INTRODUCTION, OBJECTIVES

Introduction. The urinary iodine excretion (UIE) from fasting morning urine sample is a good epidemiologic indicator for iodine state, used in populational groups (schoolchildren, pregnant women) at risk to develop iodine deficiency disorders. It is not adequate to evaluate individual iodine intake. In pregnant women, especially with chronic autoimmune thyroiditis, it is important to estimate iodine state.

Objectives. To evaluate the individual iodine state in pregnant women comparing UIE from morning and 24-hours urine samples.

MATERIAL AND METHODS

UIE was determined in 30 pregnant women: 24-hours UIE expressed in μg/L and μg/g-creatinine, and these values were compared to each other. Morning UIE was additionally assessed in 19 women, and compared to the 24-hours UIE levels

Normal UIE: 100-300 mcg/L
Normal urine creatinine: 0.8-1.8 g/24h

RESULTS

The mean 24-hours UIE was 168.3±74.7 mcg/L, with 40% lower than 278.6±118.9 mcg/g-creatinine (p=0.0001, 95%CI=58.96-160.64). The individual values expressed in mcg/L and μg/g-creatinine were in concordance in most of the cases (80%), both being normal or both being reduced.

In six women (20%) the 24-hours UIE in mcg/L suggested iodine deficiency, while the values in mcg/g-creatinine indicated normal iodine intake.

In the 19 pregnant women the mean morning UIE was 176.3±75.87 mcg/L, similar with the 24-hours UIE mcg/L, but with 30.4% lower than the 24-hours UIE mcg/g-creatinine (257.6±101.8). In 16 cases (84.2%) all the three UIE values (morning UIE, 24-hours UIE mcg/L, 24-hours UIE mcg/g-creatinine) indicated concordantly iodine deficiency or normal iodine intake, in the other three (15.8%) the different UIE suggested different iodine state.

CONCLUSIONS

Important differences were observed between the morning UIE, 24-hours UIE in μg/L, 24-hours UIE in μg/g-creatinine, however the interpretation of these were mostly in concordance (80%). In 20% the results could not clearly show iodine state.
