribution of Insulin Sensitivity and Secretion Defects to Gestational Diabetes Mellitus. Diabetes Care. 2016 Jun;39(6):1052-5. doi:10.2337/dc15-2672.

Table 1 Regarding GD subtypes, 3.4% presented predominance of low insulin sensitivity, 34.5% predominance of low insulin secretion, 41.4% both and 20.7% neither of them.

General population	HOMA	C-peptide	Stumvoll
Matsuda	r= -0.635 (P< 0.001)	r= -0.674 (P< 0.001)	r= 0.308 (P=0.011)
Stumvoll	r= -0.504 (P< 0.001)	r= -0.361 (P=0.003)	
GD	HOMA	Péptido C	Stumvoll
Matsuda	r= -0.689 (P< 0.001)	r= -0.793 (P< 0.001)	r= 0.472 (P=0.010)
Stumvoll	r= -0.544 (P=0.002)	r= -0.382 (P=0.041)

Action of Ro 60-0175, 5-HT2C receptor agonist in the central nervous system, in obese and diabetic Wistar rat

Ivaylo Bogomilov[1], Vesela Mihneva[2], Rumen Nikolov[1] & Nadka Boyadjieva[1]
[1]Medical University of Sofia, Sofia, Bulgaria, Sofia, Bulgaria, [2]Military Medical Academy Sofia, Sofia, Bulgaria

Background and AIMS
Obesity can be caused because of reduction in energy expenditure and /or increased caloric intake. Total calorie intake has increased in recent decades, and research and studies on eating behaviour have reported increased intake of foods rich in fats and sugars. Excess calories alone increase body weight and reduce insulin sensitivity, even in healthy individuals who are not obese. In addition, increased consumption of sugars and fats is associated with weight gain and the development of insulin resistance in humans. Many regulatory pathways for food intake, including those that use serotonin as a neurotransmitter, are affected by obesity or by hypercaloric diets leading to obesity. Summarizing the data known so far, it can be said that reduced serotonergic signalling and low availability of SERT are associated with hyperphagia and obesity. Because of these facts, it is important to know how brain serotonin mediation affects food behaviour.
Materials-Methods
Ro 60-0175 is a novel 5-hydroxytryptamine (HT)(2C) (serotonin) central receptor-selective agonist that we used in our study. We used forty Wistar rats separated in 2 groups- rats with obesity and diabetes and healthy rats (control group). Each of these groups was separated in other 2 - one with a daily intraperitoneal injection (i.p.) of Ro 60-0175 (for 1 mg/kg increasing till 3 mg/kg per day) and one without. In 4 weeks period, we were tracking blood glucose levels, insulin secretion and rats' weight.
Results
It was shown that after the application of Ro60-0175, the weight of the rats in the diabetic and obese group decreased by 5.5% (P< 0.05), and by 2.56% in the control group and no significant dynamic in the groups without daily intraperitoneal injection of Ro60-0175. In the diabetic and obese rats group in which Ro60-0175 was applied, we registered a reduction of hyperglycemia by 35.4% (P< 0.05) comparing the results before the start of using Ro60-0175, which is greater in the rats which reduce more body weight. The research also shows decreasing of insulin resistance by 42.1 % (P< 0.01) in diabetic and obese rats group using Ro60-0175.
Conclusion
Using Ro 60-0175 for the treatment of obesity and obesity-induced diabetes in male Wistar rats, Ro 60-0175 significantly reduces body weight hyperglycemia and peripheral insulin resistance. In the study was registered reducing of body weight not only in the obese and diabetic rats group but also in the control group

EP1098

Assessment of the impact of glycemic variability on the duration of the perioperative period in patients with diabetes mellitus and purulent infection of the maxillofacial region

Tatiana Meleshkevich[1], Evgeniya Luchina[2], Ata Orazvaliev[3], Alexander Ametov[4], Irina Kurnikova[1], Marina Shevchenko[1] & Iuliia Verzina[1]
[1]RUDN University, Endocrinology, Moscow, Russia, [2]GBUZ «City Clinical Hospital. F.I. Inozemtsev » DZM, Endocrinology, Moscow, Russia, [3]Federal State Budgetary Educational Institution of Further Professional Education, «Russian Medical Academy of Continuous Professional Education», Department of Purulent Maxillofacial Surgery, Moscow, Russia, [4]Federal State Budgetary Educational Institution of Further Professional Education, «Russian Medical Academy of Continuous Professional Education», Endocrinology, Moscow, Russia

Patients with diabetes mellitus (DM) are more likely to suffer from purulent infection, probably due to compromised immune response. Achieving target levels of glycemia is a prerequisite for the perioperative management of patients with DM. However, the specific parameters of glycemic variability, optimal glucose range for the effective treatment of purulent infection of the maxillofacial region have not been established yet.
Purpose
to assess the impact of compensation of DM on the perioperative period, the duration of hospitalization in patients with DM and purulent infection of the maxillofacial region.
Materials and methods
528 patients with DM were examined while undergoing surgical treatment from moderate purulent infection of the maxillofacial region (determined by the severity of intoxication, the extent of the lesion) for 2019-2022: with an average age of 62 ± 36 (men -245, women -283); duration of DM from 0 to 31 years. Conducted: assessment of the impact of various glycemic parameters on the hospital stay, the perioperative period.
Results
Upon admission, the level of prandial glycemia was 11.03 ± 5.79 mmol/l; postprandial glycemia - 14.37 ± 6.01 mmol/l, glycemic fluctuations throughout the day 3.54 ± 2.88 mmol/l. After correction of glucose-lowering therapy, prandial glycemia decreased to 8.46 ± 4.33; postprandial decreased up to 11.33 ± 4.57, while glycemic fluctuations during the day were 3.94 ± 2.98. Statistical data processing revealed that the level of post-prandial glycemia during the day has a maximum impact (19%) on the duration of hospital stay. The calculated model is U = 1.5X-8, where U - the days of hospitalization, x- the maximum level of glycemia, (P < 0.001). An increase in maximal postprandial glycemia by 1.0 mmol/l prolonges hospital stay by 1,5 days. The prandial levels of glycemia also effect the length of hospital stay by 10% (r2-0.10). Estimated model of days of hospitalization: U = 17-0.6X, where U- the days of hospitalization, x- level of fasting glycemia, the model is calculated with an accuracy of 95%. If maximum level of glycemia during the day is less than 12 mmol/l, the recovery time decreases up to 10 days.
Conclusions
1) The highest level of glycemia during the day is the most significant parameter affecting the perioperative period. 2) The optimal level of postprandial glycemia throughout the day should be less than 12 mmol/l in patients with DM and purulent

infection of the maxillofacial region undergoing surgical treatment. 3) When the level of postprandial glycemia increases by 1 mmol/l, the number of days of hospitalization increases by 1.5.

EP1099

Associations of Pparg Gene Polymorphic Marker with Carbohydrate Metabolism in Patients with Prediabetes

Dilara Isakova, Sergey Kolomeychuk, Irina Troshina & Ivan Petrov
Tyumen State Medical University, Tyumen, Russia

Purpose
To study the frequency of polymorphic alleles and genotypes of the PPARG (rs 1801282) gene and its effect on carbohydrate and lipid metabolism in patients with prediabetes.
Materials and methods
The object of the study were 60 patients (32% men, 68% women) with early disorders of carbohydrate metabolism (WHO criteria, 2009). The mean age was 44.3 ± 7.8 years. The average value of fasting glycemia - 5.7±0.42 mmol/l, the average level of glycated hemoglobin was 5.96±0.36%. The average value of BMI is 31.6±5.4 kg/m2. The control group consisted of 30 practically healthy people. Indices calculated: HOMA-IR, QUICKI, HOMA1-β. Investigated blood parameters (lipid spectrum, indicators of carbohydrate metabolism). The quantitative determination of C-peptide, insulin, ghrelin, leptin in plasma was assessed by flow fluorometry on laser automated analyzer Bio-PlexProHuman Diabetes 10-Plex test system, Bio -Rad, USA). Genotyping for polymorphic markers of the PPARG gene (rs 1801282) was performed using PCR with allele-specific primers from Synthol. Amplification was carried out using a programmable thermal cycler Q5 (Bio-Rad). Statistical data processing was carried out using SPSS Statistics 26.0 software. To compare the frequencies of alleles and genotypes by a qualitative binary trait, the χ^2 test was used. To assess the associations of polymorphic gene variants with different phenotypes, odds ratio (OR) and 95% confidence interval. Statistically significant differences were considered at $P < 0.05$.
Results
Analyzing the distribution of frequencies of alleles and genotypes of the polymorphic marker of the PPARG gene (rs 1801282), no statistical significance was found in the group of patients with prediabetes and in the control group. Comparative analysis showed that homozygotes for the C allele significantly differed from the carriers of the minor allele G in higher levels of WC ($P < 0.001$), glycated hemoglobin ($P < 0.001$), glycemia 2 hours after glucose loading ($P < 0.05$), C-peptide ($P < 0.001$). Also, homozygous carriers for the major allele C were associated with the level of HbA1C≥5.7% ($P < 0.001$) and the level of systolic blood pressure above the target level ($P < 0.001$). There were no significant differences in HOMA-IR, HOMA1-β parameters, which is probably due to the small sample size included in the analysis.
Conclusions
Analysis of the polymorphic marker of the PPARG gene (rs 1801282) demonstrated the association of the major allele C with higher rates of carbohydrate metabolism and B-cell secretory activity, as well as cardiovascular risk factors, which makes it possible to use this parameter as a predictor of the development of early carbohydrate disorders.

Diabetes mellitus secondary to BRCA2 gene mutation: the importance of insulin resistance and genetics in dysglycemia

Valentim Lopes, Patrícia Brito, Catarina Machado & Adriana De Sousa Lages
Hospital de Braga, Endocrinology, Braga, Portugal

Introduction
Diabetes *mellitus* (DM) results from a defect in insulin secretion and/or its action. The Breast-Cancer Susceptibility Gene 2 (BRCA2), like BRCA1, is a tumour suppressor gene, and its mutation is associated with an increased risk of breast cancer and, in males, testicular cancer. In patients with the BRCA1/2 mutation, the level of Insulin-like Growth Factor (IGF)-1 and, consequently, the peripheral sensitivity to insulin are reduced, suggesting that this could be the causal relationship between insulin resistance and the development of dysglycemia in these patients.
Clinical case
Male patient, 26 years old, with normal weight, referred to the Endocrinology consultation for DM of dubious etiology diagnosed in routine analyses with his attending physician (fasting blood glucose of 103 mg/dl and blood glucose 2h post-75g of oral glucose of 334 mg/dl). He reported polyuria and polydipsia of moderate intensity and of indeterminate evolution time, without associated weight loss. He had a diagnosis of testicular teratocarcinoma in 2012, aged 16, for which he undergone left orchiectomy, followed by chemotherapy with bleomycin, etoposide and cisplatin (between 2013 and 2014) and having the genetic study revealed mutation in the BRCA2 gene. He also has atopic eczema, currently medicated with dupilumab, without glucocorticoid therapy. He have a family history of DM in the maternal grandmother. Hypoglycemic therapy was started by his primary care physician with metformin 1000 mg/day, with subsequent referral to a tertiary treatment center. No stigmata of any endocrinopathy on physical examination, namely acanthosis nigricans, was noted. Analytically, in the first consultation, he presented an occasional measurement of glucose of 188 mg/dl, with C-peptide of 6.58 pg/ml and anterior pituitary function without alterations. Anti-pancreatic islet antibodies, anti-GAD65, anti-IA2 and anti-ZnT8 were negative. Next Generation Sequencing panel for monogenic DM did not reveal any pathogenic variant. It was then added, due to insulin resistance, pioglitazone 15 mg/day and the patient manifested an excellent glycemic control (HbA1c 5.7%, TIR 90%, TBR 4%, TAR 6% and CV 29.7%), maintaining follow-up in the Endocrinology consultation.
Conclusion
We report the case of a young, normal-weight patient with DM and mutation in the BRCA2 gene whose evaluation excluded autoimmune etiology and MODY diabetes, which highlights the clinical heterogeneity associated with dysglycemia. The possible relationship between insulin resistance and mutation in the BRCA2 gene could be the etiology of DM in this context, emphasizing the importance of assessing glucose metabolism in this population subgroup.

Köbberling disease: Familial Partial Lipodystrophy type 1 associated with thyroid cancer

Andreea Rosu[1], Anca Matei[1,2], ilona-beatrice blesneac[1], Poleuca Codruta[1], Teodora Dumitru[1], Apostol Adina Catalina[1], Mihalache Laura[2,3] & Cristina Preda[1,2]
[1]'Sf. Spiridon' Clinical Emergency County Hospital, Endocrinology Department, Iaşi, Romania, [2]University of Medicine and Pharmacy 'Gr. T. Popa', Endocrinology Department, Iasi, Romania, [3]'Sf. Spiridon' Clinical Emergency County Hospital, Diabetes and Metabolic Disorders, Iasi, Romania

Introduction
Lipodystrophic syndromes are rare and heterogeneous disorders characterized by the complete or partial deficiency of adipose tissue. They can be classified according to the extent of fat loss in generalized or partial subtypes and genetic or acquired based on the pathogenic mechanisms.
Case report
A 37-year-old man was referred to our department with a history of nonalcoholic steatohepatitis associated with high levels of triglycerides (720 mg/dl) and structural alterations of anterior cervical region on computed tomography scan: right thyroid lobe irregular hypoechoic nodules with micro-calcifications and increased vascularity and multiple superior mediastinal and right sided cervical lymph nodes with necrosis and calcifications. On physical examination, the patient had a body mass index of 31.71 kg/m2 with a clear pattern of fat loss in the extremities (especially lower limbs), with truncal obesity and a slightly increased fat in the face and neck and acanthosis nigricans in the posterior cervical region. When questioned, the patient reported these physical changes for about 6 months with an unremarkable family history. Laboratory tests showed the following results: fasting serum glucose 80 mg/dl with HbA1c 4.9%, total cholesterol 151 mg/dl, high-density lipoprotein cholesterol 59 mg/dl, low-density lipoprotein cholesterol 81 mg/dl, triglycerides 70 mg/dl, normal alanine aminotransferase and aspartate aminotransferase, but with high gamma-glutamyl transferase 216 U/l and normal hormonal profile. HOMA-IR was 3 suggestive for insulin resistance. Thyroid ultrasound showed similar features like CT scan. Truncal subcutaneous adipose tissue with minimal edema was observed on ultrasound imaging alongside with pericardial and perivascular fat on echocardiography. A whole-body dual energy x-ray absorptiometry scan showed a fat mass index of 10.02 kg/m2 (class one obesity), with slightly elevated Trunk %fat-to-Legs %fat ratio of 1.2 and an increased Arms %fat-to-legs %fat ratio of 1.52, indicating an increased truncal and arms fat mass redistribution. The patient will be directed to the surgical department for total thyroidectomy.
Discussions
A clinical diagnosis of FPLD type 1 was made by the described findings. Although it appears that this syndrome is familial, it may also occur spontaneously and only a few affected women have been reported until now. The genetic defect associated with

Köbberling-type lipodystrophy is currently unknown, but latest research suggest that this form of lipodystrophy may have a polygenic etiology. Further management includes close monitoring and multidisciplinary approach regarding metabolic complications associated with this disorder.

Cystic fibrosis: diagnostic keys and new treatments

Maria Jose Vallejo Herrera[1], Veronica Vallejo Herrera[2], Maria Carmen Bautista Recio[1] & María Cruz Almaraz Almaraz[1]
[1]Hospital Regional de Malaga, Endocrinology, Malaga, Spain, [2]Hospital Regional de Malaga, Radiology, Malaga, Spain

A 47-year-old male with a history of severe persistent asthma and recurrent respiratory infections with admissions to the Pulmonology Department. The patient underwent a study due to weight loss, diarrhoea and Ca 19.9 elevation. Imaging tests (abdominal CT and MRI cholangio) were performed, which highlighted severe pancreatic fat infiltration. The cystic fibrosis study was completed with genetics (positive: two heterozygous switches F508del and D1152H), sweat test (45 mmol/l –> Intermediate, suggests possible CF) and pancreatic elastase in feces (<5.50 mg/g). Finally, the patient was diagnosed with cystic fibrosis, heterozygous for F508del and D1152H associated with exocrine pancreatic insufficiency. He was referred for follow-up in the Pulmonology and Endocrinology consultation to optimize treatment and follow-up, as well as to assess the start of new therapies. Patients diagnosed in adulthood have slightly impaired lung function and a low incidence of pancreatic involvement, so their prognosis tends to be favorable. On the basis of the foregoing, they will require less intensive treatment and often will not need digestive enzymes or nutritional supplements. An accurate diagnosis through imaging tests is essential for the correct management of this entity. In our case, it was the key clue, since the disease was not suspected by the patient's condition. With the advent of new modulator drugs (potentiators and correctors) of the CFTR protein, a very hopeful future opens up, since it radically changes the natural history of the disease. At present, the available pCFTR modulators are divided into potentiators, such as ivacaftor (IVA), which increases the probability of opening/activation of the chloride channel; and the correctors lumacaftor (LUM), tezacaftor (TEZ), and elexacaftor (ELX), which facilitate protein processing and transport to the cell membrane, increasing the amount of pCFTR on the cell surface. Currently, there are 4 pCFTR modulator drugs authorized by the European Medicines Agency (EMA): Kalydeco® (IVA) for over 4 months, Orkambi® (LUM/IVA) for over 2 years, Symkevi® (TEZ/IVA) for over 6 years and Kaftrio® (ELX/TEZ/IVA) for ages 6 and up; in the EU the last two in combination treatment with Kalydeco® (IVA). Each of the medications described is approved for specific CF patients and mutations, so not every approved modulating therapy is indicated for all of the CFTR genotypes. Our patient benefited from treatment with Kaftrio, an oral therapy approved for patients with at least one Phe508del mutation in the CFTR gene.

Tigecycline as a ausative agent of severe hypoglycemia

Entela Puca[1], Edmond Puca[2], Klei Vrekaj[3], Sonila Bitri[4] & Nereida Xhabija[5]
[1]Service of Intern Medicine, American Hospital, Tirana, Albania, [2]Service of Infection Diseases, University Hospital Center, Tirana, Albania, [3]Service of Intern Medicine, American Hospital, Tirana, Albania, [4]Service of Toxicology, American Hospital, Tirana, Albania, [5]Service of Cardiology, American Hospital, Tirana, Albania

Drug-induced hypoglycemia is a major clinical concern. Antibiotics are one of the causative agents to cause hypoglycemia. Tigecycline, which is a glycylcycline antibiotic, has a broad spectrum of activity, including activity against drug-resistant gram-positive and negative organisms. Ifs side effects are significant but hypoglycemia and severe hypoglycemia is a rare finding during treatments. Our aim is to present an event of severe hypoglycemia in a patient with type 2 diabetes mellitus with replacement renal therapy, hemodialysis after initiating tigecycline.

Case presentation

A 54 years old female diagnosed with tip 2 diabetes mellitus was under treatment with basal-bolus insulin-therapy and oral antihypertensive drugs. She started hemodialysis 24 months ago. She complained of recurrent fever since the last 7 months and was treated with several antibiotics. In two separated blood cultures patient resulted positive for methicillin-resistant *Staphylococcus epidermidis* (MRSE). Based on antibiogram, we started treatment with tigecycline 100 mg/day. After 6-8 hours from the first dose, patient complicated with events of hypoglycemia and then continues with of severe hypoglycemia (40-47 mg/dl). Laboratory investigations showed: hemoglobin level 10 g/dl; total WBCc 14.68×10^9/l (neutrophils 82%, lymphocytes 17%); platelet count 230 K/uL (150-400); blood urea 277.83 mg/dl (0-50); serum creatinine 12.0 mg/dl (0.57-1.11); serum sodium 140.00 mEq/l (136 – 148); potassium 6.6 mEq/l (3.7-5.5); calcium 9.14 mg/dl (8.4 - 10.2); HbA1c 6.5% and procalcitonin level was 2.01 ng/ml. The patient continued to have hypoglycemia for about 16-18 hours after the last dose. We didn't find any reasons to explain the cause of episodes of hypoglycemia. Her insulin-like growth factor (IGF-1) was normal at 206.0 nmol/l (49.6–204), C peptide levels was 1.82 ng/ml (< 5.19), cortisol levels was 724 nmol/l (68.2-327) and ACTH level was 25.70 pg/ml (7.2 - 63.3). Patient didn't have high level of insulin in the blood (insulin 4.11 mIU/l range 2.6-24.9).

Conclusions

We report a case of a diabetic patient with end stage renal disease on hemodialysis that experienced severe hypoglycemia episodes induced by tigecycline. To our knowledge, this is one of the limited case reports of sustained severe hypoglycemia due to tigecycline. Severe hypoglycemia is a serious event and immediate intervention is needed to correct it otherwise the outcome can be fatal.

Impact of COVID-19 pandemic on nationwide antidiabetic drug utilization

Caner Vizdiklar[1], Volkan Aydin[2], Gokhan Tazegul[3] & Ahmet Akici[1]
[1]Marmara University School of Medicine, Medical Pharmacology, Istanbul, Turkey, [2]Istanbul Medipol University International School of Medicine, Medical Pharmacology, Istanbul, Turkey, [3]Marmara University School of Medicine, Internal Medicine, Istanbul, Turkey

Introduction

The COVID-19 pandemic resulted in various outcomes that have altered disease prevalence and drug utilization patterns. Our study aimed to evaluate the trends in the utilization and costs of antidiabetic medications before and during the COVID-19 outbreak in Turkey.

Methods

We obtained nationwide sales data for antidiabetics from IQVIA Turkey, spanning between April 2018 and March 2022. Mean monthly drug utilization and expenditure trends before the pandemic (April 2018-March 2020) and during the pandemic (April 2020-March 2022) were compared. Drug utilization was measured by defined daily dose/1000 inhabitants/day (DID) unit.

Results

Utilization of antidiabetic drugs increased significantly from 125.7 ± 12.5 DID before the pandemic to 158.3 ± 25.7 DID during the pandemic ($P < 0.001$). There was a considerable rise in the use of oral antidiabetics, with utilization increasing from 71.2 ± 6.9 DID prior to the pandemic to 90.6 ± 17.2 DID ($P < 0.001$). Moreover, insulins and their analogs were utilized more frequently during the pandemic, rising from the pre-pandemic levels of 52.4 ± 6.7 DID to 65.4 ± 10.0 DID ($P < 0.001$). Marked increases were observed in the expenses for antidiabetics, moving from 65.4 ± 8.4 to 86.7 ± 15.0 million Euros ($P < 0.001$). These increments were noted both for oral antidiabetics (from 35.8 ± 5.6 to 50.4 ± 10.2 million Euros, $P < 0.001$) and insulins (from 27.1 ± 3.7 to 33.4 ± 5.7 million Euros, $P < 0.001$).

Conclusion

Our study demonstrated a surge in the utilization and expenditure of antidiabetics in the two years of the COVID-19 pandemic in Turkey, compared to pre-pandemic levels. These results should be considered in evaluating the association of COVID-19 infection with chronic diseases such as diabetes, as well as the outcomes of interventions to facilitate access to drugs for extraordinary circumstances.

Rechallenge with a single-pill combination of sitagliptin plus extended-release metformin in patients labelled as metformin-intolerant: Mostly successful

Francisco Javier Martinez Martin[1,2], Carlos Rios-Gomez[1], Borja Santana-Ojeda[1], Ricardo Jose de Leon-Durango[1], Alba Hernandez-Lazaro[1], Claudia Arnas-Leon[1,2], Carmen Acosta-Calero[3], Agnieszka Kuzior[2], Paula Gonzalez-Diaz[4] & Paula Maria Fernandez-Trujillo-Comenge[1]
[1]University Hospital of Gran Canaria Dr. Negrín, Endocrinology & Nutrition, Las Palmas de Gran Canaria, Spain, [2]Clinica San Roque, Endocrinology & Nutrition, Las Palmas de Gran Canaria, Spain, [3]University Hospital of Gran Canaria Dr. Negrín, Cardiology, Las Palmas de Gran Canaria, Spain, [4]University Hospital of Gran Canaria Dr. Negrín, Emergency Medicine, Las Palmas de Gran Canaria, Spain

Introduction
Extended-release (ER) metformin has been available in many countries for the last two decades, and it may have definite advantages vs. conventional (i.e., immediate-release) metformin: Reportedly, it may reduce gastrointestinal adverse effects by about half, thus increasing compliance; moreover, the once-a-day schedule may contribute to increased adherence and persistence, and hopefully improved outcomes. However, ER metformin was unavailable in Spain until 2022: when generic sitagliptin became available, a single-pill combination containing 50 mg sitagliptin and 1000 mg ER metformin was released, while monocomponent ER metformin is still unavailable. We undertook to rechallenge metformin-intolerant T2DM patients treated with a DPP4 inhibitor with the sitagliptin plus ER metformin single-pill combination in order to assess its tolerability and efficacy.
Methods
T2DM patients with HbA1c $>7\%$ and GFR (CKD-EPI) >45 mL/min/1.73m^2, labelled as metformin-intolerant due to gastrointestinal symptoms, and treated with a DPP4 inhibitor (with or without additional hypoglycemic medication) were switched to the 50 mg sitagliptin plus 1000 mg ER metformin single-pill combination, taking 1 pill with the evening meal in the first month and afterwards 2 pills together if the tolerance was good. Additional medication, if any, was unchanged. Data on glycemic control were compared (paired t-test) between the baseline visit and a follow-up visit 3-4 months afterwards. Tolerance data were obtained by questionnaire in the follow-up visit. All patients included gave informed consent. Data are given as mean $\pm$ sd.
Results
38 patients were included, 24 (63%) were women, age 55 ± 8 years, diabetes duration 7 ± 3 years. 32 (84%) tolerated 1 pill, although 12 of them (32% of the total) had minor gastrointestinal symptoms which subsided along the first month and did not cause withdrawal. 27 (71%) of the patients tolerated 2 pills, although 7 of them (18% of the total) had minor symptoms after the dose increase. Fasting plasma glucose was reduced from 178 ± 38 mg/dl to 139 ± 26 mg/dl ($P < 0.001$) in those who tolerated 1 pill, and to 128 ± 19 ($P < 0.001$) in those who tolerated 2 pills. HbA1c was reduced from $8.2 \pm 1.1\%$ to $7.8 \pm 0.8\%$ ($P = 0.058$, 1 pill) and $7.6 \pm 0.7\%$ ($P = 0.015$, 2 pills). Of 11 patients who did not tolerate the rechallenge, 8 (21%) reported diarrhea, 4 (11%) flatulence, 2 (5%) abdominal pain, 2 (5%) nausea and 1 (3%) dyspepsia.
Conclusions
Rechallenge with ER metformin plus sitagliptin in patients intolerant to conventional metformin was mostly successful, with 5/6 tolerating 1 pill and 7/10 full dose. Side effects were minor, and glycemic control was improved.

Diabetes treatment with dapagliflozin and its combinations: Insights from clinical practice

Ajit Mehta[1], Akshay Bafna[2], Sandeep Goel[3], A.K. Trivedi[4], Chandrakanta Mishra[5], Preethi Naik[6], Nitin Zalte[6] & Amarnath Sugumaran[6]
[1]Jehangir Hospital, Pune, India, [2]Dr. Bafna's Cardiac Centre, Kolhapur, India, [3]Chandigarh Heart Centre, Sangrur, India, [4]Regency Hospital, Kanpur, India, [5]SCB Medical College & Hospital, Cuttack, India, [6]Cipla Ltd., Mumbai, India

Background
Despite global guidelines recommending initiation of SGLT2i drugs like dapagliflozin in type 2 diabetes (T2DM) patients with cardiovascular (CV) or renal risk, its clinical translation is still lacking in India.
Objective
To understand clinicians' perspectives regarding the association of CV risk and T2DM in Indian patients, and the need for the use of combination therapies with dapagliflozin in T2DM patients, in Indian clinical practice.
Methods
A cross-sectional, questionnaire-based survey involving 873 diabetologists and consulting clinicians was conducted. The survey questionnaire consisted of 30 questions that accessed T2DM patient profiles and clinicians' preference for treatment approach, dapagliflozin use for cardiorenal protection and its combination therapy.
Results
In routine clinical practice, 73% of clinicians observed more than 20 T2DM patients weekly. The majority of these patients (91%) were aged between 40 – 60y. The clinicians observed that these patients presented with varying comorbid conditions like obesity (39%), coronary artery disease (38%) and chronic kidney disease (14%). 37% of clinicians said CV risk was observed in 50 – 80% of T2DM patients. In the treatment of T2DM patients, 44% of clinicians preferred SGLT2i, followed by DPP4i (31%) and SU (28%) as the first choice of antidiabetic class of drug other than metformin. Among the SGLT2i class, dapagliflozin (91%) was the most preferred choice. According to 55% of clinicians, the most prominent clinical benefit of dapagliflozin was a reduction in HF hospitalisation and 69% suggested dapagliflozin to be the most effective SGLT2i in patients with renal impairment. Around 94% of clinicians agreed that early initiation and aggressive intensification of combination therapy should be done and 58% preferred SGLT2i-based combinations. In the case of SGLT2i + DPP4i fixed-dose combinations (FDC) for T2DM patients with CV or renal risk, 79% of clinicians preferred dapagliflozin based FDC (66%: dapagliflozin+ sitagliptin and 13%: dapagliflozin + vildagliptin). In comparison, 76% strongly recommended the FDC for a triple combination of dapagliflozin + sitagliptin + metformin. All the clinicians agreed that SGLT2i drugs like dapagliflozin must be initiated in T2DM patients with comorbidities, and 98% opined that SGLT2i like dapagliflozin is one drug across HF spectrum among T2DM patients. However, 89% of clinicians were concerned with dapagliflozin underutilisation in Indian patients.
Conclusion
The findings from the survey highlight the clinical benefits of dapagliflozin and its FDCs in T2DM patients with CV/renal risk. Early initiation and aggressive intensification with dapagliflozin FDCs in T2DM patients is highly recommended.

HbA1c and Lipid Profile Indices: Useful for cardiovascular risk prediction in non-diabetics?

Beyza Çiçek[1], Yildiz Okuturlar[2], Orhan Cem Deniz[2], Özgür Okuturlar[3], Ozlem Celik[4], Mustafa Serteser[5] & Sevgi Şahin[6]
[1]Çaldıran Devlet Hastanesi, Internal Medicine, Van, Turkey, [2]Acıbadem University School of Medicine, Internal Medicine, Istanbul, Turkey, [3]Özel Rami Hastanesi, Internal Medicine, Istanbul, Turkey, [4]Acıbadem University School of Medicine, Endocrinology and Metabolic Diseases, Istanbul, Turkey, [5]Acıbadem University School of Medicine, Clinical Biochemistry, Istanbul, Turkey, [6]Acıbadem University School of Medicine, Nephrology, Istanbul, Turkey

Aims
Glycosylated hemoglobin (HbA1c) is a marker which demonstrates 3-month average level of blood glucose level. In individuals with high blood sugar level for a long time is associated with increased risk of cardiovascular disease (CVD). There is a need for simple and cost-effective markers to determine the risk of CVD in primary health care settings. In this study, we aimed to investigate the value of HbA1c for predicting cardiovascular risk in healthy non-diabetic individuals.
Method
151 healthy individuals who applied to the check-up unit of Acıbadem University Hospital during 2017-2018 period is included in this study. The individuals who has HbA1c level 5.7 and above, and with an estimated glomerular filtration rate below 90 ml/min were excluded.
Results
There was no statistical difference between the mean age, HbA1c and total cholesterol levels of 70 female and 81 male. Though, in male subjects, fasting blood glucose, blood urea nitrogen, creatinine, alanine aminotransferase, aspartate aminotransferase, uric acid, homocysteine, low-density lipoprotein (LDL), triglyceride, non-HDL values and total cholesterol/high-density lipoprotein (HDL), LDL/HDL, triglyceride/glucose ratios were found significantly higher compared to women. In the correlation analysis performed seperately among male and female patients, there was a significant positive correlation of HbA1c in males with total cholesterol/HDL and LDL/HDL ratios.
Conclusion
HbA1c value may contribute to the follow-up of non-diabetic patients in terms of cardiovascular disease risk. In the study of Yan Li *et al*., it was shown that an HbA1c level higher than 5.7% in non-diabetic patients with stent implantation due to coronary artery disease leads to an increase the risk of mortality. We have seen that lipid profile indices that can be used in addition to HDL and total cholesterol values which are used to determine the 10-year risk for CVD, show a significant positive correlation with A1c in young non-diabetic male individuals. We believe that even in

Utility of nutritional ultrasound for body composition in patients affected by obesity and overweight. Utility of nutritional ultrasound for body composition in patients affected by obesity and overweight

Rossella Tozzi[1], Yaiza García Delgado[2], Rosa María Sánchez Hernández[3], Yaiza Gil Quintana[3], Diego Hernandez Hernandez[2], Verónica Dávila[3], Mauro Boronat[2], Stefania Mariani[4], Lucio Gnessi[4] & Anna Maria Claudia Wägner[3]

[1]Sapienza University of Rome, Molecular Medicine, Roma, Italy, [2]Hospital Materno Infantil de Gran Canaria, Las Palmas de Gran Canaria, Spain, [3]Universidad de Las Palmas de Gran Canaria, Las Palmas de Gran Canaria, Spain, [4]Sapienza University of Rome, Experimental Medicine, Roma, Italy

Background and aim

Dual energy X-ray absorptiometry (DXA) is considered the gold standard to evaluate BC, even if it requires the use of radiations, an expensive equipment and cannot be performed at the patient's bedside. Nutritional ultrasound (NU) evaluates BC through the assessment of muscle mass and the abdominal subcutaneous (superficial and deep-layer) and visceral adipose tissue. We aimed

at comparing the accuracy and reliability of this emerging tool with DXA in patients with overweight or I grade obesity.
Materials and methods
Patients attending the Complejo hospitalario Universitario Insular Materno-Infantil de Las Palmas de Gran Canaria (España) with a body mass index (BMI) between 25 and 34.9 kg/m^2 were enrolled. NU (Esaote Medica, high frequency 12 MHz probe) was performed at the level of the QRF (lower third of the leg) for the evaluation of subcutaneous adipose tissue (SAT) and QRF circumference(mm); abdominal ultrasound measured total superficial fat (abdSAT) deep fat and pre-peritoneal fat (PAT). BC by DXA (Hologic) included the following parameters: Fat mass (FM gr, %), Free fat mass, Trunk fat mass gr, %), Total lean mass (LM), trunk lean mass.
Results
114 patients (40 males) were included. BMI was 29.9 $\pm$ 2.8 kg/m^2 and mean age was 53.9 $\pm$ 9.9 years. FM was 35.7$\pm$7.3%, while trunk fat mass was 36.6 $\pm$6.7%. After adjustment for age and sex, leg SAT showed a significant correlation with FM gr (r= 0.42, $P<$ 0.001), FM % (r=0.45, $P<$ 0.001), trunk fat % (r=0.27, P0.004). QRF circumference had a significant association with LM (P=0.005), leg lean and trunk lean ($P<$ 0.05). AbdSAT, and PAT reported strong association with total fat and trunk fat apposition;in particular deep abdominal fat and trunk fat % (r=0.47, $P<$0.001). After stratification for gender, male reported a better correlation between QRF and trunk lean (r= 0.46, $P<$ 0.005) and between abdSAT and trunk fat %(r= 0.5, $P<$ 0.005), compared to females, which instead reported an higher correlation index between PAT and trunk fat(r=0.41, $P<$ 0.001).
Discussion and conclusions
NU demonstrated to reach good correlations with the gold standard technique for BC, with the advantage of no X-ray exposure and more feseability. QRF evaluation seems to be more predictive of lean mass in males, and abdSAT seems to be more accurate for visceral apposition. PAT was the better NU index for the visceral obesity in females. Studies with higher sample power are needed in order to validate extend the use of NU for BC in clinical settings.

Design and development of mobile application for type 2 diabetes 'Diabetes 2 Learn'

Elissavet Lykoudi[1], Georgios Lymperopoulos[2], Eleni Dokoutsidou[1], Eugenia Vlachou[1] & Nikoletta Margari[1]
[1]University of West Attica, Department of Nursing, Athens, Greece, [2]Electrical and Computer Engineer, Athens, Greece

Introduction
Worldwide, diabetes is a common metabolic disorder that creates many complications. Nowadays a mobile-based application could be included in the therapeutic approaches of self-management.
Aim
This study presents the development of a mobile application named 'Diabetes 2 Learn' for people with type 2 diabetes inside the Greek population.
Methods
Google Play and App Store were examined for their apps on diabetes and their capabilities. Extending the capabilities and features of such apps and adapting for the Greek population, a mobile app was created. Java programming language was used to create the app, which is uploaded to Google Play for Android Operating System (AOS), because of its popularity and efficiency.
Results
The 'Diabetes 2 Learn' app for type 2 diabetes can be downloaded from Google Play to mobile devices with AOS, which is widespread in smartphones. The users can read information about diabetes and its complications, diagnosis, and symptoms, as well as dietary recommendations regarding Mediterranean diet and physical activity. Furthermore, the app can record blood glucose measurements and offers mg/dl graph support. The users also have quiz options to evaluate their level of knowledge on diabetes.
Conclusions
This software application was created for people with type 2 diabetes to help them manage their care by monitoring blood glucose, checking their knowledge on diabetes and benefitting from the advantages of adhering to the Mediterranean diet. The app has also been included in a study protocol which is in progress in Greek public hospitals.

A case of Wernicke's encephalopathy after sleeve gastrectomy

Elena Sani[1], Giuliana Da Prato[1], Veronica Gremes[1], Francesco Valletta[2], Matilde Bariani[3] & Maria Grazia Zenti[4]
[1]University of Verona, Division of Endocrinology, Diabetes and Metabolism, Verona, Italy, [2]University of Verona, Department of Neurosciences, Biomedicine and Movement Sciences, Verona, Italy, [3]University of Verona, Department of Radiology, Verona, Italy, [4]Pederzoli Hospital, Diabetes and Metabolism Unit, Peschiera del Garda, Verona, Italy

Introduction
Wernicke's encephalopathy, resulting from thiamine deficiency, is a rare but serious neurological complication of bariatric procedures. The diagnosis is still difficult since the classic clinical triad (confusion, ataxia and oculomotor abnormalities) and the typical radiological features (areas of hyperintensity in mammillary bodies, thalamus, periaqueductal and periventricular gray matter) are not always present. Also, thiamine blood tests are not broadly available to confirm the diagnosis. Only a few cases of Wernicke's encephalopathy after sleeve gastrectomy have been reported in literature, nonetheless subjects can be underdiagnosed and their cases underreported.
Case presentation
We present the case of a 20-year-old female patient who developed Wernicke's encephalopathy after sleeve gastrectomy for grade II obesity (BMI 36.3 kg/m2) with metabolic complications (dyslipidemia, nonalcoholic fatty liver disease). She presented to the Emergency Department two months after surgery showing confusion, gait ataxia and horizontal nystagmus. Persistent vomiting and lack of compliance to vitamin intake were reported. She had already lost 19 kg, from 105 to 86 kg (BMI 29.8 kg/m2). Cerebral MRI showed acute bilateral lesions in periaqueductal and periventricular regions. After excluding chronic alcohol use, a diagnosis of Wernicke's encephalopathy was made. Unfortunately, thiamine dosage was not available. Parenteral thiamine supplementation was immediately administered (500 mg IV every 8 hours for 10 days), obtaining a progressive resolution of altered mental status, motor ataxia and nystagmus. On the contrary, anterograde, retrograde and working memory impairment persisted, as confirmed by cognitive tests. She was discharged with oral thiamine supplementation (300 mg daily) and underwent long-term physical, cognitive and psychological rehabilitation. After a 2-years follow up, she is compliant to a balanced fractionated diet and vitamin supplementation. Her body weight progressively reduced to 65 kg (BMI 22.5 kg/m2) and no other nutritional deficiencies developed. A new cerebral MRI showed regression of the neuroradiological findings. However, a minimal memory impairment remained.
Conclusion
Wernicke's encephalopathy is a concrete possibility after sleeve gastrectomy and should always be suspected in patients with recurrent vomiting, poor nutritional intake and non-compliance to vitamin supplementation. Immediate and aggressive thiamine supplementation is mandatory to prevent patients from irreversible neurological impairment, even though full recovery is not always achieved. A multidisciplinary approach (surgeon, endocrinologist, neurologist, dietitian, psychologist, physiotherapist) is required for the long-term management of these patients.

Maternally inherited diabetes and deafness (MIDD): easy to detect?

Rosario Fernández García-Salazar[1], Laura Manjón-Miguélez[1], María Costales Marcos[2], Carmen Burgueño Montañés[3], Daniel Santirso Rodríguez[4], Noelia García González[5] & Edelmiro Menéndez Torre[1]
[1]Hospital Universitario Central de Asturias (HUCA), Grupo de investigación en Endocrinología, Nutrición, Diabetes y Obesidad (ENDO), Instituto de Investigación Sanitaria del Principado de Asturias (ISPA), Endocrinology, Oviedo, Spain, [2]Hospital Central de Asturias (HUCA), Otorhinolaryngology, Oviedo, Spain, [3]Hospital Central de Asturias (HUCA), Ophthalmology, Oviedo, Spain, [4]Hospital Central de Asturias (HUCA), Neurology, Oviedo, Spain, [5]Hospital Central de Asturias (HUCA), Genetics, Oviedo, Spain

Introduction
Maternally inherited diabetes and deafness (MIDD) that is caused by a pathogenic variant in mitochondrial DNA (mtDNA) can cause different phenotypes based on percent heteroplasmy load, with higher mutation load corresponding with disease severity. The m.A3243G mutation causes either classic MELAS or MIDD that is a partial form. The condition is characterised by diabetes, hearing impairment and maculopathy but can have several other clinical manifestations. Early recognition is important so that management of associated conditions and screening of maternal relatives can be implemented.
Case report
Caucasian female was incidentally diagnosed with type 2 diabetes aged 24 years during a routine medical check-up. BMI was 27 kg/m^2 at the time of diagnosis. She underwent some examinations: blood test included autoimmunity and genetic

study for maturity-onset diabetes of the young (MODY) that were negative. C-peptide level: 2.87 ng/ml (1.1-4.4). Human leukocyte antigen (HLA) was positive for DR-4/DQ-8. Her diabetes was initially managed with lifestyle interventions, metformin and empagliflozin. Also has a medical history for hypertension, microalbuminuria, hypercholesterolaemia and bronchial asthma. She has hadn't other complications. 4 years after diagnosis had sensorineural hearing loss so we request a genetic testing and found a probably pathogenic variant m.3243A>G heteroplasmy mutation in the MT-TL1 gene who is envolved in MIDD and MELAS syndrome. She has strong maternal family history of diabetes but no deafness. Following this diagnosis, she was referred for retinal screening where pigmented retinal lesions were found. The neurological evaluation was normal. Other hormones test were normal too. At the time of this diagnosis (6 yr after the beginning) she had a worsening of her blood glucose levels and Insulin was introduced into her medication regimen. We also changed empaglifozine for sitagliptin and added Co-enzyme Q10 (CoQ10).

Discussion

Recognizing mitochondrial disease in a cohort of patients with diabetes is not a simple task. It is not surprising, therefore, that it is common for mitochondrial diabetes to be misdiagnosed, even in the presence of other features that may provide clues as to the underlying genetic disease. Deafness usually precedes diabetes onset by 6 yr (intervals ranging 0-16) but in our patient deafness started 4 years after the diagnosis of diabetes. HLA polymorphisms associated with type1 diabetes as well as autoantibodies have only been anecdotally reported in mitochondrial diabetes mellitus (mDM). Reported cases were positive for HLA-DQA1/DQB1, but in our case, the polymorphism affected was DR4/DQ8 that isn't described in the literature for mDM.

Metabolic Control and Perinatal Outcomes According to The Planning or Lack of Planning of The Pregnancy

Andrea Fernández Valero[1], Víctor José Simón Frapolli[2], Marta Generoso Piñar[2], Maria Molina Vega[2], Francisco J Tinahones[2] & María José Picón César[2]
[1]Hospital Virgen de la Victoria, Malaga, Spain, [2]Hospital Virgen de la Victoria, Endocrinology and Nutrition, Malaga, Spain

Objectives

To analyze the data of patients seen at the Diabetes and Pregnancy Unit, assessing the frequency of pregnancy planning and whether there are differences in the degree of metabolic control before and during pregnancy, as well as in perinatal outcomes with respect to those who do not plan. All women of childbearing age with Pregestational Diabetes Mellitus(PGDM) should receive preconception counseling to optimize glycemic control, since preconception control is associated with a reduced risk of fetal malformations and perinatal mortality. In addition, pre-existing complications and associated comorbidities should be assessed, as well as the possible use of potentially teratogenic drugs. Despite this, only a minority plan their gestation.

Materials and Methods

Retrospective observational study. Data from 72 patients seen in the Diabetes and Pregnancy Unit, between were collected and analyzed.

Outcomes

Data of 72 women of whom 86.1% were Caucasian, 6.9% Arab, 4.2% Oriental and 2.8% South American, with a mean age of 34.5+/-6.25 years. Regarding the type of PGDM, 64(88.9%) had type 1 DM and 8(11.1%) had type 2 DM, with a mean evolution of 16.34+/-8.56 years since diagnosis. Only 28(38.9%) performed a previous planning, having 26 green light by the Endocrinologist at the time of gestation.

Conclusions

In those patients who do not plan, the initial HbA1c is significantly higher than in those who do plan. An early and close follow-up in the Diabetes and Pregnancy Unit allows improving metabolic control, achieving no significant differences at the end of gestation. No significant differences were observed in terms of perinatal adverse events, however, serious complications such as intrauterine mortality, fetal distress and major malformations occurred in those who do not plan, even though they did not reach statistical significance.

The perinatal and metabolic control data are shown in the table.

Does the prebiotic and probiotic supplementation influence eating behavior in patients with obesity?

Rym Ben Othman, Zeineb Zemni, Chaima El Ghali, Berriche Olfa, Wafa Douiri, Ramla Mizouri, Nadia Ben Amor, Faten Mahjoub & Jamoussi Henda
[1]National Institute of Nutrition of Tunis, Obesity Research Unit, Bab Saadoun, Tunis, Tunisia

Introduction

Disordered eating attitudes and behaviors are common and persistent in patients with obesity. The objective of our work was to evaluate the effect of prebiotic and probiotic supplementation on eating behavior in addition to a weight loss program in an adult population with obesity.

Methods

This is an interventional study involving 45 obese patients consulting the obesity unit of the Institute of Nutrition of Tunis in 2022. Patients were divided into 3 groups matched for age, sex and BMI: diet alone (G1), prebiotics (G2) (30g of carob/d) and probiotics (G3) (1 tablet of Lactibiane/d). Eating behavior and eating disorder symptoms (number of meals/day, number of snacks/day, snacking, night eating, binge eating, bulimia nervosa episodes) were assessed at T0 and at one month after the intervention (T1). No patients took antibiotics during the intervention period and no patient stopped taking carob. The statistical level of significance was defined as $P< 0.05$.

Results

The mean age was 48.73 $\pm$7.7 years with a female predominance (93.3% of women). The number of meals per day did not change between T0 and T1 for the three groups. There was a significant decrease in the number of snacks per day between T0 and T1 only for the diet alone group ($P=0.03$). Snacking prevalence significantly decreased in the three groups between T0 and T1 (G1: $P< 0.001$; G2: P0.04; G3: $P< 0.001$). For binge eating prevalence, a significant decrease was noted in the diet alone group ($P=0.001$) and the probiotic group ($P=0.002$). We also noted a significant decrease in nocturnal eating between T0 and T1 in the three groups (G1: P0.04; G2: P0.01; G3: P0.04). Indeed, at T0, 29% of patients had nocturnal eating and at T1, none of them had any. The prevalence of bulimia nervosa episodes significantly decreased in the three groups (G1: P0.09; G2: $P<$ 0.001; G3: P0.001). For the comparison between groups: The three groups were similar for improvement of eating behavior/disorder.

Conclusion

The significant improvement in eating behavior/disorder was independent of symbiotic intake. Following a weight loss program with a multidisciplinary team including at least a nutritionist and a psychologist is a promising alternative for improving eating disorders.

Wernicke Encephalopathy Due To Bariatric Surgery: Recounting A Case Report

Guilherme V. de Assunção, Silvia Paredes & Helena Cardoso

Centro Hospitalar Universitário de Santo António, Department of Endocrinology, Diabetes and Metabolism, Porto, Portugal

Introduction
Wernicke Encephalopathy (WE) is an acute neurologic disorder caused by thiamine deficiency. It is characterized by the classic triad of encephalopathy, gait ataxia and oculomotor dysfunction. It occurs in the setting of poor nutrition caused by lack of dietary intake or malabsorption. Since both of them can happen in patients that underwent bariatric surgery it is of utmost importance to prevent, recognize and treat this severe complication.
Case Report
41-year-old female with obstructive sleep apnea, gallstone disease, gastro-esophageal reflux and class III obesity (IMC 41,9 kg/m^2) underwent bariatric surgery roux-en-y gastric bypass in 2018. Preoperative blood analyses showed a low vitamin D, folic acid and zinc and was supplement for these deficiencies. There were no postoperative complications. Three months after the surgery, the patient enter the emergency department with complaints of abdominal pain and vomiting with 1 month of evolution. Upper endoscopy was performed showing a patent anastomosis. She was discharged with prokinetics and liquid diet. One week later she returned to the emergency department with intractable vomiting, indifference, inactiveness, axial ataxia, multidirectional nystagmus and hyporeflexia. There were no motor deficits. No abnormalities were demonstrated in the brain CT and MRI and the lumbar puncture showed no alterations. Blood analysis were normal except for: folic acid 2.1 ng/ml [reference range (RR) 2.2-17.5], total proteins 0.27 g/l [RR $>$ 0.45] and thiamine 37 nmol/l [RR: 66-300]. Thiamine parenteral replacement was immediately initiated. The evolution was favourable and the patient was discharged after 2 weeks. She maintain a gait deficit with myopathy in the right thigh confirmed by electromyography and biopsy.
Conclusion
We present a patient that developed severe vomits after Roux-en-Y gastric bypass leading to a state of protein malnutrition and severe hypovitaminosis B1. She developed WE with motor deficit sequelae possibly in the context of a radiculoplexus neuropathy setting. It is important to identify vomits and prevent malnourishment after bariatric surgery since WE has a rapid onset and detrimental course. Vitamin and mineral supplementation after bariatric surgery will prevent this severe complication.

Type 2 diabetes mellitus, primary biliary cholangitis and type 2 autoimmune hepatitis - a rare association

Daniel Cosma[1], Elena-Maria Herascu[2], Mihai Pietraru[3] & Patricia Silaghi[4]
[1]Horezu City Hospital, Diabetes, Nutrition and Metabolic Diseases Outpatient Clinic, Horezu, Romania, [2]Valcea Emergency County Hospital, Gastroenterology Department, Ramnicu-Valcea, Romania, [3]Geronto-healthcare Clinic, Geriatry and Gerontology Outpatient Clinic, Ramnicu-Valcea, Romania, [4]"Iuliu Hatieganu" University of Medicine and Pharmacy, Cluj-Napoca, Romania

The hepatic autoimmune diseases are rarely associated with type 2 diabetes mellitus (T2DM). Instead, it's more often encountered in people with type 1 diabetes mellitus in the context of polyglandular autoimmune syndrome (PAS). A 64-years old female diagnosed with T2DM for 8 years, hypertension and dyslipidemia currently under treatment with Dapagliflozin/Metformin 50/1000 mg twice daily, presented for her periodic diabetes consult complaining of marked fatigability and asthenia. The lab exams revealed: thrombocytopenia (47x10^3/mm^3), hepatocytolysis (GOT=424.14U/l; GPT=371.11U/l), cholestasis, elevated ESR and CRP, a protein electrophoresis pattern with decreased albumin and elevated γ-globulin and A1c=6.76%. The viral etiology was excluded. The abdominal ultrasound displayed marked splenomegaly, portal hypertension, slightly dilation of the intrahepatic bile ducts and increased caudate lobe. Due to hepatic status, the statin treatment was stopped, a switch from Dapagliflozin/Metformin to Glipizide was made and the patient was referred for a gastroenterology consult. The immunological profile was consistent with positive anti-nuclear and intense positive anti-mitochondrial M2 and M2-3E antibodies sustaining the diagnosis of an overlap syndrome with primary biliary cholangitis (PBC) and type 2 autoimmune hepatitis. The immunosuppressive treatment with Azathioprine 150 mg/day was initiated alongside ursodeoxycholic acid, L-arginine and Silymarin which led to significant improvement in the symptoms and lab exams. A subsequent dermatological consult established also a diagnosis of scalp psoriasis. The glycemic control under Glipizide was good with A1c $<$7% until present. This case illustrated a rare association of an overlap syndrome consisting of type 2 AH and PBC in an old female with type 2 diabetes. Despite immunosuppressive treatment and the conversion from dual to Glipizide monotherapy, the patient maintained a good glycemic control, emphasizing the role of this sulfonylurea in the management of the type 2 diabetes and liver diseases.

Nondiabetic hypoglycemia: the role of psycho-neurological care in primary diagnosis

Marina Yukina, Nurana Nuralieva & Ekaterina Troshina
Endocrinology Research Centre, Moscow, Russia

Introduction
Decreased glycemia in patients without diabetes mellitus (nondiabetic hypoglycemias; NDH) is a manifestation of severe diseases from endocrinopathies to malignant tumors. The most specific symptom of NDH is association of attack with the intake of carbohydrate-containing food. Hypoglycemia is usually manifested by neurological and mental disorders, and therefore, patients initially seek medical help not from an endocrinologist, but from psychiatrists and neurologists.
Objectives
To analyze the outcomes of the choice of primary specialists for medical care in patients with NDH.
Methods
anamnesis analysis of 431 patients with NDH aged 18-93 years.
Results
In 37% of patients with NDH, the correct diagnosis is delayed, among them 63% of patients have been initially observed by psychiatrists/neurologists.
Conclusions
In a significant proportion of patients with NDH, the correct diagnosis is delayed, and most of these patients receive pathogenetically unreasonable treatment from psychiatrists/neurologists, which increases the risk of hypoglycemic coma. Thus, the alertness of doctors, especially psychiatrists/neurologists, regarding the timely detection of NDH is extremely important.

Can probiotics improve weight loss in patients with obesity?

Rym Ben Othman, Zeineb Zemni, Chaima El Ghali, Wafa Douiri, Berriche Olfa, Ramla Mizouri, Nadia Ben Amor, Faten Mahjoub & Jamoussi Henda
Obesity Research Unit, Bab Saadoun, Tunis, Tunisia

Introduction
Probiotics are made of good live bacteria and/or yeasts that naturally live in human body which are essential for the proper functioning of the microbiota. The objective of our work was to evaluate the effect of probiotics intake on anthropometric parameters in addition to a weight loss program.

Methods
This is an interventional study involving 30 obese patients consulting the obesity unit of the Institute of Nutrition of Tunis during the period from May to August 2022. Patients were divided into 2 groups matched for age, sex and BMI: diet alone and probiotics (1 tablet of Lactibiane*/day). Anthropometric measures (weight, waist circumference, BMI), body composition, and muscle strength (using handgrip dynamometer) were assessed at T0 and at one month after the intervention (T1).
Results
The mean age was 42.3 ±5.7years with a female predominance (75% of women). For the diet alone group, there was a significant decrease in body weight (-2.5 kg, *P*0,001), BMI (-0.9 kg/m^2, *P*0.001) and waist circumference (-1.7 cm, *P*0.01) between T0 and T1. For the probiotic group, in addition to the significant decrease in weight (-1.7 kg, *P*0.02), BMI (-0.8 kg/m^2, *P*0.03) and waist circumference (-2.9 cm, *P*0.001), we have noticed a significant decrease in fat mass (-2.5 kg, $P < 0.001$) and percentage fat mass (-1.7%, $P < 0.001$), as well as a significant improvement in muscle strength (+1.7 kg, *P*0.004). Although the decrease in body fat and body fat percentage and the increase in muscle strength were significant in the probiotic group and not in the diet alone group, the difference between the two groups was not significant.
Conclusion
For anthropometric parameters, the probiotic group was not superior to the diet alone group.

Does probiotics consumption improve glycemic parameters in adults with obesity?

Rym Ben Othman, Zeineb Zemni, Chaima El Ghali, Wafa Douiri, Berriche Olfa, Ramla Mizouri, Nadia Ben Amor, Faten Mahjoub & Jamoussi Henda
National Institute of Nutrition of Tunis, Obesity Research Unit, Bab Saadoun, Tunis, Tunisia

Introduction
Alteration of gut microbiota leads to increased intestinal permeability, inflammation, and metabolic disorders. The aim of our study was to determine the effect of probiotic supplementation on glycemic parameters in addition to a weight loss program.
Methods
This is an interventional study including 30 obese patients consulting the obesity unit of the Institute of Nutrition in Tunis. The patients were divided into 2 groups matched for age, sex and BMI: diet alone and probiotics (1 tablet of Lactibiane*/day). Glycemic parameters (fasting blood glucose, HbA1c, fasting insulin levels and HOMA index= insulin resistance score) were assessed at T0 and at one month after the intervention (T1).
Results
The mean age was 42.3 ±5.7 years with sex ratio Male/Female =0.25. Diabetes was found in 6.7% of patients in the diet alone group and 13.3% of patients in the probiotic group (the difference between the two groups was not significant *P*0.3). There was no significant difference between the two groups for glycemic parameters at T0 (fasting blood glucose (FBG), HbA1c, fasting insulin levels and HOMA index). For the diet alone group, there was a significant decrease only in HbA1c between T0 and T1 ($P=0.03$). For the probiotic group, we found a significant decrease in all glycemic parameters: FBG ($P=0.03$), HbA1c ($P=0.03$), insulin levels ($P=0.009$) and insulin resistance score ($P=0.008$). A statistically significant difference between the diet alone group and the probiotic group was found only for the decrease in fasting blood glucose ($P=0.02$).
Conclusion
Probiotics are superior to diet alone in improving the glycemic profile. Thus, they therefore have their place in the therapeutic arsenal of pre-diabetes and diabetes in patients with obesity.

Factitious hypoglycemia: psychosocial characteristics of patients

Marina Yukina, Nurana Nuralieva, Tatyana Zelenkova-Zakharchuk, Ekaterina Troshina & Galina Melnichenko
Endocrinology Research Centre, Moscow, Russia

Introduction
Hypoglycemia is a decrease of glucose in blood, which can lead to coma and death. One of the causes of hypoglycemia in patients without diabetes mellitus (DM) is deliberate intake of hypoglycemic drugs (factitious hypoglycaemia, FH, Munchausen syndrome).
Objectives
To present the psychosocial characteristics of patients with FH.
Methods
Anamnesis analysis of 431 patients with hypoglycemia aged 18-93 years.
Results
FH was diagnosed in 15 (3,5%) patients: due to taking antidiabetic pills ($n=5$) or insulin administration ($n=10$); age 34 (min-max: 18-47) years; $n=13$ females (87%); $n=1$ with DM and $n=11$ (73%) had relatives with DM; $n=2$ were medical workers and $n=1$ had medical worker as a relative. $n=5$ had a hypoglycemic coma in anamnesis, of them $n=2$ repeatedly. $n=4$ underwent unreasonable invasive intervention on the pancreas. FH was combined with factitious DM ($n=4$) and with factitious hypercorticism ($n=1$). Diagnosis, according to ICD-10: [F40] $n=3$, [F45] $n=2$, [F44.8] $n=1$, [F07.0] $n=1$ and [F48.0] $n=1$. $n=7$ (47%) refused psychiatric examination. 87% of patients were unemployed. The possible causes of FH were: free temporary accommodation and meals in the hospital, avoiding compulsory military service and work, speeding up kidney transplantation. After presenting evidence of FH, none of the patients confirmed this fact, but did not try to prove the opposite.
Conclusions
The main features of patients with FH are: young age, women, lack of work, relatives with DM. All patients, examined by a psychiatrist, had various mental disorders.

Comparative study on the efficacy and safety of various regimens of glucocorticoid therapy in patients with COVID-19 and Diabetes Mellitus

Tatiana Meleshkevich[1], Iuliia Verzina[1], Irina Kurnikova[1], Aleksandr Ametov[2], Evgeniya Luchina[3] & Evgeniya Tavlueva[4]
[1]RUDN University, Department of Therapy and Endocrinology, Moscow, Russia, [2]Federal State Budgetary Educational Institution of Further Professional Education, Moscow, Russia, [3]GBUZ «City Clinical Hospital. F.I. Inozemtsev » DZM, department of endocrinology, Moscow, Russia, [4]GBUZ «City Clinical Hospital. F.I. Inozemtsev » DZM, Regional Vascular Center, Moscow, Russia

Purpose
To determine the effective and safe regimen of glucocorticoids administration in patients with COVID-19 and with or without DM.
Materials and methods
We examined 276 patients with covid-19 and polysegmental pneumonia with CT (1-4) in inpatient treatment with an oxygen support level of up to 15 liters per minute, all patients were discharged from the hospital. Patients were divided into 2 groups according to the therapy they received. The first group of patients was treated with glucocorticoids (dexamethasone) - observational group of 205 patients, men -114, women -91 and the second was control group of 71 patient without glucocorticoid therapy: men -42, women -29. The number of patients with and without diabetes was assessed in each of the group. The observational group was divided into 3 subgroups according to the regimen of glucocorticoid therapy: in 1 subgroup of 68 patients dexamethasone was administered intravenous (i/v) once a day (the dose was 8 to 32 mg); in 2 subgroup patients received dexamethasone i/v 2 times a day (in a total daily dose of up to 32 mg) - 70 patients ; and in 3 subgroup of 67 patients dexamethasone was administered intramuscularly once daily (dose not less than 0.1 mg per 1 kg of body weight). In each subgroup number of patients with DM was assessed. All groups received standard therapy for COVID-19.
Results
in the observational subgroup of patients with DM at the end of the study Inflammatory factor such as: leukocytes increased by 35-41%, depending on the subgroup; the neutrophil-lymphocyte index (NLI) decreased by 28-44%; CRP decreased by 78.9-88.2% (p-0.001). In the subgroup of patients without DM, leukocytes decreased by 23-28%, NLI did not change, CRP decreased by 75-82.5% (p-0.01). In the Control group: no significant difference was obtained in the parameters of leukocytes, NLI. CRP decreased significantly in patients with DM by 39.7%, and without DM by 56.5% (p-0.0001).
Conclusions
1) The optimal regimen of glucocorticoid therapy is a single-dose intravenous or intramuscular administration of dexamethasone not less than 0.1 mg per 1 kg of body weight. 2) A statistically reliable effective and safe dose for patients with diabetes mellitus is 12 mg, without diabetes mellitus 11-12 mg.

EP1121

Vitamin D status in childhood obesity: prevalence and implications in a group of children from Romania

Amalia Ioana Arhire, Boroghina Steluta & Ionita Ancuta
Kilostop Junior, Endocrinology, Diabetes and Nutrition Department, Bucharest, Romania

Introduction
Obesity and vitamin D deficit are risk factors for inflammation, insulin resistance, hypertension and impeded bone mineralization and also cardiovascular disease. type 2 diabetes and osteoporosis. As globally both conditions reach pandemic levels and the level of vitamin D negatively correlates with obesity we studied this correlation and impact on a group of children suffering from obesity.
Materials and method
We conducted a retrospective ecologic correlational study on 71 children from the south of Romania, who attended our nutrition clinic from 2020-2021, with the age median = 12, median BMI = 27, median obesity degree 145%.
Results and conclusion
A deficit of vitamin D was found in 31 patients (43.66%), 38.02% with mild deficit and 5.63% severe deficit. The vitamin D deficit positively correlates with the obesity degree (t value = 30,45, $P < 0.00001$) and the percent of body fat (t value = 26.96, $P < 0.00001$) Vitamin D deficit is present in nearly half of the children from the group, with deficit levels that statistically positively correlate with the degree of obesity and percent of body fat. Obesity is associated with a resistance to vitamin D supplementation and a new guideline for the substitution of vitamin D in this population as doctors still prescribe doses as for normal weight children. Keywords: pediatric obesity, vitamin D, body fat, deficit.

Type 1 diabetes after 10 years of evolution : complications and metabolic profile

Ines Bani, Rym Ben Othman, Berriche Olfa, Ramla Mizouri, Nadia Ben Amor, Faten Mahjoub & Jamoussi Henda
National Institute of Nutrition of Tunis, Department A, Tunis, Tunisia

Introduction
Type 1 diabetes (T1DM) is an autoimmune disease that commonly affects a young population. Its evolution can be characterized by a frequent occurrence of degenerative complications. Our aims were to study microangiopathic complications, lipid profile, and the presence of other autoimmune diseases in type 1 diabetic patients whose diabetes has been evolving for 10 years or more.
Method
This is a descriptive cross-sectional study including T1DM patients (with diabetes of 10 years or more), conducted in department A of the National Institute of Nutrition in Tunis during the year 2022.
Results
Our study included 67 T1DM patients, predominantly female (61.2%). The average age of our patients varied from 16 to 67 years with a mean of 35 ± 12 years. The mean duration of diabetes progression was 17.7 ± 7 years. Among our patients 20.9% had hypothyroidism and 9% had hyperthyroidism. Celiac disease was present in 6% of patients. Only one patient had adrenal insufficiency. Microangiopathic complications were dominated by diabetic retinopathy (50.2%), then diabetic nephropathy (31.3%) and diabetic neuropathy (22.4%). More than 2 thirds of patients (86.6%) had poorly controlled diabetes (HB1AC > 7%) with a mean HB1AC of 10 ± 2%. Hypertriglyceridemia was present in 19.4% with a mean triglyceride level of 1.29 mmol/l. The mean LDL cholesterol level was 1.05 ± 0.23g/l. low HDL cholesterol levels were noted in 31.3% with a mean HDL cholesterol level of 1.24 ± 0.31 mmol/l. A positive association was noted between low HDL cholesterol and diabetic retinopathy ($P = 0.025$). The decrease in HDL cholesterol was also positively associated with diabetic neuropathy ($P = 0.45$) and diabetic nephropathy ($P = 0.05$).
Conclusion
Degenerative complications are common after 10 years of T1DM progression, hence the need for early management to prevent or delay the onset of chronic complications of T1DM. A low HDL cholesterol level could be a risk factor for the development of these complications.

Trends in Prescription of Anti-Diabetic Drugs and Metabolic Control in Type 2 Diabetes: 2015/2016 vs. 2020/2021

Daniela Soares[1], Isabel Palma[1], Maria Helena Neto[1], Mariana Fraga[2], Joel Pereira[1], Rosa Guimarães[1], Maria Helena Cardoso[1], Ariana Maia[1] & Lia Ferreira[1]
[1]Hospital Geral de Santo António, Endocrinology, Porto, Portugal, [2]Hospital Geral de Santo António, Nutrition, Porto, Portugal

Introduction
The development of new pharmacological classes for type 2 diabetes (T2D) treatment with extra-glycaemic benefits has led to the update of the treatment algorithm, presenting new effective alternatives to patients' insulinization. The present study aims to evaluate the evolution of prescription and its impact in metabolic control of patients enrolled on an educational diabetes program of a tertiary hospital.
Objectives
To evaluate trends on anti-diabetic drugs' prescription and metabolic outcomes in patients with T2D, comparing the two biennia 2015/2016 and 2020/2021.
Methods
240 patients were evaluated, 118 in 2015/2016 and 122 in 2020/2021, with no significant differences in general population characterization. In 2020/2021, there was a significant increase in GLP1 agonists (+72,3%, $P < 0,001$), SGLT2 inhibitors (+66,3%, $P < 0,001$) and metformin's (+10,1%, P0,030) prescription, contrary to a decrease in the use of DPP4 inhibitors (-58,9%, $P < 0,001$), insulin (-12,0%, P0,049) and sulfonylureas (-8,5%, P0,022). Additionally, there was an increase in the use of non-insulin anti-diabetic drugs in triple combination ($P < 0,001$) and in the de-insulinization rate (+11,9%, $P < 0,040$). In what concerns metabolic control, we found a higher reduction in weight (-0,4 kg vs. -4,0 kg, $P < 0,001$) and BMI (-0,16 vs. -1,38, $P < 0,001$) in 2020/2021, with no significant differences between biennia regarding HbA1c and blood pressure variation.
Conclusions
In 2020/2021, there was an increase in GLP1 agonists, SGLT2 inhibitors and metformin's use, as well as an increase in de-insulinization rate. In addition, we found a higher reduction in weight and BMI of patients. The differences found demonstrate a growing use of drugs with extra-glycaemic benefits, which reflected in a higher weight loss and allowed the discontinuance of insulin on a significative percentage of patients.

Anemia in the elderly diabetic subject

Yesmine Jallouli[1], Rym Ben Othman[2], Syrine Trabelsi[2], Berriche Olfa[2], Eya Safi[2], Ramla Mizouri[2], Faten Mahjoub[2], Nadia Ben Amor[2], Douiri Wafa[2] & Jamoussi Henda[2]
[1]National Institute of Nutrition and Food Technology, Department A, Route Tunis Sfax, Tunisia, [2]National Institute of Nutrition, Department A, Tunis, Tunisia

Introduction
Anemia is common in the elderly subject over 75 years of age. The pathophysiological mechanisms of anemia are identical to those of the younger subject and the etiological investigation is based on precise diagnostic trees.
Objective
The objective of our study is to determine the prevalence of anemia in diabetic subjects over 75 years of age and to determine the associated factors.
Methodology
This is a descriptive cross-sectional study conducted at the National Institute of Nutrition of Tunis (INNTA) in 62 diabetic patients over 75 years old hospitalized in department A during the period February-December 2022. For each patient we conducted a medical history taking,a clinical examination with a blood count.
Results
We collected 62 diabetic patients. The average age of the population was 73.23 ± 3.28 years. Sixty five percent of the patients were female. The average age of diabetes was 16.30 years $\pm$ 8. The frequency of oral disorders was 88.9%. The socioeconomic level was low in 49.2% of patients. The prevalence of anemia was 22.2% with a mean hemoglobin of 12.58 g/dl ± 1.81. A significant association was noted with sex (P:0.011). Moreover, polymedication and digestive disorders were not associated with the presence of anemia (P:0.074) and(P 0.335) respectively.
Conclusion
Anemia is often discovered by chance. It would be a marker of the health state of the elderly which justifies an early diagnosis with an adequate etiological investigation in order to avoid the repercussion on the life quality of the patients.

Uricemia and lipid profile in adult population with obesity

Zeineb Zemni[1], Nesserine Dhieb[1], Ramla Mizouri[1], Chaima Sdiri[2], Rym Ben Othman[1], Nadia Ben Amor[1], Berriche Olfa[1], Faten Mahjoub[1] & Jamoussi Henda[1]
[1]National Institute of Nutrition of Tunis, Obesity Research Unit, Bab Saadoun, Tunis, Tunisia, [2]National Institute of Nutrition of Tunis, Outpatient Departement and Functional Explorations, Bab Saadoun, Tunis, Tunisia

Introduction
Hyperuricemia is associated with an increased risk of cardiovascular diseases. The aim of this study was to examine the relationship between lipid profile and blood uric acid levels in an adult population with obesity.
Methods
Retrospective study including 200 patients with obesity who consulted the Obesity Unit of the National Institute of Nutrition in Tunis in 2021. Data were collected from patients' medical records. The lipid profile includes low-density lipoprotein (LDL), high-density lipoprotein (HDL), triglyceride (TG) and total cholesterol (TC). Hyperuricemia was defined as serum uric acid greater than 6 mg/dl (360 µmol/l).
Results
The average age was 47.21 ± 13.88 years with a sexe ratio M/F = 0.33. Mean BMI was 41.2 ± 7 kg/m2. Dyslipidemia was found in 55.6% of cases. Hyperuricemia was found in 30.3% of cases. HDL cholesterol was inversely correlated with uric acid levels (r = - 0.2, P0.005). However, there was no significant correlation between TC, LDL, TG and uric acid.
Conclusion
The results of our study showed a strong association between uric acid increase and lipid disorder in patients with obesity. The detection and treatment of these abnormalities will improve the cardiovascular prognosis of patients.

What is the Impact of Prebiotic Supplementation on Depression Symptoms in Patients with Obesity?

Rym Ben Othman, Zeineb Zemni, Chaima El Ghali, Berriche Olfa, Wafa Douiri, Ramla Mizouri, Nadia Ben Amor, Faten Mahjoub & Jamoussi Henda
National Institute of Nutrition of Tunis, Obesity Research Unit, Bab Saadoun, Tunis, Tunisia

Introduction
People with obesity are at risk of psychological complications such as anxiety and depression. The objective of this study was to assess the effect of prebiotic supplementation in addition to a weight loss program on depression symptoms in an adult population with obesity.
Methods
Interventional study involving 30 patients with obesity consulting the obesity unit of the National Institute of Nutrition in Tunis between May and August 2022. Patients were divided into 2 groups matched for age, sex and BMI: diet alone and prebiotics (30g carob/day). All patients were screened for anxiety symptoms using the HAD score (depression dimension). The questionnaire was administered at T0 and one month after the start of the diet (T1).
Results
The mean age was 40.3 ± 6.7 ± years with a female predominance (80% of women). There was a significant weight loss in each group (diet only group: -2.5 kg P0.001 and prebiotic group: -2.2 kg, P0.003). However, for the comparison between groups, there was no significant difference (P = 0.7). At T0, depression related symptoms were present in 93,3% of the patients in the diet alone group (33.3% doubtful symptoms and 60% certain symptoms) and for the prebiotic group, depression related symptoms were present in 80% of patients (26.7% doubtful and 53.3% certain). At T1, there was a significant improvement in the HAD-depression score for the diet alone group (mean difference = 2.5, P < 0,001) and for the prebiotic group (mean difference = 3.1, P0.01). There was no statistically significant difference between the two groups for the improvement of HAD-depression score between T0 and T1 (P = 0.3).
Conclusion
The prevalence of depression symptoms was high in our population with obesity. The improvement of the symptomatology expression was not related to prebiotic consumption. It's probably related to the weight loss itself.

All's well that ends well

Muhammad Shoaib Zaidi
King Saud University Medical City, University Diabetes Center, Riyadh, Saudi Arabia

Introduction
Diabetes can involve the musculoskeletal system causing frozen shoulder, Dupuytren's contracture, diabetic sclerodactyly, trigger finger, muscle infarction, diabetic amyotrophy, idiopathic lumbosacral radiculoplexus neuropathy, necrotizing fasciitis and many other complications. A case is described, who despite having multiple acute and chronic sequelae of diabetes, was successfully managed and discharged.
Case Presentation
54yrs old obese, Saudi gentleman with multiple co-morbids(Type 2 DM ≥ 10yrs, Hypertension, Chronic kidney disease(3B,A3), Proliferative DM retinopathy(awaiting intra-vitreal injections) & Grade I diastolic dysfunction), Chronic normochromic normocytic anemia(GI endoscopy-upper)-chronic inactive gastritis,(lower)-single rectal polyp(tubular adenoma on histopathology), was readmitted under Medicine department on 15.01.2023 with left hip pain, radiating to the thigh, with restricted activity for 2 weeks prior to the presentation. Rest of the workup-normal. Past history of proximal lower-limb weakness, double incontinence(2yrs) & cataract surgery. No allergies or addictions. Unremarkable family history He was on regular ACE-inhibitor, Calcium channel blocker, thiazide, loop diuretic, Linagliptin, statin, iron, Metformin and Glargine-100. Systemic review-unremarkable. BP 185/85mmHg, Pulse 74/m, regular, T-36.8 C, RR 19/m, O<info>2</info>sat 94%(on 6ltrsO<info>2</info>). Weight 104 kgs. Pallor + Bilateral pitting pedal edema + +, JVP raised. M. skeletal (Left hip) Upper medial thigh tender, but without warmth or erythema. Reduced passive and active movements of hip. Other joints unremarkable. CVS-S1, S2 audible + ejection systolic murmur + Neurology-symmetrical wasting of hands & quadriceps + absent deep tendon reflexes in lower limbs, along with bilaterally reduced vibration & pin-prick sensations. Rest-normal. The patient was diagnosed to have MRI proven extensive myositis of left pelvis & proximal thigh with focal myonecrosis and infective iliopsoas bursitis. Besides there was suspicion of early osteomyelitis of left ischio-pubic ramus & milder right sided myositis(CRP413.9 mg/l. He also developed acute on chronic kidney injury [S.Creatinine 307umol/l(59-104), and acute myocardial demand ischemia(serial ECGs-mild ST-T changes, TroponinT1040 ng/l(≥ 100 clinically significant), CPK438u/l(39-308), Echo[new RWMA(inferior wall) + mild LV systolic dysfunction(EF45%)], Myocardial perfusion scan-myocardial infarction of distal inferior wall. Other significant labs. Hb% 6.9g/dl, MCV89.8fl, TLC 17.8 $x10^9$/l,88% PMNs, HbA1c7.7%, S.albumin24.3g/l. CT chest-bilateral lower lobe opacities + mild pleural effusion. No pulmonary embolism. NCV/EMG-sensorimotor axonal polyneuropathy. The patient was treated with Frusemide, packed RBCs, Albumin, Insulin, Oxygen & broad spectrum antibiotics. An US guided aspiration & C/S from left iliopsoas bursa revealed MRSA organism and was treated for both bursitis & Osteomyelitis. He improved with the given treatment and was discharged home on 09.02.23..
Conclusion
Our patient exemplifies the presence of four co-existing musculoskeletal problems in close neighbourhood i.e. myonecrosis, myositis, infected iliopsoas bursitis and osteomyelitis. Diabetes was the common denominator amongst them.

Neuroleptics, a source of blood sugar imbalance not to be underestimed

Colna Antonio Nfad, Mohamed Malad, Hajar Srifi, Mamadou Togo & Guerboub Ahmed Anas
Military Training Hospital, Endocrinology, Rabat, Morocco

Introduction
Today, atypical antipsychotics offer the advantage of less frequent extrapyramidal effects compared to conventional neuroleptics, but they are associated with weight gain and diabetes mellitus.
Observation
A 31-year-old patient with positive diabetic heredity, followed for schizophrenia on Levomepromazine and Olanzapine. Having revealed his diabetes mellitus by a diabetic cardinal syndrome. Blood glucose = 3g/l. Urine dipstick shows ketonuria at 2 crosses, confirming the diagnosis of diabetic ketosis. Ideal weight, BMI = 18 kg/m2 and TDT = 79 cm. The physical examination was unremarkable except for a psychomotor slowdown. The aetiological assessment of the decompensation was strictly negative. The HbA1C on HPLC standardized on DCCT was 20%, a level confirmed on a second sample.

Discussion
Usually, the HbA1C levels observed at the discovery of T1DM are modest. This is explained by the noisy mode of revelation of this disease. However, in this case, the level was unusual, raising the suspicion of antipsychotic-induced T1DM. Indeed, it has been shown that the prevalence of diabetes is 10% in people treated with antipsychotics, 2 to 3 times higher than in a general population matched for age(*).
Conclusion
Drug-induced or drug-aggravated diabetes is a fairly frequent situation in clinical practice, often requiring multidisciplinary management
(*): Drug-induced diabetes: four classes at the heart of our clinical practice.12-10-2022.

Adherence to antidiabetic treatment in Tunisian type 2 diabetic patients

Syrine Trabelsi, Rym Ben Othman, Yesmine Jallouli, Berriche Olfa, Eya Safi, Ramla Mizouri, Faten Mahjoub, Nadia Ben Amor, Wafa Douiri & Jamoussi Henda
National Institute of Nutrition and Food Technology, Department A, Tunis, Tunisia

Introduction
Poor compliance in chronic diseases, including diabetes mellitus, is a major and frequent problem, with serious consequences on morbidity and mortality of diabetics.
Objective
The aim was to assess adherence to antidiabetic treatment and to determine the consequences of poor compliance.
Patients and methods
This was a descriptive cross-sectional study conducted in the National Institute of Nutrition. 200 type 2 diabetic patients hospitalized between May and September 2022 were included. For each patient, we conducted a thorough interview and a biological check-up.
Results
The average age of our population was 58.56 $\pm$ 8.9 years with a female predominance of 66%. The average age of diabetes was 13.16 $\pm$ 7.8 years with an average HbA1c of 10.28 $\pm$ 2% and fasting blood glucose of 12.13 $\pm$ 5.42 mmol/l. 1/5 of our population did not accept their diabetes. The majority of our patients were on Oral-Diabetic-Agents (ODA), 21% on insulin and 39% on ODA and insulin. Diabetes was complicated by retinopathy, nephropathy and neuropathy in 38.5%, 17% and 66.5% of cases respectively. 4/5 of our patients were adherent to the treatments. We noted a decrease in doses in 15% and omission of the usual doses in 22.5% of cases. There was a statistically significant relationship between adherence to treatment and acceptance of the diagnosis of diabetes ($P=0.03$), retinopathy ($P=0.009$) and HBA1C ($P=0.001$).
Conclusion
The lack of awareness of this problem leads to unnecessary intensification of antidiabetic treatment and may explain the large number of patients put on insulin.

Flash glucose monitoring in patients with DM3c

Ángel Rebollo-Román, Mª Carmen Serrano Laguna, Carlos Manuel Alzás Teomiro, Paloma Moreno-Moreno & Maria Angeles Galvez Moreno
Hospital Reina Sofía, Córdoba, Spain

Objective
Flash glucose monitoring (FGM) facilitates non-invasive glucose level assessment. Since November 2020 this system is subsidized in patients with type 3c diabetes (DM3c) Our objective was to describe the characteristics of these patients and their glycemic control expressed as times in range.
Methods and patients
Observational longitudinal clinical study between January 2021 and January 2023 in patients with DM3c.
Results
68 patients included. Mean age: 62.17 $\pm$ 10.43 years, with DM diagnosed with a mean age of 52.21 $\pm$ 13.02 years. 29.4% women. Mean BMI 25.33 $\pm$ 4.65 kg/m^2. 72.1% use of pancreatic enzymes in these patients. Total insulin dose 0.50 $\pm$ 0.32 UI/kg. 14.7% patients not using prandial insulin. DM3c etiology: 33.8% Chronic pancreatitis 61.8% Pancreatic surgery 4.4% Cystic fibrosis FGM metrics: A median use of 92.00% (with 85% use as 25th percentile). 10.26 $\pm$ 4.74% daily scans. 68.07 $\pm$ 19.57% time in range, 21.24 $\pm$ 11.34% time between 180-250 mg/dl, 8.47 $\pm$ 11.95% time above 250 mg/dl, 2.47 $\pm$ 1.00% time between 54-70 mg/dl, 0.28 $\pm$ 1.17% time below 54 mg/dl. Glycemic CV 32.89 $\pm$ 7.89%. 39.1%. GMI 7.07 $\pm$ 0.76%.
Conclusion
- The main cause of DM3c in our series was surgical pancreatic resection (61.8% of patients). Almost three quarters of them had also exocrine insufficiency.
- In our series of patients with DM3c, glycemic control was suboptimal due to hyperglycemia. Glycemic variation was adequate and hypoglycemia targets were met.

A 7.5 cm hyperdense heterogeneous incidental right adrenal mass: Is it cancer?

Borja Santana-Ojeda[1], Ricardo Jose de Leon-Durango[1], Alba Hernandez-Lazaro[1], Carlos Rios-Gomez[1], Claudia Arnas-Leon[1,2], Carmen Acosta-Calero[3], Agnieszka Kuzior[2], Paula Gonzalez-Diaz[4], Jennifer Maria Perez-Rivero[5] & Francisco Javier Martinez Martin[1,2]
[1]University Hospital of Gran Canaria Dr. Negrín, Endocrinology & Nutrition, Las Palmas de Gran Canaria, Spain, [2]Clinica San Roque, Endocrinology & Nutrition, Las Palmas de Gran Canaria, Spain, [3]University Hospital of Gran Canaria Dr. Negrín, Cardiology, Las Palmas de Gran Canaria, Spain, [4]University Hospital of Gran Canaria Dr. Negrín, Emergency Medicine, Las Palmas de Gran Canaria, Spain, [5]Centro Salud Escaleritas, Family & Community Medicine, Las Palmas de Gran Canaria, Spain

Introduction
Although usually considered as benign tumors, cavernous hemangiomas are venous malformations due to endothelial dysmorphogenesis and not true neoplasias. They are usually asymptomatic but occasionally can cause compressive symptoms or serious internal bleeding. They may arise in almost any vascularised organ, but their presentation in an adrenal gland is highly infrequent, and can masquerade as pheochromocytoma, adrenal carcinoma or metastatic malignant lesion.
Methods
We performed a retrospective revision of the patient's clinical record and of the literature. The patient gave informed consent.
Results (clinical case)
A 72 year-old male, with obesity, type 2 diabetes and non-alcoholic fatty liver disease was referred to our Endocrinology clinic after the finding of a large right adrenal mass in an abdominal ultrasonography performed in the context of epigastralgia, dyspepsia and hepatomegaly. His office blood pressure was normal and he had no history of hyperkalemia or hypertensive episodes. There were no signs or symptoms suggesting Cushing's syndrome, no weight loss, skin lesions suggesting melanoma or other obvious signs of metastatic malignant disease. A CT abdominal scan and adrenal function tests were ordered. Plasma metanephrines (31/54 pg/ml), aldosterone, renin and aldosterone/renin ratio were normal, plasma cortisol after overnight suppression with dexamethasone 1 mg was also normal. The CT described a grossly spherical mass of 7.5 cm diameter occupying the right adrenal; the lesion was solid, hyperdense and heterogeneous, with multiple nodular and tubular foci. The presumptive diagnosis was adrenal carcinoma, distant metastasis, pheochromocytoma or hemangioma. The left adrenal gland showed a 1.6 cm hyperdense mass, not characterizable as adenoma. There were no other findings suggesting abdominal neoplasm or metastases. With functioning pheochromocytoma ruled out, the patient underwent laparotomy and right adrenalectomy which was uneventful; during the procedure a FNAC was obtained from the left adrenal. The pathology report was: Adrenal gland of 10.5 cm containing a 7.5 cm cavernous hemangioma, partially thrombotic, in the context of cortical adrenal hyperplasia or adenoma, negative for malignancy. The FNAC from the left adrenal was negative for malignancy also. The patient remains asymptomatic and 6 months after the surgery the adrenal function remains normal. For the follow-up of the left adrenal gland, an abdominal MRI scan has been ordered.
Conclusions
Adrenal hemangiomas are infrequent, but they should be included in the differential diagnosis of adrenal masses. They can masquerade as malignant lesions. Surgical treatment is often indicated in order to ascertain the diagnosis and to avoid complications.

Rare phenotype association between pulmonary NET and prolonged hyperkalemia after an unilateral adrenalectomy for primary hyperaldosteronism

Denisa-Isabella Tănasie[1], Găloiu Simona Andreea[1,2], Maria Lavinia Popa[3], Ingrid Iordan[4], Teodor Constantin[2], Radu Iorgulescu[5] & Catalina Poiana[1,2]
[1]Carol Davila University of Medicine and Pharmacy, Bucureşti, Romania, [2]C.I. Parhon National Institute of Endocrinology, Bucureşti, Romania, [3]Spitalul Clinic de Urgenţă pentru Copii Grigore Alexandrescu, Bucureşti, Romania, [4]Centrul Oncologic SANADOR, Bucureşti, Romania, [5]Sf. Ioan Clinical Emergency Hospital, Bucureşti, Romania

Introduction
We describe the case of a 68-year-old patient, having two MEN1-associated tumors that are not part of the classical triad, with a penetrance of only 40%, and 2%, according to the medical literature. Furthermore, she developed a persistent hyperkalemia after the unilateral adrenalectomy, which is rare and often missed.
Case report
In 2011, following a non-specific symptomatology (dry cough, fatigue), a bilobectomy was performed (medium and right inferior lobes), the patient being diagnosed with typical pulmonary carcinoid, as stated by the histopathology and immunohistochemistry tests. 9 years later, in May 2020, the patient was admitted to the ER for cardiac tamponade, the neoplastic etiology being revealed by the histopathological examination. Afterwards, the outcome of the immunohistochemistry assessment was fibrino-hematic pericarditis, with mesothelial reaction, without tumor aspects. A December 2020 octreoscan scintigraphy detected pericardial and hepatic lesions, indicating pulmonary carcinoid metastases. Therefore, 1 month later, octreotide treatment was initiated (Sandostatin LAR 30 mg/month). In July 2021, the patient undertook another octreoscan scintigraphy showing only a new L4 lesion. In November 2021, the laboratory findings pointed to primary hyperaldosteronism with a high ARR (>84.2 ng/dl per uU/ml), undetectable renin with PAC>20 ng/dl (42.1 ng/dl), and hypokalemia (2.9 mmol/l). The most recent unenhanced thoracic-abdominal-pelvic CT scan identified a 22mm adenoma in the right adrenal gland, which had been registered in the patient's medical records for 10 years. Due to endocrinological assessments which indicated subclinical hyperthyroidism, and a toxic multinodular goiter revealed by the thyroid scintigraphy, the Thyrozol treatment was restarted. In May 2022, the patient underwent right laparoscopic adrenalectomy. Gross pathologic examination revealed a 1.8 cm round, well-circumscribed nodule, while the microscopic examination confirmed the adrenal adenoma diagnosis. Pre-adrenalectomy, the patient's renal function was impaired, with a 32.3mL/min/1.73 m^2 eGFR. The postoperative PAC declined to a low level: 13.1 ng/dl, while the serum potassium levels surged to 7.43mEq/l, and the eGFR further decreased to 17.5mL/min/1.73 m^2 with cortisol levels within the normal range. Subsequently, fludrocortisone 0.1 mg daily was initiated, and the patient's potassium levels returned to the ULN (5.1 mmol/l) seven months after adrenalectomy.
Conclusion
Because of this rare phenotype association of primary hyperaldosteronism and pulmonary NET, the patient falls into both MEN1 and MEN4 syndrome. Close monitoring of postoperative potassium levels is crucial following adrenalectomy, especially those with altered renal function or advanced age, as they are at a higher risk of developing life-threatening hyperkalemia. Mineralocorticoid replacement therapy should be administered if necessary.

An audit of ten years experience of medullary thyroid carcinoma management from a tertiary care hospital of north India

Ananda Mohan Chakraborty[1], Rimesh Pal[1], Soham Mukherjee[1], Uma Nahar[1], Pinaki Dutta[1], Divya Dahiya[2], Naresh Kumar Panda[3] & Sanjay Kumar Bhadada[1]
[1]Post Graduate Institute of Medical Education and Research, Endocrinology, Chandigarh, India, [2]Post Graduate Institute of Medical Education and Research, Surgery, Chandigarh, India, [3]Post Graduate Institute of Medical Education and Research, ENT, Chandigarh, India

Introduction
Medullary thyroid carcinoma (MTC) is a rare thyroid malignancy originating from parafollicular C-cells. It accounts for 5% of all thyroid carcinomas.
Methods
A retrospective registry-based analysis of demography, clinical manifestation, genetics, management, and outcome of pathologically proven MTC cases presented in a tertiary care hospital in India was done.
Results
Among 71 evaluated cases, the mean age of presentation was 43.63 $\pm$ 11.41 years, and 62% were female. The median duration of symptoms was 23 months (IQR 12-34.75 months). The most common presenting complaint was goiter, present in 57 (80.3%) patients. Among the atypical presentation, one patient had ectopic Cushing's, one with hypertensive crisis in pregnancy due to pheochromocytoma, one patient had chondrosarcoma. Disease was detected incidentally in one patient who had prostatic carcinoma and underwent a PMSA scan, one had associated VHL. Median calcitonin and CEA level at presentation were 1566 pg/ml and 147.5 ng/ml respectively. Among the 25 RET protooncogene mutation assessments, 15 had the mutation positive. Twelve patients had MEN2A and 3 had MEN2B in this cohort one had Erβ positivity. Most of the patients were presented with stage 3 disease and an increasing trend of calcitonin level was observed as the stage of presentation advanced ($P=0.015$). Surgery was the primary modality of therapy offered in 95.8% of cases. The mean fall of calcitonin was 86.37 $\pm$ 36.11 percent, dependent on the tumor stage at presentation. Twenty-five patients received tyrosine kinase inhibitors as second-line or third-line therapy, 18 received sorafenib, and 10 and 5 patients received lenvatinib, and cabozantinib respectively according to availability. Two patients received PRRT with Lu 177. Thirteen patients had hand-foot syndrome,1 patient had membranoproliferative glomerulonephritis and one had bowel perforation as TKI adverse event. Median progression-free survival (PFS) time was 84 months. Patients with stable disease after the first modality had a PFS of 156 months compared to 72 months in those who had progressive disease at first follow-up (Chi-Square:5.244; $P=0.022$).
Discussion
An audit of 10 years of experience of MTC has been reported here. Some of the atypical presentation is documented. A tumour stage and its relation with baseline calcitonin, and responsiveness to TKI along with adverse events and determinants of PFS is also depicted. Hereditary MTC had an earlier age of onset. Limitation of the study being heterogenicity and truncation of data due to the retrospective nature of the study.

An interplay between primary hyperparathyroidism, Hashimoto thyroidis and thyroid cancer

Rada Sparavalo[1] & Sanja Borozan[2]
[1]General Hospital Niksic, Department of Endocrinology, Niksic, Montenegro, [2]Clinical Centre of Montenegro, Department of Endocrinology, Podgorica, Montenegro

The incidence of well differentiated thyroid carcinoma (TC), mostly papillary, is higher among patients with primary hyperparathyroidism (PHPT) compared to the general population, despite the similar frequency of thyroid nodules. The link between TC and Hashimoto thyroiditis (HT) is attributed to chronic inflammation, but the molecular association is poorly undestood. Herein, we explore the possible interplay between HT, PHPT and papillary TC through a case report and a literature review. A 49-year-old female patient underwent right superior parathyroidectomy due to primary hyperparathyroidism and a total thyroidectomy because of a suspicious nodule. Histopathological findings were consisted of concomitant parathyroid adenoma and 2 mm papillary thyroid microcarcinoma with Hürthle cell features whereas the remaining tissue of the thyroid showed a typical pattern of HT. No capsular infiltration was detected neither the pathological lymph nodules. Postoperatively, TSH suppressive therapy was administered. Patient with PHPT should be closely monitored for the thyroid nodule on ultrasound, particularly if they have HT. The need of fine-needle aspiration (FNA) and cytological analysis of the suspected subcentimeter nodules in this setting is still to be clarified. Vice versa, when preparing for thyroidectomy, a serum calcium and parathyroid hormone should be measured. This preoperative screening can be a useful tool for detecting possible concomitant lesions and reducing reoperations and further complications.

Doege-Potter Syndrome, cause of paraneoplastic hypoglycaemia in a patient with a Solitary Fibrous Tumour: A Case Report

Anum Sheikh, Julia Calvo Latorre & Razak Kehinde
West Hertfordshire Teaching Hospitals NHS Trust, Watford, United Kingdom

Background
Non-islet-cell tumour hypoglycaemia (NICTH) is a rare paraneoplastic syndrome caused by an extra pancreatic tumour(1). Solitary fibrous tumour (SFT), amongst other tumours, is one of the rare causes of NICTH. We report a case of NICTH who presented with recurrent hypoglycaemias and was identified to have a fibrous tumour as part of the work up for his symptomatic hypoglycaemias.
Case Summary
A 75-year male had presented to the emergency department with severe symptomatic hypoglycaemia with a blood glucose of 0.9. His past medical history included hypertension and Gout. He was not on any medication that could have caused or contributed to a hypoglycaemia. His initial biochemical workup showed subnormal insulin and c peptide levels with low blood glucose reading (physiological response) in the presence of negative ketones and negative sulfonylurea screen. He also had a CT scan done as part of the workup for recurrent hypoglycaemia that showed a well-defined heterogeneously enhancing mass in the pelvis with no evidence of local or distant metastases. He was referred for surgery of his pelvis mass, the histology of which showed a SFT (immunohistochemistry positive for CD34 and STAT6, negative for S100, Sox10, CD117, DOG1, SMA and Desmin). Reassuringly, his symptoms of hypoglycaemias resolved completely post-surgery.
Conclusion
We present a case of NICTH secondary to SFT. The tumour secretes high molecular weight IGF-II(2) which has structural and biochemical homology with insulin resulting in hypoglycaemias(3). The management of NICTH is complete resection of the extra pancreatic tumour which eventually leads to resolution of the symptoms as happened in our case(4).

Parathyroid carcinoma (PC) is a rare endocrine tumor accounting for 0.5–6% or less in cases of primary hyperparathyroidism. According to The American Joint Committee on Cancer (AJCC) eighth edition, the histopathological criteria for PC include the presence of vascular invasion with capsular invasion and progression and/or metastasis to adjacent tissues. However, the small number of cases of PC makes it difficult to predict prognosis in the postoperative period of PC. We present two case report of PC: First, male patient, has chronic kidney disease in the dialysis stage and was monitored for PTH during his dialysis sessions. In September 2022 his PTH level was increase over 1911 pg/ml (15-65 pg/ml) and total calcium level corrected for albumin was 10.4 mg/dl. Because patient was also symptomatic (important bone pain), he was treated with total parathyroidectomy. Histopathological report was positive for right parathyroid carcinoma pT1NxL0V1Pn0 and Ki67 was positive in 5% of tumoral cells. Patient's calcium level decreased after the surgery needing high calcium doses and alfacalcidol. His PTH level decrease to 554 pg/ml and his calcium level normalize with orally calcium scheme. In order to detect secondary lesions, patient underwent whole body MIBI scintigraphy with no metastasis found on functional imaging. Second patient is a female patient diagnosed with a thyroid hipoechoic nodule in left thyroid lobe, with increased PTH level over 847 pg/ml and high calcium level of 13 mg/dl admitted for functional parathyroid imaging with MIBI. Scintigraphy report showed left superior parathyroid adenoma with dimensions about 1.5 cm. She was operated (October 2022) and the histopathological report was positive for parathyroid carcinoma in left superior parathyroid area pT2N0L0V0Pn0R1 with local invasion in adipose tissue and muscular strap, with Ki67 positive in 4% of tumoral cells. Her PTH level also decreased after the surgery at 112 pg/ml and she was referred for radiotherapy treatment. Functional imaging after the surgery (WBS MIBI scintigraphy) didn't found any distant secondary lesions. These case series of parathyroid carcinoma presents two different pictures: the initial diagnosis of secondary hyperparathyroidism vs primary hyperparathyroidism with no biological reason to think of parathyroid carcinoma vs many biological hints of parathyroid carcinoma, both successfully surgically treated, one with active monitoring and other with complementary radiotherapy treatment.

A diagnostic challenge: Is it metastatic papillary thyroid carcinoma or papillary thyroid carcinoma arising from intramedullar teratoma?
Davut Sakiz[1,2], Fatih Yılmaz[3] & Murat Calapkulu[4]
[1]Mardin Training and Research Hospital, Department of Endocrinology and Metabolism, Mardin, Turkey, [2]Mardin Artuklu University Faculty of Medicine, Department of Endocrinology and Metabolism, Mardin, Turkey, [3]Mardin Training and Research Hospital, Department of Pathology, Mardin, Turkey, [4]Igdir State Hospital, Department of Endocrinology and Metabolism, Iğdır, Turkey

Introduction
Papillary thyroid carcinoma (PTC) distant metastases without regional lymph node metastases are quite rare. Spinal cord teratomas are rare tumors mostly seen in children. To the best of our knowledge, the development of papillary carcinoma in intradural teratomas is theoretically possible, but has not been reported in literature.
Case report
A 36-year-old female patient admitted with the complaint of drop foot. On MRI, 20x11x20.5 mm lesion was observed at the T5 level and caused significant compression on the spinal cord. Surgical excision was performed due to drop foot. During surgery, a mass was detected on both sides of the spinal cord, the same color as the neural tissue and adherent to the cord, with a firmer consistency. Histopathological and immunohistochemical findings primarily suggested PTC metastasis. However, the presence of adipose tissue observed in the glial tissue neighborhood and the different degrees of immunoreactivity of the described glandular structures in different areas also consistent with a PTC on the basis of teratoma. With S100, glial tissue and adipocytes were positive. PAX8 and CK19 were positive in large areas. TTFI, HBME1, Galectin3, Gata3, ER, PR and EMA were positive in varying degrees and localizations. Thyroglobulin was positive in the secretions of the gland lumens. CEA, GCDP 15 and NapsinA were focal positive. In the thyroid gland no lesion or pathological FDG uptake could be detected via PET-CT. No pathological FDG uptake was observed in the neck. Also, 17x11 mm sized lesion at the lateral of the left ovary and anterior of psoas muscle had 3.5 SUVmax was reported. However this lesion was not seen in MRI evaluation. AntiTPO and antiTg were positive. In the thyroid ultrasonography, the parenchyma was heterogeneous and contained pseudonodular areas. A 4x4x6 mm well-circumscribed isoechoic solid nodule and a 6x7x8 mm isoechoic mixed solid nodule with cystic areas was observed in the left lobe. Thyroid FNAB performed from the index nodüle. The result was reported as atypia of undetermined significance. Total thyroidectomy followed by RAI ablation was planned as the treatment protocol to facilitate long-term follow up.
Conclusion
Clarification of the diagnosis of the neoplasms is imperative. Because treatment and follow-up protocols are shaped according to diagnosis. However, in some cases, the etiologic diagnosis of a neoplasm can be a real challenge for clinicians. As in our case, in unusual localized neoplasms, follow-up and treatment should be arranged by using additional diagnostic methods.

Clinical spectrum of ectopic Cushing's syndrome secondary to pheochromocytoma: A diagnostic and therapeutic challenge
Mariana Gomes Porras, Viyey Kishore Doulatram Gamgaram, Inmaculada González Molero, Stella González Romero, María Carmen Bautista Recio, Maria Cruz Almaraz Almaraz, Carolina Moreno-Torres Taboada & Gabriel Olveira Fuster
Regional University Hospital of Málaga, Endocrinology and Nutrition, Málaga, Spain

Introduction
The clinical presentation of ectopic Cushing's syndrome secondary to pheochromocytoma differs from the classic manifestations of these

endocrinopathies separately. This cosecretion causes greater morbidity, requiring a complex preoperative preparation. We describe two clinical cases, a 46-year-old male with grade II overweight and a 65-year-old female with grade I obesity, both with a personal history of hypertension poorly controlled with 7 and 3 antihypertensive drugs respectively and new-onset diabetes, the first as hyperosmolar hyperglycemic state, classified as type 2 diabetes mellitus (DM) treated with non-insulin hypoglycemic agents and insulin with progressive worsening of glycemic control despite a weight loss of 27.3% and 16.5% in the last 3 months respectively. The first case was associated with axonal sensory polyneuropathy in the lower limbs with clinical suspicion of Guillain-Barré Syndrome under follow-up by Neurology, while the second case reported paroxysmal tachycardia. On physical examination both had lower limbs edema and muscular atrophy in the extremities, but without cushing phenotype. Blood tests from the first and second cases reported: glucose 161 mg/dl and 284 mg/dl (70-100), potassium 2.2mEq/l and 2.3mEq/l (3.5-5.5), HbA1c 8.2% and 8.6% (<6.5%), pH 7.52 and 7. 48 (7.35-7.45), bicarbonate 46mmol/l and 33mmol/l (22-29), urine cortisol 9582 mgg/24h and >11253mg/24h (0.1-180), Nugent's test >75 mg/dl in both cases, ACTH 260pg/ml and 241pg/Ml (5-50), androgens, aldosterone, renin and normal ratios, metanephrine 2205 mg/24h and 1113 mg/24h (20-302), normetanephrine 1230 mgg/24h and normal (30-527) and methoxytyramine 1212 mg/24h and normal (103-434), respectively. Pituitary MRI was normal in both. In the first case, the thoraco-abdominal CT revealed multiple chronic dorso-lumbar vertebral fractures and left adrenal mass of 37 x 37mm compatible with pheochromocytoma, while the second case presented bilateral adrenal hypertrophy with right adrenal mass of 31 x 26mm compatible with pheochromocytoma. Given the clinical diagnosis of ectopic Cushing's syndrome due to pheochromocytoma, unilateral adrenalectomy was decided after being treatment with fenoxybenzamine and doxazosin, respectively, and metyrapone in both cases. Patology reported pheochromocytoma with free resection borders, PASS score 9 and 2 respectively, with ACTH expression. Both developed post-surgical primary adrenal insufficiency. Currently, both present normo-cortisolims ascertained with Synacthen test and remission of DM. Blood pressure controlled with 3 hypotensors and none, respectively.

Conclusions

In our experience, ectopic ACTH-producing pheochromocytomas are characterized by the association of uncontrolled hypertension, hyperglycemia, metabolic alkalosis and severe hypokalemia. In these scenarios, pre-surgical preparation with steroidogenesis inhibitors to maintain homeostasis is just as much a priority as alpha-adrenergic blockade.

Metachronous Double Pituitary Adenomas: Presentation of A Case and Literature Analysis

Miguel-Angel Ruiz-Gines[1], Juan-Antonio Ruiz-Gines[2] & Sandra Torres-Mateos[1]

[1]Hospital General Universitario de Toledo, Análisis Clínicos y Bioquímica Clínica, Toledo, Spain, [2]Hospital Clinico Universitario Lozano Blesa, Neurocirugía, Zaragoza, Spain

Introduction

Prolactinoma is the most frequent secreting pituitary tumor. They are usually treated with dopamine agonists (DA) (bromocriptine and cabergoline), which are very effective in most cases. DA resistance consists of the impossibility of reaching normal prolactin levels and/or reduction of the adenoma by at least 50%.

Case presentation

We present the case of a 57-year-old man affected by visual disturbances and hypopituitarism (2019). Pituitary MRI showed a 25×30×27mm pituitary cystic macroadenoma with displacement of the pituitary stalk, suprasellar extension displacing and compressing the optic chiasm (superior temporal quadrantanopia) and lateral expansion towards the cavernous sinuses. The prolactin level was very high (345 mg/dl [3.7-19.4]), starting therapy with dopamine agonists and subsequent transsphenoidal surgical treatment (subtotal resection), with an anatomopathological diagnosis of prolactinoma. Subsequently, prolactin levels returned to normal (8.48 mg/dl) and the follow-up pituitary MRI revealed a marked reduction in the size of the pituitary tumor (9×9×8mm). Visual acuity improved remarkably, as did the symptoms of concomitant hypopituitarism. A new control MRI (2021) showed persistence and progression (17×19×15mm) of the adenoma, with new compression of the optic chiasm despite continued treatment with DA, maintaining, however, prolactin levels within normal limits (13.2 mg/dl). The patient underwent surgery again by endoscopic transsphenoidal resection. The histological study showed, on this occasion, immunostaining positive for gonadotropins (LH and FSH), but negative for HGH, ACTH, TSH, and prolactin. These findings allow us to provide an explanation for the lack of response to treatment in DAs.

Conclusion and discussion

Our results would confirm the diagnosis of a metachronous macroprolactinoma with a gonadotropin-producing macroadenoma. Infrequent association (60 cases described to date), whose etiopathogenic basis would lie in the appearance of two adenohypophyseal or intraadenomatous monoclonal expansions.

Cushing's disease: a rare case of long-term pasireotide therapy

Miriam Veleno, Sabrina Chiloiro, Antonella Giampietro, Antonio Bianchi & Laura De Marinis

Endocrinology and Diabetology Department, Fondazione Policlinico Universitario A. Gemelli, IRCCS, Roma, Italy

Background

Cushing's disease, the most common cause of endogenous Cushing's syndrome, is caused by a pituitary tumor secreting adrenocorticotropic hormone (ACTH). Careful selection of treatment and management of the disease and associated comorbidities are necessary to improve prognosis.

Case Presentation

A 32-year-old patient came to our observation for appearance of weight gain with abdominal obesity, hirsutism and amenorrhea. On suspicion of Cushing's syndrome she performed ACTH assay, cortisol h24 assay, cortisol after overnight DEX 1, Liddle's test with no cortisol suppression, UFC suggestive of ACTH-dependent Cushing's syndrome. The patient performed a pituitary MRI negative for pituitary adenoma. She then underwent selective lower petrous sinus catheterization with CRH test suggestive of Cushing's disease without lateralization. An exploratory transsphenoidal neurosurgical surgery was performed with removal of small pituitary lesion with erosion of the dura mater. The histological examination documented an ACTH-secreting pituitary adenoma. Ki-67 1%. Postoperatively, the patient reported well-being, with periodic checkups documenting disease remission. After two years, the patient presented again with symptomatology suggestive of Cushing's syndrome with appearance of biochemical recurrence of disease and pituitary MRI finding of post-surgical empty sella. Therefore, therapy with Pasireotide at a dosage of 0.6 mg subcutaneously at 2000 h. and 0.3 mg subcutaneously at 2000 h. was started. After initiation of therapy, the patient developed diabetes mellitus so hypoglycemic therapy were undertaken. In addition, pasireotide therapy was reduced to 0.3 mg twice daily based on blood and urinary cortisol dosage. The patient currently presents with target values of glycated hemoglobin and an initial hypocorticosurrenalism for which pasirotide therapy has been reduced and hydrocortisone therapy has been initiated.

Conclusions

Surgical resection of pituitary adenoma is the first-line treatment for Cushing's disease. However, surgery is not always successful, and disease recurrence may occur years after initial remission. Repeat transsphenoidal surgery can be considered in patients with biochemical evidence of recurrent Cushing's disease with visible tumour on MRI. Medical therapy becomes the therapy of choice in patients for whom there is no surgical target. Pasireotide is a multireceptor-targeted, second-generation somatostatin analogue with highest affinity for somatostatin receptor subtype 5 wich are expressed in corticotropinomas. The safety profile of pasireotide is similar to that of conventional somatostatin analogs, but with a higher frequency and degree of hyperglycemia. This is because pancreatic β-cells express SSTR5, which in turn regulates insulin secretion. Glucose and HbA1C levels increase immediately after the initiation of pasireotide treatment, necessitating hypoglycemic therapy.

Participation of pituitary activins in the control of prolactin during early post-natal development. Sex differences

Dana Bornancini[1], Alejandra Inés Abeledo-Machado[2], Milagros Peña-Zanoni[1] & Graciela Diaz-Torga[1]

[1]Instituto de Biología y Medicina Experimental - CONICET, CABA, Argentina, [2]Instituto de Biología y Medicina Experimental - CONICET, CABA, Argentina

Serum prolactin levels increase progressively from birth to adulthood in female and male rats, being higher in females from birth. Although this gradual increase was associated with concomitant maturation of prolactin-releasing and -inhibiting factors, these processes do not fully explain some sex differences observed. In

in vitro studies, using lactotrophs in culture, from rats of different ages, in the absence of hypothalamic control, it was shown that the secretion of prolactin to the medium increases with age during the first weeks of life. These data suggest the involvement of intrapituitary factors. In the present work, the participation of pituitary activins, as paracrine factors, in the regulation of prolactin secretion during postnatal development was studied. Sex differences in this mechanism were also evaluated. Male and female Sprague Dawley rats aged 11, 23 and 45 days were used. Pituitary gene expression of activin subunits (*Inhba* and *Inhbb*) and activin receptors (*ActRI, ActRIIA and ACTRIIB*) was evaluated by RTqPCR. On day 11, female pituitary showed the highest expression of *Inhba* and *Inhbb*, being even significantly higher than that observed in males. The gene expression of activin subunits decreases with age in females, and the sexual differences disappears at 23 days. In contrast, the expression of *Inhbb* increases strongly at 45 days only in the pituitary glands of males, being the predominant activin subunit in this sex in adulthood. Gene expression of activin receptors (*ActRIB*, *ActRIIA*, and *ACTRIIB*) also decreases in females during postnatal development, while remaining relatively stable in males. We also evaluated the protein expression of *ActRIB* and its co-location with PRL. The proportion of lactotrophs (PRL+) expressing the receptor (ActRIB+) is highest in the pituitary glands of 11-day-old females and decreases with age. Activins have been described to inhibit PRL synthesis by inhibiting the transcription factor Pit-1 (or Pou1f1). This action not only involves the canonical pSMAD pathway, but also the phosphorylation of p38MAPK. At p11 almost all lactotrophs express p-p38MAPK in females, and its expression decreases with age with a concomitant increase in Pit-1. Our findings suggest that: the inhibitory regulation of pituitary activins on prolactin secretion is sex-specific; this regulation is more relevant in females during the first week of life and decreases with age; this intra-pituitary regulation is involved in the sex-differences observed in serum prolactin levels during postnatal development.

EP1142

The underneaths of the pituitary stalk

Maria Christina Ungureanu[1,2], Cristina Preda[1,2], Nada Akad[1], Teodora Dumitru[1] & Drozdek Karolina-Agatha[1]
[1]"Sf. Spiridon" Hospital, Endocrinology, Iasi, Romania, [2]Grigore T. Popa University of Medicine and Pharmacy, Iasi, Romania

We are presenting a 23-year-old girl with a medical history of juvenile rheumatoid polyarthritis treated with methotrexate, that first addressed to the Endocrinology Department in may 2022 for primary amenorrhoea with poorly developed secondary sexual characters: height 160 cm, weight 48 kg, BMI 18.35 kg/m2, Tanner stages P1, B3. She was treated with oral contraceptives by the gynaecologist in the past without a hormonal assessment. The lab work revealed hypogonadotropic hypogonadism with a positive response to Triptoreline, low androgen hormones, persistent low IGF1, persistent, well-tolerated hypernatremia, and no inflammatory syndrome. A GH deficiency was excluded by glucagon test - GH peaks to 9.16ng/ml. Regarding the persistent hypernatremia with values around 151mmol/l, low copeptin, high normal renin (129.8uUI/ml) and normal aldosterone level, increased serum osmolality and decreased urinary osmolality, with the absence of increased thirst, the suspicion of adipsic diabetes insipidus was raised. It was initiated treatment with desmopressin with the improvement of sodium levels and serum osmolality in the first weeks, following a recurrence of hypernatremia afterwards. The treatment with desmopressin was suspended. Genetic testing was performed for a series of genes for pituitary insufficiency and other defects of steroidogenesis with the identification of a deficiency of 5 alpha-reductase (heterozygous SRD5A1 gene). The magnetic resonance imaging of the hypothalamic-pituitary axis revealed a pituitary microadenoma of 6.7/6/4.5mm. The presence of hypernatremia with low copeptin, persistent low IGF1 with positive stimulation of GH, and the hypothalamic origin of the amenorrhea raise the suspicion of pituitary stalk lesion. We cannot exclude a link between chronic inflammation during childhood because of rheumatoid polyarthritis or the methotrexate treatment and the hypothalamic-pituitary axis involvement.

Esthesioneuroblastoma As a Cause of Panhypopituitarism: Literature Analysis and Description of An Rare Case

Miguel-Angel Ruiz-Gines[1], Juan-Antonio Ruiz-Gines[2] & Sandra Torres-Mateos[1]
[1]Hospital General Universitario de Toledo, Análisis Clínicos y Bioquímica Clínica, Toledo, Spain, [2]Hospital Clinico Universitario Lozano Blesa, Neurocirugía, Zaragoza, Spain

Introduction
Esthesioneuroblastoma (ENB), also known as olfactory neuroblastoma, is a malignant neuroendocrine tumor of the nasal fossa that arises from neurosensory receptor cells of the olfactory epithelium. It represents 3% of all nasal tumors. It presents a slow and progressive evolution that primarily affects the upper nasal mucosa and cribriform plate, with subsequent extension to the entire cavity and paranasal sinuses and can invade the orbit and cranial base.
Objective
We present the first case described in the literature of ENB with intracranial invasion as a cause of panhypopituitarism.
Case report
A 64-year-old man was assessed for bilateral hearing loss secondary to recurrent otitis, bilateral nasal respiratory failure (without associated epistaxis), holocranial headache, and sensation of stuffiness with Valsalva maneuvers. In the imaging tests (nasofibroscopy and CT of the paranasal sinuses) asymmetry was observed in the cavum, as well as a 35x30x30mm solid mass originating from the left sphenoid sinus, expansive, remodeling and rupturing the posterior wall of the sinus, clivus and sella turcica (invading the suprasellar region), affecting the pituitary stalk, with partial invasion of the cavernous sinuses, all suggestive of neoplasia of the sphenoid sinus. The laboratory study showed moderate hyponatremia, severe hyperprolactinemia (derived from compression of the pituitary stalk), central hypothyroidism, GH deficiency, and hypogonadism. The lesion was biopsied under general anesthesia (subsequently surgically removed by joint ear, nose, and throat intervention) with an anatomopathological diagnosis indicative of olfactory neuroblastoma. He required complementary radiotherapy treatment (64Gy).
Conclusion and discussion
As a neuroendocrine tumor, there are descriptions of paraneoplastic ectopic secretion of ACTH and Vasopressin in relation to olfactory neuroblastoma. No case of panhypopituitarism related to parasellar invasion of the pituitary stalk by this neoplasia has been described to date. Early diagnosis and treatment are necessary to achieve a favorable result, requiring close multidisciplinary collaboration.

Ectopic ACTH Syndrome in a Patient with ACTH-secreting Pancreatic Neuroendocrine Neoplasm and Focal Pituitary Lesion-Diagnostic Challenges

Joanna Sobolewska[1], Lukasz Dzialach[1], Wioleta Respondek[2], Agnieszka Wojciechowska-Luzniak[1] & Przemysław Witek[1]
[1]Medical University of Warsaw, Department of Internal Medicine, Endocrinology and Diabetes, Warsaw, Poland, [2]Mazovian Brodnowski Hospital, Department of Internal Medicine, Endocrinology and Diabetes, Warsaw, Poland

Introduction
Pancreatic neuroendocrine neoplasms (Pan-NENs) account for 1-2% of all pancreatic tumors. Adrenocorticotropic hormone (ACTH)-producing PanNEN is an extremely rare neuroendocrine tumor that accounts for approximately 4-16% of ectopic ACTH-dependent Cushing's syndrome.
Clinical case
A 58-year-old female with arterial hypertension and type 2 diabetes was referred to the Endocrinology Department due to abdominal pain, muscle weakness, and unintentional weight gain. The hormonal evaluation confirmed ACTH-dependent hypercortisolemia: serum cortisol at 2000 h. 29.65 μg/dl, midnight serum cortisol 30.89 μg/dl, ACTH 87.6 pg/ml, UFC: 388.5 μg/24h, serum cortisol after 1 mg of dexamethasone: 22.71 μg/dl. MRI visualized a lesion measuring 8x5 mm and infiltrating the right cavernous sinus. Both the CRH stimulation test and high-dose dexamethasone suppression test were negative, whereas the combined dexamethasone-desmopressin test was positive. Given the inconclusive results, diagnostic imaging of the chest and abdomen was performed but revealed no signs of a tumor. Due to the presence of a focal lesion in the pituitary region, exploration of the sella turcica was undertaken; however, the lesion was beyond resectability. For this reason, pharmacological treatment was started. Inferior petrosal sinus sampling was performed twice, with inconclusive results. Pharmacological treatment of hypercortisolemia (pasireotide s.c., ketoconazole, cabergoline) was introduced. The patient remained in follow-up, lasting about ten years, despite pharmacotherapy, the features of ACTH-dependent hypercortisolemia persisted, and finally, in 2022, a full-body CT, visualized a focal lesion measuring 15x14mm in the pancreas tail. SPECT-CT somatostatin-receptor scintigraphy and Ga-68-HA-DOTATATE PET-CT did not reveal increased tracer accumulation and proliferative process features with high expression of somatostatin receptors. 18F-FDG PET/CT showed no proliferative

hypermetabolic changes. The patient underwent endoscopic ultrasound with tumor biopsy, and histological examination identified neuroendocrine cells with positive ACTH, CD 56, and chromogranin staining. Since the patient did not consent to surgery, treatment with lanreotide autogel 120 mg was introduced, which led to the normalization of hypercortisolemia. The dimensions of the pancreatic lesion remained stable. After the patient's consent, one year later, a tail resection of the pancreas was performed, resulting in complete normalization of the pituitary-adrenal axis.
Conclusions
The case described shows that extensive diagnostics and patient compliance are crucial in managing Pan-NENs. Ectopic ACTH production syndrome can be caused by very small focal lesions, so diagnostics of their location may last many years. Somatostatin analogs may be a treatment of choice in preparation for surgical treatment.

Pasireotide LAR Treatment for Non-functioning Pituitary Adenoma: A Case Report

Sara Menotti[1], Antonella Giampietro[1], Quintino Giorgio D'Alessandris[2], Sabrina Chiloiro[1], Laura De Marinis[1] & Antonio Bianchi[1]
[1]Università Cattolica del Sacro Cuore, Endocrinology, Roma, Italy, [2]Università Cattolica del Sacro Cuore, Neurosurgery, Roma, Italy

Introduction
Non functioning pituitary adenomas (NFPAs) are the most common type of pituitary tumors and are often invasive, resulting in high relapse rates. The post-surgical treatment for NFPAs remains a debated issue and include radiation therapy and additional surgery. Several clinical studies have demonstrated that dopaminergic and somatostatin receptors (SSTRs) are widely expressed in NFPAs. Furthermore, recent studies have shown the potential effectiveness of somatostatin analogues in the medical management of NFPAs. Although the data are limited and controversial, NFPAs express SSTR5 and SSTR3 at high levels. Pasireotide, a multireceptor-targeted somatostatin analogue with high affinity for SSTR5, may be beneficial in the management of NFPAs.
Case presentation
We report the case of a 33-year-old female with a history of surgical resection for a macro NFPA in 2010. Despite treatment with cabergoline (0.5 mg once a week), a residual tumor in close proximity to the right cavernous sinus continued to progress on follow-up post-surgery. In 2017, the patient underwent a second endoscopic resection. She did not experience any postoperative pituitary hormone deficits. However, subsequent radiological follow-up scans showed a progressive increase in the size of the residual tumor. In May 2018, the patient was evaluated by the multidisciplinary pituitary board, which suggested performing a PET-CT scan with Gallium that highlighted focal distribution of the receptor tracer on the right side of the sellae. Furthermore, histological revision of the slide showed negative expression of SSTR2A and positive expression of SSTR5. Subsequent radiological follow-up scans showed a progressive increase in the size of the residual adenoma. In December 2020, the patient's case was re-evaluated by the pituitary board, and radiation therapy was not recommended because of the young age and absence of hypopituitarism. Approval from the Ethics Committee was requested to use Pasireotide LAR as a therapeutic option for compassionate use. In May 2021, the patient started pasireotide LAR 40 mg intramuscular every 28 days. After 18 months of treatment, the residual adenoma showed no further progression on neuroimaging. The patient had good tolerance of the drug with no adverse events.
Conclusion
In this report, we describe a case of a NFPA negative for SSTR2A treated with pasireotide LAR. Our findings suggest that pasireotide LAR may be a treatment option for young patients affected by invasive non-functioning pituitary adenomas positive for SSTR5 who are not candidates for radiation therapy. Clinical studies could expand our single case observations.

Normal adult height in a pacient with untreated congenital hypopituitarism: a case report

Stefana Bilha[1,2], Viviana Popa[1], Laura Teodoriu[2,3], Maria Christina Ungureanu[1,2] & Cristina Preda[1,2]
[1]Saint Spiridon County Hospital, Endocrinology, Iaşi, Romania, [2]Universitatea de Medicină şi Farmacie 'Grigore T. Popa' din Iaşi, Iaşi, Romania, [3]Regional Institute of Oncology, Iaşi, Romania

With congenital hypopituitarism, the clinical manifestations of pituitary hormone deficiencies usually appear during infancy or early childhood. Typically, one or more anterior pituitary hormones are deficient, and the most severe manifestations include neonatal hypoglycemia, electrolyte imbalances and failure to thrive. We present the case of a 43 year old male, with cardiovascular and metabolic comorbidities (arterial hypertension, type 2 diabetes mellitus), with no prior hospitalizations except for an episode of anaphylaxis, that was referred to the department of Endocrinology when a low FT4 was detected (0.5ng/dl) in the presence of a normal TSH. The patient was hemodynamically stable, and clinical examination revelead a height of 182.5 cm (+0.83 SD for age and sex according to national growth charts), weight = 81.5 kg, BMI = 24.5 kg/m2, pale, dehydrated skin, pectus excavatum, long, thin, laterally deviated fingers, an arched palate, as well as absent secondary sexual characteristics and congenital cryptorchidism. Endocrinological examination revelead corticotroph, tireotroph, gonadotroph and somatotroph insufficiency; undetectable estrogen and testosterone; and a prolactin level towards the lower limit of normal; and substitution treatment with Levothyroxine and Hydrocortisone was promptly initiated. Further evaluation revelead a normal ingestion and output of fluids (~1.5L/day), ruling out diabetes insipidus. Imaging studies included an abdomino-pelvic ultrasound, that releaved hypoechoic, homogenous masses in both the right and the left inguinal canal. Dual X-ray absorption bone densitometry revelead osteoporosis. Bone age was 17 years according to the wrist X-ray. MRI of the sella turcica showed a small remnant pituitary (~4.3mm height) with discreet intrasellar herniation of the suprasellar cisterna. Genetic investigations are currently underway (mlpa p018 SHOX, karyotype). While the hormonal profile and the presence of bilateral cryptorchidism suggests congenital CHPD, a surprising discrepancy was the patients' normal stature. Based on the existing literature, with around 10 similar cases described up to date, one possible explanation would be a coexisting genetic disorder associated with tall stature, such as [1] Marfan syndrome – rulled out by negative Ghent criteria score and further imaging studies (hand, foot and hip X-ray; echocardiogram; ophthalmological consult), [2] mutations in genes related to tall stature, such as SHOX duplication – genetic tests are ongoing or [3] the total absence of estradiol leaving the growth plates open, allowing growth through mechanisms independent of GH/IGF1, such as hyperinsulinism.

Presentation of A Patient with an EPI Attack and Apoplexy of A Pituitary Macroadenoma

Martina Jambrović, Andreja Maric & Maja Mikolaj Kiric
County Hospital Čakovec, Department of Internal medicine, Čakovec, Croatia

A 57-year-old female patient was presented to the neurologist in the ER because of her first grand mal-type seizure. Initial examination in the emergency department confirmed hyponatremia (Na 131 mmol/l) in laboratory findings, while CT scan of the brain and EEG were normal. During hospitalization, additional laboratory and imaging studies were performed. Neuroradiological examination was performed (CT scan of the brain, MRI of the brain and MRI of the pituitary gland), which confirmed the voluminous hippocampus on the left side and extremely widened sella turcica, with a septated cystic formation inside. The infundibulum was drawn to the right, the neurohypophysis was gracile, while the optic chiasm is drawn caudally. These were corresponded to the apoplexy of the pituitary gland (condition following haemorrhage in the area of the pituitary adenoma), which was accompanied by cystic degeneration. Hormonal tests were also performed and the results confirmed hypopituitarism (TSH was 0.90 mIU/l, fT3 4.4 pmol/l, fT4 5.9 pmol/l, FSH 1.0 U/l, LH < 0.1 U/l, estradiol 0 pmol/l, cortisol 157 nmol/l, prolactin 214 mU/l). An ophthalmological examination excluded visual field defects. Replacement therapy was initiated with levothyroxine at a dose of 75 mg and hydrocortisone 10 mg in the morning and 5 mg in the afternoon. During hospitalization her clinical condition improved and there was spontaneous recovery of serum sodium in the laboratory findings. An endocrinological control with new laboratory findings was recommended in 3 months and a control MRI of the pituitary gland in 6 months. The cause of the epilepsy was not found and further neurological monitoring is required.
Conclusion
Epi attack as s first presentation of pituitary macroadenoma.

DOI: 10.1530/endoabs.90.EP1147

EP1148

Major improvement of diabetes insipidus 15 years after diagnosis of panhypopituitarism in a patient with pineal germinoma – a case report

Viviana Popa[1], Andreea Rosu[1], Iulia Crumpei[1], Maria Christina Ungureanu[1,2] & Cristina Preda[1,2]

[1]Saint Spiridon County Hospital, Iaşi, Romania, [2]Universitatea de Medicină şi Farmacie 'Grigore T. Popa' din Iaşi, Iaşi, Romania

Pineal germinomas account for the majority of intracranial germ cell tumors. Surgery and radiation are usual management options, and secondary hypopituitarism can ensue after both. Diabetes insipidus is particularly common after surgical removal of pineal tumors, but improvement in polyuria and polydipsia years after surgery is exceedingly rare. Here, we present the case of a 49-year-old male, who was diagnosed with a pineal germinoma at the age of 20, which was surgically removed and then irradiated. The patient went without treatment until the age of 30, when he was hospitalized for inaugural diabetic ketoacidosis, and diagnosed with type I diabetes mellitus, as well as secondary panhypopituitarism. Insulin therapy, as well as hormone substitution treatment with levothyroxine, hydrocortisone, testosterone and desmopressin, was immediately started and the doses were adjusted several times during routine follow-up consultations. For the past several years, the patient has been on a steady dose of levothyroxine, prednisone and testosterone undecanoate; as well as desmopressin lyophilisate, with doses between 180 and 240 mg per day. However, recently, the desmopressin dose has been gradually lowered to 120 ug/day, and the patient was admitted for a routine check-up in our Clinic. Upon monitoring fluid ingestion and output, both were around 1 liter/day, so the desmopressin dose was gradually lowered to 30 ug/day, in the evening. One month later, fluid intake and output were roughly 2-2.5L/day under that dose. Because of that, Desmopressin treatment was stopped, and fluid intake and output increased to 4L/day. Upon reintroducing 30 mg Desmopressin daily, those values normalized. Another interesting finding was that the patient's testosterone levels repeatedly came back high-normal, despite being towards the end of the interval since the testosterone injection. This was interpreted in the context of the patient's psychiatric medication (Tianeptine, Haloperidol, Carbamazepine), which could alter SHBG levels. SHBG was measured, which came back within normal limits (80.1nmol/l). Serum βHCG levels were also normal (<0.1 mIU/ml), so further evaluation could involve measuring βHCG in CSF to assess for early recurrence. One surprising feature of this case was the sudden decrease in the Desmopressin necessary, after years of being on relatively high doses; so far, the literature has only described two similar cases, without identifying an underlying reason. This underlines the need for long to very long term follow-up in patients with secondary panhypopituitarism, and poses an interesting question for future research – what could be the reason for this suddenly quenched thirst?

EP1149

Excessive production of chromogranine A in a meningioma with somatostatin receptors expression confirmed by GA68 -DOTATATE PET

Rossana Manzanares Cordova & Pilar Rodriguez
Hospital Juan Ramón Jiménez, Endocrinology, Huelva, Spain

Background
Chromogranin A (CgA) is the most abundant granin in gastroenteropancreatic neuroendocrine tumors (GEP-NETs). As a tumor marker is moderately sensitive and nonspecific. Meningiomas are benign brain tumors that are usually to recur. Studies have shown *in vitro* and *in vivo* that meningiomas, regardless of histology and classification, express somatostatin receptors (SSTRs). GA68-DOTATATE PET is an exciting imaging modality that has shown significant advantages over conventional imaging in diagnosis and management of NETs.
Case report
This is a 56-year-old female patient who in 2021 presented an episode of high blood pressure accompanied by facial flushing and sweating. Secondary hypertension was screened with negative results including catecholamines and methanephrins, and elevated chromogranin A was detected. octresocan was requested, which showed a hyper-enhanced focus in the left paramedian frontal region that was confirmed by magnetic resonance imaging as a 9mm meningioma. An entero-MRI was also performed to rule out other more frequent NET locations, the study was negative, despite the fact that the patient was asymptomatic and maintain her blood pressure under control with a single drug, given persistently elevated CgA levels with a maximum peak of 18,846ng/ml, it was decided to complete a study with GA68 DOTATATE PET, which confirmed the unique existence of a hyper-uptake focus in the left paramedian frontal region compatible with meningioma without appreciating other foci that suggest the presence of tumor lesions with somatostatin expression, the patient was diagnosed with mengioma with somastatin receptor expression. Due to the size, finding the patient asymptomatic is decided jointly by the patient and the neurosurgeon to maintain observation without intervention for the moment.
Conclusions
PET imaging is being increasingly used to supplement MRI in the clinical management of brain tumors. A high expression of somatostatin receptor 2 (SSTR2) is found in all meningioma. [68Ga]Ga-DOTA-SSTR PET tracers are SST analogs with a high binding affinity to SSTR type 2, which make them an effective tool for imaging meningioma.

A case with pituitary metastasis from breast cancer presenting with hypernatremia

Entela Puca[1], Edmond Puca[2] & Albiona Poci[3]
[1]American Hospital 2, Endocrinology, Tirana, Albania, [2]Mother Teresa Hospital, Infectious Disease, Tirana, Albania, [3]American Hospital 2, Oncology, Tirana, Albania

The tumors that metastasis to the pituitary gland is a rare condition and generally are seen in patients in advance disease. The most common metastasis arises from breast and pulmonary cancer. We report a case of a 53 years old women with invasive ductal carcinoma diagnosed in 2017, previously treated with left radical mastectomy followed by — cycles of chemotherapy and radiation. In 2022 her disease recurred with bone metastasis. She started again the chemotherapy. One month after the last cycle of chemotherapy she presented at our emergency department with the following symptoms poor appetite, progressive general malaise, drowsiness, blurred vision, watery diarrhea, polydipsia, polyuria, nocturia. Initial laboratory work revealed hypernatremia with sodium of 157 mEq/l (136 - 148 mEq/l), low TSH 0.04 mIU/l (0.27-4.2 mIU/l), free T3 1.3 ng/ml (2.0 - 4.4 pg/ml), low free T4 0.83 ng/dl (0.93 - 1.7 ng/dl). Low LH 1.74 mIU/ml (7.7-58.5 mIU/ml) and FSH 6.92 mIU/ml (25.8-134.8 mIU/ml). ACTH 2.49 pg/mL (7.2-63.3 pg/ml), random cortisol 203 nmol/l (68.2-327 nmol/l) and a very high level of prolactin 2395 mIU/l (102-496 mIU/l), ADH 4.3 pg/ml (2-12pg/ml), GH 0.21 ng/ml (0.126-9.88). Hypernatremia and hypopituitarism prompted further studies: magnetic resonance of the pituitary region was performed. MRI with gadolinium revealed a pituitary mass 9.9 × 7.4-mm, isointense on T1 weighted images heterogeneously involving the infundibulum diameter 4.3 mm with multiple cerebral metastasis. These findings were highly suggestive of pituitary metastasis from her metastatic breast cancer. During the hospitalization she was treated with hormone therapy and was send to the oncology department for further treatment.
Conclusion
We describe a case of invasive ductal carcinoma with pituitary metastasis (PM). Aalthough rare, PM should remain in the differential of symptomatic pituitary dysfunction so proper diagnosis and treatment can be performed. Endocrine abnormalities should be corrected. Unfortunately, the presence of PM portends a poor prognosis

Non-functioning adenomas submitted to surgery: clinical characterization and outcomes

Daniela Dias[1,2], Tânia Matos[1], Catarina Silvestre[1], FIlipa Serra[1], Ana Palha[1,2], Lia Lucas Neto[2,3], Joana Tavares Ferreira[2,3], João Subtil[2,4], Francisco Tortosa[2,5], Amets Sagarribay[2,6] & Inês Sapinho[1,2]
[1]Hospital CUF Descobertas, Endocrinology, Lisboa, Portugal, [2]Hospital CUF Descobertas, Pituitary Center, Lisboa, Portugal, [3]Hospital CUF Descobertas, Imagiology, Lisboa, Portugal, [4]Hospital CUF Descobertas, Otolaryngology, Lisboa, Portugal, [5]Hospital CUF Descobertas, Anatomical Pathology, Lisboa, Portugal, [6]Hospital CUF Descobertas, Neurosurgery, Lisboa, Portugal

Introduction
Nonfunctioning pituitary adenomas (NFPAs) are a heterogeneous group of tumors with different presentations. Clinical management of these tumors is complex. Our aim was to evaluate the clinical characteristics/postsurgical outcomes of NFPAs and to identify predictive factors of good response to surgery.
Methods
Retrospective analysis of NFPA, who underwent surgery and followed in our hospital, from 2015-2022.
Results
We evaluated 15 patients (60%-male), whose median age at NFPA diagnosis was 59 (45-86) years. Adenomas were incidentally identified in 2 patients. Visual

disturbances were the most common presenting symptom (67.7%). 47% of patients had ≧1 pituitary deficits and 1 patient had panhypopituitarism. Gonadotropic axis was the most commonly affected (60%). At diagnosis, hyperprolactinemia was present in 20% of cases. Preoperative ophthalmologic evaluation showed a visual field deficit in 64% and a significant decrease in visual acuity in 40% of the patients. Preoperative MRI studies displayed adenoma diameter of 29 ± 16.2mm. Cavernous sinus (CS) was invaded in 47% of the patients and proximity/compression to the optic nerve/chiasm was present in 14 patients. Fourteen of these tumors were categorized as gonadotroph adenomas and 1 as silent corticotroph adenoma (SCA). 33% of the patients showed Ki67 values >3%. Patients with preoperative hypopituitarism, 4/7 (57%) showed improvement of pituitary function (PF) at one year. Improvement of neuro-ophthalmological symptoms was observed in all patients after surgery. Complete removal of the tumor was observed in 5 (33%) patients. Residual tumor (RT) was documented in 7 (47%) patients after first intervention. Three patients required a second surgery due to tumor regrowth, a median of 81 (60-276) months after first intervention. A fourth pituitary operation was performed in 1 patient. Stereotactic radiosurgery with gamma knife was used in one patient due to tumor progression (single case of SCA). Hyperprolactinemia at diagnosis tended to be more frequent in the group that recovered PF ($P = 0.091$). RT after surgery tended to be more frequent in the group with larger tumors ($P = 0.043$), older age ($P = 0.056$) and CS invasion at diagnosis ($P = 0.067$).

Conclusions

Patients with preoperative neuro-ophthalmological disturbances seem to benefit from surgery. In patients with tumors in progression and hypopituitarism, normalization of PF may be achieved with surgery. Hyperprolactinaemia and younger age at diagnosis, as well as tumor dimensions seem to be associated with a favorable prognosis. Our results highlight the need for a longstanding approach by a multidisciplinary team.

A Case of Chronic Hyponatremia in Clinical Practice

Larissa I. Danilova, Galina Korolenko, Irina Bourko, Maxim Lushchyk & Aliaksei Ramanouski

Belarusian Medical Academy for Postgraduate Education, Endocrinology, Minsk, Belarus

Hyponatremia - a decrease in serum sodium to 135 mmol/l or less can lead to serious complications. In patients with various pathologies and serum sodium levels of 120–125 mmol/l mortality reaches 23%, in levels less than 115 mmol/l - 50%. Biochemical verification of hyponatremia is not difficult. It is difficult to establish the cause and treatment of chronic hyponatremia. Patient S., 64 years old, was hospitalized in a state of alcoholic intoxication with a diagnosis of an extensive scalp wound of the back. History of myocardial infarction in 2020; in 2022 traumatic brain injury with traumatic subarachnoid hemorrhage. In the biochemical analysis of blood - low values of sodium are 113 mmol/l, potassium - 3.4 mmol/l and chloride - 77 mmol/l. As an emergency preoperative preparation, infusion therapy was administered, including a concentrated solution of sodium chloride. To prevent the development of alcoholic delirium, the patient was prescribed carbamazepine 200 mg 3 times a day. Therapy was carried out with a 3% solution of sodium chloride 150 ml boluses. Despite ongoing therapy, the serum sodium level did not exceed 116 mmol/l. The levels of the hormones ACTH, cortisol and thyrotropic hormone were normal. Urinary osmolality was 200 mOsm/kg, sodium concentration was 81 mmol/l. Clinical diagnosis: severe hyponatremia, asymptomatic, due to the syndrome of inadequate secretion of antidiuretic hormone due to traumatic brain injury, alcohol intoxication, taking anticonvulsants, the presence of an extensive wound surface of the back. After unsuccessful correction of hyponatremia, a decision was made to introduce fludrocortisone into the treatment regimen, starting with a minimum dose (50 mg) and then increasing to 100 mg/day (to avoid loss of potassium levels) while maintaining the infusion of 10% potassium chloride solution at a dose of 50 ml. The serum sodium level stabilized at 120–124 mmol/l, and there was no sharp decrease in the level of potassium. By the end of the hospital stay, the sodium level increased to 126 mmol/l. The syndrome of hyponatremia has been classified as chronic hyponatremia. The patient was advised to lead a healthy lifestyle (exclude alcohol), add salt to food, limit drinking regimen. The presented clinical case demonstrates how difficult it is in clinical practice to verify the cause of hyponatremia and prescribe the optimal correction of chronic hyponatremia.

Introduction

Hypertension is common in patients with Turner Syndrome (TS), and they appear to have an increased predisposition with various proposed disease related factors; sex hormone imbalance, aortopathy, increased activation of the renin-angiotensin-aldosterone system, insulin resistance, growth hormone deficiency/resistance, adverse imprinting during fetal life and renal malformations. Despite high susceptibility and unique challenges in managing hypertension in this group, there exists no consensus on screening, classification, diagnosis, and management of hypertension, predominantly due to scarcity of evidence. Undiagnosed and/or poorly controlled blood pressure (BP) can be detrimental/-lethal in patients with aortopathy. In 2020, the International-TS(I-TS) registry was established within the International-Disorders of sexual differentiation (I-DSD) platform to fill gaps in the knowledge of TS and has a network reaching 260 centres in 63 countries.

Methods

All the centres registered under I-TS registry with patients ≥ 18 years were invited to participate in this retrospective multi-centre observational study. Pseudoanonymised data relevant to the study[karyotype, hormone-replacement(HRT), hypertension diagnosis, risk factors, management, morbidity] were either directly extracted from the registry or clinicians of relevent centres were requested to complete a formatted spreadsheet using routine clinic records.

Results

Complete data were available for 12/15 accepted-to-participate centres, from 11 countries, January 2022-2023. A total 181 patients [median-age 28.5 (range:18-71)years, median-age at TS diagnosis 11(range:0-34)years, and median BMI 25.2(range:18-44)Kgm^2] were included. Monosomy X(45,X) was the commonest (42%) karyotype and 64% of all patients were receiving HRT. Twenty-four(13.3%) patients had hypertension [Characteristics at diagnosis; median age 27(range:10-56) years, median systolic-BP 150(range:125-270)mmHg and median diastolic-BP 90(60-136)mmHg)]. The majority(18/24) had primary hypertension, and 4/6 with secondary hypertension had coarctation of the aorta.

The majority of those with hypertension (62%) were 45,X [$X^2(1,n=181)=4.779$, P0.029], and 91.6% were on HRT[median daily oetrogen dose:1(range:0-2) mg]. Many patients had coexisiting vascular risk factors; type 2 diabetes:16.7%, dyslipidaemia:33.3%, family-history:8.3%. The incidence of comorbidities potentially exacerbated by hypertension were; aortic disease:37.5%, congenital cardiac anomalies:12.5%, cardiac surgery:12.5%, renal anomalies:20.8%. The majority (21/24) received angiotensin-converting-enzyme inhibitors(ACEi)/ angiotensin-receptor blocker(ARB), and 6/24 were on beta-blockers(BB).
Conclusions
Hypertension is common in TS, with a high prevalence of associated risk factors and co-morbidities, highlighting the importance of development of specific guidance. In most cases, hypertension was diagnosed as primary hypertension, despite a young age of onset. ACEi/ARB and BB were the most commonly used medications. Furthermore, this study demonatrates, the potential advantage of inclusion of a large number of individuals, which is international in applicability, with capture of local site specific details.

Family building after diagnosis of premature ovarian insufficiency - a cross-sectional survey in 324 women

Solange Cambray[1], Sophie Dubreuil[2], Isabelle Tejedor[2], Jerome Dulon[2] & Philippe Touraine[2]
[1]APHP, Paris, France, [2]Hôpital la Pitié Salpêtrière, Endocrinology and Reproductive Medicine, Paris, France

Objective
The diagnosis of premature ovarian insufficiency (POI) is a traumatic event for many patients that involves poor fertility prognosis. After such diagnosis spontaneous pregnancies are rare. The alternatives for building a family are oocyte donation, embryo donation and adoption. However, we have few information on how many women with POI finally built a family after the diagnosis and which alternative they chose.
Design
We performed a cross-sectional, descriptive study.
Methods
We conducted a survey of all the women who consulted for POI in the department of endocrinology and reproductive medicine at la Pitié Salpêtrière between 31/05/1991 and 12/01/2021. We included patients who continued to be followed up regularly by our department or were contacted by mail or phone between June and September 2021. We excluded patients with Turner syndrome, POI secondary to oncological treatment and patients under 18 at the time of the survey.
Results
324 women with POI were analysed. Mean follow-up time between the first assessment in the service and the survey was 8,1 years. 41% of the women who wanted to build a family had children after the diagnosis: 53,9% by oocyte donation 1 woman by embryo donation, 5,6% after ovarian stimulation, 13,5% adopted and 25,8% had spontaneous pregnancy after a mean time of 2,5 years. Spontaneous pregnancy rate was 8,6% in the whole cohort.
Conclusions
Having children after a diagnosis of POI is not uncommon, but more often results from oocyte donation. This study will provide enlightened information for newly diagnosed women on the possibilities to build a family after POI diagnosis.

Prevalence of MTHFR polymorphisms and metabolic outcomes in Chilean women with Polycystic Ovary Syndrome

Matías Carrasco[1], Susan Calfunao[1], Paz Martinez[1], Nicolas Crisosto[1] & Francisca Salas-Perez[2]
[1]Facultad de Medicina Campus Occidente - Universidad De Chile, Santiago, Chile, [2]O'Higgins University, Health Sciences Institute, Rancagua, Chile

Background
Polycystic ovary syndrome (PCOS) is a prevalent and multifactorial endocrine disorder, characterized by reproductive and metabolic alterations. However, the mechanisms that contribute to the development of metabolic abnormalities are not completely understood. Interestingly, women with PCOS show changes in folate and homocysteine levels suggesting an altered folate metabolism, which could be associated to changes in the methylation patterns of metabolic genes. Methylentethahydrofolate reductase (MTHFR) is one of the key enzymes in folate metabolism and it has been reported that polymorphisms in MTHFR gene could reduce the enzymatic activity.
Objective
The aim of this study is to assess the prevalence of SNP C677T (rs1801133) and A1298C (rs1801131) in *MTHFR* gene and their association with metabolic markers in PCOS women in comparison to control women.
Methodology
A total of 58 with PCOS without hormonal contraception and 77 control women with a BMI between 18 and 35 kg/m^2 (18-34 y.o.) were included in this study. Anthropometric measurements were carried out using standardized techniques and blood samples were obtained. To evaluate metabolic profiles, vitamin B12, serum and red blood cells folate (RBC) were measured, in addition to lipid and biochemical profiles, a food frequency questionnaire was performed. DNA analyses were performed in whole blood. Student's t-test or Mann Whitney test were applied for independent samples for compare both groups. To evaluate correlation, Pearson or Spearman was applied. For all analyses, a value of $P<0.05$ was considered significant.
Results
- PCOS women exhibited a significant increment in BMI in contrast to control group.
- PCOS women showed an increased Ferriman score, total testosterone, and free androgen index, accompanied by insulin-resistance.
- We found no differences in vitamin B12, serum folate and red blood cell folate, however, PCOS and control women do not achieve the daily dietary recommendations for choline and betaine.
- The distribution of C677T genotype frequency in our population was F(CC): 0.28, F(TC): 0.52 and F(TT): 0.2.
- The distribution of A1298C genotype frequency in our population was F(AA): 0.62, F(AC): 0.34 and F(CC): 0.03.
- The analysis of C677T and A128C shows that both polymorphisms are in Hardy-Weinberg equilibrium.

Conclusions
This is the first study that have reported the genotype frequency in Chilean women with PCOS. Further studies are necessary to determine the role of this genetic variants in this condition and circulating levels of choline and betaine should be measured, to validate this hypothesis due to their impact on metabolic dysfunctions.

BRCA1/2 Negative Bilateral Metastasized Breast Cancer Following Ovarian Stimulation: A Case Report

Joao Oliveira Torres[1], José Leão Mendes[2], Rui Jorge Escaleira[2], Mariana Alves Gaspar[3], Rui Malheiro[3], Diana Martins[1] & José Silva-Nunes[1]
[1]Centro Hospitalar Universitário de Lisboa Central, Endocrinologia, Diabetes e Metabolismo, Lisbon, Portugal, [2]Centro Hospitalar Universitário de Lisboa Central, Oncologia Médica, Lisbon, Portugal, [3]Centro Hospitalar Universitário de Lisboa Central, Medicina 2.3, Lisbon, Portugal

Introduction
Breast cancer is the second most common neoplasm in women. Hormonal replacement therapy and combined hormonal contraception are established extrinsic hormonal risk factors for breast cancer. Therefore, the increase in the prevalence of infertility and the use of assisted conception techniques have raised questions regarding the potential risk of hormone-dependent neoplasms. We

report the case of a woman diagnosed with bilateral metastasized breast cancer soon after ovarian stimulation.
Case report
A 42-year-old woman with a 3-month history of worsening mechanical back pain visited the medical clinic with a dorso-lumbar CT scan report showing multiple vertebral lytic lesions (D3, D6, D10, L1, L2, L3, and L4) and two vertebral compression fractures (D6 and L5). She suffered from infertility and had just finished the third cycle of ovarian stimulation for oocyte collection. Before treatment, she underwent bilateral mammography and breast ultrasound, classified as BI-RADS 3, with no further follow-up. The patient had no family history of cancer. She was admitted for diagnostic assessment, which revealed stage IV bilateral breast cancer with multiple bone metastases (vertebrae, sternum, ribs, and the right femur). In the right breast, mass biopsy showed luminal A *like*/Her2 2+ FISH negative cT1 cN1 (metastases in the right axillary lymph nodes). In the left breast, mass biopsy showed luminal B *like*/Her2 2+ FISH positive cT1mf cN0. Vertebral biopsy of L5 revealed metastasis of the left breast cancer. Next-generation sequencing for the diagnosis of hereditary breast and ovarian cancer syndrome was unremarkable. She was referred to the oncology clinic and started on docetaxel, pertuzumab, trastuzumab, zoledronate, and radiotherapy. Follow-up showed stable disease nine months after the initiation of cancer treatment.
Conclusions
Current evidence indicates that ovarian stimulation does not appear to increase the risk of breast cancer. However, treatment with gonadotropins and estradiol is contraindicated in patients with this clinical entity. Thus, in this case report, ovarian stimulation may have enhanced the aggressive behavior of breast cancer, which was most likely present at the beginning of the infertility treatment. Hence, we raise the possibility of a distinct screening for breast cancer before, during, and after ovarian stimulation, whose consequences are still unpredictable regarding the risk and natural history of breast cancer.

Cytogenetic Study in 622 Infertile Men with Spermogram Abnormalities

Salwa Ben Yahia, Hela Belil, Faouzi Maazoul, Ridha Mrad & Lilia Kraoua
Hospital Charles Nicolle, Department of Congenital and Hereditary Diseases, Tunis, Tunisia

Background
Infertility affects 15% of couples. In 50% of cases, it can be explained by male infertility with abnormal spermatogenesis. Cytogenetic causes are identified in 15% of men with infertility.
Materials and Methods
We report the results of a cytogenetic study performed in infertile men with spermogram abnormalities collected at the Department of Congenital and Hereditary Diseases of Charles Nicolle Hospital in Tunis, over 12 years from January 2011 to February 2023. A standard karyotype on peripheral blood was performed in all patients.
Results
The number of infertile patients with spermogram abnormalities collected was 622. The blood karyotype showed the presence of a chromosomal abnormality in 81 patients (13%) of whom 69/81 had azoospermia, 9/81 had oligoasthenoteratospermia, 2/81 had cryptozoospermia and one patient had sperm degradation. The mean age at the first genetic consultation was 38 years. The chromosomal abnormalities identified were Klinefelter syndrome (47,XXY) in 56/81 patients (homogeneous in 50/56 patients and mosaic in 6/56 patients), a mosaic formula associating a 45,X population, and a second population with a normal or rearranged Y chromosome in 4/81 patients, an XYY formula in 3/81 patients and a Yq deletion in 3/81 patients, a supernumerary marker chromosome in 1/81 patients, a balanced structural rearrangement in 12/81 patients (4 Robertsonian translocations, 5 reciprocal translocations, and 3 inversions) and a 46,XX formula in 2/81 patients with male phenotype and gonadal dysgenesis.
Conclusion
Our study's high rate of chromosomal abnormalities identified in infertile men (13%) emphasizes the importance of performing karyotype in men with spermogram abnormalities to search for a chromosomal cause and guide management.

Overexpression of orphan nuclear receptor REV-ERB-alpha predicts recurrence in differentiated thyroid cancer

Shih-Ping Cheng, Chi-Yu Kuo, Jie-Yang Jhuang & Ming-Nan Chien
Mackay Memorial Hospital, Taipei City, Taiwan

Background
Altered circadian clock characteristics have been shown in malignant thyroid nodules. REV-ERB-alpha is a circadian clock component that functions as a transcriptional repressor which coordinates circadian rhythm and cell metabolism. However, the protein expression of REV-ERB-alpha has not been properly investigated.
Methods
Immunohistochemical analysis was performed on our in-house tissue microarrays. Immunoreactivity was evaluated using H-scores calculated by multiplying stain intensity by the percentage of positive stained cells. Recurrence-free survival was determined using a Kaplan-Meier curve.
Results
A total of 142 cases with differentiated thyroid cancer were evaluated. Nuclear staining of REV-ERB-alpha was upregulated in follicular epithelial cells of thyroid cancer but was absent in their normal counterparts. The H-scores were positively correlated with patients' age at diagnosis (Spearman's rank correlation rho = 0.310, $P = 0.0002$). Furthermore, increasing H-scores were associated with extrathyroidal extension (Jonckheere-Terpstra trend test, $P = 0.0005$), lymph node metastasis ($P = 0.036$), and tumor-node-metastasis stage ($P = 0.001$). Patients with higher REV-ERB-alpha expression in the tumor had a shorter recurrence-free survival (log-rank test, $P = 0.018$).
Conclusion
Thyroid cancer exhibits overexpression of REV-ERB-alpha. Nuclear expression levels have a prognostic significance in differentiated thyroid cancer.

Are there any benefits of probiotic or prebiotic supplementation in hypothyroid patients? A systematic review with meta-analysis

Karolina Zawadzka[1,2], Klaudia Kałuzińska[2], Mateusz J. Świerz[3], Zuzanna Sawiec[2], Ewa Antonowicz[2], Monika Leończyk-Spórna[2], Ahmad Kamal Abadi[4], Małgorzata Trofimiuk-Müldner[5] & Małgorzata M. Bała[3]
[1]Jagiellonian University Medical College, Doctoral School of Medical and Health Sciences, Kraków, Poland, [2]Jagiellonian University Medical College, Students' Scientific Research Group of Systematic Reviews, Faculty of Medicine, Kraków, Poland, [3]Jagiellonian University Medical College, Chair of Epidemiology and Preventive Medicine, Department of Hygiene and Dietetics, Kraków, Poland, [4]University of Arak, Department of Computer Engineering, Arak, Iran, [5]Jagiellonian University Medical College, Chair and Department of Endocrinology, Kraków, Poland

Introduction
A number of studies indicate the presence of a thyroid-gut axis and the important influence of the gut microbiota on thyroid function. As prebiotics, probiotics and synbiotics show therapeutic potential in the treatment of intestinal dysbiosis, we aimed to evaluate the efficacy of their supplementation in patients with primary hypothyroidism.
Material and methods
We searched electronic databases (Ovid MEDLINE, Embase, CENTRAL), registers of clinical trials, and grey literature up to October 6, 2022. We included randomised controlled trials (RCTs). Our protocol was registered in PROSPERO (CRD42021235054).
Results
After screening 1721 references, we identified two RCTs including 136 hypothyroid participants in total. Meta-analysis after eight weeks of supplementation with predominantly Lactobacillus and Bifidobacterium strains indicated a clinically and statistically unimportant decrease in TSH (MD –0.19 mIU/l; 95% CI –0.43 to 0.06) and no effect on fT3 levels (MD 0.01 pg/ml; 95% CI –0.16 to 0.18). Data from single studies indicated no significant change in the levels of fT4, thyroid autoantibodies, BMI, levothyroxine doses, and severity of symptoms measured with validated scales. Only constipation scores showed significant improvement (MD – 8.71 points in Fecal Incontinence Questionnaire; 95% CI – 15.85 to –1.57; I2 = 0%).
Conclusion
Based on limited evidence from two randomised trials, there is no benefit from routine administration of probiotics or synbiotics in patients with primary hypothyroidism. We found no evidence on efficacy of supplementation with prebiotics.

EP1162

Can we predict medical treatment failure in Graves' disease? 4-year follow-up data in a single centre

Alexandros Leonidas Liarakos, Anna Foka, Ahmed Mohamed & Foteini Kavvoura
Centre for Diabetes and Endocrinology, Royal Berkshire NHS Foundation Trust, Reading, United Kingdom

Background
Graves' disease (GD) is the commonest cause of primary hyperthyroidism in iodine-sufficient areas. First-line treatment is a 12-18 month course of anti-thyroid drugs (ATD). However, around 50% of GD patients will relapse, requiring further assessment and definitive treatment with radioactive iodine or thyroidectomy. Identifying risk factors that predict relapse or treatment failure after stopping ATD is important in guiding management. Several risk factors have been reported in the literature from small with moderate-to-high risk for bias trials. We aimed to explore possible risk factors that can assist in identifying patients at high risk of relapse or medical treatment failure, to allow prioritisation for definitive treatment.
Methods
We retrospectively evaluated available data on consecutive patients with first presentation of GD who had positive TSH receptor antibodies (TRAbs), defined as TRAbs > 0.4 IU/l, at diagnosis at the Royal Berkshire Hospital and required ATD, between February 2017 and December 2018. Baseline demographics, TRAbs and thyroid function tests (TFTs) levels, and the presence of thyroid eye disease (TED) at diagnosis were recorded. TRAb titres were measured using the RSR Elisa TRAb 2nd generation assay. FT4 levels were measured using the Roche Cobas Elecsys Gen II assay.
Results
We included 154 individuals. The mean age was 51.6 years, 71.4% were female, and 15% had TED at diagnosis. The median (IQR) TRAb level was 2.7 (1.7, 5.7)IU/l, and the median (IQR) FT4 level was 52.6 (30.3, 81.4) pmol/l. The median follow-up of TFTs was 48 months. Median duration of ATD was 18 months. 102 (66.2%) participants relapsed or had treatment failure (i.e. ATD duration > 24 months). Gender did not affect treatment failure (females:65.5% vs males: 68.2%, *P*0.9). Median TRAb values were similar to those with no relapse (3.6 IU/l vs. 2.4 IU/l, respectively, *P*0.34). Subsequently, patients were divided into 3 sub-groups according to TRAb values (1st tertile: 0.5-1.9 IU/l, 2nd tertile: 2.0-4.3 IU/l, 3rd tertile: 4.4-31.0 IU/l). Individuals in the 3rd tertile, compared to the 1st, had a higher percentage of TED (30.4% vs. 11.1%, OR 3.5; *P*0.05), higher FT4 levels (72.4pmol/l vs. 31.6pmol/l; *P*0.0001) at the time of diagnosis, and significant risk of treatment failure (77.4% vs 54.2%, OR 2.9; *P*0.02).
Conclusions
Our study showed that patients who present with TED, higher TRAb and FT4 levels at the time of GD diagnosis are more likely to have medical treatment failure or relapse. Early referral for definitive treatment should be considered for such patients.

EP1163

The Association of Immunotherapy-Related Thyroid Disorders and Mortality in Patients with RCC and Melanomas

Michal Ehrenwald[1], Tamara Kolitz[1], Ruth Karov[1], Ronen Brenner[2,3] & Yona Greenman[1,3]
[1]Tel-Aviv Sourasky Medical Center, Institute of Endocrinology, Diabetes, Metabolism and Hypertension, Tel Aviv, Israel, [2]Wolfson Medical Center, Oncology Institute, Holon, Israel, [3]Tel-Aviv University, Sackler Faculty of Medicine, Tel Aviv, Israel

Background
Immune checkpoint inhibitors (ICPIs) are indicated as treatment for metastatic renal cell carcinoma (RCC) and melanoma, among other malignancies. This group of agents is associated with immune-related adverse events (irAEs). We aimed to further investigate the association of immune-related thyroid disorders (irTDs) with clinical outcomes and mortality rates in patients with RCC or melanoma who were treated with ICPIs.
Methods
We retrospectively analyzed all RCC and melanoma patients with normal baseline thyroid function who were treated with ICPIs at the Tel Aviv Sourasky medical center from 2016 to 2022. Demographic, clinical, and laboratory parameters were extracted using a big data platform (MDclone, Israel).
Results
We identified 149 ICPI-treated patients with RCC, of whom 108 (72.5%) were male. The average age at RCC diagnosis was 65.5 ± 10.6 years. Thyroid function abnormalities occurred in 42.3% ($n=63$) of ICPI-treated RCC patients. We analyzed 157 ICPI-treated patients with melanoma, of whom 92 (58.6%) were male. The average age at melanoma diagnosis was 68.5 ± 13.2 years. Thyroid function abnormalities occurred in 49% ($n=77$) of ICPI-treated melanoma patients. Thyroid disorders in both RCC and melanoma ICPI-treated patients were due mostly to hypothyroidism (clinical/subclinical) or thyroiditis, with hyperthyroidism occurring in fewer than 10% of patients. Mortality rates were significantly lower in RCC patients with evidence of irTDs compared with those who had no thyroid abnormality (38.1% and 62.8%, respectively. $P < 0.05$). This difference in mortality rates remained significant in subgroup analysis of men with and without irTDs (30.8% and 63.8%, respectively. $P < 0.05$) but not in women. No significant difference in mortality rates was found in melanoma patients with and without thyroid dysfunction, including in a gender subgroup analysis.
Conclusion
irTDs in patients treated with ICPI may impact prognosis in RCC. This effect was not observed in our cohort of patients with melanoma. More studies are needed to further investigate and characterize the underlying mechanisms and clinical relevance.

Coexistence of Behçet Disease and Graves

Kadir Intaş
Ağrı Diyadin State Hospital, Internal Medicine, Ağrı, Turkey

Introduction
Behcet's disease (BD) is a systemic inflamatory disorder characterized by recurring oral and genital ulcers, uveitis, and skin lesions. Graves' thyrotoxicosis is caused by an autoimmune reaction to thyroid autoantigens. Thyroid receptor antibody testing is used to diagnose Graves' thyrotoxicosis. There has previously been no evidence of a link between thyroid autoimmunity and BD. We present a case of an adult male with BD coexistence, which is uncommon.
Case Report
A 49-year-old male patient presented with complaints of palpitations, marked sweating and weight loss (11 kg) for 4 months. The patient had deep vein thrombosis 8 years ago and was diagnosed with Behçet's syndrome while investigating the cause. He was receiving colchicine 2*1 treatment for Behçet's syndrome. On examination, the patient was sweaty and had hand tremors compatible with thyrotoxicosis. The patient had painless red eyes but no exophthalmos. Mild signs of thyroid eye disease were present. Blood tests revealed biochemical evidence of severe thyrotoxicosis and thyroid receptor antibody levels were elevated. Ultrasound scan of the thyroid and radioactive iodine uptake scan showed features consistent with Graves' thyrotoxicosis and a diagnosis of Graves' thyrotoxicosis was made. The patient was started on methimazole 30 mg and propranolol 20 mg twice daily. After treatment, the patient responded well with improvement of clinical symptoms and normalisation of thyroid functions. The patient is still being followed up in the internal medicine clinic for 4 years under colchicine, methimazole and propranolol treatment.
Discussion
BH can be considered an autoimmune disease due to its many features, including spontaneous remissions and relapses. There are reports that BD is associated with other autoimmune diseases. Since autoimmunity is responsible for the etiology of BH, the possibility of an increased incidence of autoimmune thyroiditis should be considered. Furthermore, there is a significant overlap in clinical features between different conditions such as oral ulcers, uveitis, and arthralgia, and this may occur in many of these conditions. However, the hypothesis regarding the role of antibodies in BD may also share a common ground in the pathogenesis of other autoimmune diseases. Although the limited data do not provide concrete evidence of any association between the two conditions, this case highlights the question of

whether their coexistence is due to a pathogenic relationship rather than mere coincidence.

'Colloid leak'-A lightening effect

Sabaretnam Mayilvaganan, Ramakanth Bhargav Panchangam, Sarrah Idrees, Spandana Jagannath, Anjali Mishra & Gaurav Agarwal
Sanjay Gandhi Postgraduate Institute of Medical Sciences, Lucknow, India

Background
Thyroidectomy is the common most common endocrine surgical procedure varies from Scalpel to Robotic transoral thyroidectomy. Colloid nodules are common and easily operable without any difficulty. We report a phenomenon where in the surgery becomes difficult and lead to complications if not thought with this phenomenon – colloid leak.
Material and Method
The endocrine surgeon (Associate Professor) has been involved in training of over 25 superspeciality endocrine trainers over a period of nine years in a tertiary referral high volume center. He has participated in 700 Thyroidectomies of which 250 thyroidectomies for colloid goiter. We have observed this phenomenon in 5 patients over 5 years in a tertiary referral centre in north India
Result
5 male patients (46.7 $\pm$ 12.1 years) had this colloid leak. Mean BMI was (22.4 $\pm$ 2.9). FNAC was colloid in all patients. 3 had colloid leak in all planes.2 had only per thyroidal leak. All patients had Recurrent Laryngeal nerve identified. In 1 patient only 1 parathyroid gland could be identified. Mean duration of surgery was 120 $\pm$ 12 minutes. Mean blood less was 10 ml $\pm$ 2.5ml. Mean duration of stay after surgery was 48. $\pm$ 12 hours. No permanent complication was observed. All patients operated within 2 weeks of FNAC. All HPT was colloid. Immunohistochemistry revealed IgG4 stained plasma cell aggregates in the line of colloid leak.
Discussion
This phenomenon was observed in muscular males in the colloid goiters where in there is leak of colloid after FNAC and this colloid elicited an inflammatory response in the surrounding tissues as evidenced by IgG4 positive immunohistochemistry staining for plasma cells. This phenomenon was more pronounced 5 to 7 days after FNAC. The planes were stuck and mobilization of gland was difficult in one patient a small cuff of muscle had to be removed. This fact of colloid leak causing chronic inflammation may be a harbinger of chronic changes and may a role in tumorogenesis
Conclusion
Astute Endocrine Surgeon should be aware of this colloid leak phenomenon and when found the dissection should be very careful to present complications during thyroidectomy.

Challenges in operating such monstrous goitres even in this era?

Sabaretnam Mayilvaganan, Sarrah Idrees, Ramakanth Bhargav Panchangam, Spandana Jagannath & Gaurav Agarwal
Sanjay Gandhi Postgraduate Institute of Medical Sciences, Lucknow, India

A 45-year-old lady from the Iodine - deficient Himalayan belt presented to us with a gradually progressive, painless goiter for more than 20 years. Such goiters were common in her village. She neither had symptoms of hyper/hypothyroidism nor any compressive symptoms. She had four living issues and as per her, the goiter would increase in size during the second trimester of each pregnancy. On examination, she had a huge thyroid swelling involving both lobes and isthumus, measuring 20 $\times$20 cm with dilated veins over the swelling. The swelling was firm in consistency, moving with deglutition and had no retrosternal extension. There was no cervical lymphodenopathy. The diagnosis of an euthyroid multinodular goitre was made. Thyroid profile was normal; however, vocal cords could not be visualized during video laryngoscopy. CECT should retro tracheal extension. She underwent total thyroidectomy under General anesthesia. A 2-kilogram goiter was excised in toto, and the surgery lasted for 8 hours. Bilateral recurrent laryngeal nerve (RLN) and all four parathyroid glands were identified and preserved. However, intraoperatively she was found to have tracheomalacia hence, tracheostomy was done. She developed biochemical hypocalcemia on POD 2 and was started on oral calcium and vitamin D supplementation to which she responded well and became eucalcemic. Video laryngoscopy on POD 4 showed U/l paresis so tracheostomy care was continued. Video laryngoscopy on POD 12 showed bilateral vocal cords mobile, hence, she was weaned off tracheostomy gradually and was decannulated successfully on POD20. During the ICU stay patient developed ICU psychosis and required psychiatric care. Histopathology was reported as multinodular goitre. She now has normal voice, is eucalcemic and on thyroxine replacement. This case highlights the importance of thorough counselling of such patients with long standing goitre as these can cause tracheomalacia. Surgery in such cases requires utmost patience and always requires holistic hospital care by a multidisciplinary team. We almost lost the patient because of ICU psychosis when she became violent and tried to remove the tracheostomy tube by herself. Since these women are never exposed to hospital environment, she developed psychiatric rage and had to be treated accordingly.
Learning Points
1. Most of these goiters benign
2. Iodine Deficient belt
3. Huge MNG
4. Most women anemic
5. Intubation difficult-Awake preferred
6. Liberal incision
7. Strap muscles to be cut
8. RLN mostly on the surface
9. Tracheomalacia is common
10. Excess skin needs to be removed

Baseline Serum TSH Levels Predict The Thyroid Dysfunction In Cancer Patients Treated With Tyrosine Kinase Inhibitors And Immunotherapy

Neslihan Bozkoc Vasi, Goknur Yorulmaz, Duygu Bayir Garbioglu, Bulent Yildiz & Murat Dincer
Eskisehir Osmangazi University, Meselik Campus, Turkey

Developments of the cancer immunology have increased the frequency of use of targeted therapies and immunomodulatory therapies. Although these treatments are effective on cancer cells, they also have toxicity on the thyroid gland. We aimed to evaluate the tyrosine kinase inhibitors(TKI) and immunotherapies-induced thyroid disorders, their relationship on disease prognosis and baseline serum thyroid stimulating hormone (TSH) levels effect on the development of thyroid dysfunction. This study was performed at a oncology center between January 2000 and December 2019. This study inclued 161 patients who were treated with immunotherapies and tyrosine kinase inhibitors. In this study, there were 161 patients whose basal thyroid function was normal. Thyroid dysfunction developed in 52 of 161(32.3%) patients. Hypothyroidism was developed in 44 of 52(84.6%) patients, and 28 of them were received L-thyroxin replacement treatment. Mean time to thyroid dysfunction development was found 14.7 weeks. By receiving operator characteristic (ROC) curve analysis, baseline serum TSH level was found as a potential predictive factor for development of hypothyroidism with a cut off value of 1.73 mIU/l, a sensitivity of 79.5% and a specifity of 56.9% and 87.3% negative predictive value(AUC:0,69, $P <$ 0,001). Progression-free survival (PFS) time was found to be longer in patients whom occurred thyroid dysfunction during sunitinib and pazopanib treatment. Our patient population receiving immunotherapies was small and so we could not

evaluated the relationship between thyroid dysfunction and PFS duration in these patient groups. More large-scale studies and longer follow-up is needed.

Papillary Thyroid Carcinoma Post Radioactive Iodine therapy for Graves' disease

Sabaretnam Mayilvaganan, Ramakanth Bhargav Panchangam, Sarrah Idrees, Spandana Jagannath, Anjali Mishra & Gaurav Agarwal
Sanjay Gandhi Postgraduate Institute of Medical Sciences, Lucknow, India

Background
Papillary Thyroid Carcinoma after Radioactive Iodine therapy for Graves' disease is rare with few cases reported in literature.
Presentation of case
A 28 years gentleman, presented with multiple non tender swellings in the anterior aspect of the neck, insidious in onset, initially started as a single swelling in the left side of the size 3×2 cm. Three years prior, he received I 131 therapy for Graves thyrotoxicosis. Thereafter, developed hypothyroidism after 6 to 7 months and was started on thyroxine supplementations at 50 μg/day. His mother was diagnosed with Papillary thyroid carcinoma age of 54 years. On head and neck examination, he had multiple swellings over bilateral neck with enlarged cervical lymph-nodes levels II, III,V.
Investigations
Ultrasound neck reported a right lobe vascular mid pole lesion of 7×7 mm with rim calcification, the isthmus contained a 8×6×5 mm well-defined lesion with micro calcification and increased vascularity, the left lobe mid pole had an ill-defined heterogeneous 28 x 21×16 mm lesion with micro calcification, the left neck had multiple in large lymph nodes. A guided FNAC was done from the thyroid nodules and cervical lymph nodes which was suspicious of Papillary thyroid carcinoma with cervical lymph node metastasis. Preoperative laryngoscopy bilateral vocal cords the mobile.
Treatment
He underwent Total thyroidectomy with bilateral central compartment lymph-node dissection, left selective lymph-node dissection(Level II &III) and right selective lymph-node dissection (Level II,III,IV&V). At operation, the left lobe was enlarged with a hard nodule measuring 2×2 cm, in the right lobe of the thyroid a small node measuring 0.5 cm was seen with extensive bilateral lymph node involvement in the central and lateral compartments. Visual identification and recurrent laryngeal nerve (RLN) neuromonitoring was done, left RLN and right RLN had electromyography signals of 1742μV and 572μV respectively. All four parathyroids were visually identified and preserved. Gross examination of the specimen revealed multifocal greyish white tumour tissue in both lobes of the thyroid. Histopathology reported multifocal papillary thyroid carcinoma of classical type. Seventeen out of the 26 resected lymph nodes in the central compartment and bilateral lateralcompartment showed metastatic foci. Based on the above findings a diagnosis of Classical multifocal papillary thyroid carcinoma pT1pN1bpMx was made. Postoperative period was uneventful and he made a good recovery.
Discussion
Literature rare in post radioactive ablation

Breast cancer (BC) is the most common type of cancer and the leading cause of cancer-related death in women worldwide. A considerable number of these long-term survivors may therefore have an elevated risk of developing a second primary malignancy (SPM). Thyroid cancer (TC) is the most prevalent endocrine malignancy among women. Epidemiologic studies have indicated that patients with BC have a higher risk of developing TC as an SPM, and vice versa, than would be expected in the general population; and the risk of BC following TC is increased by 21% to 89% and that of TC following BC by 31% to 73%. We present a female patient with left breast carcinoma operated about 20 years ago with no medical documentation, recently diagnosed (January 2022) with papillary thyroid carcinoma TNM (AJCC 8th edition): pT2N0LV0Pn0 invasive in thyroid capsule and also in strap muscle with postoperative Thyroglobulin level of 26.7 ng/ml which indicated radioiodine ablation with 3570,29 MBq. At whole body scintigraphy were described multiple pulmonary secondary lesions, although thyroglobulin level decreased to 16 ng/ml. Structural imaging confirmed pulmonary, hepatic, splenic and even bone secondary lesions. Because the thyroglobulin level was discordant with multiple distant metastasis, we also investigate breast tumor marker CA15-3 = 442.74 U/ml (normal value: 0-32.4 U/ml) and structural images showed right breast carcinoma (bilateral breast carcinoma) confirmed by biopsy. Particularity of this case report is that secondary lesions appeared despite decreasing thyroglobulin level. Could we assume breast origin metastasis on radioactive WBS scintigraphy considering that breast cancer has sodium-iodine symporter expression? Or we could suspect thyroid related secondary lesions with abnormal low thyroglobulin level. The patient had progression of metastasis at 6 months after the radioactive iodine treatment, even if the thyroglobulin level was almost undetectable (0.3 ng/ml) suggesting an excellent biochemical response after iodine treatment for thyroid cancer.
