A 17-year-old female was referred to pediatric endocrinology for primary amenorrhea and headaches. Biochemical investigation identified hyperprolactinemia with prolactin levels of 1234 ng/ml with undetectable gonadotropin levels and pituitary imaging suggested a macroprolactinoma measuring 1.2 x1.3 x1.5 cm, with a cystic component. Treatment was initiated with cabergoline, leading to a reduction in prolactin levels to 24.8 ng/ml after 6 weeks and onset of menses after 3 months. Over the subsequent 3 years, even though prolactin levels significantly reduced, the reduction in the size of the tumor was not significant with the latest measurements of 1 x 1 x 1.2 cm with persisting cystic component with serum prolactin levels of 112 ng/ml. At the age 19 years, 2 years into treatment with cabergoline, the patient developed arthralgia with positive ANA levels with a working diagnosis of SLE. The patient also tested positive for thyroglobulin and thyroid peroxidase antibodies, indicative of Hashimoto's thyroiditis.
Discussion
A cystic prolactinoma, a less common variant, may present with discrepancy between the degree of hyperprolactinemia and tumor size. Some prolactinomas may also be resistant to treatment with dopamine agonists questioning the presence of a nonfunctioning adenomatous tissue. Hyperprolactinemia has been linked to the pathogenesis of several autoimmune disorders. Although there is some evidence of interaction between hyperprolactinemia and autoimmunity, the exact mechanisms and directionality remain unclear. Patients with SLE, in particular, have been shown to have concurrent hyperprolactinemia, with some cases showing a positive correlation between serum prolactin levels and severity of autoimmune disease. Rare patients have been described with SLE and prolactinoma.
Conclusions
This is a patient with cystic prolactinoma that responded poorly to tumor size reduction despite significant improvement in prolactin levels. The clinical course was complicated by onset of arthralgia with a working diagnosis of SLE. There appears to be a complex interplay between hyperprolactinemia and autoimmunity. Future research should aim to unravel the mechanisms underlying this interaction.

Clinical features and metabolic risk in girls with premature adrenarche

Mukhlisa Shorikhsieva[1], Sitora Muminova[2], Dilafruz Maksudova[2], Diyora Mukhammedaminova[2] & Umida Mirzaeva[2]
[1]Republican Specialized Scientific and Practical Medical Center of Endocrinology named after Ya.Kh. Turakulova, Tashkent, Uzbekistan; [2]Tashkent Pediatric Medical Institute, Endocrinology, Tashkent, Uzbekistan

Aim
To evaluate the signs of premature adrenarche (PA) in girls and its relationship with clinical signs.
Material and Methods
The study included 148 girls who had clinical signs of PA, and in 85 the corresponding pathology was confirmed. The control group consisted of 30 healthy girls. Serum levels of dehydroepiandrosterone (DHEA), dehydroepiandrosterone sulfate (DHEAS) and androstenedione (Δ4A) were analyzed. The prevalence of childhood metabolic syndrome (CMS) was assessed using modified WHO criteria.
Results
Based on these results, girls with PA and pubic/axillary hair growth (PAHG; $n = 77$) had higher levels of DHEA, DHEAS, and Δ4A than girls without PAHG ($n = 8$). Increased levels of adrenal androgens were also observed in the PA group without PAHG compared with the control group. The frequency of pMS among girls with PA was 18.5% (63/85), which was higher than the control group (10%, 3/30). The most common component of pMS among girls with PA was overweight (59% vs. 41% in the control group, $P < 0.05$). Girls with PA and PAHG were more likely to have elevated fasting insulin levels (28% vs. 10% in the control group, $P < 0.05$).
Conclusion
An increased concentration of adrenal androgens in serum is associated with the presence of pubic and axillary hair in girls with premature adrenarche (PA). Girls with PA have an elevated risk of developing metabolic syndrome, with excess weight being the most significant risk factor. The obtained data highlight the need for early monitoring of body weight and metabolic parameters in girls with PA to prevent metabolic disorders.

Development of empty sella in neurosarcoidosis; a case report

Hemmat El Haddad[1], Amr El Meligi[1], Rokaya Abdel Aziz[1], Randa Salam[1], Alaa Abdallah[1], Salma Mohamed[1], Tasneem Halaby[1], Mirette Makram[1] & Ahmed Atef[1]
[1]Cairo University, Cairo, Egypt

Introduction
Sarcoidosis is a multisystem disorder marked by noncaseating granulomatous lesions. Central nervous system involvement, estimated in 5–15% of sarcoidosis patients, localized most commonly to the leptomeninges, cranial nerves or the pituitary gland and hypothalamus, Sellar sarcoidosis comprising less than 1%, presenting with neuroendocrine related features such as diabetes insipidus, hypothyroidism, hypoadrelinism or hyperprolactineamia.
Case report
A 70-year-old woman with a medical history of hypothyroidism on levothyroxine 100 µg/day The patient was diagnosed as pulmonary sarcoidosis four years ago Multi slice CT showed mild diffuse pulmonary interstitial changes with right upper lateral area of subsegmental atelectasis and scattered atelectatic bands likely postinflammatory, focal liver lesions 2x2 cm FDG-PET/CT showed multiple uptakes in lung, liver, pitutary gland bronchoscpony revealed non caseating granuloma. The patient was diagnosed systemic sarcoidosis with propable pitutary neurosarcoidosis she was treated with prednisone(1mg/kg/day) and methotrexate 10mg once a week Follow up multislice CT abdomen showed only mildly enlarged fatty liver with no focal lesions & right renal cortical cyst. Prednisone was tapered after 1 year The dose of eltroxin decreased a couple of years later into 50mg due to constant decrease of TSH which was explained as overcorrection. A year later, She presented to outpatient clinic with weakness, fatigue, anorexia for 3 weeks Examination revealed Bp 110/80 but with orthostatic hypotension, pulse 70/minute, weight 59 kg Labs showed TSH 0.20(0.5-5mIu/l), FT4 0.52 (5-12ug/dl), Serum cortisol AM. 2.6 (5-25 mg/dl), consistent with hypopituitarism MRI pituitary showed partial empty sella with accentuated CSF in the suprasellar cistern compressing the gland against the sellar floor Her eltroxin dose was adjusted to be 75mg/day & she was given hydrocortisone 15 mg.
Conclusions
This case report demonstrates the evolution of a pituitary hyperplasia in a patient with neurosarcoidosis into an empty sella this condition is rarely mentioned among the causes of empty sella.

A case of spontaneous remission of active pituitary macroadenoma

Irina A. Vaychulis[1]
[1]South-Ural State Medical University, Internal Medicine Department, Chelyabinsk, Russian Federation

A 39-year-old female patient with history of type 2 diabetes mellitus (DM 2) and pituitary macroadenoma was referred to endocrinologist for the follow-up examination. She had regular menstrual cycle on combined oral contraceptive pills (COCPs). Her physical, ophtalmological and neurological examinations were unremarkable except for BMI of 34 kg/m^2. Further testing demonstrated CBC, liver function tests fasting blood glucose, glycated hemoglobin, creatinine, serum electrolytes, TSH levels within the normal range, but decreased GH <0,05 (reference range 0,126-9,88) ng/ml, IGF-1–34,9 (135-449) ng/ml, PRL – 2,5 (6,0-29,9) ng/ml levels and signs of pituitary macroadenoma on MRI about the same size compared to previous examination. After the first delivery (at the age of 24

years) she had irregular menstrual cycle. During the second pregnancy (at the age of 28 years) gestational diabetes was diagnosed. After the second delivery she has received COCPs. At the age of 35 years DM 2 was established. Metformin and DPP-4 inhibitors were administered. At about the same time arterial hypertension and complaints of episodic headaches have appeared. Two years later (at the age of 37 years) pituitary macroadenoma with infra-laterocellar growth with maximal size of 16 mm was detected on MRI, and she was referred to endocrinologist. Patient denied any significant changes in her appearance. Laboratory testing showed normal PRL – 17,15 (6,0-29,9) ng/ml and TSH – 1,6 mIU/ml, but elevated GH–11,7 (0,126-9,88) ng/ml and IGF-1–678,7 (135-449) ng/ml. Somatotropinoma was diagnosed, but patient refused recommended surgery. 3 months later she was admitted to the neurology department with severe headache, resistant to NSAIDs, and vomiting. No visual impairment was detected. Stroke was ruled out on CT scan. Subsequent examination showed normal GH – 0,5 (0,126-9,88) ng/ml, IGF-1 – 154 (135-449) ng/ml, TSH – 2,0 mIU/ml, fT4 – 12 pmol/l,ACTH – 9,0 (6,3-46) pg/ml and depressed PRL – 0,79 (6,0-29,9) ng/ml. The diagnosis of non-active pituitary macroadenoma was established. At the follow-up examination, presented at the beginning of the abstract, further declines in GH and IFG-1 levels were observed. This case demonstrates spontaneous remission of somatotropinoma, gradually resulted in GH deficiency, most likely caused by pituitary adenoma apoplexy. It is remarkable to note that somatotropinoma was initially revealed in the absence of obvious typical features of acromegaly. Further monitoring is needed. Medical specialists should refine their knowledge about pituitary adenoma apoplexy.

Aggressive somatotropinoma: collaborative management by endocrinologists and oncologists

Georgy Gabaidze[1], Margarita Perepelova[1], Elena Przhiyalkovskaya[1], Ekaterina Pigarova[1], Anastasia Lapshina[1], Ildar Minniakhmetov[1], Aleksandra Shutova[1], Natalya Tarbaeva[1], Alina Kolomeytseva[2] & Larisa Dzeranova[1]
[1]Endocrinology research centre, Moscow, Russian Federation; [2]N. N. Blokhin RCRC RAMS, Moscow, Russian Federation

Introduction
Acromegaly is a neuroendocrine disorder caused by chronic hypersecretion of growth hormone (GH). The primary treatment goals include achieving biochemical remission, reducing or stabilizing pituitary adenoma size, and alleviating clinical manifestations. While remission is not achieved in approximately 50% of patients, aggressive adenoma growth occurs in only 1-5% of cases.
Clinical Case Description
A 36-year-old patient was diagnosed with acromegaly after presenting with facial features enlargement and an elevated insulin-like growth factor 1 (IGF-1) level of 1000 ng/ml (reference range: 82.0–283.0 ng/ml). Brain MRI revealed a pituitary macroadenoma measuring 24×37×28 mm. Ophthalmological evaluation showed partial atrophy of the right optic nerve and strabismus. The patient underwent transnasal adenomectomy. However, five months post-surgery, the tumor measured 16×22×17 mm, with an IGF-1 level of 1549.5 ng/ml, indicating persistent disease activity. Medical therapy was initiated with 30 mg of long-acting octreotide every 28 days, later replaced with 120 mg of lanreotide every 28 days, followed by the addition of 20 mg of pegvisomant daily. One year later, MRI revealed continued tumor growth (28×29×20 mm), prompting a second adenomectomy. Despite this, the tumor further enlarged within six months (30×35×30 mm), with an IGF-1 level of 1277.6 ng/ml, necessitating radiosurgery. Two years after radiosurgery, MRI showed negative dynamics (tumor size: 32×32×24 mm) with optic chiasm compression. Given the challenging adenoma location and lack of response to conventional therapies, an oncologist was consulted. The patient underwent four courses of chemotherapy with temozolomide, and the pegvisomant dose was increased to 30 mg. However, one month after chemotherapy, tumor progression continued (32×32×38.7 mm), accompanied by worsening vision and right-sided ptosis. To assess the tumor's sensitivity to checkpoint inhibitors, an immunohistochemical study was performed. PDL-1 and VEGF expression was detected in 70–80% of tumor cells, with a Ki-67 index of 17%. Weak expression of somatostatin receptor subtype 5 (IRS-1) was also noted. Based on a multidisciplinary consensus, considering resistance to standard acromegaly treatments and positive PDL-1 and VEGF expression, a combined regimen of nivolumab and bevacizumab was initiated.
Conclusion
This case highlights the importance of extended immunohistochemical analysis and interdisciplinary collaboration between endocrinologists and oncologists in the management of aggressive somatotropinomas. Personalized treatment strategies, including immunotherapy, may be crucial for patients unresponsive to conventional therapeutic approaches.

A case of nonfunctioning pituitary macroadenoma – 7 year follow-up after transsphenoidal surgery and radiation therapy

Mariam Bulashvili[1], Nino Zavrashvili[1] & Ia Kavtiashvili[1]
[1]Tbilisi Institute of Medicine, David Tvildiani Medical University, Tbilisi, Georgia

Introduction
Pituitary macroadenomas, particularly nonfunctioning types, are benign tumors that can cause significant endocrine dysfunction due to their mass effects on surrounding structures, including the pituitary gland and optic chiasm. These tumors often present with symptoms related to hormonal deficiencies, visual disturbances, or neurological findings. Diagnosis typically involves a combination of hormonal assessments: ACTH, Cortisol, TSH, FT4, FSH, LH, Testosterone, Prolactin, IGF-1 and imaging, primarily MRI, while management often requires surgical resection. However, complete resection can be challenging, especially in larger tumors with suprasellar extension, where residual tissue may persist, potentially leading to tumor regrowth.
Case Report
A 62-year-old patient initially presented in 2018 with severe fatigue, weakness, weight loss, visual disturbance, headache and episodes of syncope, leading to the diagnosis of adrenal insufficiency. Further evaluation revealed secondary adrenal insufficiency, central hypothyroidism, and secondary hypogonadism, prompting suspicion of a pituitary disorder. MRI imaging identified a 2.7 cm pituitary macroadenoma with suprasellar extension and compression of the optic chiasm. In November 2018, the patient underwent transsphenoidal resection of the pituitary adenoma, which led to significant clinical improvement. Despite initial surgical resection, residual tumor tissue remained, with evidence of gradual growth. Radiation therapy was considered but could not be pursued at that time. In 2022 and 2023, the patient underwent two additional transsphenoidal resections of the residual adenoma. In October 2023, Gamma Knife radiation therapy was performed. The patient is currently well-managed, with no complaints, continues appropriate replacement therapy including levothyroxine, hydrocortisone, and testosterone. Subsequent imaging demonstrates gradual decrease of residual tumor.
Conclusion
This case highlights the challenges of managing large pituitary macroadenomas, particularly those with suprasellar extension and residual tissue post-surgery. It also underscores the importance of a multidisciplinary approach, including surgery and radiation, to address persistent tumor growth and prevent further endocrine dysfunction. Ongoing hormone replacement therapy and careful monitoring of pituitary function remain critical in managing the patient's long-term care.

Clinical and therapeutic management of hypopituitarism during pregnancy in a patient with PROP1-related combined pituitary hormone deficiency

Giulia Marsan[1], Sara Sturnia[1], Luisa Costantini[1], Alice Ferrero[1], Stella Pigni[1,2], Marina Caputo[3], Gianluca Aimaretti[1] & Flavia Prodam[3]
[1]University of Eastern Piedmont, Department of Translational Medicine, Novara, Italy; [2]Humanitas University, Department of Biomedical Sciences, Pieve Emanuele (MI), Italy; [3]University of Eastern Piedmont, Department of Health Sciences, Novara, Italy

Introduction
Mutations in the *PROP1* gene lead to combined pituitary hormone deficiency. The clinical and therapeutic management of hypopituitarism and particularly of adrenal insufficiency (AI) during pregnancy is influenced by lack of standard protocols, different cortisol and ACTH threshold values, a higher risk of complications (including adrenal crisis), and non-specific symptoms. We present the case of a pregnant patient with hypopituitarism due to a *PROP1* mutation.

Case presentation
A young Caucasian woman was on regular follow-up for hypopituitarism (GH deficiency, hypothyroidism, AI, and hypogonadism) due to a *PROP1* mutation (homozygous pathogenic variant c.150del(p.Arg53AspfsTer112)), receiving hormonal replacement for all deficiencies since childhood. At 28 years old, she achieved pregnancy after ovarian stimulation treatment and *in vitro* fertilization. Before pregnancy, she was treated with levothyroxine (LT4), modified-release hydrocortisone, and GH replacement therapy (GHRT). The corticotropic and somatotropic axes were adequately replaced, while LT4 dosage had been increased in preparation for assisted reproduction. Once pregnancy was confirmed, GHRT was discontinued and modified-release hydrocortisone was replaced with the standard formulation. Throughout the pregnancy, biochemical monitoring included thyroid function (fT3, fT4) blood glucose and electrolytes, while clinical monitoring focused on symptoms, blood pressure, and weight measurements every 2-3 weeks. As suggested in the literature, during the late second and third trimesters, both hydrocortisone (up to 30 mg/day) and LT4 (up to 3 μg/kg/day) dosages were increased. The patient remained clinically stable and fetal growth was normal for gestational age. At 26 weeks, a glucose tolerance test was performed with normal results. Delivery was planned at a third-level Neonatal Intensive Care and Gynecology center to enable a multidisciplinary approach. The patient delivered a healthy male newborn by C-section at 39 weeks. For adrenal crisis prevention, intravenous hydrocortisone was given at the onset of active labor, followed by a continuous infusion for 24 hours, and additional boluses in the 2 days after delivery due to moderate hyponatremia. After that, oral hydrocortisone was restarted at twice the dose used during pregnancy due to general malaise. LT4 dosage remained also increased in the postpartum period.
Conclusions
The management of AI during pregnancy is hindered by the lack of dedicated guidelines. Hydrocortisone is the glucocorticoid of choice, and a 20-40% dose increase is often needed during the last trimester. Clinical monitoring for signs and symptoms of under- or over-replacement is recommended. Gestation in patients with congenital hypopituitarism is a clinical challenge, but it can be safely managed in specialized centers.

Anthropometric or biochemical markers to predict the onset of menarche

Ja Hyang Cho[1], Hyun Ah Woo[2], Hae Woon Jung[2] & KyeShik Shim[2]
[1]Kyung Hee University Hospital at Gangdong, Kyung Hee University, School of Medicine, Paediatrics, Seoul, South Korea; [2]Kyung Hee University Hospital, Kyung Hee University, School of Medicine, Paediatrics, Seoul, South Korea

Purpose
The potential of height growth is decreased to about 2-2.5cm after menarche and many children and their parents worry about the early menarche. This study is to find out the markers to predict the onset of menarche.
Method
We collected the anthropometric data (height, weight, and growth velocity), chronologic and bone age, Tanner stage, biochemical data (serum LH, FSH, estradiol, and progesterone levels) at 12 months and 6 months before the onset of menarche in 28 girls who visited the growth clinic of a university hospital from Jan 1, 2020 to Jul 31, 2024. The data of 12 months and 6 months were compared with the paired T-test using SPSS ver.28.
Result
The comparison of the data between the 12 months and 6 months before menarche were as follows. The mean growth velocities of height were 2.94cm and 2.92cm, and weight were 1.48kg and 2.03kg ($P=NS$). The bone ages were 12.5 and 12.79 years old ($P=NS$). The Tanner stages were almost 4 in both. The serum levels of LH were 2.34 ± 1.38 and 4.06 ± 2.53 mIU/ml ($P<0.01$). The serum levels of FSH were 4.37 ± 1.69 and 5.86 ± 2.07 mIU/ml ($P<0.05$). The serum levels of estradiol were 24.52 ± 13.39 and 45.61 ± 19.7 pg/ml ($P<0.01$). The serum levels of progesterone were 0.12 ± 0.1 and 0.18 ± 0.16 ng/ml ($P=NS$).
Conclusion
The periodic measurements of baseline serum levels of LH, FSH, and estradiol are more valuable than anthropometric data to predict the onset of menarche in girls.

"Whispering" cushing syndrome: presentation of three cases

Athanasia Michou[1], Efstathios Divaris[1], Maria Poulasouchidou[1] & Zoe Efstathiadou[1]
[1]Hippokratio General Hospital Thessaloniki, Endocrinology Department, Thessaloniki, Greece

Introduction
'Whispering' pituitary adenomas (WPA) are a rare subtype of pituitary neuroendocrine tumors (PitNETs), characterized by immunohistochemical evidence of pituitary hormone production or specific transcription factors, along with biochemical activity, but minimal or no clinical symptoms. These adenomas represent 1.1–6% of surgically resected pituitary tumors and 17–22% of adrenocorticotropic hormone ACTH-positive tumors.
Aim
To describe three cases of pituitary adenomas later identified as WPAs. **Case 1**: A 36-year-old female with menstrual disturbances, headaches, and galactorrhea was diagnosed with a pituitary macroadenoma ($1.4\times1.2\times1.15$ cm). She was treated with cabergoline due to mild hyperprolactinemia, which improved her symptoms. Hormonal evaluations showed a morning cortisol of 21 μg/dl (10-20), ACTH of 37 pg/ml (7.2-63), and a normal overnight dexamethasone suppression test (ODST). After worsening headaches, she underwent transsphenoidal surgery. Histology revealed ACTH staining and a Ki-67 index of 3%. Two years post-surgery, the patient remains asymptomatic with no signs of Cushing's disease. **Case 2** A 76-year-old female was referred after pituitary macroadenoma apoplexy (adenoma size 1.9×1.6 cm), managed conservatively. The tumor had been discovered incidentally seven years earlier ($1.3\times1.1\times0.8$ cm), but no functional evaluations were conducted. The patient showed no clinical signs of hypercortisolism but had mild metabolic disturbances (overweight and osteopenia.). Biochemical tests indicated ACTH-dependent Cushing's syndrome (ACTH = 91.7 pmol/l,ODST = 11.1 μg/dl, urine cortisol = 126.8 μg/gCR). Given tumor progression, surgery was performed, and histopathology confirmed an ACTH-positive pituitary adenoma with a Ki-67 index of $<1\%$. Postoperative follow-up showed normalized biochemistry and no residual disease. **Case 3:** A 60-year-old male presented with a history of transsphenoidal pituitary adenomatectomy 17 years before. Postoperatively, he had developed deficiencies in the gonadotropic and thyrotropic pituitary axes and was placed on replacement therapy. Histological examination confirmed the diagnosis of a pituitary adenoma. Three years before, a follow-up pituitary MRI showed tumor relapse measuring 3.2×2.1 cm. The patient displayed no clinical signs of hypercortisolism, and hormonal evaluation revealed a morning cortisol level of 8.53 μg/dl, ACTH at 10.9 pg/ml. Surgery was repeated, histopathological findings were consistent with pituitary adenoma, with a Ki-67/MIB1 index of 2-3% and limited positivity for ACTH.
Conclusions
Corticotropic adenomas present with varied clinical manifestations, from subtle symptoms to no signs at all. Diagnosis relies on biochemical profiles and immunohistochemistry. Close monitoring post-surgery, including regular imaging and biochemical follow-up, is critical for managing these tumors effectively.

Acromegaly and metabolic complications: a report of 78 cases

Mashal Rajaa[1], Nassim Essabah Haraj[1], Siham El Aziz[1] & Asma Chadli[1]
[1]Ibn Rochd University Hospital of Casablanca, Morocco, Neurosciences and Mental Health Laboratory Faculty of Medicine and Pharmacy- University Hassan II – Casablanca-Morocco, Endocrinology, Diabetology, Nutrition and Metabolic Diseases Departement, Casablanca, Morocco

Introduction
Metabolic disorders caused by acromegaly are responsible for morbidity three times higher than that of the general population.
The objective
To analyze the different metabolic complications in acromegalic patients.
Patients and methods
This is a retrospective study of 78 cases of acromegaly followed at the endocrinology department of Ibn Rochd University Hospital from 2005 to 2024. All our patients underwent a metabolic assessment: fasting blood sugar, HbA1c, total cholesterol, HDLc, LDLc, triglycerides with uric acid measurement.
Results
The mean age was 45 years, sex ratio: F/M of: 0.45. The mean BMI rate was 28 kg/m^2 with overweight in 14 patients (10.9%), and obesity in 26 patients

(20.28%). On metabolic assessment: prediabetes in 18 patients (14.04%) and diabetes in 32 patients (24.96%). Dyslipidemia was observed in 41 patients (31.98%) with a mean cholesterol level of 2 g/l,mean triglyceride of 1.69 g/l,mean HDL of 0.41 g/land mean LDL level of 0.99 g/L. Hyperuricemia in 5 patients (6.25%) with a mean uric acid level of 46 mg/L. Treatment of diabetes was based on life style management associated with oral antidiabetics (88%), and insulin therapy + ADO (12%). Patients with dyslipidemia were put on life style management with statins in 58.5%.

Conclusion

Systematic screening of metabolic complications in acromegalic patients and their early and adequate management is of major interest in order to prevent the resulting morbidity and mortality.

Pituitary apoplexy complicated by subarachnoid hemorrhage: the role of stress and cabergoline therapy

Mariam Akacka[1], Kouloud Boujelben[1], Mouna Elleuch[1], Hamdi Frikha[1], Dhoha Ben Salah[1], Mouna Mnif[1], Faten Haj Kacem Akid[1], Mohamed Abid[1], Nadia Charfi[1] & Nabila Rekik Majdoub[1]
[1]Hedi Chaker University Hospital, Endocrinology Department, Sfax, Tunisia

Introduction

Giant prolactinomas, due to their size and invasive nature, can lead to serious complications. While cabergoline is effective in reducing the tumor and normalizing prolactin levels, it can cause rare but significant side effects, such as pituitary apoplexy, especially after rapid tumor reduction or physical and emotional stress.

Observation

A 45-year-old patient, with no significant family history, was diagnosed with a 7 cm invasive pituitary macroadenoma (Knosp 4), associated with a giant prolactinoma, hyperprolactinemia, and visual disturbances. Cabergoline was started due to surgical contraindication, resulting in a significant reduction in prolactin from 12,000 ng/ml to 246 ng/ml after one month. Three months later, ophthalmological exams were normal, except for the exclusion of a blind spot. Prolactin was below 0.5 ng/ml, and MRI showed a significant reduction in tumor size (35 mm). One year later, after a physically demanding move and significant psychoaffective stress, the patient developed headaches and vomiting. MRI revealed pituitary apoplexy with bilateral subarachnoid hemorrhage, without hydrocephalus. He was hospitalized, and in the absence of severe neurological signs or major visual disturbances, a conservative treatment approach was chosen.

Discussion

This case describes a giant prolactinoma treated with cabergoline, with an initially favorable response. However, after physical stress (moving), the patient developed pituitary apoplexy complicated by subarachnoid hemorrhage. Physical effort likely triggered the apoplexy due to the tumor's proximity to the subarachnoid space. Although cabergoline is effective, it can rarely cause apoplexy, especially with large adenomas, due to rapid changes in tumor vascularization. Close follow-up is essential.

JOINT3915

Co-occurrence of tuberous sclerosis and pituitary stalk interruption syndrome: a rare clinical presentation

Mohammed Salloum[1], Rama Hamed[1], Nur Azman[1] & Nouman Butt[1]
[1]Portsmouth Hospitals University NHS Trust, Department of Endocrinology, Portsmouth Hospitals University NHS Trust, Portsmouth, United Kingdom

Background

Tuberous sclerosis complex (TSC) is a rare inherited neurocutaneous disorder characterised by a diverse range of benign growths, or hamartomas, affecting multiple organ systems. These can involve the brain, eyes, heart, lungs, liver, kidneys, and skin. The expression of TSC varies considerably between individuals. Clinical diagnosis is typically supported by imaging and genetic testing, with characteristic brain lesions such as glioneuronal hamartomas, subependymal nodules, subependymal giant cell astrocytomas, white matter lesions, and arachnoid cysts being commonly observed. Pituitary stalk interruption syndrome PSIS is **diagnosed primarily through magnetic resonance imaging (MRI)** of the brain which shows the characteristic abnormalities of the pituitary stalk and posterior pituitary location, while TSC diagnosis often involves genetic testing, clinical evaluation, and imaging studies to identify the characteristic brain lesions. Though both of TSC and pituitary stalk interruption syndrome (PSIS) is rare, the co-occurrence of these two conditions is even less frequent.

Clinical Case Description

A 41-year-old female with a medical history of TSC presented with polydipsia and polyuria. Laboratory tests revealed hypernatremia, alongside highly diluted urine, which led to a diagnosis of arginine vasopressin deficiency (AVP-D) (diabetes insipidus). The patient's history of TSC included bilateral renal angiomyolipomas (AML), learning difficulties, epilepsy, autism, and lymphangioleiomyomatosis affecting the lungs, kidneys, and lymphatic system. Upon initiation of Desmopressin treatment, her sodium levels normalised, and her carers reported significant improvement in her symptoms, including a reduction in excessive thirst and inappropriate fluid intake. In the past, she had been observed licking condensation from windows due to her heightened thirst. MRI of the pituitary gland, performed under sedation, **revealed a hypoplastic anterior pituitary, an absent infundibulum, and agenesis of the posterior pituitary gland, findings that are consistent with pituitary stalk interruption syndrome (PSIS).** Notably, the anterior pituitary profile was unremarkable.

Conclusion

This case highlights the rare and complex interplay between TSC and PSIS, the occurrence of both in a single patient is uncommon. Further research into the genetic mechanisms behind these conditions may provide insights into their co-occurrence and potential management strategies.

A case of cushing disease presenting with pituitary apoplexy in an adolescent female

Clinton Roddick[1,2], Emma Chan[1] & Sarah McMahon[1]
[1]Queensland Children's Hospital, Endocrinology, Brisbane, Australia; [2]Child Health Research Center, University of Queensland, Brisbane, Australia

This is a case report of a 16yo female presenting with pituitary apoplexy, secondary to an ACTH-secreting pituitary macroadenoma. On history, they reported an eighteen-month history of weight gain, hyperphagia and behavioural disturbance requiring psychiatric hospitalisation. Other noted features of Cushing Disease included oligomenorrhoea, acne, hirsuitism, abdominal striae, buffalo hump and acanthosis. She reports subjective visual changes premorbidly, although formal testing was not sought. During this time a clinical diagnosis of polycystic ovarian syndrome and Type 2 Diabetes Mellitus were made, and the patient commenced on metformin 2g daily. Relevant biochemistry included FSH 3IU/l,LH 2IU/l,Estradiol 174pmol/l,testosterone 2.1nmol/l,free testosterone 80pmol/l,progesterone 2.1nmol/l,17-OHP 0.8nmol/l,OGTT normal. They were reviewed for obesity shortly before presentation with apoplexy. A dexamethasone suppression test one week prior demonstrated an unsuppressed morning cortisol of 550nmol/lwith ACTH not recorded. Other Cushing Disease screening was planned. Past medical history was significant for precocious puberty with thelarche from 5 years of age, and GnRH treatment between 8 and 10.5 years of age. A contrast MRI at 9 years was reported normal with no evidence of pituitary lesion. Tall stature and obesity were present at this time, with a BMI Z-score consistently +2.5 SDs. Following triptorelin cessation they achieved menarche at 12 years of age and was discharged from the endocrinology service. At diagnosis they presented with thunderclap headache, visual loss, nausea and confusion. Apoplexy was demonstrated on CT and MRI. Urgent retrieval and neurosurgical evacuation of haemorrhage and tumour residue was performed, and the patient treated empirically with high-dose steroids. Histopathology confirmed the presence of ACTH-producing pit-NET. The post-operative course was complicated by venous thrombosis, posterior reversable encephalopathy syndrome (PRES), visual impairment, and glucocorticoid withdrawal syndrome. Early assessment of the hypothalamic-pituitary-adrenal axis suggests resolution of Cushing Disease and adrenal gland recovery, however, attempts to reduce post-operative hydrocortisone below 80mg/day (50mg/m^2/day) results in significant steroid withdrawal symptoms. Due to this, we are weaning steroids slowly at an increment of 5mg/m^2/day every other week. Other pituitary hormone functions are intact, although menses have not yet resumed. Additionally, an oral glucose tolerance test was normal. This case is interesting as both

ACTH-secretion macroadenomas and pituitary apoplexy are rare in the paediatric age group. This case highlights the high morbidity associated with such a diagnosis and opens discussion into the importance of considering Cushing Disease in the setting of an increasingly obese population.

Analysis of obesity frequency in girls with central precocious puberty

Ana Luiza Padua Aratangy Pontes[1,2], Victor Cugi Gonçalves[1,2] & Cristiane Kochi[1,2]
[1]Irmandade da Santa Casa de Misericórdia de São Paulo, Unidade de Endocrinologia Pediátrica, São Paulo, Brazil; [2]Santa Casa de São Paulo, Faculdade de Ciências Médicas, São Paulo, Brazil

Context
Obesity and central precocious puberty (CPP) are linked, especially in girls, but its impact on CPP progression and treatment remains unclear.
Objectives
To assess obesity frequency in girls with CPP, analyze BMI evolution during GnRH analog treatment, and compare CPP parameters between eutrophic and overweight girls.
Methods
Data from 80 girls diagnosed with CPP and treated with GnRH analogs were analyzed (April 2017–November 2024). Anthropometric data, bone age, and pubertal staging were collected at diagnosis, treatment initiation, annually during treatment, at discontinuation, and after menarche. Height and BMI were expressed as z-scores (WHO, 2007).
Results
At diagnosis, 50% of patients were overweight. Mean (SD) zBMI was 1.1 (1.2) at diagnosis and 1.3 (1.1) at treatment discontinuation ($P = 0.067$). Girls were classified as eutrophic or overweight. zBMI increased only in eutrophic girls (0.455 vs. 0.585; $P = 0.012$). Thelarche age was similar (6.5 vs. 6.0 years; $P = 0.43$), but eutrophic girls had a shorter interval between thelarche and GnRH initiation (1.4 vs. 2.0 years; $P < 0.001$). At treatment initiation, overweight girls had higher height z-scores (1.8 vs. 1.0; $P = 0.003$). No differences were found in treatment initiation age (7.9 vs. 8.0 years; $P = 0.655$), GnRH discontinuation age (10.0 vs. 9.8 years; $P = 0.164$), or menarche age (11.3 vs. 10.8 years; $P = 0.320$). However, overweight girls had a greater difference between bone age and chronological age at treatment initiation (2.9 vs. 2.3 years; $P = 0.011$).
Conclusions
While no overall zBMI change occurred during GnRH treatment, eutrophic girls showed an increase. Despite similar thelarche ages, eutrophic girls started pubertal blockade earlier. Overweight girls had a greater bone age-chronological age difference, and their later treatment initiation may predict greater height loss. No differences were found in treatment discontinuation or menarche age. Further studies assessing final height are needed to evaluate the height loss risk in overweight patients.

Keywords
central precocious puberty, obesity, BMI, GnRH.

Abbreviations
CPP, central precocious puberty; BMI, body mass index; GnRH, gonadotropin-releasing hormone; SD, standard deviation.

Copeptin and MR-proADM, do not show the risk of cardiometabolic disease in patients with acromegaly—preliminary results

Aleksandra Jawiarczyk-Przybyłowska[1], Martyna Strzelec[1], Justyna Kuliczkowska-Płaksej[1], Katarzyna Kolačkov[1], Aleksandra Zdrojowy-Wełna[1] & Marek Bolanowski[1]
[1]Wroclaw Medical University, Department of Endocrinology and Internal Disease, Wroclaw, Poland

Background
Cardiovascular complications are a major cause of premature mortality in patients with acromegaly. Copeptin (CPP) is closely associated with plasma osmolality and is influenced by non-osmotic stimuli that play a role in the development of cardiovascular disease. Mid-regional proadrenomedullin (MR-proADM), primarily produced in the adrenal medulla, vascular endothelial cells, and the heart, has known vasodilatory effects. This study aimed to evaluate two cardiovascular biomarkers (CPP and MR-proADM) in patients with acromegaly concerning disease activity and to compare the results with those of a control group.
Methods
The study analyzed CPP and MR-proADM levels, along with hormonal and biochemical parameters, and the prevalence of cardiovascular and metabolic diseases in 53 patients with acromegaly and 26 controls.
Results
No significant differences were found in CPP or MR-proADM levels between the two groups. However, a positive correlation was observed between growth hormone (GH) and CPP levels, while a negative correlation was noted between fasting glucose and CPP levels among acromegaly patients. Additionally, there was a positive correlation between low-density lipoprotein (LDL) and MR-proADM levels, as well as between high-density lipoprotein (HDL) and MR-proADM levels in the study group. Atherogenic dyslipidemia was significantly more prevalent in patients with active acromegaly and pituitary macroadenomas compared to the control group. Acromegaly patients also exhibited significantly higher fasting glucose and insulin levels than controls.
Conclusions
Neither CPP nor MR-proADM serves as significant diagnostic or monitoring biomarkers for cardiovascular or metabolic complications in patients with acromegaly.

Prevalence and clinical characteristics of central precocious puberty: experience of single academic center in Serbia

Jelena Blagojevic[1], Maja Jesic[1,2], Vladislav Bojic[1], Smiljka Kovacevic[1], Jelena Miolski[3] & Vera Zdravkovic[1,2]
[1]University Children's Hospital, Belgrade, Serbia, Endocrinology, Belgrade, Serbia; [2]School of Medicine, University of Belgrade, Belgrade, Serbia; [3]General Hospital Stefan Visoki Department of Pediatrics with Neonatology, Smederevska Palanka, Serbia

Introduction
Central precociuos puberty (CPP) is a premature development of secondary sex characteristics (breast bud before 8 years in girls and enlargement of testicles before 9 years in boys), accompanied with growth and bone age acceleration. The gold standard for diagnosis is stimulated LH above 5 mU/lduring LHRH test. We observed the reports of increased incidence of CPP girls in the last decade.
Aim
To analyze patients with CPP diagnosed and treated in the last 10 years in the University Children's Hospital.
Methods
The design of the study was a retrospective chart review of patients treated in the University Children's Hospital between 2014 and 2024. We collected data about their birth history, family history, age at presentation of puberty, auxology data, basic LH, stimulated LH and bone age.
Results
We analyzed the prevalence of CPP patients treated at our hospital in the last decade. The available records revealed below 9 patients before 2019. In 2020 we treated 12 patients, with significant increase in 2021 (24) and stable number in the following years. In the last 5 years we noticed the rise of males with CPP and girls born small for gestational age (SGA). The average age at the initiation of the treatment with GnRH analogue treatment was 7.08 $\pm$ 2.21 years. Bone age was fairly advanced in all patients, basic LH was 1.64 $\pm$ 1.4 mU/land stimulated LH 12.7 $\pm$ 7.7 mU/L. Currently 43 (39 F/4M) patients are receiving GnRH analogue therapy every 3 months.
Conclusion
We noticed increasing numbers of CPP patients in the last decade, especially in the first years of COVID pandemic. The age at presentation remains the same, but

we observed increased number of girls born as SGA. We speculate that enlarged number of patients with CPP might be due to obesity rising trend.

JOINT2205

Fenestrated pituitary infundibulum in a young woman with ehlers-danlos syndrome: a case report

Petra Meliš[1], Mirjana Kardum Pejić[1] & Srecko Marusic[1]
[1]University hospital Dubrava, Zagreb, Croatia

Introduction

Fenestration of the pituitary infundibulum is a rare anatomical variant, often incidentally discovered on brain imaging. This case report describes a young woman with Ehlers-Danlos syndrome (EDS) who presented with frequent headaches. An magnetic resonance imaging (MRI) revealed a fenestrated pituitary infundibulum. The potential association between EDS and pituitary abnormalities is unknown. There is no known evidence about that connection in current literature.

Case Description

A 41-year-old woman with a known history of Ehlers-Danlos syndrome presented to the endocrinology clinic with MRI scan describing fenestrated pituitary infundibulum. The pituitary gland itself appeared normal in size and structure, with no evidence of adenoma or other lesions. Endocrine evaluation included assessment of the hypothalamic-pituitary-gland axes with no evidence of hormonal dysfunction.

Discussion

Fenestration of the pituitary infundibulum is a rare finding, often considered an anatomical variant without clinical significance. However, in this case, the presence of EDS raises the possibility of a connective tissue-related structural abnormality. EDS is characterized by defects in collagen synthesis, which may affect the integrity of the pituitary stalk and surrounding structures. Although functional MRI of the pituitary region could provide additional insights into potential microstructural or vascular changes, this imaging modality was not available in our clinical setting.

Conclusions

This case highlights a rare finding of a fenestrated pituitary infundibulum in a young woman with EDS. Although no endocrine dysfunction was identified, the potential link between EDS and structural pituitary abnormalities should be considered in patients with connective tissue disorders. Further studies are needed to explore this association and its clinical implications.

Why was the hypopituitary patient's life not saved?

Krisztina Kupai[1], Szabolcs Nyiraty[2] & Zsuzsanna Valkusz[2]
[1]University of Szeged, Szeged, Hungary, Department of Medicine, Albert Szent-Györgyi Medical School, SZEGED, Hungary; [2]University of Szeged, Szeged, Hungary., Department of Medicine, Albert Szent-Györgyi Medical School, SZEGED, Hungary

56-year-old male patient visited his doctor as an outpatient with fatigue and chest complaints. Acute coronary syndrome was excluded. 3 weeks later, the patient voluntarily presented to the psychiatric clinic, from where he was immediately admitted to the ward for sleep disturbance and psychomotor slowing. On admission, hypotension, elevated cardiac necro enzymes, proBNP values and hyponatraemia were seen despite continuous Na supplementation. Low sodium levels despite sodium supplementation, the patient was referred to the endocrinology department for investigation of suspected hypoadrenia. His hormone profile confirmed panhypopituitarism, underlying cranial imaging confirmed a 9x12.5x10 mm pituitary macroadenoma, no neurosurgical intervention was performed. Despite adequate hormone replacement, no improvement was seen in the patient's condition, and the clinical picture was still characterised by a high degree of weakness and anaemia. Gastroscopy and biopsy raised the possibility of amyloidosis. Subsequently, the patient was referred to the cardiology department, where cardiac MRI confirmed the diagnosis of cardiac amyloidosis. Serum immunoelectrophoresis was performed due to elevated kappa light chain values and bone marrow biopsy was performed, which revealed the presence of multiple myeloma, and AL amyloidosis was described in the heart. Recovery from heart failure therapy was initiated, he developed another hypotensive crisis, Staphylococcus aureus infection, sepsis, resulting in patient's death. The picture of hypothyroidism as part of panhypopituitarism showed similar similar clinical symptoms to AL amyloidosis. Despite hormone replacement, the patient's life could not be saved due to the severe co-morbidity, AL amyloidosis and consequent heart failure.

Diagnostic challenges in polyuria-polydipsia syndrome: a case from resource-limited setting

Ketevan Chanturishvili[1] & Ia Kavtiashvili[2]
[1]Tbilisi Institute of Medicine, Tbilisi, Georgia; [2]Tbilisi Institute of Medicine, Endocrinology, Tbilisi, Georgia

Introduction

Polyuria-polydipsia syndrome is a rare medical condition, characterized by excessive urine output ($\geq$3 L/24 hour) with continuous ingestion of fluids. This syndrome can be due to defects in antidiuretic hormone production, secretion or renal response or from primary excessive fluid intake. Correct diagnosis is crucial, as treatment protocols differ significantly. A misdiagnosis may result in severe, life-threatening outcomes. However, the challenge lies in reaching an accurate diagnosis due to a significant overlap among the different forms of Diabetes insipidus (DI) and primary polydipsia, particularly in developing countries like Georgia, where access to diagnostic tests is limited.

Case presentation

We present an 18-year-old girl with history of polydipsia, polyuria, oligomenorrhea and binge eating. On physical examination, her vitals were within normal limits and body mass index was 28.8 kg/m^2. Additional evaluation was performed, including a negative urinary pregnancy test and the exclusion of urinary tract infection. Patient denied any history of head trauma. A 24-hour urine collection test was conducted, which confirmed polyuria (8.5 L/24 h). Additional testing excluded osmotic diuresis; electrolyte levels were within normal ranges, sodium being high-normal. Osmolality measurements revealed low urine osmolality-271mOsm/kg, while serum osmolality remained within normal limits. Based on the laboratory results neither primary polydipsia nor DI could be confirmed or excluded. The patient was advised to undergo further evaluation with water deprivation test. However, this test could not be fully performed in Georgia, as osmolality measurements are sent abroad, requiring days for results. Consequently, the second phase of the test, the desmopressin challenge, could not be conducted locally. Given the patient's clinical history and laboratory findings, it was decided to proceed with partial water deprivation test, focusing on the dehydration phase, with subsequent assessment of osmolality and copeptin levels. Additionally, psychiatric evaluation was recommended to further guide the diagnostic process. Following the partial water deprivation test, urine osmolality remained low, indicating the need for desmopressin phase. However, due to financial constraints, the patient was unable to travel abroad for further testing. As a result, psychiatric and psychological treatment were initiated with close supervision. Within a few weeks, the patient reported a noticeable reduction in water intake and an overall improvement in her symptoms.

Conclusions

This case highlights the complexities of diagnosing polyuria-polydipsia syndrome, especially in developing nations. Water deprivation test remains gold standard, with desmopressin phase providing essential diagnostic value. However, limitations in diagnostic resources in Georgia create substantial obstacles. Though the water deprivation test remained incomplete, the patient's gradual improvement following psychological intervention supports the diagnosis of psychogenic polydipsia. Main emphasis of this case is the relevance of a team-based approach in managing complex endocrine disorders, especially in countries where diagnostic tools are limited.

Delayed diagnosis of pituitary apoplexy in a patient with migraine

Samira Khalilova[1], Hyma Rachabattula[1], Shemita Rafique[1] & Adrian Li[1]
[1]Princess Royal University Hospital, Farnborough, United Kingdom

Introduction
Pituitary apoplexy is a rare clinical syndrome that occurs as a result of acute haemorrhage and/or infarction within a pituitary tumour. Classical presentation includes sudden onset headache, vomiting, visual impairment and possible partial or panhypopituitarism. Pituitary apoplexy is frequently spontaneous, but predisposing factors can be identified in 10–40% of cases. As the clinical syndrome overlaps with other presentations, recognition of pituitary apoplexy is challenging, which delay diagnosis and management. We describe the case of a pre-existing history of migraines leading to a late diagnosis of pituitary apoplexy.
Clinical case
A 34-year-old man presented to the hospital with sudden onset throbbing headache and several episodes of vomiting without fever, rash or neck stiffness. He had a background of chronic migrainous headache requiring hospital admission previously. Past medical history also included type 1 diabetes mellitus, and a 12mm non-functioning pituitary macroadenoma. Initial CT head imaging did not reveal any pathology and both an MRI and lumbar puncture were planned to exclude SAH. During admission, he developed hyperglycaemia with ketosis, which was managed by an intravenous insulin infusion. His headache did not demonstrate improvement and lumbar puncture was positive for xanthochromia. On the sixth day of admission, his sodium level dropped from 133mmol/lto 108mmol/L. The medical team assessed the patient to be hypovolemic and administered intravenous fluids. The possibility of pseudohyponatraemia secondary to hyperglycaemia was also raised. On the same day, the patient reported new visual deterioration. An urgent pituitary MRI was performed and intravenous Hydrocortisone was commenced. Anterior pituitary profile showed a cortisol of 19nmol/l,FSH 1.1IU/l,LH $<$1.0IU/l,testosterone 0.5nmol/l,prolactin 40mIU/l,free T4 12.5pmol/l,free T3 2.2pmol/land TSH 0.08mIU/L. MRI showed signs of apoplexy. Severe hyponatremia was managed in Intensive Care and he was commenced on hydrocortisone, levothyroxine and testosterone, and surgery done after that. Interval surveillance pituitary MRI showed significant reduction in the size of the lesion without mass effect on the chiasm. The patient remains on replacement therapy with Hydrocortisone, Levothyroxine and Testosterone.
Discussion
This case highlights the importance of considering apoplexy early within the differential of a patient with a pituitary adenoma presenting with sudden onset headache. Delayed diagnosis of pituitary apoplexy is common in the case of undiagnosed pituitary adenoma, but can be avoided in a patient with a known diagnosis. Hyponatraemia may occur secondary to cortisol insufficiency. Therefore, when apoplexy is suspected, the management should include administration of intravenous glucocorticoid therapy.

JOINT2460

Management of macroprolactinomas during pregnancy: about 2 cases

Nada El Idrissi Dafali[1], Sana Rafi[1], Sara Ijdda[1], Ghizlane El Mghari[1] & Nawal El Ansari[1]
[1]Mohamed VI University Hospital Center VI, Department of Endocrinology, Marrakech, Morocco

Introduction
Prolactinomas are the most common pituitary adenomas and are a cause of infertility due to anovulation. Their treatment restores normal fertility. During a normal pregnancy, oestrogens cause hyperplasia of the lactotropic cells, responsible for hyperprolactinaemia and pituitary hyperplasia on MRI. Pregnancy in a patient with a prolactinoma poses several problems.
Observation
1st case: We report the case of a patient aged 40 years, followed for a macroprolactinoma, revealed at age 32, by secondary amenorrhea and bilateral galactorrhea, associated with a tumor syndrome. At the bill, hyperprolactinaemia at 305.60 ng/ml with pituitary MRI: a left lateralized pituitary nodular formation measuring: 10*8 mm. The patient was placed on cabergoline 0.5 mg: 4 cp/week, with a progressive decrease and then normalization of prolactinemia. After 7 years of treatment, the patient consults for pregnancy at 12 SA. The course of action was to reduce the dose of cabergoline to 0.5 mg/week and schedule monthly clinical follow-up. 2nd case: 33-year-old patient, followed for macroprolactinoma since the age of 25, revealed by a secondary amenorrhea, with a tumor syndrome, diplopia and galactorrhea. With an MRI pituitary adenoma occupying the entire saddle cavity measuring 11x 10 x 11 mm and a prolactinemia at 563.80 ng/ml. Treated with cabergoline, the course was marked by pregnancy. The course of action was to continue the cabergoline and schedule regular follow-up.
Discussion
When a patient has a prolactin adenoma, pregnancy will be achieved in the vast majority of cases with precautions depending on the initial tumor size. The risk of developing microprolactinomas is low, allowing for a discontinuation of dopamine agonists once pregnancy has been diagnosed. The approach differs in the case of macroprolactinomas, where the risk of progression is higher and therefore the continued dopaminergic agonist therapy during pregnancy is justified. Monitoring involves monthly clinical check-up and possibly a detailed neuroophthalmological examination, the frequency of which will depend on visual symptoms and the pre-pregnancy situation (size of the tumour; proximity of the optic pathways; presence or absence of a visual deficit before pregnancy). A pituitary MRI without contrast should be performed in case of symptoms suggestive of tumor progression or apoplexy (headaches; deficit of acuity or visual field; oculomotor disorders..).
Conclusion
Management of macroprolactinomas during pregnancy should be cautious and monthly, because the increase in tumor volume, with a risk of apoplexy, is observed in cases reported in the literature.

Non functional pituitary macroadenoma expressing GH, LH and ACTH

Chayma Zouna[1], Hasna Ouirar[1], Ikram Qasdi[1], Zineb Habbadi[1], Fatima Toulali[1], Ghizlane Sabbar[1], Kaoutar Rifai[1], Hind Iraqi[1] & Mohamed Hassan Gharbi[1]
[1]CHU Rabat, Endocrinologie, Rabat, Morocco

Introduction
Non-functional pituitary adenomas are benign neoplasms that arise from adenohypophyseal cells and are not associated with clinical signs of hormonal hypersecretion. They form a broad and heterogeneous group Plurihormonal adenomas can be classified into two groups: “PIT1-positive adenomas” (formerly known as subtype 3 silent pituitary adenomas); and plurihormonal adenomas with more than one transcription factor, known as ‘plurihormonal adenomas with unusual immunohistochemical combinations’. WE present the case of a rare plurihormonal combination of a non-functioning macrodenoma.
Observation
Patient aged 27 The onset of symptoms dates back to July 2023, with the onset of a drop in visual acuity, prompting the patient to consult an ophthalmologist for a visual field test, which revealed a bitemporal hemianopia, followed by a pituitary-hypothaloid MRI, which showed an invasive pituitary macroadenoma. adenoma, initially measuring 42*49*25mm, referred urgently for neurosurgery in view of the visual repercussions. Moreover, the patient reported no signs or symptoms related to tumour hypersecretion identified by a preoperative work-up, including IGF1, which returned normal at 184ng/ml for his age. HISTOCHIMIC study was in favour of a plurihormonal pituitary adenoma strongly expressing GH, weakly ACTH and LH, with KI67 estimated at 2% The evolution in 03 months post-op was marked by the persistence of a pituitary residue measuring 15*14*12mm on control MRI, completed by an endocrine work-up showing gonadal, thyroid and corticotropic anteropituitary insufficiency. and IGF levels normal for age. In addition, the patient did not report any tumour symptoms, such as headaches or reduced visual acuity.
Discussion
Patients with non-functional pituitary adenomas have less chance of remission than patients with functional pituitary adenomas. Adenomas can progress after surgical treatment, with regrowth rates of 15-66% in patients with non-functional adenomas treated with surgery alone, and 2-28% in those treated with surgery and radiotherapy. Long-term radiological monitoring after treatment of these adenomas is therefore recommended. No convincing prognostic factors for recurrence of these adenomas have yet been found. Clinical factors such as age, gender, tumor size and tumor invasion have limited predictive value for tumor progression. On the other hand, Ki-67 has been described as an independent cellular marker of tumor progression and recurrence.

Discordant disease activity indicators in a patient with acromegaly

Georgy Gabaidze[1], Margarita Perepelova[1], Elena Przhiyalkovskaya[1], Ekaterina Pigarova[1] & Larisa Dzeranova[1]
[1]Endocrinology research centre, Moscow, Russian Federation

Introduction
Acromegaly is a neuroendocrine disorder characterized by chronic hypersecretion of growth hormone (GH). Insulin-like growth factor 1 (IGF-1) is currently the primary marker for assessing disease activity and treatment effectiveness due to its strong correlation with GH levels. However, cases with discordant GH and IGF-1 levels pose diagnostic and therapeutic challenges.
Clinical Case Description
At 22 years old, Patients. reported back pain, recurrent fever, skin hyperpigmentation, breast discomfort with nipple discharge, and progressive enlargement of facial features, hands, and feet. Laboratory tests revealed hyperprolactinemia (1,701.0 mIU/l; reference range: 66.0–436.0) and non-elevated IGF-1 (164.0 ng/ml; reference range: 82.0–283.0). Brain MRI identified a pituitary macroadenoma measuring 26×41×34 mm. Treatment with cabergoline 0.5 mg twice weekly was initiated. At 23 years old, despite a normal IGF-1 level (85.4 ng/ml), the patient demonstrated active acromegaly with markedly elevated basal GH (80.0 ng/ml; reference range: 0.02–1.23) and insufficient suppression during an oral glucose tolerance test (OGTT) (minimum GH: 60 ng/ml at 120 minutes). MRI showed tumor progression (32×35×23 mm). The patient was started on long-acting octreotide 20 mg every 28 days. Subsequent assessments revealed persistently elevated GH (26.6 ng/ml) despite a normal IGF-1 (120.9 ng/ml). MRI showed tumor regression (32×29×23 mm), prompting an increase in the octreotide dose to 40 mg. Six months later, the patient underwent transnasal adenomectomy. Postoperatively, maximum GH suppression during OGTT was 0.6 ng/ml at 90 minutes. Immunohistochemical analysis confirmed a sparsely granulated somatotropinoma, with GH expression in tumor cells, Ki-67 <1.0%, strong somatostatin receptor subtype 2 and 5 expression (>80% of tumor cells, IRS-8), and CAM 5.2 expression in fibrous bodies. At 25 years old, laboratory results confirmed persistent disease activity: IGF-1 remained within the normal range (85.7 ng/ml), but GH was elevated (5.1 ng/ml) with inadequate suppression during OGTT (minimum GH: 3.28 ng/ml at 90 minutes). MRI showed only postoperative changes. The patient continued treatment with long-acting octreotide 20 mg daily.
Conclusion
This case highlights the need for an expanded diagnostic approach in acromegaly, particularly in cases with discordant GH and IGF-1 levels. Alongside IGF-1 measurement, GH levels—both basal and during OGTT—should be systematically evaluated to ensure accurate disease monitoring and treatment optimization.

Delayed diagnosis of pituitary apoplexy: a case report

Mariem Souissi[1], Oumaima Dimassi[1], Houcem Elomma Mrabet[1], Boubaker Fadia[1], Alaya Wafa[1] & Sfar Mohamed Habib[1]
[1]Taher Sfar University Hospital, Endocrinology-Diabetology and internal Medicine Department, Mahdia, Tunisia

Introduction
Pituitary apoplexy is a rare but life-threatening endocrine emergency, often revealing an underlying pituitary adenoma. It results from hemorrhagic or ischemic necrosis of the pituitary gland and requires prompt diagnosis and management.
Case Presentation
We report the case of a 60-year-old man with a history of COVID-19 infection one year prior, presenting with sudden onset severe headaches, vomiting, and profound asthenia. He initially consulted the emergency department, where he was treated symptomatically and discharged. However, his symptoms worsened over the next few days, and he developed anorexia and bilateral blurred vision. Subsequently, he consulted a general practitioner, who prescribed injectable corticosteroid therapy. This treatment led to a significant improvement in his symptoms, but during the course of treatment, he developed a polyuria-polydipsia syndrome. After the corticosteroid therapy was discontinued, the patient experienced a sudden deterioration of his condition, including generalized tonic-clonic seizures. This prompted further investigations. Brain MRI revealed an intra-sellar lesion with hemorrhagic components compressing the optic chiasm, consistent with pituitary apoplexy. Hormonal assessment confirmed anterior pituitary insufficiency, including corticotropic, thyrotropic, and gonadotropic deficiencies, as well as a probable central diabetes insipidus.
Conclusion
Pituitary apoplexy is most commonly associated with macroadenomas, particularly non-functional ones. Identifying the secretion profile post-apoplexy can be challenging, as it may resolve hypersecretion caused by an adenoma. In our patient, it is important to consider potential triggering factors; a recent COVID-19 infection was suspected as a possible contributing factor. Corticotropic insufficiency is the most frequent endocrine deficit and poses a significant risk to survival. Central diabetes insipidus can be unmasked by corticosteroid therapy, which may further complicate the clinical picture. Early recognition and prompt hormonal replacement therapy are crucial for patient survival and functional recovery. While surgical decompression remains an option in severe cases, conservative management may be effective in selected patients.

More than thirst: diagnosis of central diabetes insipidus in a young woman without comorbidities

Chiara Palumbo[1], Sabrina Chiloiro[1], Antonella Giampietro[1], Laura De Marinis[1], Antonio Bianchi[1] & Alfredo Pontecorvi[1]
[1]Pituitary Unit, Endocrinology, Fondazione Policlinico Universitario A. Gemelli IRCCS, Università Cattolica del Sacro Cuore, Rome, Italy

Introduction
Central diabetes insipidus is a condition caused by vasopressin deficiency, which results in an inability to concentrate urine and consequently manifests with polyuria and polydipsia. In most cases it arises after trauma, tumours or autoimmune processes[1]. The water deprivation test is the most widely used test. The test is considered positive if peak serum osmolality is > 295 mmol/kg or if peak urine osmolality is < 300 mmol/kg or if the copeptin dosage is < 2.6 pmol/L[2].
Case Study
38-year-old patient with polyuria and polydipsia that had arisen about two years previously and worsened over the last year. The patient reported a fluid intake of about 8 litres per day. No previous history of trauma. Blood tests showed normal electrolyte values, but urine tests showed a lower specific gravity than normal. An MRI with contrast of the pituitary gland showed a normal gland. Therefore, considering the patient's symptoms, we decided to perform a water deprivation test, lasting approximately 14 hours. Blood samples were taken every two hours for dosing copeptin, serum osmolarity, sodium, as well as urine samples for urinary osmolarity and urine specific gravity. From the start to the end of the test: the patient's body weight decreased by approximately 1.2 kg (92.8 Kg vs 91.6 Kg) . Serum osmolarity increased from 288 mOsm/Kg to 301 mOsm/kg and urinary osmolarity increased from 487 mOsm/Kg to 611 mOsm/Kg. The urine specific gravity increased from 1005 to 1014 g/L; sodium values increased slightly during the test from 141 to 144 mmol/L; and, finally, the copeptin value remained below 2 pmol/lthroughout the test.
Treatment
The patient started therapy with desmopressin acetate 90 mg/day.
Thake Home Message
Vasopressin is an unstable hormone and it's difficult to measure it in laboratory in contrast to copeptin, the c-terminal fragment of the vasopressin precursor, which provides a reliable indirect measure of bioactive hormone[3]. Although in our clinical case already the serum osmolarity value allowed us to make a diagnosis, the copeptin assay was essential to make a definite diagnosis of central diabetes insipidus.

A persistent headache in acromegalic patient: the positive result of combination therapy with pasireotide LAR, pegvisomant and cabergoline

Penelope Giambò[1,2], Antonella Giampietro[1,2], Pier Paolo Mattogno[1,2], Ciro Mazzarella[1,2], Liverana Lauretti[1,2], Laura De Marinis[1,2],

[1]Policlinico Universitario Agostino Gemelli, Rome, Italy; [2]Università Cattolica del Sacro Cuore, Rome, Italy

Acromegaly is a rare condition characterized by the excessive exposure to GH and IGF-1 due to a pituitary adenoma in most of the cases. The disease is associated with numerous symptoms including headache, which is frequently difficult to manage. We aim to report the clinical history of a young woman who received the diagnosis of acromegaly when she was 11 years-old and started to refer headache, localized in the right frontal and orbital area, associated with nausea and emesis and finally got hospitalized in March 2011 because of a tonic-clonic seizure. The preliminary investigations included cerebral CT scan and RM which showed a voluminous lesion of the sellar and suprasellar region, located behind optic chiasm which compressed the third ventricle with consequent hydrocephalus and shifting of the midline, and hormonal dosage (IGF-I: 1008 ng/ml; PRL 3861 ng/ml with no macroprolactin). After the execution of an endoscopic septostomy and right ventriculoperitoneal shunt, the case was collectively discussed and considering the elevated risk related to neurosurgery, the patient started cabergoline, lanreotide ATG and pegvisomant first, pasireotide LAR as only therapy secondly and then shifted again to the first combination therapy. Despite the partial biochemical control, in consideration to the low lesion shrinkage, in December 2012 a partial resection of the macroadenoma was obtained. Over the years, the patient continued the medical therapy with lanreotide, cabergoline and pegvisomant in combination with good biochemical control and stability of the residual adenoma. In 2022, the patient started to refer headache that couldn't be attributed to acromegaly progression nor ventriculo-peritoneal shunt malfunctioning. In December 2023, lanreotide was substituted with pasireotide. In the last check-ups, the patient referred optimal control of headache by the combination therapy cabergoline, pegvisomant and pasireotide LAR. Pasireotide is known to be able to improve symptoms not sufficiently controlled by fg-SRLs and it can be used as monotherapy or in combination therapy in patients with severe headache not responsive to first-generation SRL therapy, as reported in several studies. Our case report enforces knowledge about pasireotide benefits in headache treatment.

Giant macroprolactinoma mimicking a craniopharyngioma: a remarkable evolution with persistent hyperprolactinemia due to big big prolactin

Ftouh Wiam[1], Boucht Aouatif[1], Smouni Meryem[1], Aziouaz Fatima[1] & Benkacem Mariem[1]
[1]University Hospital Center Mohamed VI, Faculty of Medicine and Pharmacy of Tangier, Department of Endocrinology and Diabetology, Tangier, Morocco

Introduction
Giant macroprolactinomas are rare pituitary tumors that can present with atypical radiological features, sometimes mimicking craniopharyngiomas. While dopamine agonist therapy typically leads to significant tumor shrinkage and normalization of prolactin levels, persistent hyperprolactinemia despite radiological resolution may indicate macroprolactinemia, particularly due to Big Big Prolactin (1).
Case Presentation
We present the case of a 27-year-old male with progressive visual disturbances, headaches, and hypopituitarism. MRI revealed a large sellar and suprasellar mass with cystic components and calcifications, initially suggestive of a craniopharyngioma. However, markedly elevated prolactin levels (300 ng/ml) led to the diagnosis of a giant macroprolactinoma. Due to significant visual impairment, surgical intervention was performed, followed by cabergoline therapy (2 mg weekly). After two years, complete radiological tumor resolution was achieved, with no clinical signs of hyperprolactinemia. Despite this, prolactin levels remained elevated (170 ng/ml), prompting further analysis. Polyethylene glycol (PEG) precipitation confirmed the presence of Big Big Prolactin, a high-molecular-weight prolactin complex with reduced bioactivity (2,3). After confirmation, cabergoline was gradually tapered and discontinued.
Conclusion
This case underscores the importance of distinguishing true hyperprolactinemia from macroprolactinemia in patients with persistent hyperprolactinemia despite tumor resolution. Recognizing the Big Big Prolactin phenomenon can prevent unnecessary treatment continuation and misinterpretation of disease activity. Systematic screening for macroprolactinemia should be considered in similar cases to optimize patient management (4).

Introduction
Both the excess of growth hormone (GH) in acromegaly (Acro) and its deficiency (GHD) may lead to impaired bone metabolism and bone mineral density (BMD) and fragility. However, the exact mechanism remains unclear.
Aim
To evaluate the effects of Acro and GHD treatment on bone metabolism, including bone turnover markers, BMD and bone microarchitecture.
Methods
In this single-center prospective study 26 patients were recruited: 13 (8 males, 5 females) with Acro and 13 (6 males, 7 females) with GHD. Calcium, phosphorus (serum), parathyroid hormone (PTH), 25-hydroxy- and 1,25-dihydroxy-vitamin D and bone turnover markers: serum b-cross laps (Ct-x), Procollagen type I N-terminal propeptide (P1NP), Sclerostin (Scl) and Dikkopff-1 (Dkk-1), and BMD and trabecular bone score (TBS) measured by dual-energy X-ray absorptiometry were assessed baseline and 6 months after adequate treatment (a6m).
Results
Mean age was 50.18 ± 14.45 and 32.17 ± 10.85 yrs. in Acro and GHD group, respectively. In Acro group 7 patients had hypogonadism, whereas in the GHD group 6 patients had multiple pituitary hormonal deficiency. Median baseline GH and IGF-1 levels in Acro were 12.1 µg/l[2.91-74.4] and 652 µg/l(2.86 xULN), respectively. In the GHD group median baseline IGF-1 was 80.4 µg/l(0.95 xLLN). In Acro group a6m of treatment we observed a reduction in serum phosphorus (1.41 vs 1.06 mmol/L). We also observed increase in PTH (29.3 vs 46.4 pg/ml) and decrease in 1,25(OH)2 vitamin D (60.65 vs 54.3 pg/ml). A6m of treatment we noticed an increase in bone turnover markers: Ct-x (26.4 vs 55.7 ng/L), P1NP (290.5 vs 405.5 ng/ml), and Scl (60 vs 68 pg/ml), but a decline in Dkk-1 levels (4198 vs 3873 pg/ml). BMD increased only at the lumbar spine (1.237 vs 1.308 g/cm^3). In GHD group there was increase in serum phosphorus (1.03 vs 1,14 mmol/L). A6m of treatment decrease in P1NP (276.8 vs 256.1 ng/ml), and increase in Ct-x (26,8 vs 47,5 ng/ml), Scl (47,6 vs 64,6 pg/ml) and Dkk-1 (3394 vs 4016 pg/ml) was observed. There was no change in BMD and TBS a6m in the GHD group.
Conclusion
We present preliminary results of the study showing the impact of GH changes on bone turnover markers in patients treated for Acro and GHD.

Sarcoidosis diagnosis after succesful treatment of cushing's disease

José Vicente Rocha[1], Carolina Ochôa Matos[2], Marta Vaz Lopes[2], Mariana de Griné Severino[2], Carolina Peixe[2], Miguel António Duarte[2], Catarina Isabel Lopes[2], Mariana Lopes-Pinto[2], Ana Gomes[2] & Ema Paula Ricca Lacerda Nobre M Caetano[2]

[1]ULS Santa Maria, Endocrinology, Diabetes and Metabolism Department, Lisbon, Portugal; [2]ULS Santa Maria, Rheumatology Department, Lisbon, Portugal

Introduction
Cushing's syndrome (CS) corresponds to a state of glucocorticoid excess. Endogenous CS can be either adrenocorticotropic hormone (ACTH) dependent or independent, with Cushing's Disease (CD) being the most common cause of ACTH dependent CS. Along with increased mortality, cardiovascular, metabolic, and musculoskeletal complications, CS also leads to some degree of immunosuppression, mainly by a decrease in lymphoid tissue and lymphopenia. CS cure, on the other hand, stimulates the immune system and may result in the exacerbation of immune mediated diseases.
Case Report
A 49-year-old woman was sent to the endocrinology clinic for a left adrenal incidentaloma. Personal history was notable for severe osteoporosis (spine T-score -2.5 and femur –2.2) and an episode of panuveitis at the age of 18. Further enquiry revealed recent significant weigh gain, buffalo hump, easy bruising, lower limb oedema and hypertension. Abdominal CT scan and MRI described a 1.1cm adenoma in the left adrenal gland. Laboratorial work-up suggested ACTH-dependent hypercortisolism. Desmopressin stimulation was suggestive of CD and pituitary MRI confirmed a right pituitary adenoma with 8 × 11 × 12mm. Transsphenoidal tumorectomy was performed confirming a corticotroph adenoma. Postsurgical serum cortisol was 0.7 mg/dl, and the patient was discharged with hydrocortisone 20 + 10mg and desmopressin 60mg daily. In the following weeks a cervical/shoulder girdle discomfort appeared with progressive development of arthralgias, persistent coughing and xerostomia. Additional evaluation revealed an erythrocyte sedimentation rate of 120 mm, with a C-reactive protein of 1.84 mg/dl and an angiotensin converting enzyme of 77 IU/L. CT scan confirmed the presence of supraclavicular, mediastinal and hilar lymph nodes, with diffuse areas of consolidation and densification of the pulmonary parenchyma, mainly in the lower lobes. Transbronchial lymph node biopsy was carried out and confirmed the presence of a non-necrotizing granuloma. The bronchoalveolar lavage had lymphocytosis (26%) with a CD4/CD8 ratio of 3. Lung function tests showed a slight decrease in DLCO of 68%. ALL these findings are consistent with sarcoidosis.
Discussion and conclusion
Autoimmune disorders are a possible complication after CS cure. Thyroid disorders and rheumatological diseases are the most common occurrences. Sarcoidosis has been described, usually presenting with skin findings, pulmonary involvement or both. Glucocorticoid-withdrawal syndrome is an important alternative diagnosis with symptoms like myalgia and asthenia being common to CS, adrenal insufficiency and autoimmune disorders. A close follow-up is of utmost importance in the posttreatment period of CS and a high level of suspicion is required when clinical presentation deviates from what is expected.

Multidisciplinary approach in the management of cardiac metastasis from small intestinal neuroendocrine tumour: a case report

Leandro Augusto Silva[1], Catarina Neves[1], Sara Póvoa[1], Andreia Martins Fernandes[1], Ana Rita Elvas[1], Joana Couto[1], Teresa Martins[1], Jacinta Santos[1], Raquel G. Martins[1] & Fernando Rodrigues[1]
[1]Portuguese Institute of Oncology of Coimbra Francisco Gentil, Coimbra, Portugal

Introduction
Neuroendocrine tumours (NETs) are rare and more frequently metastasize to the abdominal lymph nodes or liver. Extra-abdominal metastases are now increasingly detected due to ^{68}Ga-SSA-PET/CT's high sensitivity. Right sided valvular dysfunction is the hallmark of carcinoid heart disease (CHD) caused by high serotonin levels secreted by liver metastasis. Cardiac metastases (CMs) are rare, occurring in about 1-4% of NETs, primarily from small intestine. They can occur in association with typical valvular involvement or may be the only manifestation of CHD. Patients may be asymptomatic or presenting with nonspecific symptoms depending on tumour location and burden.
Case
66-year-old-male, presenting with abdominal distension, diarrhea and weight loss. Underwent right hemicolectomy due to a tumour in the terminal ileum detected on colonoscopy. Histopathology revealed G2 NET (2 mitoses/10 HPF), pT4N0 LVI2 R0. Abdominal-pelvic CT showed no abnormalities; ^{68}Ga-SSA-PET/CT revealed focal uptake in the apical region of the left ventricle, initially not considered significant. 1-year post-surgery, developed diarrhea, flushing and weight loss. Second evaluation with ^{68}Ga-SSA-PET/CT continued to show myocardial uptake and identified mesenteric densification, raising suspicion of lymph node involvement. Cardiac MRI (CMR) revealed an intramural cardiac mass (12x25mm) near the apex without cleavage plans from myocardium, interfering with wall motion and suggestive of a rhabdomyoma or cardiac lymphoma. The patient was referred to our center, with chromogranin A (CgA) 703.9 ng/ml ($\leq$102), on PPI, 5-hydroxyindoleacetic acid (5-HIAA) 5.6 mg/24h ($\leq$15) and normal B-type natriuretic peptide. ECG revealed sinus rhythm and complete left bundle branch block. Transthoracic echocardiogram showed no evidence of CHD but demonstrated increased left ventricular wall thickness (apical septal segment), with localized reduced contractility. Using Sonovue contrast we observed the referred mass. A 24h ECG monitoring didǹt show significant arrhythmias. The patient had no cardiac symptoms. Based on integrated clinical assessment, CMR was revised and the mass reclassified as a CM from the known NET; cardiac biopsy (considered high-risk) was not performed and surgical intervention was not performed due its unresectability. Lanreotide 120 mg was initiated with improvement of abdominal symptoms and CgA. At 12 months, contrast echo and CMR continue to show stable intramyocardial mass.
Conclusions
CMs from NETs are rare and typically found in advanced disease. In this case, the heart was the first site of distant metastasis. Multidisciplinary discussion enabled clinical diagnosis and appropriate therapy. Despite the usual aggressive nature of other CM, NETs often have an indolent course with prolonged survival.

Radiotherapy as first line therapy for pituitary adenomas

Patrick Jarlborg[1], Sebastien Tran[2], Shahan Momjian[3], Kristof Egervari[4], Sophie Leboulleux[1], Pelagia Tsoutsou[2] & Maria Mavromati[1]
[1]Geneva University Hospitals, Service of Endocrinology, Diabetes, Nutrition and Therapeutic Patient Education, Geneva, Switzerland; [2]Geneva University Hospitals, Department of Radiation Oncology, Geneva, Switzerland; [3]Geneva University Hospitals, Division of Neurosurgery, Department of Clinical Neurosciences, Geneva, Switzerland; [4]Geneva University Hospitals, Department of Pathology and Immunology, Geneva, Switzerland

Introduction
Transsphenoidal surgery is the first-line treatment for non-functioning pituitary adenomas (NFPAs) in case of visual impairment or progressive tumor growth, for GH-secreting and ACTH-secreting adenomas, as well as for prolactinomas when medical treatment is not possible. Radiotherapy is generally proposed as second- or third-line treatment and is rarely performed before surgery. The objective of our study was to evaluate the efficacy on tumor volume control of pituitary radiotherapy as first-line treatment for patients with pituitary adenomas.
Methods
We retrospectively reviewed files from 10 patients with pituitary adenoma, who had radiotherapy as first-line treatment in a tertiary center between 2011 and 2019. We documented patient and tumor characteristics, time and reason for radiotherapy, duration of follow-up and calculated tumor volume change after radiotherapy.
Results
A total of 10 patients with pituitary adenomas (60% male) treated with first-line radiotherapy were included. Mean age upon diagnosis was 63.5 years (SD: 20.3). Five patients (50%) had NFPA, 2 had acromegaly and 3 had macroprolatinomas. Seven patients received conventional fractionated radiotherapy (VMAT) with median radiation dose of 54 Gy (Range: 45-54), while 3 patients received stereotaxic radiosurgery with median dose of 18 Gy (R: 18-24). Radiotherapy was performed after a mean follow-up of 70.9 months from diagnosis (SD: 91.6), and median maximal diameter before radiotherapy was 24.8 mm (R: 10-40). Among 5 patients with NFPAs, 3 had visual field defects upon diagnosis, 3 had panhypopituitarism and the choice of radiotherapy as first-line treatment was based on age (median age at diagnosis: 78 years, R: 61-83), in addition to comorbidities or patient preference. Among 5 patients with macroprolactinomas and acromegaly, the choice of radiotherapy was based on resistance to medical treatment and refusal of surgery. During a mean follow-up of 61.8 months after radiotherapy (SD: 46.3), tumor size decreased in 8 patients (80%), and was stable in 1 patient. Only 1 patient with a macroprolactinoma had a 6.5% increase in tumor size, 69 months after radiotherapy. Pituitary function was difficult to evaluate at last follow-up as data were missing, which was related to patients' age. Still, most had hypopituitarism at baseline and no improvement is expected with radiotherapy as with pituitary surgery. No patient had salvage pituitary surgery during follow-up.

Conclusions
Radiotherapy can be performed as first-line treatment in patients with pituitary adenomas when surgery is not an option because of patient preferences or comorbidities and achieves tumor volume stabilization or decrease.

Symptomatic rathke's cleft cyst

Lamys Abbes [1], Imen Halloul[1], Nassim Ben Hadj Slama[1], Ghachem Aycha[1], Ghada Saad[1] & Yosra Hasni[1]
[1]Faculty of Medecine of Sousse, University of Sousse, Sousse, Tunisia

Introduction
Rathke's cleft cysts (RCC) are frequent benign cystic sellar lesions (13 - 22%). Most RCC are small, intrasellar and asymptomatic. Larger cysts may compress adjacent structures and rarely become symptomatic. We report the case of hypopituitarism revealing a RCC.
Observation
A 74-year-old hypertensive menopausal patient, followed for rheumatoid arthritis and treated with corticosteroids, presented at our endocrinology department with recurrent hypoglycaemia, chronic headaches and visual disturbances. On clinical examination, visual field abnormalities are found. Hormonal testing showed basal cortisol level at 17ng/ml confirming corticotropic, thyrotropic, gonadotropic insufficiencies with a normal prolactin level at 17ng/ml. A hypothalamic-pituitary MRI revealed a cystic lesion occupying the sella turcica, measuring 27mm, with a pure liquid signal that was unmodified by gadolinium injection, displacing the optic chiasm and posterior pituitary. Therefore, the diagnosis of RCC complicated with hypopituitarism and visual compression was made and the patient was started on hydrocortisone 15mg/day and levothyroxine 75µg/day, with a follow-up MRI to monitor the cyst's long-term progression.
Conclusions
The vast majority of Rathke's pouch cysts remain small, asymptomatic, and are often discovered incidentally. Only about 1% to 5% of Rathke's pouch cysts become symptomatic, typically when they enlarge and compress nearby structures such as the optic chiasm or pituitary gland. This makes symptomatic Rathke's pouch cysts relatively rare, with their occurrence being significantly lower than that of asymptomatic cases.

Immune checkpoint inhibitor-induced hypophysitis: a case report of panhypopituitarism and acute neurological manifestations

Samraiz Nafees[1], Muhammad Haroon Riasat[1], Khaled Zamari[2], Shahzad Akbar[3], Ali Javeed[1], Sarath Vayolipoyil[1], Khush Bakht[3], Muhammad Adnan Afzal[3], Arshad Jamil[4] & Ali Hassan[5]
[1]York and Scarborough Teaching Hospitals NHS Trust, Scarborough, United Kingdom; [2]Gloucestershire Hospitals NHS Foundation Trust, Gloucester, United Kingdom; [3]Hull University Teaching Hospitals NHS Trust, Hull, United Kingdom; [4]Sandwell and West Birmingham Hospitals NHS Trust, Birmingham, United Kingdom; [5]Manchester University NHS Foundation Trust, Manchester, United Kingdom

Background
Immune checkpoint inhibitors (ICIs) have revolutionized cancer treatment, but they can cause significant endocrine-related adverse events. Hypophysitis, an inflammation of the pituitary gland, occurs in 5-10% of patients receiving combination CTLA-4/PD-1 blockade. However, recent studies suggest that the incidence may be higher, with rates up to 25% reported in patients treated with ipilimumab plus nivolumab for melanoma. This higher incidence may reflect increased awareness and recognition of this immune-related adverse event in real-world clinical practice.
Case Report
A 41-year-old male with stage IV BRAF wild-type melanoma developed severe neurological symptoms during his fourth cycle of ipilimumab/nivolumab therapy. The patient presented with progressive headache, gait ataxia, and generalized tonic-clonic seizures. Initial assessment revealed profound hyponatremia (119 mmol/l)and altered consciousness (GCS E1V1m[3]). Endocrine evaluation demonstrated complete anterior pituitary failure, consistent with panhypopituitarism. Pituitary imaging showed radiological evidence of hypophysitis. The patient's presentation illustrates that rapid-onset panhypopituitarism can manifest without classical visual field defects typically associated with pituitary enlargement. Management included high-dose glucocorticoids (IV methylprednisolone 1mg/kg), hormonal replacement therapy (levothyroxine, hydrocortisone, testosterone), and discontinuation of ICI treatment. This approach aligns with current guidelines for managing ICI-induced hypophysitis.
Conclusion
This case report illuminates several critical insights into ICI-induced hypophysitis. Rapid-onset panhypopituitarism can occur without typical visual field defects, challenging traditional diagnostic expectations. The presentation demonstrated that hyponatremia secondary to adrenal crisis may precede radiographic changes, emphasizing the critical importance of early and comprehensive endocrine evaluation. Moreover, the occurrence of seizure activity represents an uncommon neurological manifestation of acute hypophysitis, highlighting the need for heightened clinical vigilance in patients undergoing immune checkpoint blockade. The case underscores the paramount importance of multidisciplinary collaboration between oncologists and endocrinologists in managing complex immune-related adverse events. Implementing protocolized pituitary axis monitoring for patients receiving dual immune checkpoint blockade is essential. This should include rigorous baseline assessments and frequent follow-up testing to enable early detection and intervention. Ultimately, this case reinforces the critical nature of early recognition and prompt management of ICI-induced hypophysitis. Timely and comprehensive medical intervention can prevent potentially life-threatening complications and ensure optimal patient outcomes in the evolving landscape of immunotherapy.

Unmasking the giant: a pediatric macroprolactinoma mimicking a craniopharyngioma

Sara Ijdda[1], Meryam Alahyane[1], Sana Rafi[1], Ghizlane EL Mghari[1] & Nawal El Ansari[1]
[1]Department of Endocrinology, Diabetology, Metabolic Diseases and Nutrition, Mohammed VI University Hospital, Marrakesh, Morocco

Background
Macroprolactinomas and craniopharyngiomas are two sellar and suprasellar tumors that may share clinical and radiological similarities, often making differential diagnosis challenging.
Case Presentation
An 8-year-old boy presented with progressive frontal headache, visual loss, intermittent vomiting, but no galactorrhea or gynecomastia, without polyuric-polydipsic syndrome. He was not on any medication and had no family history of endocrinopathies. Clinically, with no growth delay, at Tanner stage G1P1. Brain MRI revealed a sellar and suprasellar mass 57 × 55 × 55 mm, with solid-cystic components without calcifications compressing the pituitary gland against the sellar floor, and involving the opto-chiasmatic cisterns, optic nerves, chiasm, with triventricular dilation. Biological tests showed a corticotropic deficiency. Prolactinemia was not initially assessed. The tumor was considered a likely craniopharyngioma. The patient underwent transsphenoidal surgery for tumor resection with hydrocortisone substitution. Immunostaining revealed neoplastic cells positive only for prolactin (100%) with a Ki-67 index of 4%. Three months post-surgery, MRI showed a 70% regression of the cystic component (22 cc vs 70 cc), with persistence of the solid component measuring 40 × 33 × 31 mm. The Prolactin level was 1736 ng/ml. The patient was started on Cabergoline 0.25 mg twice a week, gradually increased to 2 mg/week, Aiming to lower prolactin, shrink the tumor, improve visual function, and reverse corticotropic deficiency. Genetic testing for AIP mutation and Menin could not be performed due to unavailability.
Discussion
Unlike the craniopharyngioma, considered as the most common non-malignant sellar and suprasellar tumors in childhood, Pituitary adenomas are less common. Prolactinomas represent 50% of pediatric pituitary adenomas. Males tend to develop larger tumors with higher prolactin levels. The neuroradiological appearance of a non-homogeneous signal with a cystic component in prolactinomas can be mistaken for a craniopharyngioma. Genetic studies show that 10% of patients under 18 have mutations in AIP and MEN1 genes. The 2024 Consensus Guideline for the Diagnosis and Management of Pituitary Adenomas in Childhood and Adolescence recommends systematic serum prolactin measurement and the use of cabergoline as a first-line dopamine agonist therapy, even in the presence of visual disturbances or pituitary apoplexy. Treatment involves a progressive dose increase up to 1.5–2 mg per week. In cases of intolerance or resistance to high doses, surgery or radiotherapy may be considered as alternative options.

Conclusion
Craniopharyngiomas, though common in children, can mimic macroprolactinomas. Routine prolactin testing is crucial when assessing sellar masses to guide treatment before considering invasive surgery.

A case report of an infant with congenital hypopituitarism presenting with hypoglycemia and low beta-hydroxybutyrate

Yijuan Yvonne Lim[1], Lei Qiu Tay[1] & Anjian Andrew Sng[1]
[1]Khoo Teck Puat-National University Children's Medical Institute, National University Health System, Singapore, Singapore

Introduction
Congenital hypopituitarism is defined as the deficiency of one or more hormones produced by the pituitary gland. Diagnosis in neonates is often challenging as they often present with non-specific symptoms. We describe a case of a 7-week-old baby girl with congenital hypopituitarism presenting with hypoglycemia.
Case
A 7-week-old baby girl presented to the Children's Emergency for jitteriness, increasing lethargy and poor feeding. She was born full term with a birth weight of 3.4kg. Postnatally, she had hypoglycemia and conjugated hyperbilirubinemia diagnosed in another hospital, but was lost to follow-up after discharge. At presentation in the emergency at 7 weeks old, baby was jittery with poor peripheral perfusion. She was dehydrated with depressed fontanelles. Her tone was increased with brisk reflexes. She was not hyperpigmented, not dysmorphic and had normal female genitalia. Blood sugar at presentation was 2.4 mmol/L. At time of hypoglycemia, baby's beta-hydroxybutyrate was low at $<$0.6 mmol/land her urine ketones were trace in the urine dipstick. Insulin production was suppressed at $<$1.6 mU/l(2.6 – 24.9) and C-peptide was low at 25 pmol/l(70-1448). Cortisol was inappropriately low at 116 nmol/l(14-458) and growth hormone level was 1.58mg/l(0.12 – 7.79). Lactate was normal at 1.6 mmol/l(0.5 – 2.2), sodium 141 mmol/l(133-144), potassium 6.1 mmol/l(3.6 – 5.8), chloride 111 mmol/l(97-110), bicarbonate 17 mmol/l(16-29), urea 7.8 mmol/l(1.2-6), creatinine 24 umol/l(11-36), ALT 130 U/l(6-51), AST 232 232 U/l(23-83), total bilirubin 164 umol/l(1-12) and direct bilirubin 130 umol/l($<$5). Her plasma concentrations of several acylcarnitines were elevated. Free carnitine was within normal limits. Her urine organic acid revealed that the excretions of ketone bodies were markedly elevated in the presence of a moderate dicarboxylic aciduria (C6$>$C8$>$Cl0) and slight lactic aciduria. Overall, this profile was not indicative of a specific disorder and is suggestive of severe ketosis. MRI pituitary showed hypoplasia of the pituitary gland. Baby was subsequently started on hydrocortisone, thyroxine and growth hormone replacement, and was discharged well.
Conclusion
Hypoglycemia seen in hypopituitarism is typically ketotic. In this case report, this baby presented with hypoglycemia with low beta-hydroxybutyrate (the predominant ketone body) and urine ketones despite low insulin level and high free fatty acids. The presence of ketones was instead detected in her plasma acylcarnitines profile and urine organic acids, which was consistent with her subsequent diagnosis of central hypocortisolism.

Delayed puberty: the coin other side

Shaymaa Raafat[1,2] & Saber Waheeb[3]
[1]Alexandria University - Faculty of Medicine, Pediatric Endocrinology and Diabetes, Alexandria, Egypt; [2]Alexandria University, Pediatrics, Alexandria, Egypt; [3]Alexandria University - Faculty of Medicine, Pediatric Surgery, Alexandria, Egypt

Background
Delayed puberty in girls is defined as a lack of development of secondary sexual characteristics by the age of 13 years or absence of menarche by the age of 16 years. one of the missed causes of delayed puberty is the condition caused by Mullerian duct anomalies. They are congenital uterine anomalies presented by delayed puberty, infertility, or recurrent miscarriage. Imaging can help to identify patients who can benefit from interventions.
Objectives
This report describes the presentation and hormonal profile of a girl diagnosed with one type of Mullerian duct anomalies. Moreover, it describes the role of MRI pelvis to identify the best intervention for the girl.
Case description
A 16-year-old girl was presented with an attack of acute abdominal pain. There were recurrent cyclic attacks of pelvic pain for a few days which resolved with only analgesics. According to Tanner maturity rating, she has T4 breast development, T4 pubic hair, and T3 axillary hair. Still, she had primary amenorrhea. She had a normal hormonal profile for her age. The conclusive diagnosis was reached by doing MRI pelvis. MRI showed no well-formed uterus, two rudimentary horns with absent cervix and upper vagina.
Conclusions
Mullerian duct anomalies can be a hidden cause of delayed puberty that must be kept in mind when confronting a girl with primary amenorrhea. MRI is the gold standard to diagnose these patients and to put the optimal surgical plans as trials to save fertility.

First report of a case of post-surgical pituitary neuroendocrine tumor residue confined within the pituitary stalk

Hamza Benderradji[1,2], Frederique Defrance[1], Mélodie-Anne Karnoub[3], Claude-Alain Maurage[4], Richard Assaker[3], Marie-Christine Vantyghem[1,5], Mathieu Nobile[6], Gustave Soto Ares[6] & Emilie Merlen[1]
[1]Department of Endocrinology, Diabetology, and Metabolism, Lille University Hospital, Lille, France; [2]University of Lille, CHU-Lille, Inserm U1172, Lille Neuroscience & Cognition, Lille, France; [3]Department of Neurosurgery, Lille University Hospital, Lille, France., Lille, France; [4]Department of Pathology, Lille University Hospital, Lille, France; [5]INSERM U1190 Translational Research in Diabetes, Firendo Rare Diseases Competence Center PRISIS, (Pathologies of insulin Resistance and Insulin Sensitivity), Lille University Hospital, Lille, France; [6]Department of Radiology, Lille University Hospital, Lille, France

Pituitary neuroendocrine tumors (PitNETs) located solely in the pituitary stalk, without affecting the pituitary gland, are exceptionally uncommon. To date, only a limited number of cases has been documented in the literature. Herein, we report a case of a post-surgical PitNET residue confined solely to the pituitary stalk, observed during a morphological follow-up two years after endoscopic transsphenoidal surgery. We describe the case of a 23-year-old woman who initially presented with secondary amenorrhea and galactorrhea, leading to a diagnosis of prolactin-secreting PitNET. Owing to the failure of medical therapy with cabergoline, the patient underwent endoscopic transsphenoidal surgery. Postoperatively, her prolactin levels decreased to 30 ng/ml ($n$$<$26,5), with no evidence of pituitary dysfunction. However, one year after surgery, hyperprolactinemia recurred, accompanied by secondary amenorrhea and galactorrhea, prompting the reinitiation of cabergoline therapy to suppress prolactin secretion. Two years after the surgical intervention, routine morphological surveillance revealed a thickening of the pituitary stalk. Magnetic resonance imaging (MRI) demonstrated a 4-mm thick mass of homogeneous signal intensity on both T1-weighted and T2-weighted imaging, localized within the pituitary stalk. The patient remains free of diabetes insipidus. Comprehensive evaluation excluded alternative etiologies of pituitary stalk thickening, including lymphoma, craniopharyngioma, germ cell tumors, and granular cell tumors. The patient declined endoscopic transsphenoidal biopsy. Consequently, an annual MRI-based follow-up is recommended. During the surveillance period from 2010 to 2024, the pituitary stalk thickening remained stable. Following a multidisciplinary team review including an expert neuroradiologist, a definitive diagnosis of PitNET residue confined within the pituitary stalk was established. The patient's prolactin level remained stable at 60 ng/ml under a weekly dose of 0.75 mg of cabergoline. Although PitNET residues confined to the pituitary stalk are rare, awareness of their existence is essential for accurate postsurgical assessment. Recognizing this condition can guide appropriate management, prevent unnecessary surgical biopsies, and ensure optimal long-term follow-up.

A rare and aggressive form of B-cell lymphoma known as intravascular large B-cell lymphoma (IVLBCL) is characterized by the growth of large cells within the lumen of blood vessels. While previous studies have documented a wide range of symptoms caused by neoplastic cells obstructing small vessels in various organs, there is limited literature on IVLBCL cases with hypothalamic-pituitary functional impairment. Here, we present a rare case of IVLBCL that provoked hypopituitarism. A 58-year-old male patient presented with symptoms that progressively developed over several weeks, including deteriorated general condition, intermittent episodes of confusion, daily high fever, and polyuropolydipsia syndrome (5 liters per day). Laboratory investigations revealed mild hypernatremia (sodium, 149 mEq/l)as well as elevated serum levels of lactate dehydrogenase (LDH; 566 IU/l)and β2 microglobulin 8.31 mg/l(0.8-2.34). Basal hormone analysis demonstrated hypopituitarism. Brain magnetic resonance imaging (MRI), however, showed a lesion infiltrating the floor of the third ventricle (21 × 18 × 15 mm), extending to encompass the entire pituitary stalk. The lesion appeared homogeneous and exhibited strong contrast enhancement after gadolinium administration. ^{18}F-fluorodeoxyglucose (FDG)-positron emission tomography revealed enhanced FDG uptake of the lesion infiltrating the floor of the third ventricle, extending to encompass the entire pituitary stalk. In the biopsy of the clinically unaffected skin, immunohistochemistry revealed the presence of intravascular neoplastic cells positive for B-cell markers CD20, CD5, and MUM1, confirming the diagnosis of intravascular large B-cell lymphoma. Corticotropic and thyrotropic deficiencies were supplemented, and diabetes insipidus was treated with desmopressin. Additionally, the patient underwent R-CHOP chemotherapy, which resulted in a complete response. The patient remained in remission for six months following the cessation of chemotherapy. Hypopituitarism associated with IVLBCL was first described in 1986. A limited number of cases of IVLBCL involving functional abnormalities of the hypothalamic-pituitary axis have been reported. IVLBCL with hypothalamic or pituitary involvement can be effectively managed with hormone replacement therapy followed by chemotherapy. Consequently, timely identification of clinicopathological features is crucial for reducing mortality rates.

The First genetically confirmed case of wolfram syndrome in the philippines - a case report

Arline Sicat[1] & Gherald Bermudez[1]

[1]Far Eastern University - Dr. Nicanor Reyes Medical Foundation, Internal Medicine, Quezon City, Philippines

Wolfram syndrome is a rare disease characterized by constellation symptoms progressing from childhood to adulthood. These symptoms brought forth its other name DIDMOAD which comprises Diabetes insipidus, Diabetes mellitus, Optic atrophy, and deafness. It is a rare form of monogenic diabetes with an estimated prevalence of 1 in 770,000 in the United Kingdom, 1 in 100,000 in North America and 1 in 710,000 in the Japanese population. In this report, we describe a 26-year-old Filipina woman diagnosed with Type 1 diabetes and optic atrophy who consulted due to severe headache, fever, urinary frequency, and urgency. During her admission, she had symptoms of persistent thirst, polyuria, and nocturia. Further workup confirmed that she had urological abnormalities and Diabetes insipidus leading to the clinical diagnosis of Wolfram Syndrome. Genetic testing was then performed which showed that she had two pathogenic or disease-causing variants identified in the WFS1 gene. As healthcare providers, a high suspicion for Wolfram Syndrome should be a standard in patients who present with juvenile-onset diabetes mellitus and optic atrophy which are the primary symptoms of Wolfram Syndrome. Early recognition and diagnosis will guide us to the proper management and help improve the patient and their family's quality of life. Although there is no known cure yet for Wolfram Syndrome, treatment of manifestations includes supportive care which is often provided by multi-disciplinary specialists. The surveillance involves regular monitoring of existing manifestations, the response of an individual to supportive care, and the emergence of new manifestations.

Hormonally inactive pituitary adenomas: clinical and laboratory features and predictors of surgical treatment effectiveness

Ekaterina Filkina[1], Natalia Khutsishvili[1], Svetlana Vorotnikova[1], Ekaterina Pigarova[1], Larisa Dzeranova[1], Andrey Grigoriev[1] & Tatyana Sergeevna Kokorina[1]

[1]Endocrinology Research Centre, Moscow, Russian Federation

Introduction

The proportion of hormonally inactive pituitary adenomas (IPA) is about 10-20% of all cases of central nervous system tumors. Transsphenoidal adenomectomy is the primary treatment; however, complete tumor resection is not always achievable. The purpose of the study. To analyze the clinical, laboratory, and morphological characteristics of IPA patients and identify prognostic factors for surgical treatment outcomes.

Materials and methods

This retrospective dynamic study included 75 patients with IPA treated between 2016 and 2020. We analyzed medical history, hormonal profiles (cortisol, ACTH, TSH, free T4, LH, FSH, prolactin), imaging results (MRI), and histopathological and immunohistochemical findings. All patients underwent transsphenoidal adenomectomy as their primary treatment.

Results

Among the examined group of patients, the most common preoperative symptoms were headache (75.7%) and visual impairment (71.6%). Hypopituitarism of varying severity was diagnosed in 44% of cases, with the most frequent combination being secondary hypocortisolism, hypothyroidism, and hypogonadism. Secondary hyperprolactinemia was observed in 62.8% (49 patients). All tumors were macroadenomas, with a median volume of 7612.5 mm^3 [4180.0; 15015.0]. Giant adenomas were found in 13 patients. Histological examination confirmed the diagnosis of pituitary adenoma in 68 out of 70 cases. The predominant histological subtypes were chromophobic (38.2%) and basophilic adenomas (35.3%). Immunohistochemical analysis (performed in 27 patients) revealed staining for one or more pituitary tropic hormones in 92% of cases, indicating secretory potential. The most common morphological subtype was "silent" gonadotropinomas (56%). Ki-67 immunoexpression was analyzed in 33 patients, with a median level of 4.4% [2%; 7%]. A Ki-67 index $<3\%$ was found in 33.3% of patients, while 66.7% had values $>3\%$. Among 36 evaluated patients, non-radical tumor resection was observed in 18 (50%). Patients with no residual tumor had significantly higher Ki-67 levels (median: 6.3%) compared to those with residual tissue (median: 2.0%) ($P = 0.038$). Recurrence occurred in 8 patients with residual tumor, with a median time to recurrence of 14.5 months. Larger tumor volume before surgery was associated with a higher recurrence rate ($P = 0.017$, Mann-Whitney U-test).

Conclusions

Currently, no reliable markers predict IPA recurrence postoperatively. The presence of residual tumor tissue is a negative prognostic factor. We found no significant correlation between Ki-67 levels and recurrence; paradoxically, patients with residual tumor tissue had lower Ki-67 values. The role of Ki-67 in predicting IPA recurrence remains controversial and warrants further investigation.

The overlooked iceberg in hyponatremia in the elderly: the pituitary gland The overlooked iceberg in hyponatremia in the elderly: the pituitary gland

Mohammad Aziz Abed Miakhail[1], Özge Baş Aksu[1] & Asena Gökçay Canpolat[1]
[1]Ankara University School of Medicine, Ankara, Türkiye

Hyponatremia, characterized by low serum sodium levels, is a frequent electrolyte abnormality encountered in clinical settings. In this report, we elucidate the case of a 91-year-old patient presenting with hyponatremia. The patient has been experiencing postprandial fatigue and weakness for the past 3-4 years, with symptoms worsening after meals. The patient has been managing hyponatremia for about 6 years with dietary treatment and fluid restriction, despite a regular appetite and normal food intake. 1.5 years ago, and the patient experienced complete vision loss in the left eye in 2021 due to macular degeneration. Recent hospital admission revealed a sodium level of 125, indicating hyponatremia, along with postprandial hypoglycemia. The patient was diagnosed with SIADH and was placed on a fluid restriction and given dietary salt supplementation. Blood sugar monitoring was initiated due to concerns about early-onset diabetes. After a Holter monitor study, the patient's fatigue worsened, and blood pressure dropped to 68/48 mmHg with a heart rate of 112 bpm. IV saline improved their blood pressure, and investigations pointed toward adrenal insufficiency and hypothyroidism. Diagnosis was confirmed as secondary adrenal insufficiency and central hypothyroidism, and treatment with prednisolone and thyroid hormone replacement was started. A pituitary MRI showed a possible macroadenoma with a cystic lesion extending into the cavernous sinus and impacting the optic chiasm. The patient's sodium levels and clinical condition, including hypotension and hypoglycemia, improved with treatment.

An unsual case of hypopituitarism coincidental with rasmussen's encephalitis and rathke's cleft cyst

Genevieve Tellier[1], Rhiannon Berkeley[1], Ghislaine Sayer[2] & Anthony Wilton[1]
[1]Betsi Cadwaladr University Health Board, Ysbyty Gwynedd, Endocrinology, Bangor, United Kingdom; [2]Betsi Cadwladr University Health Board, Ysbyty Gwynedd, Radiology, Bangor, United Kingdom

Rasmussen's encephalitis is ultra-rare with precocious puberty reported in approximately 20% of cases but not endocrinopathy. Sodium valproate has been reported as causing impaired gonad, thyroid and adrenal axes function. Rathke's cleft cysts affect pituitary function to varying degrees. We report a case of a patient with Rasmussen's encephalitis, long-term valproate treatment and a Rathke's cleft cyst. A 41 year old female presented with a 1 year history of secondary amenorrhea, scalp hair loss and leg oedema. Menarche occurred at 12 years of age with subsequent regular menses. At 8 months of age she developed a right hemiparesis and epilepsy but no appertaining records were available. She had received treatment with valproate for 27 years. Examination: weight 57.6 kg, mild right hemiparesis, scalp alopecia and moderate leg oedema. Investigations at 09:00h: cortisol 202 nmol/l,ACTH 48.8 ng/l(arose at 07:00h), fT4 10.3 pmol/l,fT3 5.3 pmol/l,TSH 2.02 mmol/l,FSH 3.0 IU/l,LH 1.0 IU/l,oestradiol <100 pmol/l,prolactin 394 mU/land IGF-1 6.3 nmol/L. Renal function, liver function, bone profile and full blood count were normal. Her symptoms, signs and hypogonadotropic hypogonadism were attributed to valproate side-effects. Anticonvulsant change was declined as she had been seizure-free for 23 years, as was HRT. No clinical or endocrine changes were recorded at 1 year. She subsequently presented with general deterioration, anorexia, weight loss (weight 52.6 kg), decreased mobility, worsening leg oedema and hypotension. Investigations at 09:00h: cortisol 93 nmol/l,ACTH 10.6 ng/l,fT4 6.7 pmol/l,TSH 2.98 mU/l,FSH 1.8 IU/l,LH 0.6 IU/l,oestradiol <100 pmol/l,valproate 201 mg/land pancytopenia. MRI was declined. Treatment with hydrocortisone and change in anticonvulsant to lamotrigine resulted in improved clinical status. HRT was declined. At follow up thyroid function and IGF-1 returned to normal but ACTH, cortisol, and gonadotrophins remained low. MRI was accepted and demonstrated the presence of an intrasellar Rathke's cleft cyst.

Discussion

1. This patient's varying endocrine dysfunction is difficult to explain. Valproate could explain the original endocrine abnormalities but not those that have persisted.
2. The Rathke's cleft cyst could be responsible if it had changed in size on stopping valproate.
3. An episode of hypophysitis would be an alternative explanation.

AVP deficiency secondary to herbal remedies

Furhana Hussein[1], Ahmad Alnashrati[1], Lina Eltayieb[1], Ehsan Shakoor[1], Farhan Asghar[1], Dalya Sadulah[1], Ahmed Al-ghrairi[1] & Gideon Mlawa[1]
[1]Barking, Havering, and Redbridge University Hospitals NHS Trust, Romford, United Kingdom, London, United Kingdom

Introduction

Arginine vasopressin (AVP) deficiency involves decreased release of arginine vasopressin (AVP) which could lead to polyuria. Hence, patients usually present with polyuria and polydipsia. Lack of AVP can be resulted from disorders that act at one or more of the sites involved in AVP synthesis and secretion. AVP deficiency is a rare disorder with prevalence of 1 in 25,000 individuals and most cases are acquired. The most common acquired causes include autoimmune neurohypophysitis, primary or secondary tumours, infiltrative diseases (such as Langerhans cell histiocytosis and sarcoidosis), neurosurgery and head trauma Here we discuss a case in which AVP deficiency possibly secondary to herbal remedies.

Case Presentation

A 53-year-old male was admitted with polyuria and polydipsia. Passing around 7Litres of urine daily which was disturbing his sleep. He had no significant past medical history. He was taking herbal remedies which including Rhodiola rosea root extract, cranberry extract, royal jelly extract and resveratrol 1.5months earlier he also completed 14 days of ciprofloxacin antibiotics for prostatitis. CT head showed no acute pathology. MRI pituitary showed no acute lesions or pathology. Bloods showed hypernatraemia 147 mmol/L. Urine osmolality of 162 and serum osmolality of 304, urinary sodium was <20. He was given a trial of oral desmopressin which did not help, however when changed to intravenous desmopressin 1 microgram the patients symptoms significantly improved and was able to concentrate the urine. Discharged with nasal spray desmopressin 10micrograms twice daily and his symptoms continued to improve. Discussed in Neuro-pituitary MDT.

Conclusion

AVP deficiency is one of the main entities of the polyuria-polydipsia syndrome. Most cases are acquired and commonly include head injury, neurosurgery, cranial tumours and neurohypophysitis. There have been very limited case reports on herbal remedies causing AVP deficiency such as olive extract. There are also few cases reporting on transient diabetes insipidus in patients using quinolone antibiotics. It is important especially in these rare cases to use an MDT approach to help manage patient's symptoms.

Questions for discussion

Have you come across herbal remedies induced AVP deficiency?
Could quinolones contribute to AVP deficiency?

Input/output chart.

	Input volume (Litres)	Output volume (Litres)

Secondary corticotropic insufficiency due to arachnoid cyst: a reversibility to explore"

Karimi Meryem[1], Hajar Azagouagh[1], Amal Riad[1], Fatima Toulali[1], Kawtar Rifai[1], Hinde Iraqi[1] & Mohamed El Hassan Gharbi[1]
[1]CHU Ibn Sina, Rabat, Morocco

Introduction
Arachnoid cyst is a rare condition characterized by the accumulation of fluid in the subarachnoid space, located between the membranes surrounding the brain and spinal cord. This condition can lead to compression of brain structures and disrupt the functioning of the pituitary gland, resulting in hormonal production abnormalities. In some cases, hormonal disorders, such as corticotropic insufficiency, can be the first clinical sign revealing an arachnoid cyst.
Observation
We report the case of a 56-year-old woman with no notable medical history, who consulted for intense asthenia, headaches, and slight weight gain. Biological tests revealed low TSH, low FT4 and FT3 levels, and a decreased 8 a.m. cortisol, suggesting corticotropic insufficiency. Pituitary MRI showed an arachnoid cyst associated with atrophy of the anterior pituitary, confirming hypothalamo-pituitary dysfunction. Substitution treatment with hydrocortisone and Levothyrox was initiated, with gradual dose increases. This treatment led to regression of symptoms and a significant improvement in the patient's quality of life.
Discussion
Arachnoid cyst is a rare and often underdiagnosed condition, characterized by abnormal accumulation of fluid in the subarachnoid space. This accumulation can exert pressure on brain structures, particularly the pituitary gland, leading to hypothalamo-pituitary dysfunction. Clinical manifestations can vary, with corticotropic insufficiency being a significant feature. The uniqueness of this case lies in the reversibility of corticotropic insufficiency after substitution therapy. This reversibility, though rare, suggests that mechanical compression of the pituitary gland does not necessarily lead to irreversible damage. It opens up interesting perspectives on the underlying pathophysiological mechanisms, such as transient hypoxia, disruption of neuroendocrine signaling, or the plasticity of pituitary cells.
Conclusion
Arachnoid cyst, although rare, can lead to severe hormonal disorders, which may sometimes be reversible. Early diagnosis, along with appropriate management and careful follow-up, is essential to optimize clinical outcomes and improve patients' quality of life.

JOINT3486
Misdiagnosis: a case of craniopharyngioma revealed by diabetes insipidus
Nayla Hanane Essaidi[1], Sana Rafi[1], Sara Ijdda[1], Ghizlane El Mgahri[1] & Nawal El Ansari[1]
[1]Mohammed VI University Hospital of Marrakech, Marrakech, Morocco

Introduction
Craniopharyngioma is a rare benign epithelial tumor in children, typically located near the pituitary stalk. Although benign and extracerebral, this tumor remains serious due to frequent visual, neuro-intellectual, and endocrine sequelae, including pituitary insufficiency, growth retardation, pubertal delay, and diabetes insipidus. However, significant progress in surgery, radiotherapy, and medical management has markedly improved the prognosis of this disease.
Case report
This is a 14-year-old patient who, in 2019, developed a polyuric-polydipsic syndrome (PUPD) that significantly impaired his daily life. This led his family to consult a pediatrician, where a screening assessment for diabetes was conducted, which returned normal results, leading to a diagnosis of psychogenic PUPD. Three years later, the condition worsened, with the onset of a visual disturbance (bilateral diplopia), prompting an ophthalmologic examination followed by a brain CT scan, which suggested the presence of a craniopharyngioma, leading to his transfer to our facility for specialized care.
Discussion
Diabetes insipidus (DI) is a polyuric-polydipsic syndrome (PUPD) characterized by the excretion of large volumes of diluted, hypotonic urine due to a deficiency of antidiuretic hormone (ADH), leading to thirst and polydipsia. This condition is caused by damage to the posterior pituitary gland, often due to tumors such as craniopharyngiomas, infiltrative, traumatic, or vascular lesions, resulting in a deficiency in the production of antidiuretic hormone (arginine vasopressin). DI has been shown to occur in 46.8% of pediatric craniopharyngiomas. This central form of diabetes insipidus must be distinguished from other causes of polyuria and polydipsia, particularly psychogenic and nephrogenic causes, which are more common Treatment is primarily based on hormonal replacement, with desmopressin (Minirin) being the preferred synthetic analogue of ADH, offering a potent antidiuretic effect. In addition, proper hydration and treatment of the underlying etiology must be ensured, along with regular clinical monitoring. Nowadays, optimal management of cranopharungioma is based on a multimodal strategy involving a combination of surgery and, in some cases, radiotherapy, with the aim of controlling the disease and limiting morbidity.
Conclusion
DI is a rare condition that requires a thorough etiological investigation, with MRI playing a crucial role in diagnosis From our observation, we note that diabetes insipidus can be the first clinical sign of a craniopharyngioma, which must be differentiated from psychogenic causes. Early recognition is essential for effective treatment. Recognizing this association is crucial for early diagnosis and effective treatment, which can lead to improved long-term outcomes.

JOINT3371
A case of metastatic PITNET. diagnosis, treatment and outcomes
Agata Rzepecka[1], Sonia Kaniuka-Jakubowska[2], Anna Lewczuk[3,4] & Renata Świątkowska-Stodulska[3,5]
[1]University Clinical Center (UCK), The Medical University of Gdańsk, The Clinic of Endocrinology and Internal Diseases, Gdańsk, Poland; [2]University Clinical Center (UCK) Gdańsk, Poland, Medical University of Gdansk, Gdansk, Poland; [3]University Clinical Center (UCK), Gdansk, Poland; [4]The Medical University of Gdańsk, Gdańsk, Poland; [5]The Medical University of Gdańsk, Gdansk, Poland

Introduction
Metastatic PitNET (mPitNET) is extremely rare endocrine neoplasm, defined by the presence of craniospinal and/or systemic metastases, accounting for less than 0.2% of all pituitary tumors. Its low incidence makes both diagnosis and treatment challenging. The prognosis is generally poor, with an estimated 5-year survival rate as low as 35%. Symptoms of mPitNET are often a mixture of effects of hormonal activity, local invasiveness and distant metastasis. Surgery remains the first-line treatment - more than 80% of mPitNET cases require at least two surgeries, while more than 25% require at least four. However, depending on the individual case, additional therapeutic options may include radiotherapy, somatostatin analogs, dopamine agonists, and temozolomide (TMZ). It has been observed that patients receiving TMZ are more likely to achieve 5-year survival compared to those on alternative treatment regimens that do not include TMZ. However, since mPitNET remains a clinical challenge and frequently do not respond to first-line treatment, other therapeutic options, such as peptide receptor radionuclide therapy, immune checkpoint inhibitors, and tyrosine kinase inhibitors, have been tried.
Case Presentation
A 15-year-old, Caucasian male patient, was referred to endocrinology department due to gynecomastia, recurrent headaches, and visual disturbances. Laboratory tests did not reveal any abnormalities, while MRI revealed a large sellar mass suggestive of craniopharyngioma. The lesion was surgically removed, and histopathological examination identified a chromophobe pituitary adenoma with low ACTH expression (5% of cells). The clinical course of disease was aggressive, with numerous recurrences and mass effect. The patient had a total of seven debulking surgeries, complicated by infections (Acinetobacter baumannii) and acute hydrocephalus. Adjuvant stereotactic radiotherapy was delivered. Seven years after diagnosis, metastases were detected in the cerebellopontine angle, frontal lobe, and anterior vagal trunk. Scintigraphy showed expression of somatostatin receptors and lanreotide therapy was introduced for treatment. The patient subsequently received TMZ resulting in partial tumor regression and disease stabilization, however, severe side effects (myelosuppression, gastrointestinal symptoms) were observed. After twenty years of treatment, the patient remains clinically stable but struggles with visual impairment, epilepsy, and hypopituitarism. Current treatment includes lanreotide, antiepileptic drugs and thyroxine and hydrocortisone replacement.
Conclusion
By presenting this case, we wish to emphasize how advancements in diagnostic and therapeutic techniques, we can prolong patient's life - even in the disease with such a poor prognosis.

Combining hormone replacement therapy and adjuvant treatment for a patient with resistant prolactinoma: a new clinical strategy
Ekaterina Pigarova[1], Aurika Asanova[1], Alexandra Shutova[1] & Larisa Dzeranova[1]
[1]Endocrinology Research Centre, Moscow, Russian Federation

Introduction
Prolactinomas make up nearly 50% of all pituitary tumors, with up to 20% of cases showing resistance to traditional therapy. Hormone replacement therapy (HRT) poses unique challenges in female patients with prolactinomas, as hormonal fluctuations can impact tumor behavior and treatment effectiveness. This case highlights a potential therapeutic approach for this clinical scenario.
Material and Methods
A 39-year-old female presented with complaints of pronounced fatigue, decreased libido, persistent pain in the breasts, and a weight gain of 6 kg over the past six months. The menstrual cycle was absent due to a previous hysterectomy with left ovary resection. In 2019, the prolactin (PRL) level was 50.5 ng/ml (<26.7 ng/ml). We administered cabergoline starting at 0.5 mg per week. In 2020, pituitary MRI revealed microadenoma 2.5 × 2.5 mm. Cabergoline was increased to 4.5 mg weekly, but no significant improvement was seen. In 2021, the PRL level was 1900 mU/l,also bilateral galactorrhea of Grade 2 was noted, along with pronounced breast pain and excess body weight. An MRI scan revealed an increase in pituitary adenoma size up to 3.5 mm. Bromocriptine was added, starting at 1.25 mg twice daily and increased to 2.5 mg twice daily. After a year of combined therapy, PRL decreased to 740 mIU/l,though it didn't reach the reference range, but the patient experienced relief from breast pain. Considering the previous hysterectomy and ongoing complaints of discomfort in the breast area, tamoxifen was added to the combination therapy. In the following months, due to improved PRL levels, the cabergoline dosage was discontinued by 2022. In 2023–2024, with bromocriptine (5 mg/day) and tamoxifen (20 mg/day), PRL remained within the normal range. There were no signs of galactorrhea or breast pain, and a 10 kg weight loss was noted. Due to complaints of low mood and menopausal hot flashes, the patient was offered HRT with tibolone 2.5 mg daily with discontinuation of tamoxifen. After one month, she reported improved mood, sleep, and relief from symptoms that had troubled her for 5 years, with the PRL level also within the reference range.
Results
Tibolone, unlike traditional HRT, selectively activates estrogen receptors, minimizing prolactin secretion and tumor risk. This makes it a safer option for menopausal women with well-controlled prolactinomas.
Conclusions
HRT helps manage vasomotor symptoms and prevent osteoporosis, but estrogen can stimulate tumor growth. Tibolone's dual action—antiestrogenic on breasts, estrogenic on the hypothalamus—suggests its potential use in menopausal prolactinoma patients.

A case of arginine vasopressin deficiency following immunization with mrna-covid-19 vaccination

Eleni Korakianiti [1], Foteini Thanasoula[1], Fotini Kanouta[1], Marina Mitropoulou[1], Evangelia-Ntaniella Dimopoulou[1], Alexandra Giannou[1], Georgia N. Kassi[1] & Vasiliki Vasileiou[1]
[1]Alexandra General Hospital, Endocrinology Department and Diabetological Centre, Athens, Greece

Introduction
Vaccines against severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2), have been rapidly developed with several novel and conventional technologies. The full profile of adverse effects is yet to be elucidated. Recently, there are sporadic but increasing reports of endocrinopathy in relation to SARS-CoV-2 vaccination, including a few cases of pituitary abnormalities such as hypophysitis. Hypophysitis following SARS-CoV-2 vaccination is exceptionally rare with less than ten cases being reported in the literature and typically presents as arginine vasopressin (AVP) deficiency emerging shortly after vaccine administration.
Aim
We present a novel rare case of infundilo-neurohypophysitis related to SARS-COV-2 vaccination which led to permanent isolated AVP deficiency.
Case Presentation
A 31-year-old previously healthy man presented with polyuria and polydipsia twenty days after his third dose of SARS-COV-2 vaccine with mRNA type (Moderna). He reported increased urine output and liquid intake, almost 7 liters per day. The previous two doses of SARS-COV-2 vaccine administrated to the patient, nine and seven months before, were viral rector type (AstraZeneca). On admission physical examination was normal. Biochemical tests and endocrine work up revealed no other abnormalities except for low urine osmolarity. Sella region magnetic resonance imaging (MRI) revealed diffusely enlarged pituitary gland and thickening of the pituitary stalk. Additionally, the bright spot of the neurohypophysis was not visible. After exclusion of the majority of causes of hypophysitis and taking in consideration the time-related symptoms in the absence of other symptoms, AVP deficiency was suspected in the context of SARS CoV-2 vaccine induced hypophysitis. Thus, treatment with oral desmopressin (DDAVP) was commenced, leading to rapid resolution of symptoms and also confirming our provisional diagnosis of AVP deficiency. Currently, at 3-year-follow-up there is persistence of pituitary stalk thickening on MRI with no other abnormalities. and the patient necessitates treatment with DDAVP 60 mg twice daily in order to remain asymptomatic.
Conclusion
Although rare, there are limited data suggesting a possible association between SARS CoV-2 vaccination and the development of AVP deficiency. Increased vigilance among clinicians is crucial for early recognition and intervention. To date, AVP deficiency following the SARS CoV-2 vaccine is a rare, temporally linked event with its pathophysiology still hypothetical. Further studies are needed to explore a potential causal relationship.

Unusual endocrine trio: a case report of down syndrome with autoimmune hypothyroidism and prolactinoma

Kamar Ezzamene Mahmoud[1], Ines Bayar[1], Bilel Ben Amor[1], Sana Abid[1], Rihab Khochtali[1], Chanez Kalboussi[1], Héla Marmouch[1], Hanene Sayadi[1] & Inès Khochteli[1]
[1]Fatouma Bourguiba University Hospital Monastir, Department of Endocrinology and Internal Medecine, Monastir, Tunisia

Introduction
Down syndrome (DS) is a genetic disorder leading to a range of physical and cognitive impairments. Endocrine abnormalities such as thyroid disorders are prevalent among patients with DS. (1).
Case presentation
We report the case of a 26-year-old female patient, previously followed for DS since childhood, referred to the endocrinology department at the age of 19 after developing clinical symptoms suggestive of hypothyroidism. Laboratory tests revealed a TSH level of 11 µU/ml, FT4 of 15 pmol/l,and positive anti-TPO antibodies. A cervical ultrasound showed a heterogeneous, hypoechoic, pseudonodular thyroid gland of normal size, with decreased vascularity on color Doppler. The patient was started on Levothyroxine. At the age of 26, the patient presented with menstrual irregularities. Laboratory tests showed a TSH level of 2.02 µU/ml and hyperprolactinemia with a prolactin level of 977 mUI/ml. A pituitary MRI revealed a 5 mm anterior pituitary microadenoma. The patient was started on Cabergoline.
Discussion and Conclusion
This case highlights the complex interplay between Down syndrome and endocrine disorders, particularly hypothyroidism and hyperprolactinemia. Individuals with Down syndrome are at increased risk for thyroid dysfunction, with autoimmune hypothyroidism being one of the most common endocrinopathies observed in this population. Additionally, the development of hyperprolactinemia in this patient is of particular interest. Hyperprolactinemia is often secondary to thyroid dysfunction, especially in cases of untreated or poorly managed hypothyroidism. Prolactinomas are observed more frequently in DS compared to general population according to some observational studies (1). The patient's prolactin level of 977 mUI/ml and the MRI findings of a pituitary microadenoma led to the diagnosis of a prolactin-secreting adenoma. Treatment with Cabergoline resulted in both clinical and biochemical improvement of hyperprolactinemia. This case also underscores the importance of regular endocrine monitoring in individuals with Down syndrome, as they are susceptible to multiple endocrine abnormalities. Early diagnosis and treatment of these conditions can significantly improve the patient's quality of life and prevent long-term complications, especially in the presence of premature mortality in these patients (1).

Contribution of MRI in the diagnosis of puitary stalk interruption syndrome

Wided Debbabi[1], Mouna Elfarouki[1], Samah Allous[1], Hajer Marzouk[1] & Issam Kharrat[1]

[1]Ibn Aljazzar University Hospital, Faculté de Médecine de Sousse, Endocrinology Departement, Kairouan, Tunisia

Introduction

Pituitary stalk interruption syndrome is a rare etiology of antero-pituitary insufficiency. Somatotropic insufficiency may be isolated or immediately combined with wide clinical heterogeneity. The aim of this study is to determine the importance of hypothalamo-hypophyseal MRI in the positive diagnosis of SITP.

Materials and methods

Retrospective analysis of 7 observations (4 males and 3 FEMALES) ranging in age from 6 to 26 years Investigated by pituitary MRI for Antero pituitary insufficiency.

Results

Pituitary MRI revealed no visualization of the pituitary stalk in 5 patients, and a very thin stalk in tow. An ectopic hypothalamic post-hypophysis was found in 5 patients. Post-hypophyseal extinction was noted in two patients. Hypoplasia of the anterior pituitary glandular parenchyma with a small sella was noted in 4 patients. Isolated growth hormone (GH) deficiency was noted one patient with thin stalk, whereas the absence of a pituitary stalk was associated with combined hormone deficiency (panhypopituitarism was noted in tow patients).

Discussion

SITP is a rare congenital malformation which is characterized by antero-pituitary deficiencies. Etiologic diagnosis is performed radiologically by an MRI showing the association of a thin or absent pituitary stalk, an ectopic post-hypophysis and/or a hypoplastic or absent anterior pituitary. It provides a morphological study of the hypothalamo-hypophyseal axis and helps to establish clinic-radiological correlations.

A clinical case: chromosomal abnormalities and hypogonadism

Sanobar Samijonova[1]

[1]Tashkent pediatric medical institute, Department of endocrinology, Tashkent, Uzbekistan

Introduction

An inversion of chromosome 9 is a change in the structure of a chromosome caused by a 180° rotation of one of its internal sections. It is the result of two simultaneous breaks in a given chromosome. It is not known where the break occurs, and which nucleotide sequences change during this process. The prevalence of this karyotype feature is 1-3% of the total population. A clinical case. The patient went to the doctor in November 2024 at the medical center of Endocrinology of in Tashkent, Uzbekistan, complaining of an absence of menstruation. From the medical history: the patient was born in 2010 with a weight of 3100 grams with a normal pregnancy. Since birth, she has been under the supervision of an orthopedist with a diagnosis of congenital dislocation of the hip joint. In September 2024, uterine hypoplasia was detected at a medical examination at the school and was sent for further follow-up to the endocrinology center. An objective examination by a gynecologist-endocrinologist revealed that the external genitalia corresponded to the female sex. Mammary glands and secondary hair were poorly developed. Sexual development according to Tanner: Ax-1, Pb-2, Ma-2, Me-0. Her body type was normosthenic, with a shortened torso and a massive lower jaw. Laboratory data showed a significant decrease in hormone levels: Androstenedione 0.39 ng/ml, Sex hormone binding Globulin 108 nmol/l,LH 0.03 mIu/ml, Progesterone 0.46 ng/ml, Prolactin 2.71 ng/ml, Testosterone 0.13 nmol/l,Estradiol 12.9 pmol/l,Free Androgen index 0.12 %. The level of FSH was within the normal range - 4.88 mIu/ml. Instrumental studies have shown on ultrasound of the uterus and appendages a decrease in the volume of the uterus (infantile uterus 3-4 grade) and on MRI of the pelvic organs - MRI-signs of hypoplasia of the uterus. Based on the results of the geneticist's observation, karyotyping was performed, where cytogenetic examination data showed Karyotype XX, inv 9 (p12;q13) and based on the results of all laboratory and instrumental studies and the geneticist's conclusion, the final diagnosis was made: Hypogonadotropic hypogonadism (chromosomal aberration, inversion of chromosome 9 p12;q13). Complication: Primary amenorrhea. Delayed sexual development.

Conclusions

The patient is currently receiving hormone replacement therapy, vitamin therapy, and she is under the supervision of an endocrinologist and gynecologist. It is recommended to follow up again after 3 months, follow a healthy lifestyle, regular physical activity, and a balanced diet.

JOINT2246

Psychosis as a rare clinical presentation of sheehan syndrome: case report and review of the literature

Eléazar Niyogushima[1], Sara Ijdda[1], Sana Rafi[1], Ghizlane El Mghari[1] & Nawal El Ansari[1]

[1]CHU Mohamed VI, Endocrinology, Marrakech, Morocco

Introduction

Sheehan syndrome is hypopituitarism due to pituitary necrosis resulting from hemorrhagic choc during pregnancy. The clinical picture is characterized by post-partum amenorrhea and absence of lactation. Psychotic presentations are rare. This article reports an exceptional case of sheehan's syndrome with a psychiatric presentation.

Case report

The patient was 65 years old, not known to have an endocrinopathy. She had been known to be diabetic for 24 years and was being followed for heart disease. She had been menopausal for 25 years following her last delivery, which was complicated by post-partum haemorrhage, absence of milk production and return from childbirth. Admitted to the emergency department, she presented with psychomotor agitation consisting of delusions of persecution and bizarre delusions, auditory and visual hallucinations, repetitive gestures and aggressive behaviour. This picture was preceded by asthenia and a digestive picture of abdominal pain, vomiting and diarrhea. Clinical examination revealed a disoriented patient, pale skin and mucous membranes, hypotension, depigmentation of the nipples, axillary and pubic depilation, and edema of the lower limbs. Biological tests revealed normocytic normochromic anemia with hemoglobin at 8g/dl, hyponatremia at 117mmol/l,8 hour cortisol level at 2.9µg/dl, ultrasensitive thyroid stimulating hormone at 0.55mUI/l,T4L less than 5.15pmol/land T3 less than 1.64 pmol/l. Magnetic resonance imaging revealed an empty sella turcica. The patient underwent hormone replacement with glucocorticoids and thyroxine, with a spectacular evolution.

Discussion

The pathophysiology of the psychiatric manifestations of Sheehan syndrome is unclear. It seems to result from a complex interaction between hormonal deficiencies and metabolic and electrolyte changes in the central nervous system, such as hyponatremia. The latter is known to cause cognitive deficits and is not usually associated with psychotic symptoms in the absence of disturbances of consciousness and neurological signs. Hypothyroidism may play a more important role in pathogenesis, as it is systematically associated with neuropsychiatric manifestations. It is associated with mood symptoms rather than psychosis, although psychotic presentations without mood disorders have been reported. Dramatic improvement with glucocorticoids and thyroxine suggests a possible link with these hormonal deficiencies.

Conclusion

Psychosis in patients with Sheehan's syndrome is uncommon. This rare presentation of Sheehan syndrome with psychosis not only represents the close association of organic pathology to psychiatric manifestations but also illustrates the possible psychiatric adverse effects of panhypopituitarism and its metabolic consequences. Clinicians should have a high index of suspicion in case of postpartum- psychosis presenting with significant obstetric history.

Cushing's disease due to invasive macroadeoma with crooke cellular transformation and mgmt methylation

Clara Rosario fuentes gomez[1], Leire Agea Diaz[1], Leire Garaizabal Azkue[2], Sheila Gonzalez Gonzalez[1], Clara Zazpe[1], Rafael Micó[1], Laura Fragueiro[1] & Maider Sanchez goitia[1]

[1]Hospital Universitario Araba, Endocrinology, Vitoria, Spain; [2]Hospital de Mendaro, Endocrinology, Mendaro, Spain

We present the case of a 41-year-old woman with clinical symptoms of asthenia, proximal muscle weakness, behavioral changes, Cushingoid facies, visual disturbances and weight gain of 1.5 years. She also had a previous pelvic fracture with osteopenia in densitometry and hypertension of three months' evolution. In the study due to clinical suspicion of Cushing's syndrome, an elevation of urinary free cortisol was observed five times above the upper limit of normal, a dexamethasone suppression test of 1 mg of 26 mg/dl, elevated nocturnal salivary cortisol and inappropriately elevated ACTH repeated on three occasions. In ophthalmological study showed bilateral homonymous left quadrantanopia with bilateral left hemianoptic loss of sensitivity compatible with right parietotemporal lesion. Pituitary resonance imaging describes a giant pituitary mass measuring 5.1 × 3.5 × 4.2 cm with extensive growth to the interpeduncular cistern and prepontine cistern, extension through the floor of the sella turcica to the sphenoid sinus, invasion of the right cavernous sinus with hydrocephalus and signs of intracranial hypertension requiring placement of a shunt valve. Surgery was performed in 2022 first with transcranial surgery and required a second transsphenoidal surgery one month later due to significant tumor remnant. The main complications of the surgery were diabetes insipidus and hypothalamic syndrome with psychomotor agitation that was difficult to control, as well as secondary hypothyroidism and central catheter infection. The pathological study showed Ki67 of 4%, positivity for ACTH, alpha subunit, presence of Crooke cells and MGMT methylation and negativity for p53. In the hormonal study one month after surgery, the patient presented data of adrenal insufficiency with cortisol < 1 mg/dl and in the continuous resonance, the tumor residue was 3.7x2.7x2.2 cm. She received treatment with radiotherapy-protontherapy on the tumor residue, which remained stable in the following three years. Cushing's disease due to invasive macroadenoma with positivity for Crooke cells occurs rarely. The positivity of these cells and MGMT methylation predispose to invasive macroadenomas with persistence of tumor residues and, in general, recurrence of Cushing's disease. In our case, the patient remains without data of hypercortisolism and the tumor residue remains stable after three years of surgery and protontherapy.

Kallmann-morsier syndrome: a genetic mystery behind amenorrhea and anosmia

Karimi Meryem[1], Ghita Khamel[1], Hajar Azagouagh[1], Ghizlane Sabbar[1], Kawtar Rifai[1], Hinde Iraqi[1] & Mohamed El Hassan Gharbi[1]
[1]CHU Ibn Sina, Rabat, Morocco

Introduction
Kallmann-Morsier syndrome is a rare genetic condition characterized by the association of hypogonadotropic hypogonadism (HH) with anosmia or hyposmia. This condition results from a defect in the embryonic migration of GnRH-producing neurons and olfactory neurons. Diagnosis is often delayed due to the significant variability in clinical manifestations.
Case Report
We present the case of a 17-year-old single female patient who consulted for primary amenorrhea. The medical history revealed anosmia present since childhood, with a family history of anosmia reported in her father. Clinical examination revealed normal development of secondary sexual characteristics, corresponding to Tanner stage S3P3. Biological assessments showed hypogonadotropic hypogonadism, with low LH and FSH levels, indicating dysfunction of the hypothalamic-pituitary axis. Paraclinical evaluations revealed:.
- A normal breast ultrasound,.
- A normal transthoracic echocardiogram,.
- An MRI of the olfactory bulbs showing complete agenesis of the left olfactory bulb and hypoplasia of the right olfactory bulb, thereby confirming the diagnosis of Kallmann syndrome. The treatment implemented was progressive hormone replacement therapy. Estradiol was gradually introduced over two years to promote the development of secondary sexual characteristics and ensure bone health. Subsequently, progesterone was added to simulate a physiological menstrual cycle.
Discussion
Kallmann syndrome was first described in 1944 by Franz Josef Kallmann, a German-born geneticist who emigrated to the United States. This condition results from a defect in the embryonic migration of GnRH-producing neurons and olfactory neurons, caused by genetic mutations, particularly in the **KAL1**, **FGFR1**, and **PROKR2** genes. Although rare, this syndrome should be considered in any patient presenting with primary amenorrhea associated with hypogonadotropic hypogonadism and anosmia or hyposmia.
Conclusion
This case highlights the importance of suspecting Kallmann syndrome in adolescent girls presenting with primary amenorrhea accompanied by anosmia. Early and appropriate management, including hormone replacement therapy, optimizes pubertal development, improves bone health, and ensures a better quality of life.

Acromegaly and kidney cancer what is the link?

Chayma Zouna[1], Ikrame Qasdi[1], Hasna Ouirar[1], Zineb Habbadi[1], Fatima Toulali[1], Ghizlane Sabbar[1], Kaoutar Rifai[1], Hind Iraqi[1] & Mohamed Hassan Gharbi[1]
[1]CHU Rabat, Endocrinologie, Rabat, Morocco

Introduction
Acromegaly is a chronic disease associated with an increased risk of cancer. A recent survey study conducted in Italy demonstrated an increased incidence of all malignant tumors in acromegalic patients, as well as gender differences in the incidence of malignant tumor types, with an increased incidence of thyroid, colorectal and breast cancer in women, while thyroid, kidney and colorectal cancer in men.
Observation
73-year-old patient with history of Enucleation for papillary renal carcinoma in 2013. Diagnosed in our training for Acromegaly clinically confirmed by dysmorphic syndrome acro-facial biologically IGF1 rate elevated to 2.6N with morphologically a hypotalamo-hypophyseal MRI in favor of a left paramedian pituitary micro-adenoma. Acromegaly: severe obstructive sleep apnea syndrome. 28-year history of hypertension complicated by non-sequelae ischemic stroke on dual therapy. Diabetes for 02 years on Metformin. Colonoscopy: presence of a histologically resected pedunculated polyp compatible with a tubulovillous adenoma with low-grade dysplasia. The patient was referred to neurosurgery for transphenoidal removal of the adenoma.
Discussion
IGF-1 synthesized locally in connective tissue adjacent to renal epithelial cells acts as a paracrine or autocrine factor in the kidney. The degree of IGF1R gene expression is different throughout the nephrogenic zone, with stronger expression in glomeruli and tubular epithelium of the medulla, and weaker expression in proximal tubules [12]. IGF1R affects the transformation of renal cells to malignancy by inducing cell proliferation, dedifferentiation and inhibiting apoptosis. RCC cells are sensitive to exogenous IGF-1 stimulation. Expression of IGF1R and the development of ccRCC were found to be associated, indicating that it may be a possible molecular prognostic marker as well as a potential target for new therapeutic interventions. Therefore, treatment of acromegaly and control of disease progression in acromegalic patients with any type of cancer are mandatory.

Height blood pressure and acromegaly: about 78 cases

Mashal Rajaa[1], Nassim Essabah Haraj[1], Siham El Aziz[1] & Asma Chadli[1]
[1]Ibn Rochd University Hospital of Casablanca, Morocco, Neurosciences and Mental Health Laboratory Faculty of Medicine and Pharmacy- University Hassan II – Casablanca-Morocco, Endocrinology, Diabetology, Nutrition and Metabolic Diseases Departement, Casablanca, Morocco

Introduction
Acromegaly is a rare condition secondary to hypersecretion of GH often by a pituitary adenoma. High blood pressure is frequently found, aggravating the cardiovascular complications of acromegaly and improving its risks of morbidity and mortality.
The objective
Is to specify the frequency and evaluate the clinical and paraclinical characteristics of High blood pressure in acromegalic patients.
Patients and methods
This is a retrospective, descriptive study of 78 patients hospitalized in the endocrinology, diabetology and metabolic diseases department of Ibn-Rochd University Hospital, Casablanca from January 2007 to December 2024.
Results
Elevated blood pressure – hypertension was found in 27 cases (21%), with a mean age of 54 years (36–72) and a sex ratio: F/M of 2.45. Mean blood pressure was

150/90 mmHg. Grade 1 was found in 51%, grade 2 in 34% and grade 3 in 15%. Hypertension was well controlled in 58% under monotherapy and in 32% under dual therapy. Hypertension was resistant in 22% under dual therapy and in 12% under triple therapy and was associated with diabetes or prediabetes in 79% of cases, and with dyslipidemia in 52%. Hypertensive retinopathy was found in 38% of cases, positive microalbuminuria (42%) and hypertensive heart disease (19%). Hypertension did not regress in any patient after surgical management.
Conclusion
In a third of cases, high blood pressure is found and is an integral part of the cardiovascular complications that determine cardiovascular morbidity and mortality.

JOINT2444
Parhon's syndrome: the difficult path to finding the root cause
Irada Gasymova[1], Ekaterina Pigarova[1], Larisa Dzeranova[1] & Aurika Asanova[1]
[1]Endocrinology research centre, moscow, russian federation

Introduction
Parhon's syndrome, also known as the syndrome of inappropriate antidiuretic hormone secretion (SIADH) or antidiabetes insipidus, is a rare disorder characterized by excessive secretion of antidiuretic hormone (ADH) from the posterior pituitary gland or an ectopic source. This results in dilutional hyponatremia, which requires hospitalization in 15–20% of cases.
Materials and methods
Patient S., a 66-year-old male, has been hospitalized multiple times since March 2024 due to recurrent episodes of hyponatremia, with serum sodium levels dropping to 108 mmol/l,accompanied by seizures and falls. Parhon's syndrome was suspected.
Results
In June 2024, the patient was admitted to the Department of Neuroendocrinology at the Endocrinology Research Centre. Hormonal studies showed no evidence of hypothyroidism (TSH: 0.487 mIU/l,free T4: 16.8 pmol/l)or adrenal insufficiency (ACTH: 28 pg/ml, cortisol: 326.7 nmol/L). Heart failure was ruled out (NT-proBNP: 10 pg/ml; reference range: 0–125 pg/ml). Upon admission, laboratory findings included serum sodium of 119.9 mmol/l,blood osmolality of 247–249 mOsm/kg (reference: 280–300), and urine osmolality of 415–603 mOsm/kg (reference: 300–1200). Initial treatment involved an infusion of 3% NaCl, followed by oral therapy with 0.9% solution of NaCl. After five days, sodium stabilized at 133.6 mmol/lwith fluid restriction (800 mL/day) and furosemide (80 mg/day). As prior imaging showed no brain, thoracic, or abdominal tumors, further tests were done to explore a possible ectopic ADH source. A whole-body PET/CT (June 2024) revealed a hypermetabolic lesion in the right back, diagnosed as elastofibroma, but a follow-up PET/CT (July 2024) showed no tumors. A core biopsy failed due to insufficient tissue visibility. A surgeon suggested the 18F-FDG uptake was due to nonspecific changes from prior falls linked to hyponatremia. With fluid restriction, furosemide (80 mg/day), and NaCl (200 mL/day), serum sodium levels remained stable (138–141 mmol/L). Reducing furosemide to 40 mg/day led to sodium levels of 135–138 mmol/l,but stopping it caused a drop to 132.8 mmol/l,requiring reintroduction at 40 mg/day to maintain normal levels. Ongoing sodium monitoring was advised.
Conclusions
Despite the absence of a confirmed source of ADH hypersecretion, this case underscores the importance of early diagnosis, understanding the pathophysiology of Parhon's syndrome, and implementing an effective treatment strategy. Proper management prevents severe complications associated with hyponatremia and inappropriate therapy, ultimately improving the patient's quality of life.

JOINT2843
Metyrapone as a bridge therapy after pituitary radiation for aggressive Cushing's disease: a case report
Andreea-Alexandra Grosu[1], Viorica Nicuta[1], Cristina Stancu[1] & Corin Badiu[1]
[1]"C.I. Parhon" National Institute of Endocrinology, Endocrinology 4, Bucharest, Romania

Primary therapy in Cushing's disease consists of transsphenoidal surgery but when the tumor is aggressive, patients can undergo targeted radiotherapy. Due to its late effect, medical therapy like metyrapone is an option for managing hypercortisolism till radiotherapy is achieving maximal therapeutic effect, limited because of poor tolerability and lack of data regarding long-term efficacy. To document the significant changes on metyrapone in our patient we used: body weight, systolic blood pressure, ability of doing squats, Quality of Life, Beck Depression Inventory assessment, glycosylated hemoglobin test (HbA1c) along with biochemical parameters. The patient is a 56-year-old female with medical history of severe psychiatric symptoms (major depression, episodes of hypomania) and cognitive impairment along with proximal muscle weakness and metabolic complications: obesity, uncontrolled type 2 *diabetes, resistant hypertension, all caused by* pituitary adenoma diagnosed in February 2022. In April 2022 the patient was referred to neurosurgery for transsphenoidal pituitary surgery. The immunohistochemistry was positive for ACTH with high proliferative index (ki-67: 14%). Postsurgical MRI scan indicated residual tumor presence. A second and third surgery attempts couldn't control hypercortisolism. In August 2023 she started stereotactic pituitary radiation followed by metyrapone, initially 250 mg daily then titrated up to 250 mg twice/day, well tolerated. We documented the changes before and after initiating metyrapone treatment: weight loss was 13 kg, diabetes was controlled with metformin and GLP-1 analogue (HbA1c from 10.1% to 6%), proximal muscle strength increased from 1 to 5 squats, maximum systolic blood pressure was 150 mmHg. Psychiatric symptoms ameliorated, concentration, comprehension, verbal control and spatial abilities improved. Regarding biochemical changes: plasma ACTH decreased from 132.9 pg/ml to 64.58 pg/ml, 24-hour urinary free cortisol from 172.51mg/24h to 52.2mg/24h, morning serum cortisol normalized (20.76mg/dl) as well as late-evening salivary cortisol (0.18mg/dl). She continues with 500 mg metyrapone per day with a favorable evolution. Neurosurgery in tertiary centers is the first line treatment in Cushing's disease and should remain the mainstay of its management, followed by radiotherapy in aggressive cases. Only few medications have been proven to be beneficial as a bridge therapy while waiting for the effect of stereotactic pituitary radiation to be complete and metyrapone could be one of them.

JOINT1203
Combined therapy of somatostatin analogue with pegvisomant for the management of acromegaly
Anna Brona[1], Jowita Halupczok-Żyła[2], Aleksandra Zdrojowy-Welna[1] & Marek Bolanowski[1]
[1]Wroclaw Medical University, Department and Clinic of Endocrinology and Internal Medicine, Wroclaw, Poland; [2]Wroclaw Medical University, Department of General and Experimental Pathology, Wrocław, Poland

Combined therapy of somatostatin analogue and growth hormone receptor antagonist for the management of acromegaly. A 35-year-old woman was diagnosed with acromegaly in January 2021. She was consulted by an endocrinologist due to enlarged hands and feet. She also complained of a change in facial features, weight gain, excessive sweating, and severe headaches. Laboratory tests confirmed the diagnosis of acromegaly. MRI of the pituitary gland revealed a pituitary tumor of 22 × 32 × 26 mm. She was referred to the neurosurgery department. The surgery was not complete, the remnant tumor was 25 × 28 × 16 mm and comprised the right cavernous sinus. The patient was suggested to start radiotherapy but did not agree. A first generation somatostatin analogue was introduced. IGF-1 concentration was 492 ng/dl (115-307). Due to the lack of improvement, a second generation of somatostatin analogue was started. At the beginning patient received 40 mg of pasireotide. After a few months, IGF-1 concentration was still elevated [416 ng/dl, (115-307)]. Then the dose was increased to 60 mg. During the nine months of treatment, a normal IGF-1 level was observed only once (306 ng/dl, (115-307)], in January 2023. The patient was dismissed from this treatment due to the lack of normalization of IGF-1 and the poor tumor shrinkage. The patient underwent radiotherapy in June 2023. It was not possible to introduce Gamma Knife radiosurgery. It was decided to apply irradiation with a total dose of 54 Gy. Severe headache appeared soon after cessation of pasireotide and aggravated after radiotherapy. It was decided to administer pegvisomant until the effects of radiotherapy appeared. Before administration of pegvisomant, an MRI was done and revealed a residual tumor measuring 17 mm x 20 mm x 20 mm infiltrating the right cavernous sinus and almost completely encasing the internal carotid artery segment. The tumor grew between the base of the right frontal lobe and the inner surface of the right temporal pole toward the optic canal. It did not infiltrate the right optic nerve or the optic chiasm. The initial dose was 10 mg in October 2023. The permanent reduction in IGF-1 level was achieved with a dose of 20 mg. Due to a headache

that impaired quality of life significantly, pasireotide was administered again as emergency therapy in November 2023. It was very effective in managing headaches. The patient continues therapy addressing both IGF-1 concentration and the most disturbing symptom.

Barriers to timely diagnosis of cushing's disease in the outpatient setting

Tamara Dojcinovic[1], Jelena Malinovic Pancic[1,2], Bojana Caric[1,2] & Aleksandra Markovic[1,2]

[1]University Clinical center of the Republic of Srpska, Medical faculty, University of Banja Luka, Banja Luka, Bosnia and Herzegovina; [2]School of medicine, University of Banja Luka, Banja Luka, Bosnia and Herzegovina

Introduction

Cushing's disease is a rare condition, particularly when compared to Cushing's syndrome, with an incidence of 0.7 to 2.4 cases per million individuals. Due to its rarity, diagnosis is frequently delayed, which results in a notable increase in morbidity. First line treatment is pituitary surgery, and remission in obtained in 80% of patients with microadenoma, and 60% of those with macroadenoma. In the event of failure of surgical treatment, and if reoperation is not feasible, the introduction of steroidogenesis inhibitors and radiotherapy may be considered.

Case report

We present the case of 38-year-old female patient with hypercorticism which was reffered to our institution from outpatient endocrinologist. She was diagnosed with diabetes mellitus type 2 at the age of 33, and hypertension at the age of 30. Due to irregular mestrual cycles, she was followed by endocrinologist and gynecologist as a polycistic ovary syndrome. At the age of 38, due to worsening of diabetes and obesity, her outpatient endocrinologist obtained Dex screening cortisol levels which were unsupressed, and reffered her for further testing. We did extensive hormonal work up which confirmed ACTH dependent hypercortisolism. Pituitary NMR showed pituitary macroadenoma sized 3,1 cm. The patient also presented with an adrenal incidentaloma, and subsequent evaluation confirmed the presence of a nonfunctional tumor with radiological characteristics consistent with an adenoma. She was operated on by experienced neurosurgeon, and postoperative follow up comfirmed that did not achieve remission, and since tumor invaded cavernous sinus, gama knife was performed. Subsequently, patient in still not in remission regarding Cushings disease, while she has well controlled diabetes and hypertension.

Conclusion

In conclusion, as previously mentioned, the diagnosis of Cushing's disease is frequently delayed due to its rarity, particularly in less experienced centers. Consequently, in young women presenting with amenorrhea and diabetes, secondary causes of diabetes should be considered to ensure timely diagnosis and appropriate treatment.

The interplay of hormones and neuroplasticity: how hormonal changes shape brain adaptation to stress and learning

Shakhzoda Aripkhodjaeva[1] & Zulaykho Shamansurova[1,2]

[1]Central Asian University, Endocrinology, School of Medicine, Tashkent, Uzbekistan; [2]Institute of Biophysics and Biochemistry at the National University of Uzbekistan, Metabolomics, Tashkent, Uzbekistan

Introduction

Neuroplasticity responds to hormonal shifts through brain self-adaptation and reorganization resulting in substantial influence on stress responses along with learning and environmental change adaptation capability. This article investigates how hormones affect neuroplasticity through examination of five significant hormones including cortisol together with estrogen and testosterone and oxytocin and thyroid hormones based on data from literature.

Material and Methods

Published data from past two decades from source such as MedLine, PubMed, Scopus, WebofScience, Google Scholar regarding hormonal changes in neuroplasticity were analysed and presented as summary.

Results

Stress-induced cortisol regulation affects both synaptic plasticity and memory consolidation processes in the brain while estrogen and testosterone support neurogenesis activities and synaptic remodeling and cognitive functions throughout the areas that include hippocampus and hypothalamus. The hormone estrogen specifically controls serotonin manufacturing processes in the brain as well as controlling serotonin receptor operation to affect cognitive functioning. The stress and memory responses are directly influenced by progesterone and its metabolites although their performance changes throughout the menstrual cycle. When a woman takes hormonal birth control the medicine changes the way her brain looks by modifying gray and white matter structure. The research paper examines sexual brain differences in network connections particularly regarding the default mode network while demonstrating how sex hormones control such functional brain networks. Researchers need to understand how hormones influence brain function because this knowledge enables proper development of treatment methods for neuropsychiatric disorders such as depression and anxiety where sex-specific differences are prominent. Research needs more focus on hormonal treatments of brain disorders because this review establishes that hormone changes affect neural flexibility and mental wellness at varying stages of life.

Conclusion

Changes in brain neuroplasticity can affect in dual way: neuroplasticity can changes hormones secretion, hormones disregulation can changes brain functional activity. Underlying molecular mechanisms should been taken in account in treatment neurologic and endocrine diseases. Deep understanding that process can help in improving preventive managements in adaptation to stress and learning.

Corticotherapy revealing a pituitary adenoma

Redhouane Longo[1], Mourad Benrabah[1], Mohamed El Horri[2] & Mounia Gharnouti[1]

[1]Regional University Military Hospital, Oran, Algeria; [2]Military University Hospital Specialized in Orthopedic Surgery Rehabilitation and Orthoprosthetics, Algiers, Algeria

Introduction

Prolonged corticosteroid therapy exerts a negative feedback control on the hypothalamic-pituitary axis, resulting secondary adrenal insufficiency. Recovery of normal adrenocortical axis function is most often spontaneous. We report here a case of non-secreting pituitary adenoma revealed by corticosteroid therapy.

Observation

A 20-year-old woman was referred to us for the management of a pituitary microadenoma evolving in the context of Cushing's syndrome. During questioning, a skin allergy is reported for which long-term corticosteroid therapy had been prescribed. Not having been properly informed, the patient abruptly interrupted her treatment and consulted her doctor because of the sudden onset of asthenia and arterial hypotension, in which case a requested hormonal assessment revealed a low cortisol level at 40.19 nmol/lwith non-increasing ACTH level at 9.67 pg/ml. Having been convinced of the central origin of the adrenal insufficiency, and disregarding corticosteroid intake notion, magnetic resonance imaging was requested, revealed a 4 mm pituitary microadenoma left side. It should be noted that the rest of pituitary assessment did not objectify any hypo or hypersecretion of the other axes. After a withdrawal protocol, cortisol levels at 3 months had returned to 339.50 nmol/l,and the patient was still being followed-up.

Discussion

Pituitary adenomas of any type are rare. intrasellar lesions prevalence in the general population is 6-10%, mainly microadenomas. Non-functional pituitary adenomas are pituitary tumours that do not secrete any hormone. Since 1948, synthetic corticosteroids are widely used in medical practice due to their anti-inflammatory, anti-allergic and immunosuppressive properties. Addition to their therapeutic effects, corticosteroids exert a negative feedback effect on the corticotropic axis, inhibiting the secretion of ACTH and cortisol. This phenomenon is also called iatrogenic or exogenous Cushing's syndrome.

Conclusion

Better management of prolonged corticosteroid therapy will help us to assess the real adrenal insufficiency incidence, and to propose adequate prevention of this side effect.

Craniopharyngioma in adolescence: from diagnosis to ongoing care

Natela Navasardyan[1], Yelena Aghajanova[2,3], Irina Muradyan[2], Lusine Avagyan[3] & Lusine Navasardyan[3,4]
[1]Surb Astvatsamayr MC, Yerevan, Armenia; [2]"Muratsan" University Hospital Complex, Yerevan, Armenia; [3]Yerevan State Medical University, Yerevan, Armenia; [4]"Arabkir" MC, Yerevan, Armenia

Introduction
Craniopharyngiomas are rare, benign tumors that arise near the pituitary gland, predominantly affecting children and adolescents. Although benign, these tumors can lead to significant morbidity due to their proximity to critical structures like the hypothalamus and pituitary gland. Early diagnosis and appropriate treatment are essential, particularly when hypothalamic involvement occurs, as it can complicate management and influence long-term endocrine function.
Case Description
A 15-year-old female presented with a history of severe, recurrent headaches and syncope. Initial blood and biochemical tests were within normal limits. Endocrine testing revealed normal thyroid function, undetectable LH and subnormal FSH levels, Tanner stage 2 sexual development and decreased height velocity (SDS -1.9 in 2025 vs. SDS -1.3 in 2023). Magnetic resonance imaging (MRI) revealed hydrocephalus and a mass located in the chiasmatic region, suggesting a craniopharyngioma. The patient underwent surgical resection of the mass, and histological examination of the resected tissue confirmed the diagnosis of craniopharyngioma. Postoperatively, the patient developed polyuria, which raised concerns for arginine vasopressin deficiency, thus desmopressin was initiated. Electrolyte disturbances (including sodium and potassium shifts) and low urine specific gravity were observed as well. Given the persistent polyuria (20 L per day), the dose of desmopressin was increased, and within 2-3 days the patient was improved (diuresis 3L per day). Her laboratory results have since normalized. The patient is under ongoing follow-up care by both an endocrinologist and an oncologist for continued monitoring of her recovery and management of potential long-term endocrine effects, including the evaluation of sexual development as part of her follow-up care.
Conclusions
Craniopharyngiomas should be considered in the differential diagnosis of adolescents with unexplained neurological symptoms and growth delay. While the patient's craniopharyngioma was managed with initial success, the case underscores the necessity of lifelong multidisciplinary follow-up to address hormonal deficiencies, metabolic complications, and psychosocial challenges. It is important to find the balance between tumor control and preserving quality of life in adolescents with this condition.

Non-surgical management of patients with pituitary macroadenomas: case report

Isuru Ashan Jayaweera[1], Ruhansa Galgoda Lineage[1], Yuliya Dydyshka[1] & Veranika Labashova[1,2]
[1]Belarusian State Medical University, Minsk, Belarus; [2]Republic Center of Endocrinology and Medical Rehabilitation, Minsk, Belarus

Introduction
Particular clinical difficulties are presented by patients with mixed hyperproduction, as well as situations with secondary hyperprolactinemia due to compression of the pituitary stalk. Thus, the aim was to study the results of using of dopamine receptor agonists in patients with macro-adenomas and hyperprolactinemia.
Material and Methods
An observational study was performed on clinical cases of three patients referred for management and treatment at the Republican Endocrinology Centre. The observation period was from the beginning of 2022 to the present.
Results
Patient 1. A 38-year-old man consulted a doctor due to a constant, terrible headache. During the interview, he noted a change in appearance over the past 4 years. The headache has increased worse since March 2022, nasal congestion appeared. In the sellar region, a tumor with uneven clear contours with overall dimensions of 67*53*85mm, a heterogeneous structure with the presence of calcifications and small cystic components, measuring up to 7 mm, is determined. Serum tests: TSH 1,27 mIU/nL, Free T4 14,21pmol/l,Prolactin 10000mIU/l,-Cortisol 214.5nmol/l,IGF-1: 956.6 ng/ml, HbA1 – 6,24%. *Ophthalmologist's report*: long-standing papilledema; OD - absolute scotoma in the posterior pole next to the optic disc, OS - widening of the blind spot. In a year treatment prolactin 369.7mIU/l,GH 0.556ng/ml, IGF-1 251.7, then prolactin 282mIU/L. Dynamics Pt MRI: 67*53*85mm (May2022) vs. 35*18*40mm (October2022) vs. 27*15*25 mm (March2023). Patient2. A 23-year-old man with any symptoms and changes in health. In February 2021 he consulted a doctor with the results of a hormonal analysis: TSH 1,98 mIU/nL, fT4: 15,3 pmol/l,prolactin: 6 395mkIU/l,-MonoProlactin: 5650mIU/l87%, FSH 33,43 mIU/l,total testosterone – 1,97pmol/l,cortisol: 419nmol/l,HbA1C 5.3%. PT MRI: a pituitary adenoma was detected in the left half measuring 7.5x10x9.5 mm without displacement of the pituitary stalk. Cabergoline 0.5mg twice a week was prescribed. Patient3. A 38-year-old woman consulted a doctor about dizziness and lack of menstrual cycle. Hormonal status parameters: TSH 3,09mIU/nL, FreeT4: 14.72pmol/l,Prolactin: 123100 mkIU/ml, MonoProlactin: 97736mkIU/ml–79.4%, FSH 5.54 mIU/l,Estradiol: 57.71pmol/l,Cortisol: 389.8nmol/l,IGF-1: 135.5ng/ml. PTMRI: a pituitary adenoma 22x20x19mm with clear contours of a solid structure, suprasellar growth, compression of the chiasm. Normalization of prolactin occurred after several months of treatment, but to resume the menstrual cycle it was necessary to increase the dose of cabergoline.
Conclusion
The use of cabergoline is an effective and safe treatment for pituitary macroadenomas in the first step.

The relationship between reproductive hormones, testis size, mating strategy, and spermatogenesis efficiency across primates

Louise Sørensen[1,2], Vasili Pankratov[3], Juliana Berner[4], Hanne Frederiksen[1,2], Mikkel Schierup[3], Christina Hvilsom[4], Kristian Almstrup[1,2,5] & Sofia Winge[1,2]
[1]Copenhagen University Hospital, Department of Growth and Reproduction, Copenhagen, Denmark; [2]International Center for Research and Research Training in Endocrine Disruption of Male Reproduction and Child Health, Copenhagen, Denmark; [3]Aarhus University, Bioinformatics Research Centre, Aarhus, Denmark; [4]Copenhagen Zoo, Copenhagen, Denmark; [5]University of Copenhagen, Department of Cellular and Molecular medicine, Copenhagen, Denmark

Background
In humans, it is well-described that spermatogenesis is tightly regulated by reproductive hormones. Spermatogenesis is also an evolutionarily conserved process, which ultimately results in the production of spermatozoa. Common across all mammals are processes that maintain a stem cell pool, a proliferation phase, meiosis and a final differentiation process. Despite being a conserved process, spermatogenesis also undergoes rapid evolutionary changes driven by selective pressures favouring male reproductive success. Primates represent an excellent population to investigate spermatogenesis since many species are evolutionary close but also differ considerably regarding testis size and mating strategies. Comparison of the spermatogenic efficiency across primates can provide valuable insights into how evolution has influenced the complex interplay between reproductive hormones and testicular function and potentially provide insight into why human male fertility has decreased.
Methods
Hormones were measured in serum samples from nine primate individuals representing six different species using ELISA or LC-MS/MS. Histological evaluations of testicular tissue were performed by immunohistochemistry using antibodies against melanoma-associated antigen 4 (MAGE-A4) to stain spermatogonia and nuclear transition protein 1 (TNP1) to stain elongated spermatids. A total of thirteen individuals representing eight species. Germ cells positive for the two antibody markers were quantified using the Qupath software, and the ratio of TNP1-positive spermatids and MAGE-A4-positive spermatogonia was calculated.
Results
Whereas the percentage of MAGE-A4-positive spermatogonia was similar between all individuals, there were remarkable differences in the percentage of TNP1-positive spermatids. Species that have a monogamous mating strategy had lower TNP1/MAGE ratios, indicating a lower spermatogenic efficiency and species with a harem mating strategy showed intermediate ratios, whereas species

with polygynandrous mating systems showed the highest TNP1/MAGE ratios, suggesting a more efficient spermatogenesis when multiple males are present per female. Interestingly, all primates showed high levels of the spermatogenesis hormone marker, inhibin B compared to human reference ranges. The inhibin b levels were particularly high in the chimpanzees, likely caused by their large testis size. The harem-living species had the highest testosterone levels and their dihydrotestosterone (DHT) levels were above human reference ranges suggesting that these hormones could reflect male dominance.
Conclusions
Our preliminary data indicates that the mating strategy among primates affects both testis size and the efficiency of spermatogenesis, which again is reflected by inhibin B levels. Humans had the lowest inhibin B levels of all investigated primates, which corroborates the poor testicular function observed among humans.

Characterization of intracrine androgen production in human genital skin fibroblasts

Baraah Alnawasreh[1], Alexandra E. Kulle[1] & Paul-Martin Holterhus[1]
[1]University Hospital Schleswig-Holstein, Department of Pediatric Oncology and Rheumatology, Division of Pediatric Endocrinology and Diabetology, Kiel, Germany

Introduction
Differences of sex development (DSD) comprise a heterogeneous group of conditions with an atypical sex development. Disorders of steroid biosynthesis are often directly or indirectly involved. Steroid hormones are typically measured in the bloodstream, while locally produced intracrine steroids in peripheral tissues remain underexplored. 5-α-Reductase type 2(SRD5A2) converts testosterone to dihydrotestosterone (DHT), a potent androgen critical for male genital development in the fetal period and puberty. Deficiency of this enzyme, caused by mutations in the SRD5A2 gene, leads to an autosomal recessive DSD with varying degrees of undervirilization in individuals with a 46, XY karyotype. This study focuses on the analysis of the intracrine steroidome associated with SRD5A2 deficiency in cultured genital skin fibroblasts (GSF) to improve the understanding of peripheral androgen biosynthesis.
Method and Cell culture
GSFs from molecular proven SRD5A2-deficient persons (labioscrotal folds) and controls (scrotum) were cultured in DMEM-based medium at 37°C, 5% CO_2. Cells were seeded in 6-well plates (6×10^4 cells/2 ml/well) and incubated with testosterone, DHEA, and 17-hydoxyprogesterone (17OHP) at three concentrations (1, 10 and 100 nM). Supernatants were analyzed by LC-MS/MS after 24 h pre-incubation (before hormone incubation) or after additional 72 h of hormone incubation.
- **ARD515**: homozygous p.Arg227Gln.
- **ARD249**: homozygous Gly196Ser.
- **GS451**: homozygous p.Ile199Asn.

Results
DHT production was significantly reduced in SRD5A2-deficient cells compared to control cell lines confirming the underlying molecular defect. At 100 nM testosterone, the mean DHT production in SRD5A2-deficient cells was 5.54 nM $\pm$ 2.69 ($n = 3$), while in control cells it was 46.65 nM $\pm$ 30.58 ($n = 3$). Additionally, there was a notable back-conversion to androstenedione in the SRD5A2-deficient cells, with levels of 8.84 nM $\pm$ 2.79 ($n = 3$), compared to 0.15 nM $\pm$ 0.22 ($n = 3$) in control cells. Similarly, the metabolism of DHEA and 17OHP showed distinct differences between the SRD5A2-deficient and controls.
Conclusion
A limited but detectable conversion of testosterone to DHT occurs in SRD5A2-deficient cells, suggesting that residual enzymatic activity may be involved. The observed back-conversion of testosterone to androstenedione highlights the complexity of steroidogenesis in SRD5A2 deficiency. To fully explain this back-reaction, Further androgen biosynthesis pathways should be included in steroid measurements to understand androgen biochemistry in these cells better.

Reproductive hormones in 46, XY differences/disorders of sex development and healthy populations

di mao[1] & Chunxiu Gong[2]
[1]Department of Endocrinology, Genetics, Metabolism, Beijing Children's Hospital, Capital Medical University, Department of Pediatrics, The Sixth Affiliated Hospital of Harbin Medical University, Harbin, China; [2]Department of Endocrinology, Genetics, Metabolism, Beijing Children's Hospital, Capital Medical University; Department of Pediatrics, The Sixth Affiliated Hospital of Harbin Medical University, Beijing, China

Background
Reproductive hormones evaluation plays a critical role in diagnosing 46 XY Differences/Disorders of Sex Development (DSD). However, there is limited data on hormonal levels in both prepubertal and pubertal stages, particularly when compared to healthy cohorts.
Objective
The aim of this study was to investigate the differences in hormonal levels between 46 XY DSD patients and healthy controls during prepuberty and puberty, specifically focusing on luteinizing hormone (LH), follicle-stimulating hormone (FSH), testosterone (T), estradiol (E2), anti-müllerian hormone (AMH), and inhibin B (INHB).
Methods
In this retrospective, semi-longitudinal study, serum samples were collected from two cohorts: 46 XY DSD patients (i) 201 with steroid 5α-reductase deficiency (5aRD), (ii) 120 with Androgen Insensitivity Syndrome (AIS), (iii) 95 with NR5A1 mutations, and 52 healthy male controls. Hormonal measurements of LH, FSH, T, E2, AMH, and INHB were performed using chemiluminescent immunoassays (Immulite 2000, Siemens Healthcare, Sudbury, UK).
Results
Compared to age-matched healthy controls, patients with 5aRD exhibited significantly elevated LH and FSH levels between 1 and 9 years of age, higher LH and INHB levels from 9 to 11 years, and a notable increase in T levels. Between 11 and 13 years, 5aRD patients had higher levels of LH, T, E2, AMH, and INHB, with elevated LH, T, and E2 levels observed in those older than 13 years. AIS patients demonstrated increased levels of LH, T, and E2 between 1 and 9 years, higher T and INHB levels between 9 and 11 years, and elevated LH, T, and E2 levels in those aged over 11 years. *NR5A1* mutation patients showed higher levels of LH, FSH, and T, along with lower AMH levels between 1 and 11 years. After 11 years, these patients exhibited elevated LH, FSH, and E2 levels, with decreased AMH and INHB levels.
Conclusions
Distinct hormonal secretion patterns were observed in all three 46 XY DSD conditions compared to healthy controls. The 5aRD patients exhibited signs of earlier pubertal development, characterized by elevated LH, INHB, and a rising trend in T levels between 9 and 11 years. The AIS cohort demonstrated features of androgen resistance in their hormonal profiles. In patients with *NR5A1* mutations, early pubertal development was noted between 1 and 11 years, but the absence of a significant increase in T levels, alongside decreased AMH and INHB levels after 11 years, suggests the onset of gonadal dysfunction.

Evaluating the FIB-4 score as a screening tool for NAFLD in PCOS: a cross-sectional study

Valentina Elezovic Kovacevic[1,2], Sanja Ognjanovic[1,2], Bojana Popovic[1,2], Dusan Ilic[1], Milica Opalic Palibrk[1], Lena Radic[1], Katarina Krstic[1] & Djuro Macut[1,2]
[1]Clinic of endocrinology, diabetes and metabolic diseases, Clinical Center of Serbia, Belgrade, Serbia, Departemet of neuroendocrine tumors and hereditary cancer syndroms, Belgrade, Serbia; [2]Faculty of Medicine University of Belgrade, Belgrade, Serbia

Patients with polycystic ovary syndrome (PCOS) have an increased risk of non-alcoholic fatty liver disease (NAFLD), which often results in more severe hepatic steatosis and liver fibrosis. The prevalence of NAFLD in PCOS patients ranges from 34% to 70%, and the possible mechanisms behind this association involve

insulin resistance, inflammation, and hyperandrogenism. This study aimed to analyze the FIB-4 score, a widely recognized tool for assessing NAFLD risk, in a cohort of women with PCOS.
Methods
PCOS was diagnosed according to the ESHRE/ASRM criteria, and patients were classified into four phenotypes: PCOS-A (anovulation, hyperandrogenism, polycystic ovary morphology), PCOS-B (anovulation, hyperandrogenism), PCOS-C (hyperandrogenism, polycystic ovary morphology), and PCOS-D (anovulation, polycystic ovary morphology). FIB-4 score was calculated to assess NAFLD risk, with a cut-off value of >1.3 used to suggest advanced fibrosis.
Results
A total of 168 women with PCOS were included in the study, with a mean age of 26.1 ± 6.4 years and a mean BMI of 24.5 ± 5.8 kg/m^2. The most prevalent phenotypes were PCOS-A (40.7%), followed by PCOS-D (22.6%), PCOS-C (23.2%), and PCOS-B (13.6%). The mean HOMA score was 3.3 ± 1.86, and 58.8% of patients had confirmed hyperandrogenism. The median FIB-4 score was 0.397 ± 0.152, and no participants had a FIB-4 score above 1.3. Statistically significant differences were observed only between phenotypes A and C ($P < 0.05$). Significant correlations were found between FIB-4 and SHBG ($\rho = 0.335$, $P < 0.001$), free androgen index (FAI) ($\rho = -0.257$, $P < 0.001$), triglycerides ($\rho = 0.199$, $P < 0.05$) and androstendione ($\rho = -0.259$, $P < 0.001$). In multiple regression analysis, SHBG ($B = 0.001$, $Beta = 0.184$, $P < 0.05$) and androstendione ($B = 0.002$, $Beta = 0.277$, $P < 0.05$) showed small but significant associations with FIB-4, whereas FAI and triglycerides did not appear to be significant predictors.
Conclusion
The study suggests that the FIB-4 score may not be an effective screening tool for NAFLD in younger women with PCOS, as none of the participants had a FIB-4 score above 1.3. Although SHBG and androstendione showed small but statistically significant correlations with FIB-4, further research is needed for better understanding the role of metabolic factors in NAFLD risk in PCOS.

Evolution in the health-care demand at the transgender care unit of malaga after 25 years of experience

Mariana Gomes Porras[1,2], Mónica Tomé García[1], Guadalupe Cano Oncala[3] & María Cruz Almaraz Almaraz[1]
[1]Regional University Hospital of Malaga, Endocrinology and Nutrition, Málaga, Spain; [2]PhD Student at the University of Malaga, Málaga, Spain; [3]Regional University Hospital of Malaga, Clinical Psychology, Málaga, Spain

Introduction
The first unit for transgender health-care within the Spanish public health system was created in 1999 in Andalusia. The Transgender Care Unit (TCU) of Malaga is functionally dependent on the Endocrinology and Nutrition service and is composed of a multidisciplinary team, including specialists in Endocrinology, Clinical Psychology, Plastic Surgery, Gynecology, Urology, Otorhinolaryngology, and Phoniatrics.
Objective
To compare the sociodemographic profile of transgender people undergoing endocrinological follow-up at the TCU of Malaga during the period from 1999 to 2024.
Methodology
Descriptive, retrospective, and cross-sectional study that include transgender people under endocrinological follow-up at the TCU of Malaga from 1999-2024. The inicial assessment is performed by Endocrinology for individuals over 14 years of age, with psychological evaluations being voluntary in accordance with current legislation. The collected data included the number of consultations (initial and follow-up) in the last two years, the mean age $\pm$ standard deviation at the first consultation, the ratio of transgender women/transgender men (MTF/FTM), the frequency of psychopathology, and the psychological support received.
Results
The number of consultations has increased exponentially, reaching 1,609 and 1,794 consultations per year in 2023 and 2024, respectively. First consultations accounted for 18% of visits, while the remaining 82% were follow-ups. The average age of individuals attending for the first time has decreased, from 28.5 years in the first decade to a range of 22.2–23.9 years in 2023–2024. The proportion of individuals under 18 years old increased from 8.2% in the first decade to 30% in the second decade, reaching 40% in 2024. A reversal in the biological sex ratio of individuals seeking transition was also observed. The MTF/FTM ratio initially stood at 2.45 but gradually decreased to a ratio of 0.66 in 2024, with 39.5% identifying as MTF and 60.5% as FTM. It is noteworthy that a high percentage of individuals presented psychopathology (43–50%). The most common conditions were anxiety-depression disorder, attention deficit hyperactivity disorder, and autism spectrum disorder. The rate of suicidal ideation and/or attempts was 22%. The majority of people (50.6% to 80.8% in 2023–2024) accepted receiving psychological support at the onset of their medical transition.
Conclusion
The high demand for health-care by transgender people, combined with the significant proportion of minors with psychopathology, highlights the complexity of assessing the gender identity. It is essential to provide transgender care in specialized multidisciplinary teams.

The impact of gender dysphoria diagnosis on parents of transgender youth: the role of heteronormativity and mentalization

Paola Lorello[1], Sara Vasaturo[1], Raffaella Di Mase[2], Donatella Capalbo[1], Cristiano Scandurra[3] & Mariacarolina Salerno[1]
[1]Unit of Paediatric Endocrinology - University of Naples "Federico II", Transaltional Medical Science Department, Naples, Italy; [2]Pediatric Endocrinology Unit, Department of Mother and Child, University of Naples "Federico II", Naples, Italy; [3]Department of Neurosciences and Reproductive and Odontostomatological Science, University of Naples Federico II, Naples, Italy.

Purpose
The diagnosis of gender dysphoria (GD) can be a traumatic experience for parents of transgender youth. The aim of this cross-sectional study was to examine the role of heteronormative beliefs and attitudes on the traumatic impact of GD diagnosis in mothers and fathers of transgender youth, as well as the mediating role of mentalization, i.e. the ability to psychologically understand one's own and others' behaviors and emotions.
Methods
A total of 75 couples of mothers and fathers ($N = 150$) of adolescents who received a GD diagnosis answered questions about heteronormativity, mentalization, and the traumatic impact of diagnosis. Mean age of adolescents at diagnosis of GD was 16.3 ± 1.0 years, 49 were assigned male at birth (AMAB) and 26 were assigned female at birth (AFAB) Heteronormativity was assessed using the Italian version of the Heteronormative Attitudes and Beliefs Scale Mentalization was measured using the Italian version of the Reflective Functioning Questionnaire. The traumatic impact of the GD diagnosis was assessed using the Italian version of the Impact of Event Scale-Revised.
Results
Results showed that heteronormative attitudes were significantly higher in fathers than in mothers. Moreover, heteronormative beliefs were positively associated with greater traumatic impact of GD diagnosis only in fathers, whereas heteronormative attitudes were associated with greater traumatic impact of GD diagnosis in both mothers and fathers. Finally, an impaired mentalizing functioning mediated the relationship between heteronormative attitudes (but not beliefs) and the traumatic impact of a child's GD diagnosis only in fathers, but not in mothers.
Conclusion
When transgender youth enter the health care system because of their gender incongruence, their entire family must be supported to create an accepting and affirming environment in which gender-related stress and negative emotions can be effectively processed. ubmitted.

Mental health assessment in women with PCOS: evaluating anxiety and depression using GAD-7 and PHQ-9

Katarina Krstic[1], Sanja Ognjanovic[1], Bojana Popovic[1], Dusan Ilic[1], Valentina Elezovic Kovacevic[1], Milica Opalic Palibrk[1], Lena Radic[1], Bogdan Milenkovic[1] & Djuro Macut[1]
[1]Clinic for Endocrinology, Diabetes and Metabolic Diseases, University Clinical Centre of Serbia, Department for Endocrine Tumors and Hereditary Cancer Syndromes, Belgrade, Serbia

Introduction
Polycystic ovary syndrome (PCOS) is the most common endocrine and metabolic disorder, affecting 6–10% of women of reproductive age worldwide. It is defined by clinical and/or biochemical features, including hyperandrogenism (HA), ovulatory dysfunction (OD), and polycystic ovarian morphology (PCOM), with patients classified into four distinct phenotypes. Despite the physical symptoms, PCOS is also associated with psychological challenges. The aim of this study is to evaluate the mental health of women with PCOS using the Generalized Anxiety Disorder 7-item scale (GAD-7) and the Patient Health Questionnaire-9 (PHQ-9), focusing on anxiety and depression.
Subjects and methods
We analyzed 111 female patients, divided into two groups: PCOS ($n = 70$, age: 26.14 ± 6.734 years) and the control group ($n = 41$, age: 26.98 ± 6.912 years), matched by age. We assessed anthropometric parameters (BMI and waist circumference), androgen levels (total testosterone, SHBG, FAI) and mental health questionnaires (GAD-7 and PHQ-9). The analysis was performed using SPSS software.
Results
The two groups showed differences in BMI values (PCOS:Controls: 25.581 ± 5.742 vs. 23.007 ± 4.411) and waist circumference (PCOS:Controls: 81.53 ± 14.417cm vs. 76.17 ± 10.998cm). A clear difference was observed in androgen levels, which were notably higher in patients with PCOS ($P < 0.01$). No significant differences were found in the results of the GAD-7 and PHQ-9 questionnaires between the groups ($P > 0.05$). There was no significant correlation between the mental health questionnaires (GAD-7 and PHQ-9) and BMI, waist circumference, or androgen levels in either group ($P > 0.05$). Furthermore, no correlation was found between these parameters within the PCOS group.
Conclusion
The results of this study did not reveal a significant correlation between mental health assessments (GAD-7 and PHQ-9) and anthropometric parameters or androgen levels in either group. This suggests that, although physical differences are evident in patients with PCOS, psychological factors such as anxiety and depression may not be directly linked to these specific body indicators. These findings highlight the complexity of the relationship between PCOS and mental health, suggesting that further research is required to explore potential underlying factors.

JOINT3491

Leptin levels may not have a role in the development of pubertal gynecomastia

Zdravka Todorova[1,2]
[1]Clinic of pediatric endocrinology, Specialized Hospital for Active Treatment of Pediatric Diseases, Sofia, Bulgaria, Sofia, Bulgaria; [2]Medical faculty, Medical University-Sofia, Sofia, Bulgaria, Sofia, Bulgaria

Introduction
Leptin(L) is a signal from adipose tissue in the regulation of energy metabolism. Except of this other peripheral tissues contribute to its level and are being influenced through L receptors. Such have been found in the anterior lobe of the pituitary, gonads and in mammary epithelial cells. There is characteristic sexual dimorphism in L in both lean or obese individuals. Men have lower serum levels than women and this difference is found from puberty. L has a complex and bidirectional interplay with sex steroids. It has the ability to increase the activity of CYP19 aromatase thereby leading to increased estrogen (E) and in turn estrogens increase mRNA synthesis and L level. In addition, an inverse correlation with androgens has been reported and further in high-grade obesity high L has a suppressive effect on testosterone(T). On the basis of these data it could be speculated that L is part of the control of breast parenchymal proliferation and with other factors, could be involved in the development of pubertal gynecomastia (PG).
Aim
To investigate L in adolescents with PG at different stages of pubertal development with normal weight or obese and to compare it with L in a control group at the same age and BMI. To find a correlation between L and levels of sex steroids.
Methods
A total of 50 boys with PG, admitted to tertiary Pediatric endocrinology department in a single university hospital were included. They were divided into three groups according to pubertal stage: Tanner stage 2, mid pubertal stages 3-4 and a group with completed puberty. Anthropometric measurements, leptin and hormonal investigations were collected and compared with a group of 64 controls without PG matched in pubertal stage and anthropometrics.
Results
The investigation of leptin level in the three groups, matched for BMI and pubertal stage, did not prove statistically significant difference. Correlation was sought between L and sex hormones, free and biologically activeT, as well as the ratio of T and E2. Correlations were not found in all three groups of PG patients with normal weight or obese. A correlation was found in adolescents 3-4 Tanner stage in the control group with normal BMI: a strong positive between L and SHBG($r = 0{,}915$, $P < 0{,}01$) and correspondingly a strong negative correlation between L and freeT($r = -0{,}730$, $P < 0{,}05$), bioavailable T($r = -0{,}734$, $P < 0{,}05$), FAI($r = -0{,}914$, $P < 0{,}01$).
Conclusion
The presented study did not prove the role of L on development of PG, but confirmed its role on androgen levels in boys without PG.

Long term pubertal outcome of patients with prenatal diagnosis of ovarian cysts

Yannis Bonnin[1], Sarah Garnier[1], Marie-Pierre Guibal[1], Eric Dobremez[2], Aurélie Cazals[1], Benoit Tessier[1], Nadège Fauconnet Servant[1], Najiba Lahlou[3], Charles Sultan[1], Francoise Paris[1] & Nicolas Kalfa[1]
[1]Hôpital Lapeyronie, CHU Montpellier, Montpellier, France; [2]Hôpital Pellegrin, CHU Bordeaux, Bordeaux, France; [3]Laboratoire BPR-AS, PANNES, France

Prenatal ovarian cysts (POC) require close postnatal follow-up and sometimes surgery in case of complications. Long-term outcome and pubertal development have not been reported in these patients and would be useful to rationalize treatment, follow-up and parental counselling. This study aims to compare pubertal development and plasmatic AMH level of patients with POC compared to healthy controls. This prospective case-control study included patients with diagnosis of POC and healthy controls without endocrine disease. Each child underwent a clinical evaluation of pubertal development (Tanner stages, age of onset), a dosage of plasmatic AMH, LH and FSH. Early puberty was defined as thelarche before 9y and late as after 13y. 105 children were included (56 cases). Mean age was 13.8 yearsd. Mean ages of thelarche (10.85 vs 11.04, $P = 0.630$), pubarche (10.96 vs 11.03, $P = 0.860$) and menarche (12.4 vs 12.23, $P = 0.845$) were not different between cases and controls. Neither early (4 vs 2, $P = 0.643$) nor late (2 vs 7, $P = 0.080$) puberty was more frequent in case of POC. Plasmatic AMH was comparable between cases and controls (36.75 vs 39.90, $P = 0.742$), FSH and LH concentrations were not increased in cases (FSH:4.43 vs 3.87, $P = 0.31$; LH: 4.05 vs 3.37, $P = 0.38$), even in ovariectomy group (FSH:4.7 vs 3.94, $P = 0.23$; LH:4.17 vs 3.45, $P = 0.22$). Patients with POC develop a normal puberty and have levels of plasmatic AMH and gonadotropic hormones similar to controls. These data are reassuring for the pubertal outcome of these patients and that may alleviate their follow-up, at least for those without ovariectomy.

The impact of thyroid autoimmunity on clinical outcomes in euthyroid women undergoing ART: a systematic review

Michail Misirgis[1], Arriana Gkouvi[2], Gesthimani Mintziori[1], Maria Grammatikopoulou[2] & Dimitrios Goulis[1]
[1]Unit of Reproductive Endocrinology, 1st Department of Obstetrics and Gynecology, Medical School, Aristotle University of Thessaloniki, Thessaloniki, Greece; [2]Unit of Immunonutrition and Clinical Nutrition, Department of Rheumatology and Clinical Immunology, Faculty of

Medicine, School of Health Sciences, University of Thessaly, Biopolis, Larissa, Greece

Introduction
Data on whether thyroid autoimmunity negatively affects assisted reproduction outcomes in euthyroid women are conflicting: Some meta-analyses suggest antithyroid autoantibodies (ATA) negatively impact ART outcomes, while others find no effect. A closer look shows that TSH levels and the degree of ATA elevation are key factors to consider. Another crucial element is the better ART outcomes in ATA(+) women with ICSI compared to IVF. The rise of ICSI and evolving definitions of SCH may explain the trend of reduced impact of ATA in recent studies, as well as the contradictions with older studies. These opposing data have prompted us to formulate the following research question: In euthyroid women of infertile couples undergoing ART, does the presence of ATA lead to fewer pregnancies, more miscarriages, and ultimately fewer live births?.
Material and Methods
Following PRISMA guidelines, we searched PubMed, Embase, and Cochrane databases from January 2006 to April 2024 for observational studies comparing the impact of ATA on clinical outcomes in euthyroid ATA(+) vs. ATA(-) women undergoing ART, using strict inclusion and exclusion criteria. Possible confounding parameters were extracted from each study, and quality was assessed with the NOS scale. Due to variability among studies, a qualitative synthesis was employed. Desired outcomes were clearly defined, and the calculation method (based on participants, pregnancies, or total ART cycles) was carefully evaluated.
Main Results
35 studies were eligible for inclusion. Of 14 studies on the biochemical pregnancy rate, 3 found significant differences. For clinical pregnancy rate, 4 of 29 studies showed lower CPR in ATA(+) women. 1 of 6 studies on ongoing pregnancy rate found a decrease in ATA(+) women. In delivery rate, 1 of 4 studies reported a lower rate. 7 of 28 studies on miscarriage rate indicated higher MR in ATA(+) women. The live birth rate was lower in 2 of 15 studies. None of the 3 studies on cumulative live birth rate showed adverse effects. To improve comparability, studies with similar features were grouped. Emphasis was placed on studies examining cumulative live birth rate, first IVF attempt, and large sample size.
Conclusion
Most studies found no negative impact of ATA on IVF outcomes. Although some data suggest otherwise, particularly for MR, studies with larger sample sizes or those focusing on the first IVF attempt show no adverse effect of ATA. Similarly, ATA positivity does not appear to affect CLBR.

Spironolactone repurposing in the management of benign premature adrenarche with facial acne

Marianna Rachmiel[1,2], Gabby Atlas[3] & Margaret Zacharin[3]
[1]Pediatric Diabetes and Endocrinology Institute, Shamir (Assaf Haroffeh) Medical Center, Beer Yaakov, Israel; [2]School of Medicine, Tel Aviv University, Tel Aviv, Israel; [3]Murdoch Children's Research Institute, Royal Children's Hospital, Department of Endocrinology, Melbourne, Australia

Background
Premature adrenarche (PA) is common among 5-9 years old children, mainly females. The outcome is usually benign in the absence of a definable cause for androgen excess, but some patients seek management for their symptoms of hyperandrogenism, body odor, axillary or pubic hair but some experience significant distress and seek for treatment for facial acne. Management of hyperandrogenism (including acne) among pubertal and adult females includes "off label" use of spironolactone, a steroidal aldosterone antagonist. licenced for use as a diuretic but has also an anti-androgenic effect in higher doses. As such, it has been used for treatment of prepubertal acne associated with benign PA at the Royal Children Hospital, Melbourne.
Aim
To characterize those patients who received spironolactone compared to a similar population who received standard of care dermatological preparations only, or no treatment at all, and to assess their growth, puberty, short and long term outcome parameters and safety.
Methods
A retrospective case-control study included all patients diagnosed with benign PA between 2000 and 2024. Case/control ratio was 1:2. Data included clinical, growth and laboratory assessments.
Results
Study population included 8 females who were treated with spironolactone, median age 8.3 years (range 7.5,11.7), and 16 female who were not treated with spironolactone, median age 6 years (range 4.2,9.2). The spironolacton group was significantly older at presentation, $P < 0.001$. Spironolactone doses ranged from 25 to 100 mg/day, with most patients stabilizing at 50 mg/day. 75% of those treated experienced initial improvement in acne severity. However, 62.5% required additional therapies as additional topical creams, retinoic acid, oral antibiotics and oral contraceptive pill at follow-up visits, suggesting partial long-term efficacy. Minor adverse events occurred in 25% of treated patients but resolved without discontinuation. No significant electrolyte abnormalities or renal dysfunction were reported. Both groups initiated central puberty at comparable ages (mean 9.2 vs. 9.3 years), indicating that spironolactone did not delay puberty onset. Final heights aligned with mid-parental targets in both cohorts, alleviating concerns about growth suppression. The study noted that most patients stabilized at lower doses (1–1.5 mg/kg) compared to adult acne regimens (2.5 -3mg/kg), potentially balancing efficacy and safety in children.
Conclusions
spironolactone offers a viable option for benign PA-associated acne. Our findings support cautious off-label adoption, while advocating rigorous longitudinal monitoring and further prospective trials to solidify a role for spironolactone in pediatric acne management.

Efficacy of preoperative hormonal treatment in severe cases of hypospadias: a case-control study

Laura Lucaccioni[1], Anna Insalaco[2], Viola Trevisani[1], Sara Vandelli[2], Beatrice Pellesi[3], Filippo Ghidini[4], Chiara Sartori[5], Francesca Poluzzi[6], Paolo Repetto[6], Pier Luca Ceccarelli[6] & Lorenzo Iughetti[1]
[1]Department of medical and surgical science of the mother, children and adults, University of Modena and Reggio Emilia, Modena, Italy; [2]Post graduate school of Pediatrics, University of Modena and Reggio Emilia, Modena, Italy; [3]Medical School, University of Modena and Reggio Emilia, Modena, Italy; [4]Service de Chirurgie Pediatrique, Hopitaux Civils de Colmar, Colmar, France; [5]Department of Pediatrics, AUSL IRCCS Arcispedale Santa Maria Nuova, Reggio Emilia, Italy; [6]Surgical Unit, Azienda Ospedaliero-Universitaria di Modena, Modena, Italy

Background
Severe proximal hypospadias repair remains a surgical challenge due to the elevated risk of complications. Success rates vary according to the severity of the malformation, with glans width (GW) < 14 mm recognised as an independent risk factor for poor outcomes. Preoperative hormonal treatment (PHT) has been proposed to enhance penile size and improve tissue quality prior to surgery, although its efficacy and the optimal regimen of administration remain controversial. This case-control study evaluates the efficacy of a tailored PHT regimen in patients with severe hypospadias and compares surgical outcomes between patients who received PHT and those who did not.
Methods
A retrospective study of the medical records of patients with proximal (PXH) or midshaft (MSH) hypospadias who underwent surgical repair in the same centre between August 2001 and May 2024. Since June 2020 patients with GW < 14 mm and/or significant ventral curvature (> 30°) at preoperative assessment received PHT as daily treatment with 2% transdermal testosterone gel(2 mg/day) for 30–60 days, except for one patient who received topical androstanolone 2.5% due to 5alpha-reductase deficiency. Hormonal treatment was discontinued at least 1 month prior to surgery(mean 55 ± 23 days). Penile length(PL), GW, and adverse effects were recorded pre- and post-treatment by the same Paediatric Endocrinologist. Surgical outcomes and short-term postoperative complications were assessed by the same surgeon.
Results
A total of 42 patients were included: 14 received PHT (5 MSH, 9 PXH) and 28 no-PHT (10 MSH, 18 PXH). Mean age at surgery was 2.68 ± 1.75 and 2.09 ± 1.13 years, respectively (p:0.38). In the PHT group no adverse effects due to the hormonal treatment were reported. A mean increase of 45 ± 27mm(+50%) for GW and of 80 ± 42mm(+41%) for PL were measured, with a relevant Cohen's effect size for both parameters(d = 0.75 and d = 1.10, respectively). The overall complication rate (CR) between the two groups was 66% in PHT (urethrocutaneous fistula 78%, glandular dehiscence 22%) and 71% in no-PHT (urethrocutaneous fistula 75%, glandular dehiscence 15%, urethral stenosis 15%) (p:0.4), over a mean follow-up period of 31 ± 15 months. For MSX cases, CR was 20% for PHT while 50% for no-PHT.
Conclusions
PHT was found to be a non-invasive, well-accepted, and effective treatment for enhancing penile size prior to surgical repair of severe hypospadias. Although a direct

impact on complication rates could not be established for PXH, due to the reduced sample size, the improvement in MSX cases is significant.

Evaluation of cardiovascular risks in people with gender dysphoria who received gender-affirmig hormone therapy

İlkin Muradov[1], Serhat Uysal[1], Enes Karaca[1], Cem Sulu[1], Pinar Kadioglu[1] & Emre Durcan[1]

[1]Istanbul University- Cerrahpasa, Department of Endocrinology, Metabolism and Diabetes, Istanbul, Türkiye

Objective

Cardiovascular diseases are proven to be the most common cause of death in the world. A number of scoring systems have been proposed to predict this risk. The prevalence of cardiovascular disease in individuals with gender dysphoria (GD) has been investigated in many small-group studies. In this study, we aimed to assess the cardiovascular risk scores of female-to-male (FtM) GD receiving gender-affirming hormone therapy (GAHT).

Materials and Methods

This was a cross-sectional study. Individuals with GD who received GAHT for at least 1 year were included in the study. A total of 43 FtM GD who consequtively applied were included. In addition, healthy cis-men ($n = 15$) and cis-women ($n = 15$) with the same body mass index and age were included in the study. Sociodemographic data, smoking status, glucose, lipid profiles, total testosterone levels of those who received GAHT for at least 1 year were measured. The atherogenic index of plasma (AIP), atherogenic coifficent (AC) and visceral adiposity index (VAI) were calculated for each participant.

Results

The mean age of FtM GD was 29.1 $\pm$ 5.7, the mean age of cis-women was 25.7 $\pm$ 3 years and the mean age of cis-men was 25 $\pm$ 0.8 years. In the present study, the neck circumference of cis men was significantly higher than that of cis-women and FtM GD ($P = 0.005$; $P = 0.002$, respectively). In addition, the neck circumference of FtM GD was statistically higher than that of cis-women ($P < 0.001$). While there was no statistical difference between FtM GD and cis-men in terms of waist-to-hip ratio ($P > 0.05$), the waist-to-hip ratio was significantly increased in FtM GD compared to cis- women ($P < 0.001$). When comparing the waist-to-height ratio, the waist-to-height ratio was statistically significantly increased in FtM GD compared to cis-women ($P < 0.001$). FtM GD had a statistically significantly higher TG/HDL ratio than cis-women ($P = 0.006$). When comparing the groups in terms of AC, there was no statistically significant difference between cis-women and cis-men, and between cismen and FtM GD ($P > 0.05$ for all). AC was statistically significantly increased in FtM GD compared to cis- women ($P = 0.007$).

Conclusion

This study suggests that FtM GD who received GAHT may have an increased cardiovascular risk compared to cis women. Our findings emphasize the importance of routine cardiometabolic risk assessment in FtM GD who have undergone GAHT.

JOINT1124

Safety of puberty blockers and testosterone therapy for cardiovascular health in adolescents with gender dysphoria

Rheure Alves-Lopes[1], Angela Lucas-Herald[2,3] & Avril Mason[2]

[1]University of Aberdeen, Aberdeen, United Kingdom; [2]Royal Hospital for Children, Glasgow, United Kingdom; [3]University of Glasgow, Glasgow, United Kingdom

Puberty blockers (GnRH analogues) are used to delay pubertal progression in adolescents with gender dysphoria, alleviating distress associated with undesired physical changes. However, concerns about their long-term safety, efficacy, and potential irreversible effects have led to their use being halted for adolescents in the UK, except within the context of approved clinical trials. This study evaluates cardiovascular safety in adolescents on GnRH analogues, with a focus on mean blood pressure measurements obtained through ambulatory blood pressure monitoring (ABPM). Thirteen adolescents (birth-assigned: 6 males, 7 females), including 3 trans men on testosterone therapy, were assessed. Clinic systolic blood pressure (SBP) and 24-hour ABPM were measured. Analyses included comparisons between smokers and non-smokers, correlations between SBP/ABPM and BMI, and differences between trans men with and without testosterone therapy. One patient did not tolerate ABPM, and analyses were conducted for the remaining participants. Clinic SBP and 24-hour ABPM measurements were comparable between birth-assigned males and females (Clinic - Male: 124.8$\pm$1.90 mmHg *vs* Female: 125.6$\pm$2.50 mmHg; ABPM - Male: 86.22$\pm$2.54 mmHg *vs* Female: 84.63$\pm$1.47 mmHg). Smoking status (tobacco and vape) did not affect clinic SBP or 24-hour ABPM measurements (Clinic - Non-smokers: 123.12$\pm$1.52 mmHg *vs* Smokers: 129.50$\pm$3.03 mmHg; ABPM - Non-smokers: 83.57$\pm$1.66 mmHg *vs* Smokers: 88.72$\pm$1.32 mmHg). ABPM measurements showed minimal association with BMI ($R^2 = 0.31$, $P = 0.06$). Those assigned female at birth with and without testosterone therapy had similar ABPM results, including awake and asleep periods (Testosterone naive: 85.51$\pm$2.20 mmHg *vs* Testosterone: 83.46$\pm$1.54 mmHg). A nocturnal dip > 10% was observed in both those birth-assigned male and female. These findings suggest that puberty blockers and, in some cases, testosterone therapy, are safe regarding cardiovascular function in adolescents with gender dysphoria. This study offers valuable evidence supporting the cardiovascular safety of these treatments in this population and underscores the importance of further longitudinal research in larger cohorts to strengthen these conclusions.

[1]Imperial College London, Department of Metabolism, Digestion and Reproduction, London, United Kingdom; [2]Imperial College Healthcare NHS Trust, Department of Endocrinology, London, United Kingdom; [3]Imperial College London, Department of Computing, London, United Kingdom; [4]University College Hospitals NHS Foundation Trust, London, United Kingdom

Introduction

Adipokines, such as leptin and adiponectin, are secreted from adipose tissue and signal to the hypothalamus to indicate sufficient energy availability, which is requisite for reproductive health. Leptin is a permissive signal for hypothalamic GnRH function. Functional hypothalamic amenorrhoea (FHA) is caused by insufficient energy availability and is a low leptin state. Indeed, leptin administration restores pulsatile LH secretion in FHA. Conversely, adiponectin levels decrease with bodyweight, especially central obesity with associated insulin resistance. Polycystic ovary syndrome (PCOS) is strongly associated with insulin resistance and central adiposity. Herein, we directly compare circulating leptin and adiponectin concentrations in women presenting with oligo/amenorrhoea due to either FHA or PCOS.

Methods

Women aged 18-35yrs were classified as Healthy ($n = 47$), FHA ($n = 44$), or PCOS ($n = 73$; stratified by BMI as lean [BMI: $<25 kg/m^2$; $n = 33$], overweight [BMI:25-30kg/m^2; $n = 15$] or obese [BMI: $>30 kg/m^2$; $n = 25$]). Serum adiponectin and leptin were measured by DELFIA assay. Insulin and glucose were collected following an 8-hour overnight fast. Reproductive hormones were collected during the follicular phase, or following a progesterone-induced bleed in PCOS. Groups were compared by Kruskal-Wallis and associations assessed by linear regression.

Results

Leptin was positively related to BMI in all groups, whereas adiponectin was negatively related to BMI only in Healthy and PCOS groups. Despite similar BMI (Healthy 21.2, FHA 20.4, Lean PCOS 21.1kg/m^2), women with FHA had lower leptin and higher adiponectin levels. Median (IQR) leptin (ng/ml) was: Healthy 12.50 (5.80-18.25), FHA 5.20 (3.05-8.78), Lean PCOS 8.90 (6.40-17.10) ($P < 0.0001$); and adiponectin (mg/ml) was: Healthy 9.90 (7.80-13.30), FHA 14.05 (10.98-17.10), Lean PCOS 9.20 (7.10-10.90) ($P < 0.0001$). Women with FHA were more insulin sensitive than Healthy and Lean PCOS groups (HOMA-IR 0.63 vs 1.05 and 0.94 respectively, $P = 0.002$). Adiponectin was inversely associated with HOMA-IR in Healthy ($r = -0.06$; $r^2 = 0.25$, $P = 0.002$) and PCOS ($r = -0.14$; $r^2 = 0.18$, $P = 0.0004$), but this relationship was reversed in FHA ($r = +0.04$;

$r^2=0.18$, $P = 0.013$). Adiponectin was inversely associated with free androgen index (FAI) (r=-0.32; $r^2=0.11$, $P = 0.005$), whereas leptin was positively associated with FAI (r=+0.06; $r^2=0.22$, $P < 0.0001$) in PCOS. Adiponectin was positively associated with LH in PCOS (r=+0.26; $r^2=0.14$, $P = 0.001$), but not in FHA. Leptin was positively associated with LH (r=+0.09; $r^2=0.14$, $P = 0.014$) and oestradiol in FHA (r=+1.27; $r^2=0.14$, $P = 0.012$), but negatively associated with LH in PCOS (r=-0.03; $r^2=0.10$, $P = 0.007$).

Conclusion

These data highlight the divergent interaction between adipokines and reproductive/metabolic markers in women with FHA and PCOS, providing novel insights into the value of adipokines in the assessment of women with oligo/amenorrhoea.

Pharmaceutical disruption of steroidogenesis

Guillaume Ollitrault[1], Cecilie Hurup Munkboel[2], Karine Audouze[3], Malene Louise Johannsen[4], Zakariya Ur Rehman[2], René Jørgensen[5], Olivier Taboureau[1], Bjarne Styrishave[2] & David Kristensen[6]
[1]Inserm U1133, CNRS UMR 8251, Université Paris Cité, Paris, France; [2]University of Copenhagen, Copenhagen, Denmark; [3]Inserm U1133, CNRS UMR 8251, Université Paris Cité, Paris, France, Paris, France; [4]Copenhagen University Hospital - Rigshospitalet, Copenhagen, Denmark; [5]Roskilde University, Copenhagen, Denmark; [6]Roskilde University/Copenhagen University Hospital - Rigshospitalet, Roskilde, Denmark

Concern has been raised over negative endocrine side-effects of synthetic chemicals, as active pharmaceutical ingredients (APIs), on the health of humans. While studies have investigated side-effects of APIs in humans and animals, these employed different analytical methods, measured different endpoints, investigated only one or few APIs together and often overlooked their direct effect on hormonal production. This makes it difficult to assess the scale of the problem that APIs might have on endocrinology. Additionally, comparing existing data from different studies is often challenging due to differences in analytical methodologies, such as hormone quantification techniques or the use of different model systems. Here, we present findings from a comprehensive investigation on the effects of APIs on human steroidogenesis, the quintessential hormonal pathway at the center of endocrinology. We examined the effects of 70 APIs, representing all major pharmaceutical classes used worldwide, on 16 hormones involved in steroidogenesis at physiological relevant concentrations. Our analysis identified five distinct clusters of APIs based on their effects on steroidogenesis, with only 17 APIs showing no impact. The initial enzyme in steroidogenesis, CYP11A1, was identified as the most concerning target due to its promiscuity in binding lipophilic and nitrogen-rich compounds, including prevalent pharmaceutical classes such as fungicides, antidepressants, antibiotics, and lipid-lowering statins. As pharmaceutical use continues to rise and environmental pollution with APIs becomes more pervasive, these findings show that APIs might pose a significant threat to humans through the disruption of steroidogenesis at physiological relevant doses.

The role of autocrine androgen signalling for leydig cell function

Tessa Kazubek[1], Natalie Taege[1], Alexandra E. Kulle[2], Paul-Martin Holterhus[3], Jens Mittag[1] & Isabel Viola Frielitz-Wagner[4]
[1]University of Lübeck, Center of Brain Behavior and Metabolism, Institute of Experimental Endocrinology, Lübeck, Germany; [2]University Hospital Schleswig-Holstein, Department for Pediatric Oncology and Rhematology, Division of pediatric Endocrinology and Diabetes, Kiel, Germany; [3]University Hospital Schleswig-Holstein, Kiel, Germany; [4]Childrens Hospital University Hospital Schleswig-Holstein, Campus Lübeck, Lübeck, Germany

Introduction

Patients with CAIS have a genetic defect in the androgen receptor, resulting in an external female genitalia with the presence of intra-abdominal testicles. While these testes do not exhibit functional spermatogenesis, they seem to serve as an important source of steroid hormones that also induce puberty. However, it remains unclear in how far the defective AR-mediated signalling impacts Leydig cell steroidogenic activity and function.

Research Aim

Here we aim to characterize the production of steroid hormones in a Leydig cell line and the responsiveness to different stimuli to establish a robust model system to test possible autocrine mechanisms.

Material and Methods

The MLTC-1 cell line was stimulated with progesterone, 8-Br-cAMP, hCG, LH, and a combination of LH and hCG or inhibited with ketoconazole. Moreover, the cells were transfected with plasmids encoding a dominant negative androgen receptor as well as enzymes affecting steroid production. Supernatants were collected at 4 and 24 hours post-stimulation, and androgen concentrations were quantified using liquid chromatography–mass spectrometry (LC-MS). Additionally, RNA and protein expression of steroidogenic enzymes were analysed 24 hours after stimulation.

Results

Stimulation of MLTC-1 cells generally resulted in a significant increase in androgen concentrations at the 4-hour time compared to 24 hours, suggesting that the initial stimulatory effect diminishes over time. Stimulation with LH exhibited the most pronounced effect, increasing androgen concentrations in the supernatant 50-fold compared to untreated control cells. In contrast, progesterone and 8-Br-cAMP did not induce a significant increase in androgen production. The inhibitor ketoconazole, however, effectively reduced androgen concentrations at 1 μM and 10 μM without compromising cell viability, whereas 100 μM negatively impacting cell growth. Transfection with plasmids expressing a dominant negative androgen receptor or enzymes modulating steroid hormone production demonstrated that the steroid profile could be successfully modulated in these cells.

Conclusion and Outlook

Our findings demonstrate that MLTC-1 cells can be used as a robust Leydig cell model for steroidogenesis, as evidenced by their responsiveness to LH. Moreover, transfecting these cells as a first step towards a gene therapy to modulate steroid production in CAIS patients is generally feasible.

Fertility information needs in adult survivors of childhood cancer - first results of the FeProCAYA study

Miriam Wilhelm[1], Karamdeep Khinda[2], Tana Dornbrach[2], Klaus Hönig[2], Karin Bundschu[3], Katharina Hancke[3], Martin Wabitsch[4] & Christian Denzer[1]

Background

Endocrine late effects impacting reproductive function are a major concern for childhood cancer survivors. Despite increasing research, significant knowledge gaps persist regarding thresholds and risk factors for hypogonadism, genetic predispositions, fertility preservation efficacy, and the role of communication and decision-support tools.

Methods

FeProCAYA, a cohort study within the FePro-Ulm research center at the University Medical Center Ulm (funded by the Federal Ministry of Education and Research, BMBF), examines fertility risks in individuals treated for childhood and adolescent conditions associated with impaired adult fertility. This analysis assessed endocrine late effects, fertility-related quality of life (WHOQOL-BREF), and reproductive concerns (RCAC) in long-term childhood cancer survivors ($\geq$20 years post-diagnosis) via an online questionnaire.

Results

From clinical records, 225 eligible survivors (diagnosed $<$18 years) who received potentially gonadotoxic treatment at the University Medical Center Ulm between 1999 and 2004 were identified. Of these, 169 with valid postal addresses were invited to participate, and 51 (30 female; response rate 30.2%) completed the survey. The median age was 28.0 years (range 20–40), with a median follow-up of 23.0 years (range 20–26). Endocrine conditions were self-reported by 60.8% ($n = 31$), most commonly hypothyroidism ($n = 15$), osteoporosis/repeated fractures ($n = 12$), sex hormone replacement ($n = 6$), and growth hormone deficiency ($n = 4$). A BMI $\geq$25 kg/m^2 was reported by 41.2% ($n = 21$). While 21.6% ($n = 11$) had children, 66.7% ($n = 34$) expressed significant fertility concerns, and 62.8% ($n = 32$) reported unmet information needs regarding fertility after cancer. Notably, only 49% ($n = 25$) recalled receiving fertility counseling before treatment or during follow-up care.

Conclusions

Structured and repeated reproductive health counseling during long-term follow-up may help address unmet information needs and improve fertility-related quality of life in childhood cancer survivors, a population already facing a high disease burden.

Effect of FSH therapy on semen parameters in male idiopathic infertility: a real-life experience

Valeria Lanzi[1,2], Arianna Cremaschi[1], Rita Indirli[1,2], Giulia Carosi[1,2], Giovanna Mantovani[1,2] & Emanuele Ferrante[1]
[1]Fondazione IRCCS Ca' Granda Ospedale Maggiore Policlinico, Endocrinology Unit, Milan, Italy; [2]University of Milan, Department of Clinical Sciences and Community Health, Milan, Italy

Introduction
Infertility is the inability to conceive following one year of unprotected intercourse. About 30% of cases are related to male factors alone, and in 30% of these no specific cause for subnormal semen parameters can be found. However, a meticulous diagnostic process is essential before diagnosing the patient as having idiopathic infertility. The use of FSH treatment has been suggested in idiopathic infertile men with FSH plasma levels < 8 IU/lto increase sperm quantity and quality and pregnancy rate.
Methods
Twenty-three males with idiopathic infertility were assessed. Data on specific causes of infertility and genetic, environmental and lifestyle risk factors for infertility were investigated, along with basal hormonal and semen parameters. Patients with FSH plasma levels < 8 IU/l,oligo/asthenozoospermia and no seminal tract obstruction were treated with FSH. New semen analyses were assessed three and six months after treatment in 18 and 6 patients, respectively.
Results
Mean age of the 23 enrolled patients was 37.4 ± 4.8 years. We evaluated risk factors for infertility and found that 5 patients (21.7%) were current smokers, 10 (43.5%) had BMI ≥ 24.9 kg/m^2, 4 (17.4%) had either impaired fasting glucose or diabetes. 12 patients (52.2%) had sonographic evidence of varicocele (10 $\leq$ II grade, 2 III grade), furthermore 4 underwent surgical correction. Median testosterone levels were 4.62 ng/ml (IQR 4.0-5.8). Baseline semen analysis showed that 20 patients (86.9%) had oligozoospermia [median spermatozoa concentration: 4.6×10^6/ml (IQR 1.2-13); median total number: 16.2×10^6 (IQR 5.1-32.7)]; 21 (91.3%) had asthenozoospermia [median total motility: 26% (IQR 12-37)]; 22 (95.6%) ha teratozoospermia. Patients were treated with FSH 150 UI 3 times per week. After 3 months of treatment there was no statistically significant improvement in semen parameters. Six patients were evaluated after 6 months of treatment and showed an improvement in semen parameters, although not significant probably due to the small sample size [median spermatozoa concentration: 8.1×10^6/ml (IQR 1.9 – 14.9)($P = 0.46$); median total number: 24.6×10^6 (IQR 6.5-47.5)($P = 0.46$); median total motility: 43% (IQR 30.8-60.5) ($P = 0.71$)].
Conclusion
The careful search for factors related to altered semen parameters could reduce the number of men diagnosed as having idiopathic infertility, allowing better management in the clinical practice. Our data, even though on a limited number of patients, seem to suggest that prescribing FSH therapy for more than 3 months could lead to an improvement in semen parameters. Further studies on larger series are needed.

Impact of thyroid autoantibodies on ovarian reserve and embryo quality in euthyroid women undergoing assisted reproductive technology

Chiara Sabbadin[1], Alice Sorgato[1], Mirvana Gjergji[2], Elena Pagin[1], Luciana Bordin[2], Eugenio Ragazzi[3], Caterina Mian[1], Loris Marin[2] & Alessandra Andrisani[2]
[1]Endocrine Unit, University Hospital of Padua, Padua, Italy; [2]University Hospital of Padua, Department of Women's and Children's Health, Padua, Italy; [3]University of Padua, Department of Pharmaceutical and Pharmacological Sciences, Padua, Italy

Introduction
The impact of thyroid autoimmunity on female fertility and assisted reproductive technology (ART) outcome is still controversial.
Aim
The aim of this study was to evaluate the impact of thyroid autoantibodies (TAA) on ovarian reserve, ovarian response and oocyte quality in euthyroid infertile patients undergoing ART.
Material and Method
Retrospective study on 294 women undergoing ART at the University Hospital of Padua. Every patient underwent to the evaluation of FSH, LH, 17β-estradiol, TSH, free thyroxine (fT4), anti-thyroid peroxidase antibody (anti-TPO), anti-tireoglobulin antibody (anti-TG) and anti-Müllerian hormone (AMH) on the 2nd–5th day of menstrual cycle. In the same moment, pelvic sonography was performed to estimate antral follicle count (AFC). All patients underwent a standardized controlled ovulation stimulation (COS) process and the number and quality of retrieved oocytes was evaluated. Exclusion criteria: TSH >4 mUI/L; previous or concomitant medications for thyroid disease.
Results
The mean age of the patients was 37.6 years and the BMI was 23.7 kg/m^2. Three patients with TSH>4 mUI/lwere excluded. Of the 199 patients undergoing CS, 42 presented at least one thyroid autoantibody (TAA+): 22 were positive for both TAA, 6 for anti-TG only, 14 for anti-TPO only. Based on Bologna criteria, 60% were normo-responders, 19% poor-responders, and 21% high-responders. A total of 1348 oocytes was retrieved, including 285 in patients with TAA+ and 1063 in patients with negative antibodies (TAA-). Comparison of normo, poor and high-responders showed no statistically significant differences in BMI and TTA positivity. Considering the two groups TAA+ and TAA-, no statistically significant differences emerged for AMH levels, AFC, total oocyte count and rate of mature oocytes at pick-up. TSH was higher on average in the TAA+ group than in the TAA-. AMH and AFC values were significantly lower in patients with anti-TPO only compared with those with anti-TG only. In contrast, there was no evidence of a difference in the number of total and mature oocytes according to TAA positivity.
Conclusions
The presence of anti-TPO is associated with a decreased ovarian reserve, but it seems to be not correlated to a poor response in ART. Further studies are needed to better evaluate the impact of anti-TPO on female fertility and ART outcomes.

Body proportions, hypothalamic-pituitary-gonadal function, testicular morphology and the risk for gonadal malignancy in males with 46,XX testicular DSD and 47,XXY Klinefelter syndrome

Julia Rohayem[1], Mirkka Hiort[2], Joachim Wistuba[3], Agnethe Berglund[4], Claus H. Gravholt[5] & Jörg Gromoll[6]
[1]Children's Hospital of Eastern Switzerland, St.Gallen, Department of Clinical and Surgical Andrology, Centre of Reproductive Medicine and Andrology, University of Münster, Münster, Germany, St.Gallen, Switzerland; [2]Department of Plastic Surgery, University of Münster, Münster, Germany, Department of Plastic, Reconstructive and Aesthetic Surgery, Fachklinik Hornheide, Münster, Germany, Münster, Germany; [3]Department of Clinical and Surgical Andrology, Centre of Reproductive Medicine and Andrology, University of Münster, Münster, Germany, Münster, Germany; [4]Department of Molecular Medicine, Aarhus, Denmark, Department of Clinical Genetics, Aarhus, Denmark., Aarhus, Denmark; [5]Department of Clinical Medicine, Aarhus University, Aarhus, Denmark., Department of Endocrinology, Aarhus, Denmark, Aarhus, Denmark; [6]Department of Reproductive and Regenerative Biology, Centre of Reproductive Medicine and Andrology, University of Münster, Münster, Germany, Münster, Germany

Background
Individuals with 46,XX testicular DSD (T-DSD) and 47,XXY Klinefelter syndrome (KS) have a male phenotype, but sex chromosome aneuploidy with a supernumerary X chromosome. In contrast to KS, T-DSD males lack a major part of the Y chromosome. In both conditions, testicular dysgenesis leads to hypogonadism with infertility. While biological paternity can be achieved in a subset of KS men using assisted reproductive technology, this is impossible in men with T-DSD, where spermatogenesis cannot take place due to the absence of the Y chromosomal AZF region.
Aim of the study
To gain insight into the effects of X-linked supernumerary genes with and without additional Y-chromosomal gene deficiency on human body proportions, hypothalamic-pituitary-gonadal (HPG) axis function, testicular morphology and the risk of gonadal malignancy.
Patients and Methods
Retrospective and cross-sectional data from ($n = 50$) males with T-DSD aged 14-67 years and ($n = 91$) males with KS were evaluated, including medical history data, anthropometric and hormonal data, testicular ultrasound imaging and histological images of testicular biopsies.
Results
Men with T-DSD had a shorter stature than predicted from parental target height (TH). In contrast, final height of the KS men exceeded their TH. Both males with T-DSD and KS had significantly reduced testicular volumes and ultrasound

imaging of their testes showed reduced echogenicity of the gonadal parenchyma, with multiple hypoechogenic areas in older men. Biopsies from these areas within the testes evidenced benign Leydig cell hyperplasia. There were no cases of testicular malignancies observed in either cohort. Hypergonadotropic hypogonadism developed during adolescence in both conditions, with decompensation of testicular endocrine function occurring at different times in life. LH serum concentrations were inadequately low for serum testosterone concentrations mainly in older men with T-DSD. The vast majority of T-DSD males had Inhibin B concentrations below the detection limit at any age, in contrast, Inhibin B was measurable in some young KS males.
Conclusions
Final height in males with T-DSD and KS does not result from hypogonadism, which occurs similarly in both conditions, but rather from the absence or presence of Y chromosomal genes. In both KS and T-DSD, decompensation of endocrine testicular function occurs at variable times in the course of life, but a relative central HPG axis deficiency contributes to this only in T-DSD. Focal areas of reduced echogenicity within the testes of men with KS and TDSD on ultrasound are not indicative of malignancy but correspond to clusters of hyperplastic Leydig cells.

What can we learn from the largest north african cohort of testicular disorders of sex development?

Hamdi Frikha[1], Nesrine Dhieb[1], Khouloud Boujelben[1], Yesmine Elloumi[1], Dhoha Ben Salah[1], Mouna Mnif[1], Hassen Kamoun[2], Mohamed Abid[1], Mouna Elleuch[1] & Nabila Rekik Majdoub[1]
[1]Hedi Chaker University Hospital, Endocrinology, Sfax, Tunisia; [2]Hedi Chaker University Hospital, Human Genetics, Sfax, Tunisia

Introduction
Testicular disorders of sex development (T-DSD) represent a heterogeneous group of congenital anomalies affecting sexual differentiation. In North Africa, these conditions have long been underexplored due to limited access to genetic analysis. This study aims to describe the epidemiology, phenotypic characteristics, and genetic features of T-DSD in this region.
Methods
We conducted a cross-sectional descriptive study including patients diagnosed with DSD and confirmed testicular tissue, followed at the endocrinology reference center in southern Tunisia. All patients underwent clinical assessment of sexual maturation using Tanner and Prader staging, as well as steroid hormone profiling. Genetic analysis was performed using next-generation sequencing (NGS) at the genetics department.
Results
We identified 50 North African patients from 40 families, with two-thirds of cases involving consanguineous unions. The most common etiologies were testosterone biosynthesis defects (38%) and gonadal dysgenesis (32%). The mean age at first consultation was 17.98 ± 11.89 years (range: 1 day–60 years), with no significant difference between etiological subgroups. The most frequent reason for medical consultation was primary amenorrhea (62%), except in 46,XX DSD cases. Complete pure gonadal dysgenesis showed a strong phenotypic correlation with mutations in key sex differentiation genes (SRY and NR5A1), whereas partial pure gonadal dysgenesis exhibited variable male phenotypes associated with MAP3K1 mutations. Androgen receptor abnormalities (AIS: 10%; 5α-reductase deficiency: 12%) presented with diverse phenotypes, with genotype-phenotype correlation established only for the R753X mutation in the AR gene. Patients with testosterone biosynthesis defects showed variable phenotypic expression, but specific traits such as pubertal virilization suggested 17βHSD3 deficiency in which we proved the founder effect for the C206X mutation. Strong phenotype-genotype correlation was observed only in cases of LH resistance. In 46,XX T-DSD cases ($n = 3$), the degree of masculinization was dictated by the presence of the SRY gene.
Discussion
Testicular DSDs represent a heterogeneous group of disorders. In our cohort, testosterone synthesis defects were the most predominant category, likely due to the high incidence of consanguinity. Unlike larger pediatric series, our cohort primarily included peri-pubertal individuals. Clinical presentation was highly variable but could be guided by static and dynamic hormonal assessments. Molecular analysis has become essential, though sometimes insufficient. Our findings on phenotype-genotype correlations aligned with the literature for CAIS, LH resistance, complete gonadal dysgenesis, 17βHSD3 deficiency, and XX DSD. However, we refuted a previously suggested correlation for the MAP3K1 gene mutation.

Genotype-phenotype correlation of patients with androgen insensitivity syndrome: a cohort study including 9 families

Ilknur Kurt[1], Senol Demir[2], Zehra Yavas Abali[1], Bilgehan Bilge Geckinli[2], Serap Turan[1], Abdullah Bereket[1] & Tulay Guran[1]
[1]Marmara University School of Medicine, Department of Pediatric Endocrinology, Istanbul, Türkiye; [2]Marmara University School of Medicine, Department of Medical Genetics, Istanbul, Türkiye

Background
Androgen Insensitivity Syndrome(AIS) is an X-linked disorder and the most common cause of disorders/differences of sexual development(DSDs) in individuals with a 46, XY karyotype. AIS is classified into complete(CAIS), partial(PAIS), and mild(MAIS) forms based on clinical and genetic findings. Phenotypic expression varies from normal female external genitalia in complete CAIS, to normal male genitalia with infertility or gynecomastia in MAIS. The phenotype may be variable in PAIS including incomplete virilization. This study aimed to evaluate the clinical and genetic characteristics of AIS.
Materials and Methods
The data about the medical history, and clinical examination were recorded from the patient files. Chromosomal analysis was performed in all. Next-generation sequencing(NGS) was performed using the *SOPHIA*™ Clinical Exome Solution(CES) v3 and Illumina NovaSeq platform, covering 6,300 genes.A custom gene panel targeting 24 genes associated with XY DSD was analyzed using the Sophia DDM platform. The study included 15 patients from 9 families with hemizygous variants in the *AR* gene (NM:000044.6).
Results
Among 15 patients, seven presented with a female external genital phenotype, six showed incomplete virilization, and two siblings had unique presentations(one with undescended testes, the other with oligoasthenospermia). The consanguinity ratio was 27%. Based on molecular genetic analysis,7 patients were classified as PAIS, 6 as CAIS, and 2 as MAIS. Four patients with CAIS presented with primary amenorrhea, and two were diagnosed after testicular tissue was observed during hernia surgery. All were assigned as female, and five of them underwent gonadectomy in the pubertal period. Frameshift variants[c.1625_1629dup, p.(Arg544Leufs20)($n = 2$, novel); c.1890del, p.(Lys631Serfs*2*)($n = 2$)] and nonsense variants [c.1921C>T, p.(Gln641*)($n = 1$, *novel*); c.1605C>G, p.(Tyr535*)($n = 1$)]were identified in the CAIS group. In PAIS, four presented in the neonatal period with incomplete virilization, while three presented with pubertal virilization. Neonatal cases were assigned male gender, while pubertal cases transitioned from female to male. All patients with PAIS had microphallus, undescended testes, and four had hypospadias, and all underwent orchiopexy. Missense variants [c.2134C>G, p.(Gln712Glu)($n = 4$), c.1794C>A, p.(Ser598Arg)($n = 1$,*novel*), c.1789G>A, p.(Ala597Thr) ($n = 1$)] were identified. One of the patients with peviously reported c.2072A>G, p.(Asp691Gly) variant was presented with complete female phenotype. Two siblings had the MAIS phenotype and one of them presented with undescended testes, while the other had oligoasthenospermia. Both patients were reared as male gender.A missense variant [c.1174C>T, p.(Pro392Ser) ($n = 2$)] was detected. Elevated Anti-mullerian hormone concentrations were detected in pubertal patients except the patients with oligoasthenospermia only.
Conclusion
The combined evaluation of genetic and clinical characteristics is critical for diagnosing and managing AIS and underscores the importance of individualized patient care. Our study identified 9 variants, including 3 novel ones, contributing to the understanding of phenotypic variability of the AIS.

JOINT3432

Impact of gender-affirming hormone therapy on cardiovascular risk in transgender individuals

Esra Eraslan Aydemir[1], Rifat Emral[1] & Asena Gökçay Canpolat[1]
[1]Ankara University Faculty of Medicine, Endocrinology and Metabolism, Ankara, Türkiye

Introduction
Transgender people receive hormone treatments of the opposite sex during the transition process. There are many studies showing that the cardiovascular risks of individuals change as a result of this transition process. It is well-known that

transgender individuals have changes in body composition, body fat distribution, and cardiovascular lipid profile.
Methods
Records of 81 female-to-male and 19 male-to-female patients over the age of 18 who applied to the endocrinology and metabolic diseases outpatient clinic of Ankara University Faculty of Medicine between 2018-2024 were reviewed. We aimed to investigate whether there is a change in cardiovascular risk in both transgender men and women during the transition process using some simple laboratory indices. Lipid parameters requested before treatment and at the 3rd, 6th, and 12th months of treatment, as well as during final follow-ups, were analyzed for transgender men receiving testosterone therapy.
Results
Of the 100 patients evaluated, 81 (81%)were transgender male whereas 19 (19%) were transgender female. The average age at first hospital admission was 22.45 years (SD: 4.425), and the average age at which symptoms were first noticed was 10.3 years (SD: 3.65). Based on this data, there was an average delay of 12.1 years between the onset of symptoms and seeking medical help. Among the 81 patients applying for female-to-male transition, 22 (27.1%) reported using a testosterone preparation obtained independently, without medical supervision. Additionally, 16 patients (19.7%) underwent mastectomy before the transition process upon their own decision, and 2 patients (2.49%) had undergone hysterectomy before transitioning. For evaluating cardiovascular risk profiles of the transgender male, Castelli risk index-1 (Total cholestrol/HDL-C), cardiac risk ratio-II (LDL/HDL-C), and triglyceride/HDL ratios were analyzed before treatment and during follow-up. The total cholesterol/HDL ratio was found to have increased significantly ($P = 0.016$), the LDL/HDL ratio also showed a significant increase ($P = 0.03$), while the triglyceride/HDL ratio did not show a statistically significant change ($P = 0.887$).
Conclusion
We found an increase in Castelli 1 Risk Score and CRI-II, but no difference in tg/HDL-C in transgender males after testosterone therapy. It is known that gender-affirming masculinization treatments can lead to elevated blood pressure, changes in lipid profiles, and increased hematocrit levels, thereby raising cardiovascular risks. This suggests that these young individuals who will receive long-term testosterone therapy should be carefully monitored for other cardiovascular risks throughout their lives, and appropriate medical agents should be used if necessary.

Raised sex hormone binding globulins levels in men: a retrospective observational study

Syeda Safa Fatima[1], Aviral Batra[1], Alan Dodd[1] & Atul Kalhan[1]
[1]Royal Glamorgan Hospital, Cwm Taf Morgannwg University Health Board, Endocrinology & Diabetes, Llantrisant, United Kingdom

Introduction
Sex hormone binding globulins (SHBG) are glycoproteins synthesized in liver, which have high specificity and affinity to bind with sex steroids. Raised levels of SHBG are observed in thyrotoxicosis, hepatic disease, anorexia, growth hormone deficiency and rarely due to oestrogen secreting tumours. Aging and medications (e.g. cytochrome P450 enzyme inducers) are also associated with an increase in SHBG levels.
Objectives
We carried out a retrospective analysis of all the raised SHBG test measurements in men (aged $>$ 18 years), recorded and logged in our University teaching hospital over last 10-years (2014-2024). The primary objective of this observational study was to ascertain possible underlying cause of raised SHBG levels in this cohort apart from registering the final clinical outcome.
Methodology
The existing biochemistry data based was searched for all the raised SHBG test results in men (aged $>$ 18-years) over last 10-years irrespective of their serum testosterone levels. A retrospective analysis of case notes and biochemical & radiological investigation results available on clinical portal was carried out.
Results
We retrieved a list of 123 raised SHBG test results over a period of 10-years in men aged 20-83 years. After excluding the duplication of test results, a total of 45 men ($n = 45$) were included in the final analysis. Table 1, sums up the key observations of our retrospective study:.
Conclusion
Hepatic dysfunction, hyperthyroidism, aging and iatrogenic factors remain well known contributory factors for raised SHBG levels. Oestrogen secreting tumours have been described in literature as rare though important pathology which need to be kept in mind while evaluating men with high SHBG levels. Contrary to what has been described in medical literature, we observed anabolic steroid use associated with raised SHBG levels in 5 of our patients (and the SHBG levels normalized after stopping the anabolic steroids).

Table 1: Underlying etiology of increased SHBG.

Underlying Etiology	Number(n)
Hepatic dysfunction	12
Medications (including carbamazepine, phenytoin)	8
Hyperthyroidism	5
Anabolic steroid use	5
Type 1 Diabetes (no other cause)	3
Nutrional deficiencies related to previous gastro-intestinal surgery	2
Transgender man undergoing transition therapy	1
Immunoassay analytical interference	1
An increased age	3
No known etiology	5

Free testosterone and shbg play independent roles in insulin resistance and metabolic alterations of women with pcos

Maria Giovanna Lando[1], Flavia Tosi[1], Veronica Gremes[1], Federica Rosmini[1], Federico Lucarini[1], Tom Fiers[2], Bruno Lapauw[2], Jean-Marc Kaufman[2] & Paolo Moghetti[1]
[1]University of Verona and Azienda Ospedaliera Universitaria Integrata Verona, Endocrinology, Diabetes and Metabolism, Verona, Italy; [2]Ghent University Hospital, Departments of Clinical Chemistry and Endocrinology, Ghent, Belgium

Context/Object
The relationship between hyperandrogenemia and metabolic abnormalities in women with polycystic ovary syndrome (PCOS) is still object of study. The biological effects of testosterone are modulated by SHBG, a protein, regulated by several factors, which binds circulating testosterone and regulates its bioavailability. Both the increase of free testosterone (FT) and the reduction of SHBG have been associated with insulin resistance and metabolic alterations. Whether SHBG may play an independent role in this phenomenon is still unclear, and the use of SHBG in FT calculation makes this analysis very difficult. Aim of this study was to investigate potential differences in the relationships of SHBG and FT with the metabolic, hormonal and phenotypic features of PCOS, using a measurement of serum FT independent of SHBG assay.
Study design and Subjects. Cross-sectional study including 280 women with PCOS diagnosed by the Rotterdam criteria.
Methods
FT was measured by equilibrium dialysis with subsequent direct assay of the hormone by LC-MS/MS on the dialysate. Total testosterone and androstenedione were assayed by LC-MS/MS. Insulin sensitivity was measured by the hyperinsulinemic euglycemic clamp.
Results
Both SHBG and FT showed statistically significant and opposite relationships with anthropometric and metabolic parameters. Categorizing women with PCOS on the basis of their SHBG and FT levels (normal SHBG/normal FT, $n = 74$; low SHBG/normal FT, $n = 39$; normal SHBG/high FT, $n = 39$; low SHBG/high FT, $n = 128$), the two subgroups with low SHBG, and either normal or high FT, had worse anthropometric and metabolic profiles than subjects with normal SHBG/normal FT. This phenomenon was especially enhanced in women with low SHBG/high FT. Conversely, the subgroup with normal SHBG/high FT differed from women with normal SHBG and normal FT only for higher fasting insulin. In multivariable analysis, age, fat mass, insulin sensitivity and FT were all independent predictors of SHBG, whereas only insulin sensitivity and SHBG, but not fat mass, were independent predictors of FT. After adjusting data for age and fat mass, both FT and SHBG were independent predictors of insulin sensitivity. Moreover, in logistic analysis, the presence of metabolic syndrome was independently predicted by SHBG, but not by FT.
Conclusions
In women with PCOS, low SHBG and high FT levels are independently associated with insulin resistance, and the coexistence of these features enhances metabolic abnormalities.

Severe obstructive sleep apnea syndrome and continuous positive airways pressure therapy impact on testosterone levels in male patients with severe obesity

Alessandro Amodeo[1], Nicoletta Del Duca[2], Alessandro Chilà[1], Antonio Musolino[1], Ilinka Garavaglia[1], Elisa Delle Donne[1], Ilaria Gentile[1], Silvia Federici[1], Luca Persani[1,3], Massimo Scacchi[4,5], Marco Bonomi[1,3] & Biagio Cangiano[1,3]
[1]University of Milan, Department of Medical Biotechnology and Translational Medicine, Milan, Italy; [2]Istituto Auxologico Italiano, IRCCS, Division of General Medicine, Ospedale San Giuseppe, Oggebbio-Piancavallo, Verbania, Italy; [3]Istituto Auxologico Italiano, IRCCS, Division of Endocrine and Metabolic Diseases, Milan, Italy; [4]University of Milan, Department of Clinical Sciences and Community Health, Milan, Italy; [2]Istituto Auxologico Italiano, IRCCS, Division of General Medicine, Ospedale San Giuseppe, Oggebbio-Piancavallo, Verbania, Italy

Background
To date, the relationship between Obstructive Sleep Apnea Syndrome (OSAS) and testosterone levels in males has not yet been fully elucidated. Some studies reported a correlation between severe OSAS and hypogonadism in patients with obesity, regardless of body mass index (BMI). However, few data from longitudinal studies show the effect of continuous positive airways pressure (CPAP) on gonadal function.
Aim
To investigate the factors related to low testosterone levels in a large cohort of males with severe/complicated obesity, the role of the OSAS in the diagnosis and severity of hypogonadism, and the effects of ventilation therapy on hormonal status.
Subjects and methods
210 male inpatients with grade II (BMI $\geq$ 35 Kg/m^2) complicated or grade III (BMI $\geq$ 40 Kg/m^2) obesity were included in this cross-sectional study. Polysomnography or overnight oximetry and blood tests for inflammation indices, metabolic and hormonal profiles were performed during admission. Decompensated OSAS was defined as Apnea/Hypopnea Index (AHI) in newly diagnosed, or Oxygen Desaturation Index (ODI) in treated patients, above 30 events/hour. Univariate analyses were performed to investigate the conditions related to the decrease in testosterone levels (inflammation, diabetes, eating disorders, waist circumference, previous diagnosis of OSAS, decompensated OSAS). A logistic regression and a multiple linear regression were carried out to identify the independent factors associated with hypogonadism (i.e. testosterone $\leq$ 10.4 nmol/l)and to continuous testosterone levels respectively. Lastly, a prospective longitudinal study of 15 newly diagnosed patients was performed to evaluate the effects of CPAP therapy on hormonal control after 3-6 months of treatment.
Results
130 out of 210 patients showed low testosterone levels. Type 2 diabetes mellitus and C-reactive Protein (CRP) were independently associated with hypogonadism (p-value 0.03 and 0.01, respectively). The correlation between decompensated OSAS and hypogonadism was significant in the univariate, but with only a trend to significance in multivariate analysis (p-value 0.02 and 0.06, respectively). Only waist circumference, CRP, and T2DM were significantly associated with the progressive decline in testosteronemia at linear regression. After 3-6 months of CPAP therapy, ODI was significantly associated with the improvement in testosterone levels, independently from BMI, at multivariate regression (p-value 0.04).
Conclusions
decompensated OSAS, rather than its diagnosis, was found to correlate with low testosterone values also in male patients with severe obesity. As expected, our findings confirmed the contribution of T2DM, waist circumference and inflammation to the deflection of gonadal function. In addition, CPAP therapy was shown to improve testosterone levels.

Alteration of the tryptophan concentrations in women with polycystic ovary syndrome (PCOS)

Katarzyna Paczkowska[1], Dominik Rachoń[2], Andrzej Berg[3], Jacek Rybka[4], Katarzyna Kapczyńska[4], Marek Bolanowski[5] & Jacek Daroszewski[6]
[1]Endocrinological Ambulatory Care, Turek, Poland; [2]Medical University of Gdansk, Department of Clinical and Experimental Endocrinology, Gdansk, Poland; [3]Medical University of Gdansk, Department of Pharmaceutical Chemistry, Gdansk, Poland; [4]Polish Academy of Sciences, Laboratory of Medical Microbiology, Hirszfeld Institute of Immunology and Experimental Therapy, Wroclaw, Poland; [5]Wroclaw Medical University, Department of Endocrinology, Diabetes and Isotope Therapy, Wroclaw, Poland; [6]Center for Clinical Endocrinology, Wroclaw, Poland

Introduction
Polycystic ovary syndrome (PCOS) is one of the most common endocrinological disorders affecting reproductive age women worldwide; it is conventionally linked mostly to childbearing age; however, it has an influence on patients' health throughout their lifespan. Tryptophan (Trp) is one the amino acids classified as an essential, meaning the body can only obtain it through external sources. It serves as a building block for proteins and acts as a substrate for several signaling molecules.
Methods
The study population comprised 326 women: 208 diagnosed with PCOS and 118 healthy individuals. PCOS was diagnosed according to the revised 2003 Rotterdam criteria. Numerous anthropometric, biochemical and hormonal measurements were performed using standard techniques and commercially available methods. Assessment of branched-chain and aromatic amino acids levels was performed with a gas-liquid chromatography combined with tandem mass spectrometry.
Results
Statistical analysis revealed noticeably higher tryptophan levels in PCOS women compared to the control group: 53.66 $\pm$ 11.42 vs. 49.81 $\pm$ 11.18 nmol/ml ($P <$ 0.01) and the significant increase of the tryptophan concentration in the PCOS group was also observed in the subpopulations of women with metabolic disturbances, such as insulin resistance, abdominal obesity or obesity. On the other hand, further analysis conducted in PCOS group, revealed that, in contrary to other aromatic amino acids, there is no difference in tryptophan level between women with and without diagnosed metabolic issues, including obesity (53.03 $\pm$ 9.69 53.88 $\pm$ 11.85; P = 0.53) and insulin resistance (53.70 $\pm$ 11.08 53.68 $\pm$ 11.66; p= 0.80).
Conclusion
Alteration of tryptophan level seems to be independent from metabolic disturbances and further studies of the kynurenine pathway, which is the main metabolic pathway for tryptophan, are needed to assess the role of tryptophan and its metabolites in the PCOS pathogenesis.

Semen cryopreservation and semen quality in transfeminine adolescents prior to hormone therapy

Mohsin Aslam[1], Pernille Norup[1,2], Mette Haahr[3,4], Anne Katrine Pagsberg[3,5], Annamaria Giraldi[3,4], Niels Jørgensen[1,2] & Katharina Main[2,3,6]
[1]Copenhagen University Hospital - Rigshospitalet, Department of Growth and Reproduction, Copenhagen, Denmark; [2]Copenhagen University Hospital - Rigshospitalet, University of Copenhagen, International Centre for Research and Research Training in Endocrine Disruption of Male Reproduction and Child Health (EDMaRC), Copenhagen, Denmark; [3]University of Copenhagen, Department of Clinical Medicine, Copenhagen, Denmark; [4]Mental Health Centre Copenhagen, Mental Health Services – Capital Region of Denmark, Copenhagen, Denmark, Sexological Clinic, Copenhagen, Denmark; [5]Copenhagen University Hospital, Mental Health Services - Capital Region of Denmark, Child and Adolescent Mental Health Center, Copenhagen, Denmark; [1]Copenhagen University Hospital - Rigshospitalet, Department of Growth and Reproduction, Copenhagen, Denmark

Background
Some transgender individuals wish to become biological parents in the future and transfeminine persons may be offered cryopreservation of semen before starting hormone therapy. However, there is a lack of knowledge about semen cryopreservation outcomes among transfeminine adolescents seeking gender-affirming care.
Aim
To investigate transfeminine adolescents who decide for or against semen cryopreservation.
Methods
This is a retrospective observational national cohort study of 58 transfeminine individuals aged <18 years, assessing clinical data, semen parameters, and reproductive hormone levels.

Results
Among the 58 individuals, 23 (39.7%) opted for semen cryopreservation and successfully collected a semen sample. They were older and more advanced in pubertal development compared to those who did not: median age was 16.4 years (range 13.7-19.4) vs 15.8 years (11.7-17.9), Tanner stage G5 (4-5) vs G3 (2-4), and testis volume 20 ml (15-25) vs 8 ml (3-20). Among 17 individuals with no prior hormone therapy, the median sperm concentration was 11.1 $\times$ 10^6/ml (0.02-163), semen volume 1.8 mL (0.2-3.9), total sperm count 17.8 $\times$ 10^6 (0.1-214.2), and percentage of progressively motile spermatozoa 46% (8-74). Reproductive hormones were within normal ranges for age and sex assigned at birth.
Conclusion
The prevalence of adolescents opting for semen cryopreservation was comparable to other countries with a publicly financed national healthcare system. Overall, semen quality was impaired, which may be attributable to young age, intense gender dysphoria, and lifestyle.

Temporal trends in serum testosterone and luteinizing hormone levels indicate an ongoing resetting of hypothalamic-pituitary-gonadal function in healthy men: a systematic review

Daniele Santi[1,2], Giorgia Spaggiari[1], Chiara Furini[1,2], Valentina Griseta[1,2], Eric Zizzi[3], Antonio Raffaele Michele Granata[1] & Manuela Simoni[1,2]
[1]Unit of Endocrinology, Department of Medical Specialties, Azienda Ospedaliero-Universitaria of Modena, Modena, Italy; [2]Department of Biomedical, Metabolic and Neural Sciences, University of Modena and Reggio Emilia, Modena, Italy; [3]PolitoBIOMed Lab, Department of Mechanical and Aerospace Engineering, Politecnico di Torino, Torino, Italy

Background
Male fertility is progressively impairing over time, probably related to a multifactorial genesis, involving mainly lifestyle and environmental factors. Only few data suggest temporal trends in serum testosterone levels.
Objective and Rationale
The aim of the study was the evaluation if a Temporal trend in serum testosterone levels exists in healthy men.
Search Methods
A systematic search of the literature between 1971 and July 2024 was performed, selecting study groups in which testosterone serum levels were measured for any reason in healthy men. Exclusion criteria were: (i) subjects' age $<$18 years old, (ii) conditions affecting testosterone levels, (iii) subjects' enrolment based on testosterone serum levels and (iv) blood examinations performed in a time-frame interval $>$10 years. As secondary endpoints, luteinising hormone (LH), follicle-stimulating hormone (FSH), sex hormone binding globulin (SHBG) serum levels and body mass index (BMI) were collected when available.
Outcomes
1,256 papers, accounting for 1,504 study groups, were selected, including 1,064,891 subjects (mean age 42.0$\pm$7.0 years). A significant negative linear regression between testosterone serum levels and year of measurement was detected (P = 0.033). The comprehensive decline in testosterone serum levels over the years was confirmed with meta-regression analysis using the number of patients included in each study, subjects' age and body mass index (BMI) to adjust testosterone trend. No temporal trend was observed regarding BMI in this population. LH serum levels showed a significant decline over the years, adjusting for subjects' age, while no trend emerged considering FSH. The decline in testosterone serum levels was confirmed adjusting data according to the assay used for testosterone measurement and after matching with environmental and demographic data.
Wider Implications
This study is the first comprehensive meta-regression analysis suggesting a progressive decrease in serum testosterone and LH levels in healthy men, independent of age and BMI. The observed decline in both testosterone and LH levels could be a consequence of an ongoing resetting of the hypothalamic-pituitary testicular function.

Circulating gut hormone concentrations in women presenting with menstrual disturbance

Bijal Patel[1], Arthur Yeung[1], Maria Phylactou[1], Jovanna Tsoutsouki[1], Kanyada Koysombat[1], Megan Young[1], Sandhi Nyunt[1], Aaran Patel[1], Aureliane Pierret[1], Elisabeth Daniels[1], Ambreen Qayum[1], Agata Zielinska[1], Yusra Omar[1], Pei Eng[1], Edouard G Mills[1], Simon Hanassab[1], Channa Jayasena[1], Tricia Tan[1], Anna Kowalka[1], Sophie Clarke[1], Alexander Comninos[1], Ali Abbara[1] & Waljit Dhillo[1]
[1]Imperial College London, London, United Kingdom

Background
Polycystic Ovary Syndrome (PCOS) and Functional Hypothalamic Amenorrhoea (FHA) are the commonest causes of secondary amenorrhoea. PCOS is typically associated with increased bodyweight, appetite, insulin resistance, and metabolic dysfunction, whereas FHA is typically associated with lower body weight and decreased energy availability. Importantly, there are only limited inconsistent data describing gut hormone levels in these conditions and no direct comparisons. Ghrelin is reported to be reduced in PCOS and increased in FHA. Additionally, administration of ghrelin decreases LH pulsatility in healthy women, consistent with a possible causal role in FHA. GLP-1 is reported to be reduced or unchanged in PCOS. PYY3-36 is reported to be increased in FHA, and reduced or unchanged in PCOS. PYY1-36 is converted to the more active isoform PYY3-36 by the enzyme Dipeptidyl peptidase-4 (DPP4). Here, we provide the first direct comparison of levels of gut hormones in women with metabolically divergent causes of menstrual disturbance.
Methods
Fasting total ghrelin, total glucagon like peptide-1 (GLP-1), and peptide YY isoforms (PYY1-36, PYY3-36) were measured in women aged 18-35 years in the follicular phase who were healthy (n = 47), had PCOS (n = 73), or FHA (n = 44). Ghrelin (Merck Millipore) and GLP-1 (Mercodia) were measured by ELISA, whereas PYY1-36 and PYY3-36 by in-house LC-MS/MS (Acquity UPLC with TQ-S). Groups were compared by the Kruskal-Wallis Test with post hoc Dunn's test.
Results
Mean ($\pm$SD) ghrelin levels were lower in PCOS (1004 $\pm$572 pg/ml) than healthy women (1316 $\pm$616; P = 0.0043), or in FHA (1369 $\pm$570; P = 0.0012) . However, this was predominantly due to higher BMI in PCOS, and levels did not differ in those with lean PCOS (BMI $<$25 kg/m^2; P = 0.39). In PCOS, ghrelin was negatively correlated with the Ferriman-Gallwey score (r=-0.30, P = 0.015) and Free Androgen Index (FAI) (r=-0.6531, P $<$0.0001). PYY1-36 (pmol/l)was reduced in FHA (0.31 $\pm$0.5) compared to PCOS (0.75 $\pm$0.74; P = 0.0001), and even to those with lean PCOS (0.69 $\pm$0.74; P = 0.0068). Neither ghrelin nor PYY1-36 correlated with other reproductive hormones. No changes were observed in PYY1-36 or GLP-1 between the groups.
Conclusion
This is the first study to directly compare gut hormone levels in patients presenting with menstrual disturbance due to PCOS or FHA. Ghrelin levels were lower in women with PCOS (albeit mainly due to bodyweight). However, PYY1-36 levels were higher in PCOS than FHA independent of bodyweight. Taken together, these data inform our understanding of the intricate coupling between reproductive function and metabolism in common reproductive disorders.

Primary amenorrhea secondary to β-thalassemia major: a case report

Nada Ait Kassi[1], Chaimaa El Hadri[1], Fatima Toulali[1], Ghizlane Sabbar[1], Habbadi Zineb[2], Kaoutar Rifai[1], Hinde Iraqi[1] & Mohamed El Hassan Gharbi[1]
[1]Ibn Sina Hospital Mohamed V University, Endocrinology, Rabat, Morocco; [2]Ibn Sina Hospital Mohamed V University, Endocrinology, Rabat, Morocco

Background
Primary amenorrhea can stem from a variety of etiologies, including hypogonadotropic hypogonadism, a condition frequently seen in patients with β-thalassemia major due to iron overload from repeated blood transfusions. This iron toxicity primarily affects endocrine organs, including the anterior pituitary, leading to endocrine complications.

Case Presentation
We report the case of a 17-year-old adolescent, with a history of β-thalassemia major diagnosed at birth, who presented with primary amenorrhea and growth delay. She receives blood transfusions every 21 days and chelation therapy to manage iron overload. Clinical examination revealed a weight of 30 kg and height of 145 cm (BMI = 14 kg/m^2), with pubertal development assessed at Tanner stage S2 (breast) and P3 (pubic hair). Laboratory tests showed low FSH (0.97 mIU/ml) and estradiol levels (<24 pg/ml), with normal TSH. Pelvic MRI indicated uterine hypoplasia and small ovarian volume, while pituitary MRI showed anterior pituitary atrophy, compatible with iron overload. Hormone replacement therapy was considered to correct the endocrine deficiencies and promote pubertal development.
Discussion
β-thalassemia major is frequently associated with endocrine disorders, predominantly due to iron overload impacting the anterior pituitary. This disruption in hormonal secretion leads to hypogonadotropic hypogonadism, which is the primary cause of primary amenorrhea in thalassemic females. In this case, clinical and radiologic findings confirmed central hypogonadism with low FSH and estradiol levels and pituitary atrophy. Hormone replacement therapy is essential for inducing and maintaining secondary sexual characteristics and preventing long-term complications, such as osteoporosis. Despite advancements in transfusion and chelation therapies, endocrine complications remain a significant concern for thalassemic patients, particularly during adolescence.
Conclusion
Primary amenorrhea due to iron overload is a common complication in adolescent females with β-thalassemia major. This case underscores the importance of early detection and appropriate therapeutic intervention, including hormone replacement therapy, to enhance quality of life and prevent long-term complications in these patients.

Androstenedione method comparison of three automated immunoassays and ID-LC-MS/MS in routine testing and disorders of steroid synthesis

Sonja Kunz[1], Nicole Reisch[1], Matthias Auer[1], Pierre Lukas[2], Etienne Cavalier[2], Martin Reincke[1] & Martin Bidlingmaier[1]
[1]LMU Klinikum Innenstadt, Medizinische Klinik und Poliklinik IV, München, Germany; [2]Department of Clinical Chemistry, University of Liege, CHU de Liege, Liege, Belgium

Introduction
Androstenedione is a steroid hormone produced in the adrenals and gonads, commonly used in the diagnosis and monitoring of hyperandrogenism and congenital adrenal hyperplasia (CAH) in conjunction with other hypothalamic and pituitary hormones. Excess androgens such as androstenedione are also evaluated in conditions including polycystic ovarian syndrome (PCOS) and adrenal tumours. We present here the comparison of three commercially available immunoassays and one isotope dilution liquid chromatography mass-spectrometry method (ID-LC-MS/MS) for androstenedione in frequently investigated patient groups with changes in steroid biosynthesis.
Methods
We evaluated the correlation between the Elecsys Androstenedione (Roche, Mannheim, Germany) and IDS Androstenedione (IDS, Boldon UK) automated immunoassays in a set of 141 remnant routine serum samples (CHU de Liege). The IDS method was additionally compared to the automated Liaison Androstenedione (DiaSorin, Salluggia, Italy) in a set of 119 routine samples (LMU Munich and CHU Liege), and in a set of 94 samples with clinical diagnosis (n = 20 CAH, n = 20PCOS, n = 13 adrenal carcinoma, n = 21 adrenal insufficiency, n = 20 post-menopausal females). Androstenedione levels were also determined with a validated ID-LC-MS/MS (Chromsystems, Gräfelfing, Germany) in the same samples.
Results
The Roche and IDS Androstenedione methods showed excellent correlation (Passing-Bablok regression IDS = 1.05*Roche – 0.11ng/dl, R^2=0.99) with no systematic bias across the range of samples (Bland Altman mean bias 5.5%). Agreement between the IDS and Diasorin assays in general routine samples was acceptable, but results were approximately 33% lower with IDS compared to Diasorin (IDS = 0.67*Diasorin + 3.44ng/dl, R^2=0.97, mean bias -33.5%). The overall difference between the two assays was similar in the samples from specific patient groups where excess androgens commonly occur (IDS = 0.74*Diasorin – 5.4ng/dl, R^2=0.94, mean bias -35.9%). In the same set of samples where values were additionally determined with LC-MS, the IDS had a mean -0.2% bias (IDS =1.18*LC-MS -12.67, R^2=0.79) while mean bias on the Diasorin was 38% (Diasorin = 1.56*LC-MS - 51ng/dl, R^2=0.97).
Conclusion
Our investigation into the performance of three commercially available automated immunoassays for Androstenedione revealed a close alignment between measurements from the IDS and Roche methods, the latter being standardised to ID-LC-MS/MS. While there was a good agreement overall, the Diasorin assay measured 33-38% higher than the IDS and ID-LC-MS/MS in routine samples and samples where androgens can often exist in excess. Values generated by the IDS assay were also closely aligned to ID-LC-MS/MS, indicating adequate clinical specificity in this recently available method.

The impact of gender dysphoria on mental health of transgender and gender non-conforming patients – 7-year of experience in the first gender unit for youth in poland

Tomasz Jakubowski[1,2], Wiktoria Kempińska[1,3], Aleksandra Antosz[1,3], Jakub Gawlik[4], Agnieszka Bielska-Brodziak[5] & Aneta Gawlik-Starzyk[1,3]
[1]Upper Silesian Child Health Center, Public Clinical Hospital No. 6 of the Silesian Medical University, Institute of Psychology, University of Silesia, Katowice, Poland; [2]Institute of Psychology, University of Silesia, Katowice, Poland; [3]Faculty of Medical Sciences, Medical University of Silesia, Department of Pediatrics and Pediatric Endocrinology, Katowice, Poland; [4]The University Hospital, Kraków, Poland; [5]Faculty of Law and Administration, University of Silesia, Katowice, Poland

Introduction
The worldwide trend of rising referrals of youths to gender clinics is widely discussed and observed in Poland as well. To our knowledge, there is no data presenting the medical and psychological status of gender dysphoric youth in Central Europe. Similarly, the data about the relation between the Gender Minority Stress (GMS) and health – both mental and somatic – is scant.
Aim
Here, the mental health diagnoses and endocrinological status based on steroid metabolome from 24-hr urinary collection are analysed in the context of minority status-related data.
Methods
This prospective study has examined consecutive series of children and adolescents diagnosed due to gender incongruence/dysphoria in accordance with WPATH SOC-8 in one university center between July/2017 and Sep/2024. Clinical and laboratory data was collected in unified medical records.
Results
The population consists of 269 participants (female: male at birth -230:39) with the mean/median age of diagnosis 15.8/16.1 years and the mean age of gender identity mismatch onset of 12 years. Mental health diagnoses among our patients include: mood disorders - 59.8%, anxiety disorders - 26.0%, adjustment disorders - 3.8%, psychotic disorders - 4.6%, conduct/disruptive disorders – 0.8%, substance use disorders - 2.3%, eating disorders - 12.6%, personality disorders – 9.6%, attention deficit hyperactivity disorder – 9.6%, autism spectrum disorders – 22.6%. Further statistical analyses have revealed that gender dysphoria is a positive predictor of a number of mental health diagnoses (P <0.05) and correlates positively with values of THF+allo-THF/THE (reflects 11ßHSD1 activity), α- and β-cortolone (cortisone metabolites) (P <0.05). Negative association was found between the age of gender incongruence onset and values of F/E (11ßHSD1 activity) and positive between the age of coming out to friends and relatives and values of tetrahydrocortisone (THE), tetrahydrocortisol (THF) and β-cortol (cortisol metabolite) (P <0.05). The results of the intergroup differences analysis have shown that adolescents who have parental acceptance of their minority status report lower intensity of gender dysphoria than those who have no parental support in this respect.
Conclusions
The analyses further indicate the significance of gender dysphoria alleviation for transgender and gender non-conforming adolescents' mental health. Our results show that Gender Minority Stress (including gender dysphoria) influences the glucocorticoids balance, which indicates a need for further investigation.

Comparison of metabolic outcomes in lean and obese women with polycystic ovary syndrome

Emna Mraihi[1], Taieb Ach[2], Fatma Ben Abdessalem[1], Imen Halloul[2], Wiem Saafi[2], Hamza Elfekih[2], Ghada Saad[2] & Yosra Hasni[2]
[1]Faculty of Medicine Ibn Al Jazzar Sousse, University of Sousse, Sousse, Tunisia; [2]University Hospital Farhat Hached Sousse, Sousse, Tunisia

Introduction
Polycystic ovary syndrome (PCOS) is a common endocrine disorder affecting up to 20% of women of reproductive age. Characterized by ovarian dysfunction, hormonal imbalances, and metabolic abnormalities, PCOS has traditionally been associated with obesity. However, increasing numbers of lean women are being diagnosed with PCOS. While obesity exacerbates metabolic disturbances, non-obese PCOS women may also present significant metabolic issues. This study compares the metabolic profiles of lean and obese women with PCOS.
Subjects and Methods
This analytical cross-sectional study included 122 women diagnosed with PCOS at the Endocrinology and Diabetology Department of FARHAT HACHED Hospital in Sousse between January and December 2024. Participants were divided into two groups based on BMI: Obese PCOS (O-PCOS; BMI >25 kg/m^2) and Lean PCOS (L-PCOS; BMI <25 kg/m^2). Metabolic parameters assessed included anthropometric data, markers of insulin resistance, and glycemic and lipid profiles.
Results
Of the 122 participants, 38 (31.1%) were lean and 84 (68.9%) were obese. The average age was 23.61 $\pm$ 4.97 years. The mean BMI was 32.26 $\pm$ 5.85 kg/m^2 for O-PCOS and 21.85 $\pm$ 1.98 kg/m^2 for L-PCOS ($\boldsymbol{P < 0.001}$). Android fat distribution was significantly more prevalent in the obese group (72.6% vs. 13.2%; $\boldsymbol{P < 0.001}$), with mean waist circumferences of 90.56 $\pm$ 10.22 cm in O-PCOS and 75.66 $\pm$ 4.59 cm in L-PCOS. Acanthosis Nigricans was significantly more common in O-PCOS (76.2%; $\boldsymbol{P < 0.001}$). In terms of the lipid profile, hypertriglyceridemia was observed in 14.3% of obese and 13.2% of lean women ($\boldsymbol{P = 0.028}$), and hypercholesterolemia was present in 7.1% of the obese and 5.7% of the lean participants ($P = 1.000$). Additionally, the metabolic syndrome was more prevalent in O-PCOS (44% vs. 2.6%; $\boldsymbol{P < 0.001}$). Lastly, impaired fasting glucose was noted in 19% of obese and 5.3% of lean women ($P = 0.055$), and impaired glucose tolerance was detected exclusively in obese participants (22.6%; $\boldsymbol{P = 0.001}$).
Conclusion
Obese women with PCOS exhibited more pronounced metabolic abnormalities, including higher rates of metabolic syndrome, insulin resistance, and glucose intolerance. However, lean women also displayed notable metabolic disturbances. These findings underscore the importance of comprehensive metabolic assessment and individualized management strategies in all PCOS patients, regardless of BMI.

Evaluation of thyroid hormone sensitivity in polycystic ovary syndrome

Esra Kizmaz[1], Meric Coskun[2], Ethem Turgay Cerit[2], Altinova Alev[2], Mujde Akturk[2], Fusun Toruner[2], Ayhan Karakoc[2] & Mehmet Muhittin Yalcin[2]
[1]Gazi University Faculty of Medicine Department of Internal Medicine, Ankara, Türkiye; [2]Gazi University Faculty of Meicine Department of Endocrinology and Metabolism, ankara, Türkiye

Background
Polycystic ovary syndrome (PCOS) is a complex disorder that is associated with an increased risk of cardiometabolic disorders. The metabolic dysfunction seen in PCOS has been tried to be explained by the presence of hypothyroidism, and it has been emphasized that cardiometabolic dysfunction becomes apparent when TSH is high. However, this relationship could not be demonstrated in euthyroid PCOS patients. In this context, we hypothesized that the metabolic dysfunctions in euthyroid PCOS patients could partly be explained by the presence of acquired mild thyroid hormone resistance (THR). We aimed to evaluate thyroid hormone sensitivity using thyroid hormone sensitivity indices and its relationship with homocysteine and PAI-1 levels in PCOS patients.
Methods
Patients aged 18-50 years with a diagnosis of PCOS were included in the PCOS group. Subgroup analysis of the patients was performed by grouping them as TSH <3.0 μIU/ml and TSH ≥ 3.0 μIU/ml. Euthyroid subjects matched for age and body mass index (BMI) with the patient group, were included in the control group. TSH index (TSHI), thyrotropin thyroxine resistance index (TT4RI), thyroid feedback quarter-based index (TFQI) were calculated using TSH and fT4; TSHI(fT3), thyrotropin triiodothyronine resistance index (TT3RI), TFQI(fT3) were calculated using TSH and fT3; fT3/fT4 ratio was calculated using fT3 and sfT4. Statistical analysis was performed using the IBM SPSS 26.0 program. The level of statistical significance was accepted as $P < 0.05$.
Results
Although no statistically significant difference was found between the PCOS and control groups in terms of central and peripheral thyroid hormone sensitivity indices; fT3 and TFQI(fT3) were statistically signifcant between TSH ≥ 3 PCOS and TSH ≥ 3 control group. Positive correlations were found between TFQI value and HDL and total cholesterol levels and between TSHI, TSHI(fT3), TT3RI and TT4RI and waist circumference in the PCOS group, whereas negative correlations were found between TFQI(fT3) value and fasting glucose and between fT3/fT4 and fasting glucose, LDL and total cholesterol levels.
Conclusions
In our study, we thought that decreased thyroid hormone sensitivity may be one of the factors involved in the increased cardiometabolic risk in PCOS. More multicenter prospective studies with larger sample groups are needed to elucidate this relationship.

Physical growth of chinese girls' menarche onset

Qiao Wang[1] & Chunxiu Gong[1]
[1]Beijing Children's Hospital, Endocrinology, Genetics and Metabolism, Beijing, China

Objective
We aimed to identify the contributing physical predictors for menarche and further to establish critical weight for menarche onset in Chinese girls.
Methods
This was a retrospective study. The sample was composed of 253 girls who visit within 3 months after menarche. For propensity score matching, data of 253 girls with similar chronological age and mid-parental height who haven't menarche yet were collected. All girls were from Beijing city, China and visit pediatric clinic during 2018 to 2023. Receiver operator characteristic curve was performed to determine cutoff values. Multivariate logistic regression was used to construct a nomogram. The discriminatory ability of the model was determined by calculating the area under the curve (AUC). Moreover, calibration analysis and decision curve analysis (DCA) of the model were performed.
Results
The average age of menarche of the 253 girls was 10.2 ± 1.0 years, with average weight of 42.9 ± 6.8kg, height of 148 ± 5.1cm and BMI of 20.2 ± 2.5kg/m^2, with significant higher compared to pre-menarche girls with similar age and mid-parental height ($P < 0.01$). Among the girls of different menarche age groups, height, weight, BMI, and their standard deviation scores were compared, there was significant difference between groups except weight ($P = 0.088$). Based on receiver operating characteristic (ROC) curve analysis, weight of 36.6kg was significantly related to menarche occuring, and the specificity and sensitivity were 65.2% and 81.7%, respectively. A nomogram was built based on weight, the proportion of height to mid-parental height, and bone age. The predictive model yielded an AUC of 0.818 (95% CI, 0.780, 0.856). The predictive model was well-calibrated, and DCA showed when the threshold probability of menarche below 80%, using the proposed nomogram to predict menarche would obtain more benefit than using weight prediction alone.
Conclusions
Menarche age is highly related to physical development. The optimal critical value of weight has important application value in menarche. Besides, a nomogram was constructed for predicting menarche by physical status. Physical growth, as a simple and easily obtainable information, can be reliable indicators for predicting menarche.

Ovarian suppression using GnRH analog followed by estrogen and progestin for the classic form of lipoid congenital adrenal hyperplasia: A case report and its implications for ovarian morphology

Tomohiro Ishii[1 2], Junya Shindo[3], Nobuhiro Hashimoto[2 4], Naoko Amano[1], Toshihiro Tajima[5], Tomonobu Hasegawa[2] & Tsutom Kamimaki[4]
[1]Tokyo Metropolitan Children Medical Center, Endocrinology and Metabolism, Tokyo, Japan; [2]Keio University School of Medicine, Pediatrics, Tokyo, Japan; [3]Ashikaga Red Cross Hospital, Ashikaga, Japan; [4]Shimizu Municipal Hospital, Pediatrics, Shimizu, Japan; [5]Jichi Medical University, Pediatrics, Shimotuke, Japan

Background
Lipoid congenital adrenal hyperplasia (LCAH) is caused by pathogenic variants in *STAR*, encoding steroidogenic acute regulatory protein. LCAH is characterized clinically by impaired steroidogenesis and pathologically by cholesterol ester accumulation in the adrenal glands and gonads. Most 46,XX patients with the classic form of LCAH undergo spontaneous puberty but develop premature ovarian failure in later life. In addition, approximately 33% of women with LCAH experienced large ovarian cysts or ovarian torsion requiring cystectomy or ovariectomy, respectively (Ishii T, *et al*. J Clin Endocrinol Metab 2020;105:1870–1879). These ovarian complications are potentially associated with hypergonadotropinemia; however, effective interventions to prevent such complications remain unclear. Here, we report a 46,XX female with LCAH who underwent GnRH analog followed by estrogen and progestin, with detailed monitoring of ovarian morphology.
Case Presentation
The patient was an 18-year-old Japanese female diagnosed with LCAH after presenting primary adrenal insufficiency and adrenal hyperplasia with low CT attenuation in the neonatal period. Genetic analysis of *STAR* identified compound heterozygous pathogenic variants (p.Gln258* and p.Glu218Val). With glucocorticoid and mineralocorticoid replacement, she exhibited breast development at 10 years of age and pubertal response of serum gonadotropins to GnRH stimulation. After thorough discussions with her guardians, subcutaneous injections of leuprorelin acetate were initiated and maintained until the transition to estradiol and norethindrone at 14 years of age. Ovarian morphology, including the maximum cyst diameter and ovarian volume, was regularly assessed using ultrasonography and MRI. Before leuprorelin therapy, the maximum cyst diameter was 13 mm (greater than 9 mm, corresponding to +2.0 SD for her age), which reduced to 6 mm after 6 months of treatment and remained within the reference range. Ovarian volume SD scores decreased from +0.82 and -0.12 before therapy to -0.85 and -0.72 at 12 months, respectively, and stabilized within the normal range. At the most recent follow-up, she had not developed ovarian cysts or hyperplasia under the control of estradiol and norethindrone.
Discussion and Conclusion
This is the first reported case of LCAH who underwent ovarian suppression with GnRH analog followed by estrogen and progestin. Despite the presence of a large ovarian cyst before therapy, no subsequent large ovarian cysts, ovarian hyperplasia, or ovarian torsion were observed during the therapy. These findings suggest that this therapeutic approach may prevent such ovarian complications in patients with the classic form of LCAH. Further clinical studies are warranted to evaluate the efficacy and safety of this intervention.

Evaluating olfactory and gustatory function in patients with hypogonadotropic hypogonadism

Elżbieta Marczak[1], Maria Szarras-Czapnik[1], Karolina Piskadło[2], Rafał Jowik[2], Karolina Dżaman[3] & Elżbieta Moszczyńska[1]
[1]The Children's Memorial Health Institute, Department of Endocrinology and Diabetology, Warsaw, Poland; [2]Miedzyleski Hospital, Department of Otolaryngology, Warsaw, Poland; [3]Centre of Postgraduate Medical Education, Department of Otolaryngology, Warsaw, Poland

Introduction
Hypogonadotropic hypogonadism (HH) is a condition marked by deficient secretion of gonadotropin-releasing hormone (GnRH), resulting in impaired sexual development and reproductive function. Olfactory dysfunction, including anosmia and hyposmia, frequently accompanies HH due to the shared embryological development of the olfactory system and the hypothalamic-pituitary axis. Recognizing sensory impairments in smell and taste in boys with HH is critical for early diagnosis and treatment planning.
Aim of the Study
To conduct a standardized evaluation of olfactory and gustatory function in a group of boys with HH and to explore associations between clinical symptoms, sensory dysfunctions, and genetic findings.
Materials and Methods
patients aged 8-17 years with confirmed HH were assessed for olfactory and gustatory function using standardized smell identification tests "Sniffin Sticks KIDS Polska," "Screening 6-odor smell test," and taste recognition using "ODOFIN Sniffin Sticks." A control group consisted of individuals without pubertal disorders. Additional assessments included magnetic resonance imaging (MRI) of the hypothalamic-pituitary region and olfactory bulbs, as well as genetic testing for mutations linked to HH.
Results
Olfactory dysfunction was identified in seven out of eight patients, with one exhibiting normal olfactory function. One patient demonstrated complete taste impairment (hypogeusia), while another exhibited partial taste dysfunction with difficulty recognizing sour and salty flavors. Genetic testing for HH-related mutations revealed three cases of Kallmann syndrome (two patients with KAL1 gene mutations and one with a PROK2 mutation). All three had olfactory impairments, and one also exhibited hypogeusia.
Conclusions
Olfactory and gustatory assessments in patients with HH provide valuable diagnostic insights and can help guide genetic testing. These non-invasive tests offer a practical approach to identifying sensory dysfunctions and refining diagnostic strategies.

Primary gonadal dysfunction after oncological treatment in a cohort of childhood medulloblastoma survivors

Luminita Cima[1], Marina Iliescu[1], Raluca Stan[1], Diana Puscasu[1], Iustina Grosu[1], Sabina Maria Dumitrache[1], Mihaela Tarna[1], Codruta Comsa[2], Oana Iaru[2], Monica Dragomir[2], Carmen Gabriela Barbu[1] & Simona Fica[1]
[1]Elias University Hospital, Carol Davila University of Medicine and Pharmacy, Endocrinology, Bucharest, Romania; [2]Oncologic Institute, Bucharest, Romania

Background
Medulloblastoma is a cerebellar tumour that is usually diagnosed during childhood. Since the 5-year survival rate has risen, due to new therapeutic approaches, a high proportion of survivors develop late endocrine complications. These endocrinopathies may consist of hypothalamic–pituitary and growth disorders, obesity and metabolic syndrome, but also primary gonadal dysfunction. Gonadal insufficiency and infertility may impact the physical status and quality of life of these young patients. Therefore, we aimed to evaluate primary gonadal insufficiency in 31 subjects diagnosed with medulloblastoma that were treated with cranial and spinal radiotherapy apart from chemotherapy.
Material and Methods
We performed anamnesis, physical examination and hormonal profile in 31 survivors of childhood medulloblastoma that were evaluated in our clinic for long-term endocrine complications, median age at diagnosis 6 years (IQR 10), median follow-up length 31 month (IQR 35). Primary gonadal impairment was defined by any of the following: delayed/arrested puberty, primary/secondary amenorrhea, irregular menses, FSH >25 mIU/ml, low estradiol, low AMH.
Results
Primary gonadal dysfunction was present in 9 patients (29%) and occurred at a median time of 13 months (IQR 40). Our study showed a statistically significant correlation between primary gonadal dysfunction and underweight status ($P = 0.005$) and the age at diagnosis and treatment initiation ($P = 0.038$), respectively. There was no correlation between gonadal impairment and obesity, hypothyroidism, treatment protocol.
Conclusion
Our study demonstrated a high prevalence of primary gonadal insufficiency in survivors of childhood medulloblastoma that usually present with hypothalamic–pituitary damage as a result of radiotherapy. Therefore, we recommend counselling patients with a diagnosis of medulloblastoma with regards to potential damage to the gonads and thereby offer fertility preservation procedures in selected patients.

A novel de novo mutation of the DHX37 gene in patients with 46,XY DSD

Afaf Alsagheir[1], Abeer Alabduljabbar[2], Sara Abid[3], Dania Farooq[3], Sara Aljazaeri[3], Yara Khamag[3], Raghad Alhuthil[2] & Latifah Alfahad[4]
[1]Section of Pediatric Endocrinology, Department of Pediatrics, King Faisal Specialist Hospital and Research Centre, Riyadh, Saudi Arabia; [2]Department of Pediatrics, King Faisal Specialist Hospital and Research Centre, Riyadh, Saudi Arabia; [3]College of Medicine, Alfaisal University, Riyadh, Saudi Arabia; [4]Department of Radiology, King Faisal Specialist Hospital and Research Centre, Riyadh, Saudi Arabia

Introduction
The set of conditions referred to as 46, XY gonadal dysgenesis (GD) is marked by abnormalities in sexual development. As in DHX37, an autosomal gene located on chromosome 1, encodes an RNA helicase that plays a crucial role in essential RNA processes. Mutations in DHX37 are associated with a range of DSD phenotypes, such as atypical genitalia and hormonal disruptions, thus makes it crucial to highlight DHX37 gene importance in sex differentiation and the significance of genetic testing for diagnosing DSD cases.
Objective
To report a novel mutation and to update the literature regarding the manifestation of the case of a De Novo heterozygous variant in DHX37 that causes 46, XY gonadal dysgenesis, which is a rare condition in DSD.
Case Presentation
We report 3 cases in King Faisal Specialist Hospital and Research Centre, Riyadh, Saudi Arabia, presented with unusual manifestations and subsequently diagnosed with an uncommon disease. Initially presented with ambiguous genitalia, further karyotyping revealed the presence of a positive SRY gene and a 46XY chromosomal pattern.
Conclusion
A total of 3 cases following in pediatric endocrinology clinic having 46 XY Disorder of Sexual Development (DSD). Consequently, a heterozygous missense variant of DHX37 was discovered using whole exome sequencing which was not reported before in our region. One of the cases had a novel Missense variant and we suggest upgrading the variant classification of DHX37:c.1433G>T p.(Gly478Val) to likely pathogenic, according to the evidence found in our patient.
Keywords
DSD, DHX37 gene, 46XY, ambiguous genitalia, Saudi Arabia.

Exercise habits and activity levels in an international sample of people with PCOS

Melissa Masters[1,2]
[1]Metropolitan State University of Denver, Department of Nutrition, Denver, United States; [2]Metropolitan State University of Denver, Nutrition, Denver, United States

Background
Polycystic Ovary Syndrome (PCOS), an endocrine disorder affecting 9-18% of reproductive-aged females, can negatively impact health in many ways. Physical activity may be used to promote health in PCOS. This study investigated exercise habits and activity levels in an international sample of people with PCOS.
Methods
Participants were recruited from social media sites from January-February 2024. Eligibility criteria included being $\geq$ 18 years of age and having a prior diagnosis of PCOS. Survey questions included demographics, self-reported height and weight to calculate body mass index (BMI), and the short-form international physical activity questionnaire (IPAQ). Descriptive analyses were performed. Categorical data were analyzed as count and frequency and numerical data as median and standard deviation.
Results
Most participants (n = 101) were between the age of 26-35 (56.4%, n = 57), from North America (69.3%, n = 70), were diagnosed with PCOS more than 10 years ago (39.6%, n = 40), and had a BMI in the obese range (66.3%, n = 63). The median BMI of participants was 33.12 kg/m^2. Approximately 52.5% (n = 53) of respondents reported no days of vigorous activity and 44.6% (n = 45) reported no moderate activity. Median time spent doing vigorous exercise (n = 48) per bout was 60.0$\pm$42.7 minutes, median metabolic equivalents of a task (MET-min/week) minutes of exercise per week of vigorous exercise was 960$\pm$1415.8 and average days of vigorous activity per week was 1.2$\pm$1.7. Median time spent doing moderate exercise (n = 56) per bout was 40.0$\pm$79.0 minutes, median MET-min/week of moderate exercise was 360$\pm$1415.8 and average days of moderate activity per week was 1.5$\pm$1.9. Most participants reported walking regularly with 22.4% (n = 22) walking 1-2 times/week and 66.3% (n = 65) walking 3 or more times/week. Median time spent walking (n = 87) per walking bout was 40.0$\pm$80.5 minutes, median MET-min/week of walking was 693$\pm$1389.3 and average days of walking per week was 4.1$\pm$2.6. Only 14 (13.9%) of the 101 respondents reported no activity each week. Based on total MET-min/week, 35.6% (n = 36) of participants were categorized as achieving low levels of activity each week (including those reporting no activity), 39.6% (n = 40) moderate levels, and 24.8% (n = 25) high levels. Median total MET-min/week was 996$\pm$2414.9.
Conclusions
People with PCOS may predominantly engage in low intensity exercise like walking and less in vigorous and moderate intensity exercise. Most participants did not participate in vigorous intensity exercise which may be most beneficial for PCOS management. Future research should further examine activity levels in people with PCOS and identify optimal exercise intensity for this population.

Ten-year experience of a referral center for transgeneder and gender diverse children and adolescents in north-east of italy

Anna Roia[1], Federico Sandri[1], Giulia Bresciani[1], Massimo Di Grazia[1], Giovanna Morini[1], Dora Cosentini[1], Chiara Cervesi[1], Diego Mugno[1], Marco Carrozzi[1], Lucia De Zen[1], Gabriella Zito[1], Gianluca Tamaro[1], Alessandro Ventura[1,2], Egidio Barbi[1,2] & Gianluca Tornese[1,2]
[1]Institute for Maternal and Child Health IRCCS "Burlo Garofolo", Trieste, Italy; [2]Department of Medicine, Surgery and Health Sciences, University of Trieste, Trieste, Italy

Background
In 2015, the APEVAGE clinic (Ambulatorio Pediatrico per la Varianza di Genere, Pediatric Clinic for Gender Variance) was established at the Institute for Maternal and Child Health "Burlo Garofolo" in Trieste. It is one of the few Italian centers dedicated to transgender and gender-diverse (TGD) childrens and adolescents. The clinic is run by a multidisciplinary team, including pediatric endocrinologists, psychologists, child psychiatrists, bioethicists, as required by Italian regulations for prescribing and reimbursing triptorelin. Additionally, the clinic provides access to a fertility specialist.
Methods
Data were collected from individuals referred to the clinic from 2015 to 2024.
Results
Eighty individuals have been evaluated, with referrals increasing over time (up to 21 new cases in 2022), showing no differences by assigned sex at birth (P = 0.432). The median age at first visit was 15.3 years (IQR 13.6–16.4; minimum 4.8 years), increasing significantly over the years (P = 0.035). Thirty-one individuals (39%) were diagnosed with gender dysphoria (GD) according to DSM-5 criteria (required by Italian regulations for the prescription and reimbursement of triptorelin). Of these, 14 (45%) were referred directly to adult endocrinologists due to their proximity to 18 years of age. The remaining 15 (48%) started triptorelin at a median age of 16.7 years (IQR 16.0–17.2; minimum 14.5 years), with no significant differences between assigned sex at birth: 8 transitioned to gender-affirming hormone therapy (GAHT) after a median of 6 months (IQR 5–6; minimum 3) on triptorelin in pediatrics, 2 initiated GAHT directly with adult endocrinologists, 5 are still on triptorelin, either due to age below 16 or having started treatment recently. Two individuals recently diagnosed with GD are considering their next steps. Fertility preservation was discussed with 26 individuals with GD (83%), of whom 5 (16%) chose to conserve their gametes (3 assigned female at birth, 2 assigned male at birth).
Conclusions
The APEVAGE clinic provides essential care for TGD minors, reflecting a growing demand for specialized services in Italy. Most individuals with GD began treatment with triptorelin, with many transitioning to GAHT. Fertility preservation discussions were integral, with a subset opting for gamete conservation. These findings highlight the importance of multidisciplinary care and the need for early access to services to support TGD youth effectively.

Complete androgen insensitivity syndrome (CAIS) management: balancing malignancy risk, hormonal benefits, and patient autonomy

Elżbieta Marczak[1], Maria Szarras-Czapnik[1], Agata Skórka[2,3], Kinga Kowalczyk[4], Gabriela Grochowska[4], Małgorzata Walewska-Wolf[5], Barbara Antoniak[5], Katarzyna Bajszczak[6] & Elżbieta Moszczyńska[1]
[1]The Children's Memorial Health Institute, Department of Endocrinology and Diabetology, Warsaw, Poland; [2]The Children's Memorial Health Institute, Department of Medical Genetics, Warsaw, Poland; [3]The Children's memorial helath Institute, Department of Genetics, Warsaw, Poland; [4]The Children's Memorial Health Institute, Department of Pediatric Urology, Warsaw, Poland; [5]The Children's Memorial Health Institute, Gynecological Outpatient Clinic, Warsaw, Poland; [6]The Children's Memorial Health Institute, Psychiatric Outpatient's Clinic for Children and Adolescents, Warsaw, Poland

Objective
This study aims to evaluate the clinical presentation, hormonal profile, genetic characteristics, and management strategies in patients with Complete Androgen Insensitivity Syndrome (CAIS). We explore the necessity of gonadectomy by weighing its benefits—such as reducing malignancy risk—against its drawbacks, including loss of endogenous hormone production and psychological impact. Additionally, we analyze histopathological findings in patients who underwent gonadectomy.
Methods
A retrospective review was conducted on medical records of 16 patients diagnosed with CAIS between 2004 and 2024 at a tertiary care university hospital. All patients, aged between 3 days and 19 years, had a confirmed mutation in the androgen receptor (AR) gene.
Results
Most patients were diagnosed in the prepubertal period due to inguinal hernias. Familial cases were identified in four instances. Hormonal evaluations revealed elevated antimüllerian hormone (AMH) levels in prepubertal patients, reflecting the presence of testicular tissue, and markedly high testosterone levels during puberty. In three cases, gonadal biopsy was performed during inguinal hernia repair due to atypical gonadal appearance inconsistent with the female phenotype. Given the relatively low malignancy risk, 11 patients retained their gonads, while five underwent gonadectomy and subsequently received estrogen replacement therapy. Psychological assessments indicated better well-being in patients who retained their gonads compared to those who underwent early gonadectomy. All patients received regular ultrasound monitoring of the gonads.
Conclusions
Our findings highlight the importance of considering CAIS in females presenting with inguinal hernias or primary amenorrhea. Delaying gonadectomy until after puberty facilitates spontaneous sexual maturation, secondary female characteristic development, and natural growth progression while minimizing psychological distress associated with early surgery. Given the low malignancy risk and benefits of gonadal preservation, a personalized approach that includes delayed or even omitted gonadectomy may be warranted. Furthermore, postponing surgical decisions allows patients to actively participate in their medical management, emphasizing the significance of patient autonomy in healthcare decision-making.
Keywords
Complete androgen insensitivity syndrome, AR gene, primary amenorrhea, inguinal hernia, gonadectomy, gonadal preservation.

Introduction
Advances in cancer treatments have significantly improved the prognosis of pediatric cancers, with 5-year survival rates approaching 75-80%. However, fertility is affected in 8-12% of female survivors. Several studies suggest that cancer survivors have a similar likelihood of maintaining pregnancy beyond 20 weeks, but preterm birth rates are higher, with nearly 9% of babies born to mothers with cancer being premature (<37 weeks) compared to 6% in those without cancer treatment.
Objective
To evaluate the characteristics of pregnancies in patients undergoing oncological treatment in the childhood-juvenile stage.
Population and methods
Patients with a history of oncological disease in the childhood-juvenile stage treated at the Professor Alejandro Posadas National Hospital were studied, evaluated during the period from 11/01/2020 to 10/31/2022 by determining AMH, antral follicle count, and FSH determination. The participants were recruited during the follow-up of the long-term effects of cancer treatment. Descriptive statistics were presented.
Results
71 pubertal and young adult patients were evaluated, 40 had the cancer diagnosis being prepubertal (56.3%) and 31 after having started puberty (43.7%). The median age at the start of cancer treatment was 8.1 years (0.9-17.6) and at the end of treatment was 10.1 years (2.1-20.3). The median of follow-up was 11.8 years (5-25) and at evaluation 19.9 years (10.8-31.9). The diagnosis was ALL in 59.2%, Hodgkin's lymphoma in 11.3%, AML in 7% 53% received only chemotherapy treatment (CMT), 15.5% (CMT + RT); 15.5% (CMT + surgery). All participants who received BMT (8.4%) as part of their treatment had ovarian function and follicular reserve impairment. Thirteen patients had at least one pregnancy prior to evaluation, 3 of which became pregnant twice and 1 had a twin pregnancy. Of the 17 gestational products: 6 were TNB (4 AGA, 2 SGA), 8 PTNB (4 AGA, 4 SGA), 2 spontaneous abortions (9 and 11 weeks), and 1 legal pregnancy interruption (12 weeks). The age of the first pregnancy was 18.8 (15.2-23) years. 18.3% managed to conceive without using assisted reproduction techniques. Two of the patients who subsequently became pregnant had AMH values < 1 ng/ml and none of the patients who achieved pregnancy had FSH values ≥25 IU/L.
Conclusion
In our study, 18.3% of cancer survivors had a recorded pregnancy. Patients would benefit from more frequent obstetric monitoring to reduce the risk of possible gestational complications.

A rare case of a child with a 46XY disorder of sex development with multiple congenital anomalies

Dalar Tumasyan[1], Hasmik Khachatryan[2,3] & Renata Markosyan[1,3]
[1]Wigmore Women's & Children's Hospital, Endocrinology Department, Yerevan, Armenia; [2]Muratsan University Hospital Complex, Endocrinology Department, Yerevan, Armenia; [3]Yerevan State Medical University, Endocrinology Department, Yerevan, Armenia

Introduction
Disorders of sex development (DSDs) are rare conditions involving atypical chromosomal, gonadal, or anatomical sex development. Among these, 46XY DSD is particularly significant due to its association with gonadal dysgenesis and an elevated risk of gonadal malignancy. Early diagnosis and management are critical to prevent complications, but challenges arise when additional congenital anomalies or delayed presentations are present.
Objective
We present a rare case of a child with a 46XY karyotype, presented with a disorder of sex development (DSD). This case highlights the complexity of managing a pediatric patient with 46XY DSD and developmental anomalies.

Case description
A 10 years old female patient, was referred to the endocrinology department for evaluation of short stature. A neurologist first evaluated her at 7–8 months of age following multiple consultations for mild mental retardation, developmental delays, and dysmorphic features, including a flat nose, low-set eyebrows, and small, low-set earlobes. The brain MRI at the time showed no abnormalities. Dysmorphic features and Turner syndrome-like dysembryogenesis symptoms prompted genetic evaluation. Karyotyping revealed a 46XY genotype, confirming the diagnosis of 46XY DSD. Further investigations revealed bifurcated kidneys, left kidney pyelectasis, and anomalies of the coronary vessels. Upon admission to the endocrinology department, a physical examination revealed hypertelorism of the nipples, an enlarged clitoris, a narrow vagina, and hypoplastic internal sex organs. Laboratory investigations demonstrated significantly reduced anti-Müllerian hormone (AMH) levels at 0.012 ng/ml and testosterone at 2.5 ng/dl (both below the normal range). IGF-1 was 68.2 ng/ml (IGF-1 SDS: -2.38), with a bone age of 6 years, reflecting delayed skeletal development. The hCG stimulation test results showed no increase in testosterone levels. Given the high risk of gonadal malignancy associated with 46XY DSD, diagnostic laparoscopy and gonadectomy were planned but postponed due to asymptomatic leukocyturia detected during preoperative testing. The patient now remains under close monitoring and is preparing for the surgery. Considering the presence of gonadal dysgenesis, growth hormone treatment is planned to begin after gonadectomy.
Conclusions
This case underscores the critical importance of timely multidisciplinary evaluation in 46XY DSD patients. Early genetic testing and endocrinological referral are essential for optimizing outcomes and preventing delays in diagnosis and management. This case also highlights the importance of vigilant monitoring for gonadal malignancy, necessitating timely surgical intervention when feasible as there is a high risk of gonadal malignancy.

Polycystic ovary syndrome: what we know about it?

Fatima Al Haj Diab[1], Ahmed MohamedAhmed[1], Yuliya Dydyshka[1] & Elena Brutskaya-Stempkovskaya[1]
[1]Belarusian State Medical University, Minsk, Belarus

Introduction and Aim
Approximately 70%of people with PCOS are undiagnosed.
The aim was to study the knowledge of PCOS among medical students.
Materials and Methods
It was a cross-sectional study by questionnaire method. The research involved survey consisting of 15questions, first9 questions were about the definition, symptoms and the diagnostic criteria of PCOS; the second part was about the student's experience and opinion. The sample size was 17 students(14 females and 3males) from international faculty of general medicine (4-5courses) 20-25years old with BMI between 23,5 and 32,5kg/m^2.
Results
In "What is PCOS from your point of view?",58,8%answered that is a disease, the other answered that PCOS is an ultrasound diagnosed symptom. In "What is the correct definition for PCOS?" there were significant debate about the convenient definition:29,4%(5students) chose that it is reproductive disorder, 35,3 ($n = 6$) answered it's a metabolic disorder, and the rest chose none of the above choices. In "What is the most affected age?" most of the students answered18-38. Coming "How can you tell ovulation had happened?" 47,1%(8students) answered that by hormonal changes and ultrasound, 29,4%($n = 5$) chose by mood swings and feelings, however the rest confirmed that test is the one to know if ovulation had happened. There was similar answer in "Gallwey Score is used to test?" most of them had confirmed that they had never heard about it. Majority had answered that dysmenorrhea is the needed criteria to diagnose PCOS, only 17,7%(3students) chose that infertility and psychosexual dysfunction is the needed one. It was a popular opinion the female should be treated from PCOS despite of her planning pregnancy, so 64,7% (11students) chose that any female who has dysmenorrhea should be suspected with PCOS. Question10 was only for females, if they use any application to check their menstrual cycle, however in answering question 4about the normal cycle length all had the same answer21-35. Most the students confirmed that the female should check her hormone levels every3 months. Apparently, most of them think that PCOD(disorder) is different from PCOS(syndrome). There was difference in opinions about who should treat PCOS:58,8%($n = 10$)chose gynecologist,23,5($n = 4$) added their own opinion and the others chose the endocrinologist.
Conclusion
The most of the female students use menstrual calendar, however they didn't know what is the normal cycle length. Although every one of the medical students had different point of view and thoughts about the best treatment for PCOS, but all had confirmed that PCOS is a huge misunderstanding topic.

Diabetic turner syndrome patients – conclusions from the bulgarian diabetes registry

Ralitsa Robeva[1,2], Atanaska Elenkova[1,2], Maria Orbetzova[3,4], Sabina Zacharieva[1,2], Emanuil Markov[5] & Dimitar Tcharaktchiev[1,2]
[1]Department of Endocrinology, Faculty of Medicine, Medical University-Sofia, USHATE "Acad. Iv. Penchev", Sofia, Bulgaria; [2]Expert Center for Rare Endocrine Diseases - USHATE "Acad. Iv. Penchev", Sofia, Bulgaria; [3]USHATE "Acad. Iv. Penchev", Sofia, Bulgaria; [4]Faculty of Medicine, Medical University-Plovdiv, Plovdiv, Bulgaria; [5]Technical University, Sofia, Bulgaria

Background
The Bulgarian healthcare system requires individual compulsory health insurance administered by the National Health Insurance Fund (NHIF), operating with the health data of 2.75 million Bulgarian women. The Bulgarian Diabetes Register (BDR) collected all pseudonymized NHIF electronic health records of patients with diabetes mellitus type 1 or type 2 (T1DM or T2DM), with the latest dataset being from 2018 (1). BDR includes outpatient NHIF records from all primary care providers and specialists in secondary care nationwide for every visit of a patient suffering from DM.
Methods
The available data about diabetic patients with Turner syndrome (TS) (ICD-10 Q96, ORPHA:881) from the BDR were extracted and analyzed. The collected information included age, type of diabetes, diabetes complications, treatment, concomitant diseases, and a number of medical consultations yearly.
Results
A total of 19 diabetic patients (median 40 [13-69] years) with TS have been found in the BDR database. 84.2% of patients were with DMT2, while 15.8% were with DMT1. Diabetic neuropathy was found in 7 (36.8%) of the patients. The TS patients showed significant co-morbidity and a high number of consultations with general practitioners and/or clinical specialists yearly - an average of 14 (2-29) in 2018.
Conclusions
The lower-than-expected prevalence of diabetic TS patients in the BDR might result from TS or DM underdiagnosis. Diabetic TS patients have a high prevalence of complications and co-morbidities and require high healthcare resources. More efforts should be made by the public health system in the country to ensure the proper diagnosis of TS. Furthermore, regular estimation of carbohydrate metabolism in TS patients is paramount for the early diagnosis of DM in the affected women and the prevention of complications and high medical costs.

Etiologic distribution of adult-onset male hypogonadism in the modern era: retrospective cohort study from finnish tertiary center

Patrik Forsman[1], Antti Jokiniitty[2], Heini Huhtala[3] & Henri Honka[4]
[1]Faculty of Medicine and Health Technology, Tampere University, 33520, Finland; [2]Department of Internal Medicine, Tampere University Hospital, Tampere, Finland; [3]Faculty of Social Sciences, Tampere University, Tampere, Finland; [4]Department of Internal Medicine, University of Turku, Finland, Turku, Finland

Although signs and symptoms associated with male hypogonadism are commonly encountered in endocrinology outpatient clinics, their clinical implications are not well characterized. In present study, we aimed to describe the etiologic distribution, as well as the anthropometric and biochemical features of adult-onset male hypogonadism, using electronic health record data of individuals referred for an endocrine evaluation between 2020-2022 due to low testosterone and hypogonadal symptoms. Of the total of 119 individuals referred, 88 patients who had low testosterone (*i.e.*, less than 10 nmol/l)on repeated measurements constituted the study population. Patients were grouped into four categories according to the etiology of hypogonadism: primary hypogonadism ($n=13$), morbid obesity-associated secondary hypogonadism (MOSH) ($n=49$), prior anabolic-androgenic steroid use (AAS) ($n=5$), and hypogonadotropic hypogonadism (HGHG) ($n=21$). The latter group included patients with a specific disease of the pituitary gland ($n=6$), as well as patients with prior and/or current opioid/glucocorticoid use ($n=8$), patients with obstructive sleep apnea without morbid obesity or other sleep disorders ($n=3$) and patients with miscellaneous etiology of HGHG ($n=4$). The median serum testosterone levels were 6.7 [5.0-9.4], 7.3 [5.9-8.6], 6.3 [2.8-8.0] and 6.9 [3.9-8.2] nmol/lin primary, MOSH, AAS and HGHG groups, respectively (NS in Kruskal-Wallis test) and symptoms distribution (NS in chi-square test) were comparable among the groups whereas luteinizing hormone (LH) levels were higher in patients with primary hypogonadism (10.8 [5.0-21.2] U/l)than other groups (4.1 [2.2-5.4], 1.3 [0.0-2.5] and 2.9 [0.3-4.5] U/lin MOSH, AAS and HGHG groups, respectively, $P < 0.001$). Prevalence of hypertension and obstructive sleep apnea (both $P < 0.01$) were higher in MOSH compared to the rest of the groups although glucose and lipid profiles were comparable among the groups. Surprisingly, serum testosterone levels in the MOSH group were inversely correlated with gonadotropin levels (LH: $r=-0.42$, $P<0.01$; FSH: $r=-0.41$, $P<0.01$); this was not observed in HGHG group. In summary, morbid obesity is the leading cause of adult-onset male hypogonadism whereas cases due to specific conditions affecting HPT axis, such as prolactinoma or testicular failure, are rare. Although negative feedback of testosterone on gonadotropins is preserved in hypogonadal men with morbid obesity, gonadotropin secretion is insufficient for maintaining adequate testosterone levels. This is in contrast with hypogonadotropic hypogonadism, which is characterized by a total disruption of HPT axis regulation.

Obstetrical outcomes after oocyte donation in turner syndrome: retrospective study among patients with primary ovarian insufficiency

Hugo Saignes[1], Aude Brac De La Perrière[2], Bruno Salle Leyris De Campredon[1], Laurence Pral-Chatillon[1], Gaëlle Soignon[1], Elsa Labrune[1] & Eloïse Fraison[1]

[1]Hospices Civils de Lyon, Reproductive medecine and biology, Lyon, France; [2]Hospices Civils de Lyon, Endocrinology, Diabetes & Metabolism, Lyon, France

Turner syndrome is a chromosomic disease affecting 1 fetus in 2500. In more than 95% of cases, these patients have primary ovarian insufficiency (POI), consisting of premature cessation of ovarian function before the age of 40. When a pregnancy is expected, usually, *in vitro* fertilization (IVF) with oocyte donation is necessary. Current data suggest increased obstetric and perinatal morbidity for these pregnancies, such as hypertensive disorders. A retrospective monocentric cohort study was conducted in the reproduction medicine ward of the University Hospital Center of Lyon. The study population included all patients aged 18 to 40 who had received at least one embryo transfer after IVF with oocyte donation, in POI context, with or without Turner syndrome, from January 1, 2007 to December 31, 2023. 97 patients were included. Live birth rate, obstetrical and perinatal outcomes were compared between the 2 populations. Embryo transfer success (live birth) was conducted by adjusted logistic regression. Several odds-ratio were estimated, depending on the rank of transfer attempt. A purely descriptive analysis of obstetrical and perinatal data was conducted. 29% of the embryo transfers resulted in a live birth among the Turner patients, and 27% among the other POI patients. A statistically significant decrease of live birth rate in the first attempt among the Turner was seen, with an odds ratio at 0,09 (0,01; 0,64) and a p-value at 0,017. No statistical difference was noted for the third transfer and beyond, with a p-value at 0,095. The obstetrical and perinatal morbidity was high, with 70% of cesareans, 18,7% of premature births and 26% of non-cephalic fetal presentations for Turner patients. The retrospective nature of the study is responsible of selection bias. A more precise analysis of the obstetric outcomes would require distinguishing single-fetal pregnancies from multiple pregnancies, having their own morbidity. Live birth rates in our study are high, in line with lower miscarriage rates than usually found in the literature. The optimization of hormonal replacement therapy prior to ART course, and of the artificial cycle during embryo transfer seem to be plausible explanations of the better results. The obstetrical and perinatal morbidity is high, as expected.

Key words

Turner syndrome, primary ovarian insufficiency, oocyte donation, obstetrical outcomes.

Case report of a newborn child with dsd due to 46,XX/46,XY chimerism

Marie Ritter[1], Geeske Muehlschlegel[1], Franka Hodde[1], Johanna Weekes[1], Olimpia Alice Manzardo[1], Paul-Martin Holterhus[2], Alexandra E. Kulle[2] & Clemens Kamrath[1]

[1]Department of General Paediatrics and Adolescent Medicine, Section of Paediatric Endocrinology and Diabetology, University Medical Centre, University of Freiburg, Freiburg, Germany; [2]Department of Paediatric Oncology and Rheumatology, Division of Peadiatric Endocrinology and Diabetes, University Hospital Schleswig-Holstein, Kiel, Germany

Background

We present the case of a newborn child with prenatal diagnosis of 46,XY karyotype in non-invasive prenatal testing (NIPT) in two tests in combination with a female internal and external genital phenotype in prenatal ultrasound.

Case Presentation

The child was born at term with a birth weight of 3575g and a length of 50cm. External genitalia were unremarkably female without virilisation or malformations. On postnatal ultrasound, the internal genitalia showed a uterus. However, gonads could not be identified with certainty. The postnatal karyotype from blood lymphocytes showed a 46,XX(2)/46,XY(18) chimerism. A second postnatal karyotype from oral mucosa showed a 46,XY karyotype in all cells analyzed. A plasma steroid analysis obtained at the age of 3 months during the so-called 'mini puberty', analyzed by liquid chromatography-tandem mass spectrometry (LC-MS/MS), showed testosterone and estradiol levels below the lower limit of detection ($<$ 0.02 nmol/l[reference: 0.1-0.7) and $<$5 pmol/l[10-193], respectively). However, laboratory analysis showed significantly elevated Anti-Müllerian hormone (AMH) and Inhibin B levels for female gender (21 ng/ml [0.08-8.9] and 210 pg/ml [4.8-83], respectively), which could be interpreted as confirmation of the presence of Sertoli cells and thus the presence of male gonadal differentiation.

Conclusions

In a newborn child with undoubtedly female external genitalia, karyotype from peripheral blood showed a chromosomal 46,XX/46,XY chimerism, whereas the karyotype from oral mucosa did not. When interpreting this, we must take into account that cell mosaics may have a different expression in different tissues. Elevated levels of AMH and Inhibin B indicate testicular gonadal differentiation. However, this is currently in contradiction with the presence of a uterus on ultrasound. The absence of testosterone is consistent with female external genital differentiation. As estradiol is not detectable by a highly sensitive LC-MS/MS method, we have no information on possible ovarian differentiation of the gonads. As only 2 out of 20 cells in the peripheral blood showed the 46,XX constellation, we also initiated array-CGH analysis and exome sequencing. Finally, a minimally invasive gonadal biopsy should be performed to assess the presence of ovotestes and the risk of gonadal tumor development. Medical care will be provided throughout childhood and adolescence, including hormone therapy if necessary and counselling on gender identity issues.

RAB5B Gene expression and its association with insulin resistance in women with PCOS

Taruna Arora[1], Khurshid Padder[2], Nusrat Jahan[2], Mohmad Yousuf[2] & Mohd Ashraf Ganie[2]
[1]Division of RCN, ICMR Headquarters, New Delhi, India; [2]Department of Endocrinology, Sher-i- Kashmir Institute of Medical Sciences, Srinagar, India

Polycystic Ovary Syndrome (PCOS) is a complex endocrine, reproductive, and metabolic disorder accompanied by hyperandrogenism and hyperinsulinemia mediated insulin resistance, but the precise molecular mechanism remains unclear. The study aimed to explore the potential link between RAB5B gene expressions and insulin resistant among women with PCOS.A total of age matched 270 subjects were enrolled in this study which included 135 PCOS women and 135 apparently healthy controls. The study participants were subjected to detailed medical history, clinical examination and physical examination. All subjects were further evaluated for biochemical, hormonal and inflammatory. Expression levels of *RAB5B* gene were analyzed using gene-specific primers and the SYBR® Green PCR Kit (Qiagen, Germany) and their qPCR reaction mix, according to the manufacturer's guidelines. Student t-test and ANOVA were used to evaluate the differences in the means of various parameters. The HOMA-IR (2.28 ± 1.4 *vs.* 1.36± 0.73) was significantly elevated among women with PCOS than controls ($p<0.001$). We also found that the QUICKI (0.35±0.04 *vs.* 0.37±0.04), MATSUDA (12.59±4.71 *vs.* 15.47± 4.33) and FGIR (11.56±7.06 *vs.* 14.32±8.66) were higher in controls than women with PCOS ($P<0.001$). Our findings revealed that women with PCOS exhibited significantly higher RAB5B mRNA levels compared to apparently healthy controls. This study highlights a potential link between RAB5B gene expression and insulin resistance, particularly in relation to insulin indices, in women with PCOS.

The role of triglyceride-glucose index in women with polycystic ovary syndrome: a systematic review and meta-analysis

Alireza Azarboo[1], Amin Javidan[1], Parisa Fallahtafti[1], Sayeh Jalali[1], Shabboo Moayyed[1] & Azadeh Tarafdari[2]
[1]School of Medicine, Tehran University of Medical Sciences, Tehran, Iran; [2]Department of Obstetrics and Gynecology, Imam Khomeini Hospital Complex, Tehran University of Medical Sciences, Tehran, Iran

Background
Polycystic ovary syndrome (PCOS) is one of the common disorders affecting women of reproductive age. Insulin resistance (IR) plays a pivotal role in its pathogenesis, leading to metabolic complications such as hyperglycemia, dyslipidemia, and increased cardiovascular risk. The triglyceride-glucose (TyG) index, a surrogate marker of IR, has gained attention for its simplicity and diagnostic accuracy across metabolic disorders. This study aims to comprehensively assess the role of the TyG index in PCOS and its utility as a diagnostic and prognostic biomarker.
Methods
A systematic review and meta-analysis were conducted following PRISMA guidelines. PubMed, Scopus, Embase, and Web of Science were searched up to December 2024. Observational studies reporting TyG indices in PCOS and control groups were included. Subgroup and meta-regression analyses explored sources of heterogeneity. Sensitivity analysis and publication bias assessments ensured robustness.
Results
Fifteen studies (7,175 participants) were analyzed. The TyG index was significantly higher in women with PCOS compared to controls (SMD 0.34, 95% CI 0.14–0.54, $I^2 = 70.9\%$). Subgroup analysis revealed a significant association in Chinese studies (SMD 0.42, 95% CI 0.35–0.49, $I^2 = 0\%$) and cross-sectional studies (SMD 0.45, 95% CI 0.32–0.57, $I^2 = 3.2\%$). The TyG index exhibited excellent diagnostic accuracy for distinguishing PCOS from controls (AUC 0.86, 95% CI 0.80–0.94, $I^2 = 80.8\%$). Similarly, the TyG-BMI index showed a significant association with PCOS (SMD 0.34, 95% CI 0.10–0.57, $I^2 = 0\%$) and excellent diagnostic performance (AUC 0.81, 95% CI 0.75–0.88, $I^2 = 0\%$). Meta-regression analysis identified no significant impact of age, BMI, or lipid profiles on heterogeneity.
Conclusion
This meta-analysis uniquely highlights the triglyceride-glucose index as a robust and clinically significant marker for PCOS women. While the homeostatic model assessment of insulin resistance (HOMA-IR) is widely used, its reliance on insulin measurements limits its practicality in routine clinical settings. In contrast, the TyG index, derived from simple triglyceride and fasting glucose measurements, provides a more accessible and cost-effective alternative, facilitating early screening for insulin resistance, particularly for identifying metabolic risks in the PCOS population. Given that PCOS encompasses a heterogeneous spectrum of metabolic, hormonal, and ovarian dysfunctions rather than a single uniform disease, future research should focus on stratifying the TyG index's association with insulin resistance across different PCOS phenotypes. Establishing phenotype-specific thresholds and refining its predictive capabilities for long-term cardiometabolic outcomes will be crucial in optimizing risk assessment and personalized management in this heterogeneous population.

Bone mineral density and trabecular bone score in adolescents and young women with primary ovarian insufficiency

Noah Gruber[1,2], Shai Bar-Shira[1,2], Myriam Safrai[2,3], Moran Shapira[2,3] & Yael Levy-Shraga[1,2]
[1]Sheba Medical Center, Edmond and Lili Safra Children's Hospital, Pediatric Endocrine and Diabetes Unit, Ramat Gan, Israel; [2]Tel-Aviv University, Faculty of Medical and Health Sciences, School of Medicine, Tel Aviv, Israel; [3]Sheba Medical Center, Department of Obstetrics and Gynecology, IVF Unit, Ramat Gan, Israel

Background
Primary Ovarian Insufficiency (POI) is associated with osteoporosis and an increased risk of fractures. However, scarce data exists on the trabecular bone score (TBS) in adolescents with POI. We aimed to evaluate bone mineral density (BMD) and TBS in adolescents and young adults with POI.
Methods
This retrospective study included girls aged 10–24 years with POI who underwent at least one dual-energy X-ray absorptiometry (DXA) scan at our institution between 2020 and 2025. POI was defined as irregular menses and follicle-stimulating hormone (FSH) levels >20 IU/lon two occasions at least one month apart. Clinical data, including hormonal levels and POI etiology, were extracted from medical records. Measurements were compared between girls with Turner syndrome (TS) and those without Turner syndrome (non-TS).
Results
Twenty-four girls underwent DXA scans at a mean age of 17.7±2.2 years (range 15.3–21.7). POI was diagnosed at a mean age of 14.8±3.3 years, earlier in TS (11.7±2.6) than in non-TS girls (16.4±2.5). The mean FSH level at diagnosis was 75.3±41.4 IU/l,lower in TS (48.3±23.2) than in non-TS girls (88.7 ± 42.5, $p=0.01$). Most girls presented with amenorrhea (96%, $n=23$): among them, 52% ($n=12$) had primary amenorrhea, 48% ($n=11$) had secondary amenorrhea, and one was diagnosed through fertility counselling. The mean L1-L4 bone mineral density (BMD) Z-score was -1.55±1.24, the total body less skull BMD Z-score was -0.62±0.92, and the L1-L4 TBS Z-score was -0.87±0.78. In three patients with repeated DXA scans, TBS Z-scores increased from 1.37±0.13 to 1.44± 0.07 after an average of 1.7±0.7 years of hormone replacement therapy (HRT). TS girls had higher mean L1-L4 BMD Z-scores (-0.26±1.25 vs. -2.08±0.76, $p=0.007$), total body less skull BMD Z-scores (0.12±0.56 vs. -0.90±0.75, $p=0.01$), and TBS Z-scores (-0.17±0.91 vs. -1.15±0.51, $p=0.03$) compared to non-TS girls. TS girls also had a longer duration of HRT before DXA (3.10±3.34 vs. 0.38±1.42 years, $p=0.07$). The mean age at DXA was similar between TS (17.89±2.75) and non-TS girls (17.61±1.91).
Conclusions
Girls with POI exhibited low L1-L4 BMD and TBS Z-scores, which improved with HRT. TS girls had significantly better bone health metrics than non-TS girls, potentially due to a longer duration of HRT. These findings underscore the critical need for early diagnosis and intervention to optimize bone health in this population.

Transitioning care in hypogonadism: a retrospective analysis

Ana Torrão Pinheiro[1], Teresa Tavares[2], Catarina Figueiredo[3], Miguel Saraiva[4], Maria João Oliveira[3], Lia Ferreira[3], Isabel Palma[4] & Teresa Borges[3]
[1]Endocrinology Department, Centro Hospitalar Universitário de Santo António, Porto, Portugal; [2]Centro Hospitalar Universitário de Santo António, Pediatric Department, Porto, Portugal; [3]Centro Hospitalar Universitário de Santo António, Pediatric Endocrinology Unit, Pediatric Department, Porto, Portugal; [4]Centro Hospitalar Universitário de Santo António, Endocrinology Department, Porto, Portugal

Introduction
The transition from pediatric to adult endocrinology care is a critical period for patients with hypogonadism. Effective management during this phase is essential to ensure continuity of care, adherence to treatment, and proper management of associated concerns such as fertility and bone health. This study aims to evaluate the characteristics and clinical outcomes of patients with hypogonadism undergoing transition from pediatric to adult care.
Methods
A retrospective analysis was conducted on all patients who transitioned from pediatric to adult endocrinology care between January 2022 and January 2025, following the establishment of the sexual medicine transition clinic at our centre. Epidemiological and clinical data were collected.
Results
A total of twenty-two individuals ($n = 22$) transitioned to adult endocrinology care over the 3-year observation period, with a median age at transition of 18.9 years (interquartile range (IQR) 18.5-19.7). The cohort comprised 59% females ($n = 13$). The primary diagnosis included Turner syndrome ($n = 7$, 32%), gonadal dysgenesis ($n = 5$, 23%), Klinefelter syndrome ($n = 4$, 18%), Kallmann syndrome ($n = 2$, 9%), androgen insensitivity syndrome ($n = 1$, 4%), mosaic trisomy 22 ($n = 1$, 4%), Triple X syndrome ($n = 1$, 4%), and a single case of hypergonadotropic hypogonadism of unknown etiology. Hypogonadism was diagnosed in 91% ($n = 20$) of patients, with hypergonadotropic hypogonadism being the predominant subtype, accounting for 82% ($n = 18$). Hormone replacement therapy was initiated in 86% ($n = 19$) of patients, with a median age at initiation of 14.1 years (IQR 12.0-15.5). Short stature was observed in 36% ($n = 8$), of whom six received growth hormone therapy, initiated at a median age of 6.8 years (IQR 3.1-10.6) and continued for a median duration of 7.3 years (IQR 5.8-12.4). A multidisciplinary team was involved in 82% of cases ($n = 18$), and no patients were lost to follow-up during the transition period. Bone mineral density assessment was performed in 73% ($n = 16$), while fertility-related discussions were documented in 45% ($n = 10$).
Discussion
This study highlights the diverse etiologies and complexities of hypogonadism in transition care. Despite high rates of hormone therapy initiation and multidisciplinary involvement, gaps remain in fertility discussions and bone health monitoring. Optimizing transition pathways with standardized protocols can enhance continuity of care and patient outcomes. Future efforts should focus on addressing these gaps and exploring patient-reported outcomes to further improve the quality of care for this population.

Psychosomatic outcomes in adulthood among north african patients with testicular DSD

Hamdi Frikha[1], Nesrine Dhieb[1], Dhoha Ben Salah[1], Yassmine Abdelkafi[1], Khouloud Boujelben[1], Mohamed Abid[1], Mouna Mnif[1], Mouna Elleuch[1] & Nabila Rekik Majdoub[1]
[1]Hedi Chaker University Hospital, Endocrinology, Sfax, Tunisia

Introduction
The long-term outcomes of adults living with disorders of sex development (DSD) remain poorly studied. This study aims to characterize the somatic and psychosocial features of an adult North African population with testicular DSD.
Methods
This was a cross-sectional descriptive study conducted at the DSD reference center in Sfax, Tunisia, including 30 adult patients ($\geq$18 years old) of diverse North African origins diagnosed with testicular DSD. The study assessed sexual development, cardiometabolic profile, bone mineralization, and psychosocial outcomes.
Results
The mean patient age was 23.68 ± 8.8 years. The most common diagnoses were steroidogenesis defects (38%) and gonadal dysgenesis (32%). The average follow-up duration was 8.2 ± 4.7 years. All patients received hormone replacement therapy aligned with their assigned civil gender, resulting in appropriate sexual development (Tanner stage 4.15 ± 1.14). Three cases of de novo hypertension and hypertriglyceridemia were identified. Glucose intolerance tests were negative among all patients. Bone demineralization was found in 9 out of 17 evaluated patients, predominantly and most severely among those with complete androgen insensitivity syndrome. All patients identified as cisgender with a binary heterosexual orientation. Access to mariage and sexual activity was reported only in patients over 30 years old without genital anomalies. The unemployment rate was high (70%).
Discussion
Genetic anomalies and hormone therapy contribute to an unfavorable metabolic and bone profile in testicular DSD. Contrary to literature reports, no cases of gender identity disorders or homosexuality were observed, likely due to socioreligious factors. Access to marital and sexual life was delayed and correlated with the absence of genital anomalies, reflecting feelings of shame and barriers to reproduction. Social integration also appeared to be impaired. These findings highlight the need for larger longitudinal studies for further validation.

The effect of gender-affirming hormone therapy on the occurrence of axial spondyloarthritis in people with gender dysphoria

Shalala Shukurova[1], İlkin Muradov[2], Emre Durcan[2], Cem Sulu[2], Sinem Esatoglu[2], Melike Melikoglu[3] & Pinar Kadioglu[2]
[1]Istanbul University- Cerrahpasa, Department of Internal Medicine, Istanbul, Türkiye; [2]Istanbul University- Cerrahpasa, Department of Endocrinology, Metabolism and Diabetes, Istanbul, Türkiye; [3]Istanbul University- Cerrahpasa, Department of Rheumatology, Istanbul, Türkiye

Objective
Axial spondyloarthritis (axSpA), especially radiographic axSpA, is more frequently observed in males, and the role of testosterone in the etiology remains controversial. Our study aims to determine the prevalence of axSpA in people with gender dysphoria (GD) undergoing gender- affirming hormone therapy (GAHT) and to assess whether testosterone therapy increases disease prevalence in female-to-male (FtM) GD.
Materials and Methods
Using a structured questionnaire prepared by the rheumatology department, the medical histories of people receiving GAHT were collected in face-to-face or telephone interviews. HLA-B27 and C-reactive protein (CRP) levels were determined in participants who had been suffering from chronic back pain for more than three months and whose symptoms started before the age of 45, in line with the entrance criteria of The Assessment of SpondyloArthritis International Society (ASAS) classification for axSpA. X-rays of the sacroiliac joints and magnetic resonance imaging (MRI) were also performed.
Results
In the first step, a total of 280 individuals with GD were approached, and 250 (61 male-to female (MtF), 189 FtM) participated in the study. Inflammatory back pain was identified in 6% of participants with GD (13 FtM, 2 MtF). All patients were HLA-B27 negative. The sacroiliac joint radiographs of three FtM GD individuals showed findings suggestive of axSpA, but they did not meet the modified New York criteria for radiographic axSpA. Three FtM GD individuals with suspicious radiologic findings had chronic structural lesions suggestive of chronic sacroiliitis on sacroiliac MRI. In the second step, we also examined 41 FtM GD individuals for chronic back pain before starting GAHT. At baseline, 10 subjects reported chronic back pain, of which only 2 had inflammatory back pain, while the remaining 8 had mechanical back pain. After one year of GAHT only one individual continued to suffer from chronic back pain. Remarkably, this person was one of the two individuals who had reported inflammatory back pain before starting GAHT.
Conclusion
According to the ASAS criteria, the prevalence of inflammatory back pain in this cohort was 6%, similar to the general population. Although none of the patients met the modified New York criteria for radiographic axSpA, three FtM GD had radiographic findings suggestive of sacroiliitis. early-stage axSpA. Although

there is ongoing debate about whether non-radiographic axSpA is an early stage of radiographic axSpA or whether these 2 entities are mutually exclusive, longitudinal follow-up of these individuals to monitor disease progression is warranted.

Evaluation of test results according to body mass index of patients who had a gnrh stimulation test with a preliminary diagnosis of precocious puberty

Nil Beril Calıskan[1], Gulin Karacan Kucukali[1], Erdal Kurnaz[1], Keziban Aslı Bala[1], Şenay Savaş Erdeve[1] & Meliksah Keskin[1]
[1]University of Health Sciences, Pediatric Endocrinology, Ankara, Türkiye

Introduction
The appearance of secondary sex characteristics 2-2.5 standard deviation score (SDS) earlier than the expected age is defined as precocious puberty. Childhood obesity has emerged as an important public health problem in recent years. GnRH stimulation test is considered the gold standard in the diagnosis of precocious puberty. Our study aims to determine possible differences in responses according to body mass index in female patients who underwent GnRH stimulation test with the preliminary diagnosis of precocious puberty.
Materials and Methods
In this retrospective study, female patients aged 6-9.5 years who applied to tertiary Pediatric Endocrinology clinic between September 2022 and December 2023 and underwent GnRH stimulation test with the preliminary diagnosis of precocious puberty were included. Patients were grouped according to their BMI SDS values as normal weight (BMI SDS between -1.5 and +1.5), overweight (BMI SDS between +1.5 and +2) and obese (BMI SDS > +2). Detailed anamnesis of the patients was taken and their demographic data, anthropometric measurements, laboratory results and radiological imaging were evaluated.
Results
Among the 241 girls included in the study, 147 (60.99%) were of normal weight, 46 (19.08%) were overweight, and 48 (19.91%) were obese. The mean chronological age of all cases was 7.8 $\pm$ 0.66 years, the mean bone age was 9.4 $\pm$ 1.2 years, and the mean height age was 8.7 $\pm$ 1.28 years. When comparing the three groups, no significant difference was found in chronological ages. However, there was a difference in bone ages and height ages ($P < 0.05$). While there was no significant difference in basal LH and E2 levels, a difference was found in basal FSH levels ($P < 0.05$). Differences were also observed in peak LH and peak FSH responses ($P < 0.05$).
Discussion
In our study, the test results of patients who underwent GnRH stimulation test with the preliminary diagnosis of precocious puberty were evaluated according to their BMI SDS, and a difference was detected between the groups in peak LH and peak FSH responses. The low peak LH responses in overweight and obese patients as a result of the GnRH stimulation test performed when basal LH levels are not sufficient to make a diagnosis indicate that it may be more appropriate to evaluate the results of the GnRH stimulation test, which is considered the gold standard test in terms of pre-puberty, together with other test results in these patients.

Multidisciplinary team (MDT) clinics for children and young people with differences in sex development (DSD): evaluation of clinical outcomes and patient/caregivers' experiences

Alexis Lordudass[1], Nabeel Jogee[1], Anju Goyal[2], Julie Jones[1], Kay Metcalfe[3], Melanie Newbould[4], Jaqueline Nicholson[5], Indi Banerjee[1], Mars Skae[1] & Leena Patel[1,6]
[1]Royal Manchester Children's Hospital, Department of Paediatric Endocrinology, Manchester, United Kingdom; [2]Royal Manchester Children's Hospital, Department of Paediatric Urology, Manchester, United Kingdom; [3]Royal Manchester Children's Hospital, Department of Clinical Genetics, Manchester, United Kingdom; [4]Royal Manchester Children's Hospital, Department of Paediatric Histopathology, Manchester, United Kingdom; [5]Royal Manchester Children's Hospital, Department of Paediatric Clinical Psychology, Manchester, United Kingdom; [6]University of Manchester, Division of Medical Education, Manchester, United Kingdom

A multidisciplinary team (MDT) approach is recommended to provide holistic patient-centred care for those affected by Differences in Sex Development (DSD). We evaluated regional DSD services in a large Children's hospital with the aim to investigate 1) clinical outcomes for patients, and 2) patients/caregivers' experiences of the service.
Methods
Electronic records of all patients who attended the DSD MDT clinics over a 5-year period (2019-2023) were reviewed retrospectively for clinical outcomes. Feedback using questionnaires (7 items on 5-point Likert-scale) and semi-qualitative survey (4 items) completed by a subset of patients/caregivers attending 3 clinics during 2024 were analysed.
Results
Fifty-eight patients were reviewed at 98 appointments. Median age at the start of this study was 4.4 years (36 days-17.9 years). Karyotype was 46XY in 30 (51.7%), 46XX in 23 (39.7%) and other in 5 (8.6%) patients. Pathophysiology categorization suggested defects in gonad differentiation in 22 (38%) [19 (33%) gonadal dysgenesis, Mullerian ducts in 3 (5%)], steroid biosynthesis in 22 (38%), androgen action in 11 (19%) and unknown in 3 (5%). A definitive diagnosis was made in the DSD clinic in 33/58 (56.9%). The commonest diagnosis was 21 hydroxylase deficiency congenital adrenal hyperplasia ($n = 15$, 25.9%). Before attending the clinic, gender assigned was male for 21 (36.2 =%) and female for 37 (63.8%) patients. Reconstructive genital surgery had been done in 21/58 (36.2%) patients before they attended the clinic. Specialists in endocrinology, urology, clinical psychology, clinical genetics, nursing and biochemistry were present at each clinic. MDT discussions with patients/caregivers led to complex decisions about gender reassignment from female to male ($n = 3$), prophylactic gonadectomy owing to risk of malignancy (8/19, 42.1% patients with gonadal dysgenesis; 4/9, 44% with androgen insensitivity) and external genital surgery ($n = 10$, 17.2%). All 9 patients/caregivers who attended 3 clinics completed questionnaires; 100% were 'very satisfied' with the clinic and found the MDT 'very helpful', 89% 'felt comfortable asking questions' and over 75% 'understood everything about their complex condition'. Semi-qualitative review suggested that the clinic was meeting the needs of patients/caregivers, and no changes were requested.
Discussion
This MDT clinic contributed to shared decisions for complex interventions, including gender reassignment, prophylactic gonadectomy and reconstructive genital surgery, supported by positive feedback from patients/caregivers. From the feedback responses, the MDT recognizes a need to give patients/caregivers more opportunities and encouragement so that they feel completely comfortable asking questions, and which may contribute to enhancing their understanding about their complex condition.

Thyroid status of women in preparation for *in vitro* fertilization

Asalkhon Jilonova[1,2], Khurshida Nasirova[1] & Khurshida Shodieva[3]
[1]Tashkent pediatric medical institute, endocrinology and pediatric endocrinology, Tashkent, Uzbekistan; [1]Tashkent pediatric medical institute, endocrinology and pediatric endocrinology, Tashkent, Uzbekistan; [3]Tashkent medical academy, Fertility IVF, gynecology, Tashkent, Uzbekistan

Introduction
Hypothyroidism affects the reproductive function of the female body, leading to infertility. Prolonged disturbance of hormonal status with infertility requires the use of *in vitro* fertilization (IVF) programmes.
Purpose
To evaluate the thyroid gland status of women for preparation for the IVF programme.
Material and Methods
The patients are divided into the following groups: 32 patients with history of female infertility with hypothyroidism conceived by IVF- first group, 22 patients with history of female infertility with hypothyroidism conceived naturally - second group. Out of 54 patients, 37 (68.5%) had primary and 17 (31.5%) had secondary infertility.

Results
Common complaints in women of both groups were ectodermal disorders like dry skin, hair loss, brittle nails which occurred in half of all patients. Hyperprolactinaemia was significantly more frequent in women of the first group (31.3%), increased blood pressure was observed in 5 (16.1%) patients of the first group and in 1 (4.5%) of the second group. On palpation of the thyroid gland and examination of imaging techniques, particularly ultrasound, the following thyroid changes were found. Nodular goitre was found in 9 (16.7%) patients. One patient underwent fine-needle aspiration biopsy (FNAB) of the nodule due to its exceeding its size by more than 10 mm and to confirm its benignity. Hypoplasia of the thyroid was observed in 7 patients, diffuse goitre of the first degree in 21 (38.9%) women. Autoimmune thyroiditis (AIT) with confirmation of hormonal studies was found in 25 (46.3%) patients. To make a final diagnosis, the hormonal profile of the women was investigated, which showed the following results. In women of the first group thyroid hormone (TSH) was higher than normal and hypothyroid state lasted longer, due to this there was an increase in prolactin levels in the blood. The increase of luteinizing and follicle stimulating hormones in the same group indicated pronounced menstrual cycle disorders in the form of menorrhagia in 48%, oligomenorrhoea in 14.8% and increase of anovulatory cycles in 54.8% of cases. Decrease in the number of antral follicles was observed in 40.7% of cases, which is one of the indicators of reduced ovarian reserve.
Conclusion
In conditions of thyroid hormone imbalance, also higher levels of luteinising and follicle stimulating hormones and low levels of progesterone in relation to the second group, manifested more often by menorrhagia and oligomenorrhoea, decreased ovarian reserve necessitates correction of hormonal status for IVF efficiency.

Time is testicular: early cryptorchidism care to avert tumors

Nada Ait Kassi[1], Dounia Talbi[2], Zineb Habbadi[1], Fatima Toulali[1], Ghizlane Sabbar[1], Kaoutar Rifai[1], Hinde Iraqi[1] & Mohamed El Hassan Gharbi[1]
[1]Ibn Sina Hospital Mohamed V University, Endocrinology, Rabat, Morocco; [2]Ibn Sina Hospital Mohamed V University, Endocrinology, Rabat, Morocco

Background
Cryptorchidism, or undescended testis, is a prevalent anomaly of the male genitourinary system and a well-established risk factor for testicular tumors. This case highlights the critical importance of early intervention in cryptorchidism to prevent malignancy.
Case Presentation
We report the case of a 54-year-old male with neglected bilateral cryptorchidism since childhood, presenting with abdominal pain and distension over the past three years. Imaging revealed intra-abdominal masses, leading to surgical resection, which confirmed bilateral testicular tumors. The patient underwent 25 sessions of chemotherapy with positive outcomes.
Investigations
Routine blood tests were normal. Imaging studies, including ultrasonography and contrast-enhanced CT, identified large homogeneous masses in the bilateral lumbar regions. The serum α fetoprotein (AFP) and β human chorionic gonadotropin (HCG) levels were normal, while lactate dehydrogenase (LDH) was elevated.
Outcome and Follow-up
The patient showed a favorable response to chemotherapy and remains under regular follow-up.
Discussion
Testicular tumors, predominantly germ cell tumors (GCTs), are the most common malignancies in men aged 20–40 years, with cryptorchidism increasing the risk by 4–6 times. Early orchidopexy significantly reduces malignancy risk by relocating the testis to the scrotum, thus promoting normal germ cell development. This case underscores the rarity of bilateral synchronous abdominal GCTs in cryptorchidism and highlights the necessity of early detection and intervention.
Conclusion
Prompt management of cryptorchidism is crucial in preventing malignant transformation and ensuring better patient outcomes.

Anti mullerian trends after aGnRH initiation in trans boys adolescents

Andrea Jimenez-Barrios[1], Jesús Domínguez-Riscart[1], Sandra Ruiz-Ramos[1] & Ana Garcia-Zarzuela[1]
[1]Puerta del Mar Universitary Hospital, Pediatric department, cadiz, Spain

Introduction
People identifying as transgender continues to increase year after year, and with it, the healthcare services offered to this community. In 2016 our health system established the care program for this population. Its purpose was to standardize healthcare for transgender minors based on the most reliable and solid information currently available. We know trangender medicine could have an impact on health. The analogues of gonadotropin-releasing hormone (aGnRH) are a commonly used treatment to achieve puberty suppression in adolescents who experience gender dysphoria and desire sex reassignment. However, the effect on fertility that their use may have on transgender adolescents remains unknown.
Objective
The aim is to analyze how gonadotropin-releasing hormone analogues impact on the fertility of transgender adolescents undergoing pubertal suppression.
Study Methodology
The study included transgender male adolescents who attended the Gender Diversity unit at Puerta del Mar University Hospital from January 2015 to December 2024 Who had initiated pubertal suppression (PS) with aGnRH. We register Anti-Müllerian Hormone (AMH) available every 6 months after aGnRH initiation during 18 months. Non-parametric statistical tests were performed.
Results
We recruited 38 adolescents. Median current age 15.4 (14.8-16.3 years old. Median PS age was 13.4 (12.2-14.5) years old. 73%has tanner stage 5. We observed no significant changes in AMH in first 18 months after aGnRH initiation (p-value: 0.347). No differences in AMH were observed when comparing PS in tanner 2-3 vs PS in tanner 4-5 (p-value: 0.431).
Conclusions
In our cohort we could establish no relevant changes in AMH after aGnRH initiation. Studies with larger participants could be performed to better support these results.

Association between folic acid levels and physiological and developmental indicators in children with developmental delays

Si Chen[1] & Xinran Cheng[1]
[1]Chengdu Women's and Children's Central Hospital, Chengdu, China

This study investigates the relationship between folic acid levels and various physiological and developmental indicators in children with developmental delays. Folic acid plays a crucial role in human growth and development, particularly in neurological development and metabolism. A total of 110 children with developmental delays were selected for the study, and a range of physiological indicators were collected, including gestational age, birth weight, height, weight, BMI, thyroid function, folic acid, vitamin D, lactate, homocysteine, and free fatty acids. Developmental assessment was conducted using the Gesell Developmental Schedule to evaluate social adaptability, gross motor skills, fine motor skills, language ability, and personal-social competence. The findings reveal that children with folic acid levels above 24 ng/ml scored significantly higher in vitamin D, lactate levels, and the five domains of the Gesell Developmental Schedule (social adaptability, gross motor skills, fine motor skills, language, and personal-social competence) compared to those with folic acid levels below 24 ng/ml. Additionally, children with higher folic acid levels had significantly lower birth weight and homocysteine levels than those with lower folic acid levels, with statistically significant differences. However, no significant differences were observed between the two groups in terms of BMI, gender, age, and thyroid hormone levels. The results suggest that higher folic acid levels may be positively associated with neurological development and metabolic health in children with developmental delays, highlighting the potential importance of folic acid in child growth and development. Future research should explore the long-term effects of folic acid supplementation in children with developmental delays and the underlying mechanisms at play.
Keywords
Developmental delay, Gesell Developmental Schedules, Folic acid.

Yoga intervention effects on metabolic profiles in polycystic ovary syndrome: plasma metabolomics analysis

Deepika Kumari[1], Yashwant Kumar[2], HP Sharma[1], Neena Malhotra[1], Reeta Mahey[1] & Rima Dada[1]
[1]AIIMS, New Delhi, India; [2]THSTI, Faridabad, India

Introduction
Polycystic ovarian syndrome (PCOS) is a complex endocrinopathy characterized by hyperandrogenism, ovulatory dysfunction, and polycystic ovarian morphology. It affects 5–20% of women of reproductive age worldwide. Its pathogenesis involves oxidative stress (OS), mitochondrial dysfunction, and inflammation. It increases risk for dyslipidemia, fatty liver disease, cardiovascular diseases (CVD), and type 2 diabetes (T2DM). Pharmacological treatments often yield inconsistent results with side effects, highlighting the need for alternative approaches. PCOS is a lifestyle disease, that can be best managed by lifestyle modification like Yoga.
Objectives
To explore the effects of Yoga on metabolic profile in women with PCOS.
Methods
This study involved 80 women (40 diagnosed with PCOS, 40 age and BMI matched healthy control women). PCOS women underwent 12-week Yoga practice (5 days/week, 1 hour/day) including physical postures (Asanas), regulated breathing (Pranayama), and meditation (Dhayana) under a trained therapist. Clinical characteristics and laboratory biochemical data were recorded, followed by a metabolome analysis using LCMS. In addition, the depression scale (BDI-II) and quality of life (WHO-BREF-QOL) were assessed.
Results
Post Yoga intervention we have observed significant improvement in clinical parameters of PCOS women. The metabolome analysis showed 20 significant differentially expressed metabolites (DEMs) involved in the tricarboxylic acid (TCA) cycle, antioxidant pathway, pentose phosphate pathway (PPP), pyrimidine, and tryptophan metabolism, bile acid biosynthesis, urea cycle, mitochondrial electron transport chain, and fatty acid biosynthesis that address key factors of pathogenesis in PCOS. Furthermore, also observed a significant reduction in depression severity and improvement in quality of life after the 12 week regular Yoga practice.
Conclusion
Yoga positively targets key pathological pathway involve in OS, mitochondrial dysfunction, and inflammation. It improves endocrine and reproductive health and lowers the risk of dyslipidemia, CVD, and T2DM. Hence, it can be used as an adjunct for PCOS treatment.

Clinical, biochemical, instrumental and genetic evaluation of a group of patients with hypogonadotropic hypogonadism

Zaira Benetti[1,2], Elisabetta Sciarroni[1], Luisa Pignata[1], Marianna Scordo[1], Emilio Fiore[1], Elena Benelli[1], Lucia Montanelli[1] & Massimo Tonacchera[1]
[1]University of Pisa, Pisa, Italy; [2]University of Pisa, Endocrinology, Pisa, Italy

Hypogonadotropic hypogonadism is a rare endocrine disorder secondary to congenital or acquired diseases affecting the hypothalamus or pituitary gland. The congenital form is caused by alterations in genes that fuel the development and migration of GnRH-secreting neurons or interfere with the physiology of the hypothalamic-pituitary axis. It can be classified into Kallmann Syndrome (associated with anosmia) or normosmic congenital isolated hypogonadism (associated with normosmia). Congenital forms are characterized by micropenis, cryptorchidism, eunuchoid proportions and delayed puberty in males and by primary amenorrhea in females. Acquired forms may result from numerous functional or organic causes impairing the physiology of the hypothalamic-pituitary region, manifesting as erectile dysfunction, reduced libido and infertility in males and secondary amenorrhea in females. In this prospective study 31 patients (23 females and 8 males) were recruited at the Department of Endocrinology in Pisa for disorders related to hypogonadotropic hypogonadism. For each patient, medical history and clinical characteristics (pubertal development stage, signs or symptoms of estrogen or androgen deficiency) were evaluated. Ultrasound of the pelvis (to assess uterine and ovarian size and structure) and scrotum (to evaluate testicular location and size) was performed. Hormonal profiles, bone densitometry, brain and sella turcica MRI (to check for hypoplasia or absence of olfactory bulbs), olfactory tests (if anosmia was present) and genetic analysis of genes associated with hypogonadotropic hypogonadism were conducted. In 18 female patients (all with secondary amenorrhea) and one male patient, hypothalamic-pituitary axis dysfunction was suspected to have a functional cause (associated with significant weight loss, severe emotional stress or excessive physical exercise). Brain MRI of one female patient with primary amenorrhea revealed a triventricular hydrocephalus, while two patients were found to have an "empty sella." One patient presented with a markedly reduced pituitary gland size. Four patients exhibited anosmic congenital hypogonadism or Kallmann Syndrome, associated with various mutations in the KISS1R gene and hypoplasia or aplasia of the olfactory bulbs. Two patients were found to have normosmic congenital hypogonadism, linked to mutations in the GnRHR gene and the CHD7 gene respectively. Finally, one male patient presented with hypogonadism in the context of Hartsfield Syndrome, associated with a mutation in the FGFR1 gene. Most of our patients showed impaired bone mineral density. In conclusion, hypogonadotropic hypogonadism is a rare endocrine disorder with various clinical manifestations. Its diagnosis requires careful integration of clinical, biochemical, instrumental, and genetic investigations to determine its etiology, enabling appropriate treatment of the condition.

Differences of sexual development – a portuguese single-center case series of the last 24 years

Inês Rua[1], Joana Serra-Caetano[1], Isabel Dinis[1], Alice Mirante[1] & Rita Cardoso[1]
[1]Paediatric Endocrinology, Diabetes and Growth Unit, Paediatric Department, Paediatric Hospital, Coimbra Local Health Unit, Coimbra, Portugal

Introduction
Differences of Sexual Development (DSD) include a group of congenital disorders associated with atypical development of the chromosomal, gonadal or phenotypic sex. The most frequent clinical manifestations are atypical genitalia at birth or postnatal virilization, delayed/absent puberty, primary amenorrhea and infertility.
Aim
To characterize DSD patients followed in our center in Portugal.
Methods
Paediatric patients diagnosed with a DSD and followed in our paediatric endocrinology unit in the last 24 years (2000-2024). Sex chromosome' DSD were included.
Results
We identified 206 patients, 54% male (assigned at birth) and with a median age at first appointment of 6.5 years (IQR 10.2). In 31% ($n = 64$) the diagnosis was prenatal. The most frequent clinical manifestations were atypical genitalia (28.2%, $n = 58$), including micropenis, cryptorchidism (uni or bilateral), hypospadias, clitoromegaly and posterior fusion of the labia; followed by short stature (19,4%, $n = 40$), neurodevelopment disorder (17%, $n = 35$) and delayed puberty (5,8%, $n = 12$). Associated malformations were found in 24.7% ($n = 51$) patients: cardiac in 13% ($n = 27$), of the urinary tract in 4.3% ($n = 9$), microcephaly/micrognathia in 3.4% ($n = 7$) and orthopaedic in 2,4% ($n = 5$). A karyotype was performed in 87% of the cases ($n = 180$) and a molecular study was carried out in 23% ($n = 48$). In terms of classification, 66% ($n = 136$) belonged to sex chromosome' DSD group, 13.1% ($n = 27$) to XY DSD, 12.1% ($n = 25$) to the XX DSD, 4.4% ($n = 9$) had gonadal development disorders, 3.9% ($n = 8$) isolated hypospadias and 0.5% ($n = 1$) persistent Mullerian duct syndrome. Of the 206 patients, 116 (56.3%) underwent medical treatment: 32.5% ($n = 67$) puberty induction, 20.3% ($n = 42$) somatotropin, 3.9% ($n = 8$) LHRH analogue and 10.2% ($n = 21$) glyco/mineralocorticoid replacement. 17% ($n = 35$) underwent surgical treatment.

Conclusion
DSD are rare conditions, associated with differences in internal and/or external genitalia. Due to its complexity, these patients must be followed in multidisciplinary and specialized teams, throughout their lives.

Neuroanatomical insights into gender identity: the role of hypothalamic subregions in therapy-naïve transgender individuals

Adriana Lages[1,2], Otília C. d'Almeida[3], Pawel Tacikowski[3], Gustavo Rodrigues[4], Sandra Paiva[4], Luísa Ruas[4], Leonor Gomes[1,4] & Miguel Castelo-Branco[1,3]
[1]Faculty of Medicine, University of Coimbra, Endocrinology, Coimbra, Portugal; [2]ULS Braga, Endocrinology, Braga, Portugal; [3]Institute for Nuclear Sciences Applied to Health (ICNAS), Coimbra, Portugal; [4]ULS Coimbra, Endocrinology, Coimbra, Portugal

Background
Gender incongruency potentially has a multifactorial etiology but little is known about specific neuroanatomic regions consistently associated with this condition. We aimed to recognize the potential role of hypothalamic subregions in therapy-naïve transgender population to provide a better understanding on neuroendocrine pathways involved in gender identity.
Methods
Transgender and age-matched cisgender participants were recruited from a national tertiary center and from the local community, respectively, during the same temporal period. All subjects were right-handed. Gender incongruence was diagnosed according to ICD-10-CM criteria following independent psychiatric evaluations. T1-weighted structural data were acquired using a 3T Siemens MAGNETOM Prisma MRI scanner. Automated hypothalamic subunits segmentation was conducted using FreeSurfer v7.3.2. Blood samples were collected to measure anterior pituitary hormone levels. Preliminary statistical analyses were performed in SPSS v28 at a 5% significance level.
Results
From 40 participants, 34 were included in the final sample (9 CisMale, 10 CisFemale, 9 TransMale, 6 TransFemale). Mean age was 24.5 ± 7.38 y in the transgender group and 25.5 ± 5.69 y in the cisgender group. Specifically, the TransFemale group exhibited a significantly larger left inferior tubular (infTub) hypothalamic subunit volume (153.6 ± 15.50 mm^3) compared to TransMale *group* (121.2 ± 18.44 mm^3). No significant differences were found for this region between cisgender and transgender subgroups *(*CisMale 140.7 ± 24.96 mm^3, CisFemale 127.7 ± 16.62 mm^3). No additional significant volumetric differences were found in the right infTub or the other subunits, bilaterally (anterior-inferior, anterior-superior, posterior, superior tubular regions). Exploratory correlation analysis between hypothalamic left infTub volumes and anterior pituitary hormone levels (FSH, LH, total testosterone, TSH, T4I and prolactin) in each transgender group was performed. There was a strong significant negative correlation ($r = -0.872$, $P = 0.024$) between left infTub volumes and total testosterone levels in TransFemale participants. No other significant correlations were found.
Conclusion
Our findings suggest a potential neuroanatomical region of interest in therapy-naïve TransFemale individuals, characterized by increased volume in the left infTub hypothalamic subregion. Interestingly, the hypothalamic hormone kisspeptin, a key regulator of reproductive behavior, is predominantly expressed in the infundibulum. Given the functional association of infTub with the infundibular (arcuate), preoptic, and ventromedial nuclei—critical regulators of metabolic function and sexual behavior—further research is warranted to elucidate its role in gender identity and neuroendocrine regulation.

JOINT2414

Leydig cell ovarian tumor in initially normal sized ovaries - a case report

Kristina Groti Antonic[1]
[1]University Medical Center, Ljubljana, Faculty of Medicine, Ljubljana, Department Of Endocrinology, Diabetes and Metabolic Diseases, Ljubljana, Slovenia

Introduction
Hirsutism can be caused by many factors, which can be divided into distinct phenotypes: ovarian, adrenal, other endocrinopathies, iatrogenic and idiopathic. Hyperandrogenism manifests itself through excessive body hair growth in male pattern, balding in the male pattern, acne, menstrual disorders and deeper voice. Ovarian Leydig cell tumors are a rare type of androgen-secreting tumor. They account for less than 0.1 % of all ovarian neoplasms and are predominantly unilateral, benign, and found in the ovarian hilum.
Case presentation
The phenotypic characteristics of a 64-year old female patient showed the presence of features of hyperandrogenism. The hirsutism was evaluated at 18/36 on the Ferriman-Gallwey scale. Male type androgenic alopecia presented as hair loss in front of the scalp. Excessive face hair was removed by laser treatment. The patient reported rare pains in the abdomen, but she indicated that first symptoms of excessive body hair appeared 3 years before being admitted. The gynecological history was regular (normal monthly cycles until menopause at the age of 47, pregnant 2 times). Laboratory tests and imaging examinations were performed. Total testosterone was increased to 12.9 nmol/l(normal range for females up to 1.0 nmol/L), FAI index was high at 40.3, androstendion and DHEAS were normal. Erythrocytosis was also present, (4.93 g/dl; normal range for females up to 4.0 g/dl). Cushing syndrome, PCOS and other causes of hirsutism were excluded. Initial transvaginal ultrasound was normal. Abdominal computer tomography (CT) showed intraductal papillary mucinous neoplasm, ovaries were described as normal. Control abdominal ultrasound showed slightly enlarged right ovary, high total testosterone and erythrocytosis were persistently showing in laboratory tests. Patient was referred to gynecologist for bilateral adnexectomy. One year later the removal of adnexa on both sides was performed. Histopathologic examination revealed a 1 cm Leydig cell tumor in hilum of the enlarged right ovary.
Conclusion
A case of unilateral Leydig cell tumor in an initially normal sized ovary under abdominal ultrasound and CT in postmenopausal female is described. Our case highlights the importance of thorough pelvic examination as well as consideration of steroid cell tumors causing androgen excess even if ovaries appear normal in size. Radiological studies alone are not enough to diagnose ovarian pathology, as often any such lesions will be small and the affected ovary within the expected normal size. Excess androgens and erythrocytosis combined with hirsutism in the absence of other endocrinopathies should raise the suspicion of a Leydig cell ovarian tumor.

Primary amenorrhea in adolescents: a deep dive into the causes and characteristics

Ilayda Altun[1], Elvan Bayramoğlu[1], Hasan Karakas[1], Gökçe Velioğlu Haşlak[1], Mert Uçar[1], Abdurrahman Güney[1], Hande Turan[1] & Olcay Evliyaoglu[1]
[1]Istanbul University Cerrahpasa, Cerrahpasa Medical Faculty, Pediatric Endocrinology, Istanbul, Türkiye

Introduction
Primary amenorrhea is a failure to menstruate by the age of 15 in the presence or absence of pubertal development or by the age of 13 without signs of puberty. Pathologiesvin any of functional and structural components of the hypothalamus, the pituitary, the ovaries and the genital out flow tract, other endocrine problems can lead to amenorrhea. To date, only a few studies have attempted to characterize the causes of pediatric patients with primary amenorrhea. This study aimed to identify the causes and clinical characteristics of adolescents presenting with primary amenorrhea.
Methods
Medical records of adolescents with primary amenorrhea between 2010 and 2025 years were retrospectively reviewed. Data were abstracted on patient's medical history, etiology of primary amenorrhea, laboratory evaluation, imaging results and genetic analyzes.
Results
The study included 53 children who met the criteria for primary amenorrhea. Hypergonadotropic hypogonadism, hypogonadotropic hypogonadism, congenital mullerian defects and other endocrine disorders were diagnosed in 27(51%) ,6(11.3%),9(17%) and 11(20.8%) of the patients respectively. Among the patients diagnosed with hypergonadotropic hypogonadism and POI; 16 (30.19%) had normal 46XX karyotype. MRPS22, MCM9, CLPP, FMR1 premutation, FSHR variations were detected in 5(9.43%) patients with normal 46,XX karyotype. Gonadal dysgenesis was determined ın 11(20.75%) patients. Systemic other endocrine causes of primer amenorrhea (adrenal disease, prolactinoma, malnutrition, 5 alpha reductase deficiency, androgen insensitivity syndrome,

Table 1: Etiology of primary amenorrhea.

46XY ovotesticuler syndrome) were diagnosed in 11(20.8%) patients. Müllerian agenesis with normal female sexual characteristics was found in 9(16.98%) patients. Etiology of primary amenorrhea is summarized in table 1.

Conclusions

In our study, we found that the most common cause of primary amenorrhea is POI with normal karyotype, followed by systemic endocrine diseases. Chromomosamal abnormalities were the most cause of POI in adult studies. This study shows that in adolescent patients with POI other systemic and genetic factors should also be sought.

Bridging endocrinology and genetics: uncovering familial partial lipodystrophy type 2 in an adolescent with primary amenorrhea

Maria Cristina Marinescu[1], Simona Galoiu[1,2], Iulia Grigore[1], Ileana Nitu[1], Iuliana Gherlan[1,2], Elena Braha[1] & Catalina Poiana[1,2]

[1]National Institute of Endocrinology "C.I. Parhon", Bucharest, Romania; [2]University of Medicine and Pharmacy "Carol Davila", Bucharest, Romania

Introduction

Familial partial lipodystrophy, Dunnigan type (FPLD2), is a rare genetic disorder characterized by the loss of subcutaneous adipose tissue from the trunk, buttocks, and limbs. Its prevalence is estimated to be less than 1/100,000 in Europe. FPLD2 is commonly associated with metabolic complications, elevated androgen levels and consequently disruptions in the hypothalamic-pituitary-ovarian axis.

Case Presentation

A 14-year-old patient presented with primary amenorrhea and significant hirsutism that developed over the past two years. Clinically, she had a BMI of +1.6SD, full moon facies, acanthosis nigricans, hirsutism, and muscular hypertrophy. Laboratory findings revealed dyslipidemia, marked insulin resistance, and hormonal hyperandrogenism. Pelvic ultrasound showed ovaries with a predominantly stromal appearance. Progestin therapy was recommended to induce menstruation, with follow-up planned for further investigation. At 19 years, the patient returned with a diagnosis of high blood pressure. Menarche occurred at 15 under progestin therapy, but bradymenorrhea persisted. Her BMI was 28 kg/m^2, with absence of adipose tissue in the limbs, chest, abdomen, but accumulation in the facial, cervical, axillary, and inguinal regions, giving a Cushingoid appearance with muscular hypertrophy and phlebomegaly. Hirsutism and acanthosis nigricans worsened. Clinical examination revealed normal external genitalia, and the breasts had a tubular appearance with sparse adipose tissue. Biochemical analysis showed severe mixed dyslipidemia, significant insulin resistance (HOMA-IR = 13), and evolving ovarian hyperandrogenism (FAI=10.8%). Pelvic ultrasound revealed micro-polycystic ovaries. Cardiac examination indicated grade III hypertension without structural heart changes. Further investigations with FIBROMAX revealed a NashTest-Score of 0.5 (N1). Next-generation sequencing (NGS) identified a heterozygous mutation in the LMNA gene (chr1-156106775 C>T, NM_170707.4 c.1444C>T), confirming the diagnosis of FPLD2. We resumed the anamnesis and found that the patient's paternal grandmother had a similar phenotype and died from complications of type 2 diabetes. The father also exhibits suggestive traits and will undergo evaluation.

Conclusion

This case highlights the importance of a multidisciplinary approach integrating endocrinologic, genetic and metabolic assessments in evaluating adolescent girls with primary amenorrhea. Understanding the connection between metabolic disturbances, hormonal imbalances, and reproductive dysfunction is crucial. Early diagnosis and management of FPLD2 are essential for preventing long-term reproductive issues and mitigating the risks of severe insulin resistance, dyslipidemia, and cardiovascular disease.

Biochemical hyperandrogenism: a diagnostic pitfall

Yassmine Abdelkafi[1], Khouloud Boujelben[1], Mouna Elleuch[1], Hamdi Frikha[1], Dhoha Ben Salah[1], Faten Haj Kacem Akid[1], Mouna Mnif[1], Mohamed Abid[1], Nadia Charfi[1] & Nabila Rekik Majdoub[1]

[1]Hedi Chaker University Hospital, Endocrinology Department, Sfax, Tunisia

Introduction

Biochemical hyperandrogenism, defined by an elevated serum testosterone level, is a frequent reason for endocrine consultation. However, the absence of clinical signs of hyperandrogenism challenges the diagnosis and requires thorough investigation to identify potential physiological, pathological, or analytical interferences.

Observation

We report the case of a 34-year-old woman referred for the evaluation of isolated biochemical hyperandrogenism, with elevated total testosterone levels (up to 3.76 ng/ml) but no clinical signs of hyperandrogenism or virilization. The patient had a history of cyclic metrorrhagia treated with norethisterone (Primolut Nor). Comprehensive hormonal and imaging assessments, including adrenal and ovarian MRI, ruled out tumoral and non-tumoral endocrine causes. Notably, after discontinuation of Primolut Nor, serum testosterone levels gradually normalized (0.24 ng/ml at two months and 0.21 ng/ml at three months post-withdrawal).

Discussion and Conclusions

This case illustrates the pitfall of analytical interference in the assessment of biochemical hyperandrogenism. Norethisterone, a synthetic progestin, is structurally similar to anabolic steroids and has been reported to cross-react with certain immunoassays for testosterone measurement, leading to falsely elevated results. This highlights the importance of considering drug-induced analytical interference in cases of discordance between biochemical and clinical findings. Confirmatory methods such as liquid chromatography-mass spectrometry (LC-MS) should be considered in doubtful cases to avoid unnecessaryinvestigations and misdiagnosis.

Introduction
The rise in referrals of transgender and gender diverse children and adolescents to clinical diagnosis is a widely discussed topic around the word. Similarly to adult population they are at risk for weight-related problems resulting from pathological eating behaviors, which in turn negatively influence the individual's metabolic health.
Aim
We assess the basic sociodemographic and metabolic profile of the youth population in the first clinical unit dedicated to transgender youth in our country.
Methods
This prospective study has examined a consecutive series of transgender and gender diverse children and adolescents (TGDC&A) based on WPATH SOC-8 between July/2017 and Sep/2024. Clinical and laboratory data was collected in unified medical records. Sociodemographic and TGDC&A history has been analysed alongside anthropometric and metabolic parameters. The population has been divided into registered female (RFAB) or male at birth (RMAB) groups.
Results
The population consists of 269 participants (230 RFAB, 39 RMAB), with increasing number of diagnosis in subsequent years 2017 (July-Dec) - 2/0, 2018 - 9/0 2019-16/3, 2020-18/4, 2021- 52/3, 2022- 68/22, 2023- 51/4, 2024 (Jan-Sep) 14/3 (RFAB/RMAB, respectively), with the mean/median age of diagnosis 15.8/16.1 years and the mean age of gender identity mismatch onset of 12 years. BMI distribution, fasting components of the metabolic syndrome and cortisol in circadian rhythm are presented in table.
Conclusions
Sociodemographic fluctuations in the proportion of RFAB/RMAB are visible, however difficult to explain now. The increased risk of abnormal BMI, mostly elevated in RFAB and decreased in RMAB, and higher risk of metabolic syndrome/complications are key issues to consider when preparing patients with GI/GD for medical transition.

Cabergoline treatment reduces androgen levels and restores menstrual cycles in women with hyperprolactinemic polycystic ovary syndrome

Aslı Sığınır[1], Hayri Bostan[2], Emre Sedar Saygili[1], Ceren Tufan[1] & Ersen Karakilic[1]

[1]Canakkale Onsekiz Mart University Faculty of Medicine, Endocrinology and Metabolism, Canakkale, Türkiye; [2]Canakkale Mehmet Akif Ersoy State Hospital, Endocrinology and Metabolism, Çanakkale, Türkiye

Purpose
Cabergoline is widely used to treat hyperprolactinemia, but its effects on polycystic ovary syndrome (PCOS) remain unclear. Since hyperprolactinemia is present in nearly 30% of PCOS cases, this study aims to assess the impact of cabergoline on androgen levels and clinical outcomes in hyperprolactinemic PCOS (hPCOS)cases, discussing these findings with the results in prolactinoma cases.
Methods
A total of 66 women aged 18 to 40 were included in this retrospective cohort study, with 36 in the PCOS group(median 24.0(22.0-27.5) years) and 30 in the prolactinoma group(median 28.0(23.7-33.0) years). Only patients who had been started on cabergoline treatment and had available follow-up data were included. Hormonal profiles and clinical findings, including hirsutism and menstrual cycle regularity, were assessed before and after cabergoline treatment.
Results
After cabergoline treatment, significant reductions in prolactin and total testosterone levels were observed in both hPCOS and prolactinoma groups. In the hPCOS group, total testosterone decreased from 0.65 to 0.49 ng/ml ($p<0.001$) and dehydroepiandrosterone-sulphate levels from 407.5 to 301.0 µg/dl ($p<0.001$)(Table-1). In the prolactinoma group, total testosterone decreased from 0.39 to 0.29 ng/ml ($p<0.001$) (Table-2). Menstrual irregularities improved markedly in both groups, with prevalence decreasing from 83.3% to 5.6% in hPCOS group and from 80.0% to 10.0% in the prolactinoma group($p<0.001$). Furthermore, in hPCOS group, the prevalence of hirsutism was decreased from 86.1% to 61.1%($p=0.007$).
Conclusion
Cabergoline is effective in lowering prolactin and androgen levels while improving menstrual regularity in both hPCOS and prolactinoma patients, highlighting its potential as a valuable therapeutic option for PCOS.

Background
Anti-Müllerian Hormone (AMH) and Inhibin B (INB) are key glycoprotein hormones produced by granulosa cells that serve as key markers of ovarian reserve. INB modulates FSH secretion at the pituitary gland, whilst AMH stimulates hypothalamic GnRH neuronal pulsatility *in vitro*. Anovulatory menstrual disturbance results from reproductive disorders including polycystic ovary syndrome (PCOS), functional hypothalamic amenorrhea (FHA), and congenital hypogonadotropic hypogonadism (CHH). The prevalence of polycystic ovarian morphology on ultrasound is increased in FHA and PCOS. However, there is limited data directly comparing AMH and INB in women with PCOS, FHA, and CHH.
Methods
We investigated levels of AMH and INB in women aged 18-35yrs classified as: healthy controls (n = 46), PCOS (n = 73), FHA (n = 44), or CHH (n = 8). Groups were compared by Kruskal Wallis test with *post hoc* Dunn's test and continuous variables by correlation.
Results
Median (IQR) AMH (pmol/l)was higher in PCOS 42.9 (27.75–56.95) than in healthy controls 22.1 (14.0–26.85; P <0.0001), FHA 25.8 (14.0–30.44; P = 0.0018), and CHH 4.3 (8.4–21.45; P = 0.0001). AMH differentiated PCOS from FHA, with an area under the ROC curve (auROC) of 0.705; P = 0.0002, whereas for lean PCOS (BMI <25kg/m^2) vs FHA, auROC was 0.762; P <0.0001. AMH was positively correlated with LH in PCOS (P = 0.003, r = 0.34), but negatively in FHA (P = 0.017, r=-0.21). Additionally, AMH negatively correlated with FSH in FHA (P = 0.001, r=-0.49) and healthy controls (P = 0.005, r=-0.41). Among women with PCOS, higher BMI was associated with lower AMH levels (P = 0.0139, r=-0.287). Median INB levels (ng/l)were similar in PCOS (77) and healthy controls (79), but lower in FHA (58, P = 0.0421) and markedly reduced in CHH (7, P = 0.0001). INB reliably differentiated CHH from FHA (auROC 0.98; P <0.0001). Women with PCOS and obesity (BMI >30kg/m^2) had lower INB levels than their non-obese counterparts (67 vs. 87-90; P = 0.015) with a negative correlation between INB and BMI (P = 0.0108, r=-0.297). INB positively correlated with LH (P = 0.002, r = 0.46), and FSH (P = 0.002, r = 0.45) in FHA, as well as with FSH in healthy controls (P = 0.029, r = 0.32).
Conclusion
Although AMH was slightly higher in FHA than healthy women, it was markedly elevated in women with PCOS. INB levels were lower in FHA but markedly reduced in CHH. Both AMH and INB decreased with increasing BMI. Despite its established role in inhibiting FSH secretion, INB positively correlated with FSH in both FHA and healthy women. These data suggest that AMH and INB are valuable biomarkers in the evaluation of anovulatory menstrual disturbances.

Beyond genetics: exploring the challenges of diagnosis and management in 46xy disorders of sex development

Alina-Elena ?chiopu[1], Anca Matei[1,2], Cristina Preda[1,2] & Maria-Christina Ungureanu[1,2]
[1]Saint Spiridon Hospital, Iasi, Romania; [2]University of Medicine and Pharmacy, Iasi, Romania

Background
Disorders of sex development in individuals with a 46XY karyotype pose significant diagnostic and therapeutic challenges due to heterogeneous etiologies and overlapping clinical features. Despite advances in genetic testing, many cases lack a definitive molecular diagnosis, complicating management. The differential diagnosis includes androgen insensitivity syndrome, gonadal dysgenesis, enzymatic defects in androgen biosynthesis, and other endocrine or receptor-related abnormalities. While stimulation tests are widely used, they are costly, time-consuming, and may yield inconclusive results. Whole-exome sequencing has improved diagnostic precision but does not always identify causative mutations, emphasizing the need for a broader approach.
Case Presentation
A male infant with a 46XY karyotype presented at birth with ambiguous genitalia, including penoscrotal hypospadias and bilateral undescended testes. The External Masculinization Score was 3. Laparoscopy confirmed the absence of Mullerian structures, and testicular biopsy revealed normal testicular parenchyma. A comprehensive diagnostic evaluation included genetic and biochemical assessments. Partial androgen insensitivity syndrome was ruled out through androgen receptor gene sequencing. Initial hormonal testing suggested 5-alpha-reductase type 2 deficiency, with a testosterone-to-dihydrotestosterone ratio of 30.8 following human chorionic gonadotropin stimulation. However, repeat testing two years later showed a ratio of 12, challenging this diagnosis. Whole-exome sequencing failed to identify pathogenic variants in SRD5A2 or other relevant genes, further complicating classification.
Management and Follow-up
Due to significant undervirilization, testosterone therapy was initiated before surgical interventions. The patient later underwent bilateral orchidopexy, penile elongation and staged urethroplasty. Ongoing multidisciplinary follow-up, involving endocrinology, urology, and psychological support, remains essential to monitor pubertal development and long-term well-being.
Discussion and Conclusion
This case highlights the complexities of diagnosing and managing 46XY disorders of sex development when biochemical markers suggest an enzymatic defect, yet genetic confirmation is absent. The variability in testosterone-to-dihydrotestosterone ratios underscores the limitations of hormonal assays and the need for functional enzyme activity testing. Stimulation tests, though commonly used, require careful interpretation as they do not always yield definitive results. Whole-exome sequencing has enhanced diagnostic accuracy, yet unexplained cases persist, underscoring gaps in the understanding of sexual differentiation. A standardized, multidisciplinary approach integrating endocrinology, genetics, pediatric urology, and psychological support is crucial for optimizing patient outcomes. Advances in molecular diagnostics and functional assays will be pivotal in refining diagnostic pathways and guiding individualized management.

Keywords

Mutations in MSH5 in primary ovarian insufficiency in adolesent: a case report

Beata Sawicka[1], Justyna Michalak[1] & Artur Bossowski[1]
[1]Department of Pediatrics, Endocrinology, Diabetology with Cardiology Division, Medical University of Bialystok, Bialystok, Poland

Background
Primary ovarian insufficiency (POI) is characterized by 4 to 6 months of amenorrhea and elevated serum FSH and LH in females less than 40 years. Ovarian insufficiency is uncommon in pediatrics and typically results from a chromosomal abnormality or treatment for malignancy. Idiopathic POI in which no apparent precipitant is identified is even rarer.
Case report
The 17- year- old girl was diagnosed with primary amenorreha. She was born from a normal pregnancy, delivery in 40hbd, in good general condition, weight 2350g, length 52cm. The neonatal period was complicated by hypoglycemia, needing 10% intravenous glucose. Due to delayed puberty, the girl was consulted by a gynecologist, who diagnosed hypergonadotropic hypogonadism (FSH-166.5; LH- 49.43). MRI scan excluded pathological changes in the pituitary gland. The uterus and ovaries were identified on an ultrasound. The girl was confirmed to have a normal female karyotype (46,XX). Genetic testing found a pathogenic variant in both alleles of the MSH5 gene. Disorders of the MSH5 gene are associated with primary ovarian insufficiency, a disease inherited in an autosomal recessive manner. A girl is given estrogen and progesterone as treatment.
Results
1. Primary ovarian insufficiency should be considered in the diagnosis of primary amenorrhea. 2. Recognizing POI in teens who present with amenorrhea is essential in order to provide appropriate endocrine, and gynecologic care and counseling. 3. In patients with primary ovarian insufficiency, the risk of comorbidities and the possibility of genetic inheritance of the condition should be determined.

Case report and literature review: a 46,xx infant with atypical genitalia diagnosed with primary ovarian insufficiency (POI) caused by hfm1 gene variants

Zheng Yuan[1], Ming Cheng[1], Xi Meng[1], Bingyan Cao[2] & Chunxiu Gong[1]
[1]Beijing Children′s Hospital, Capital Medical University, National Center for Children′s Health, Beijing, China; [2]Capital Institute of Pediatrics, Beijing, China

Introduction
Primary Ovarian Insufficiency (POI) due to single gene variant is classified as a 46,XX difference of sexual development. Variants in the *Helicase Family Member 1* (*HFM1*) gene are associated with POI in females and non-obstructive azoospermia in males.
Case Report
We described a case of POI with unique genital characteristics, including clitoromegaly, fusion of the labia majora, an opening of the urethral meatus at the perineum, and the absence of the vaginal opening. Hormonal analysis revealed hypergonadotropic hypogonadism. Genetic testing identified two variants in the *HFM1* gene: c.1978-2A>C and c.2681-3T>A. A comprehensive analysis of published cases with *HFM1* gene variations was conducted to summarize the range of variants and phenotypes associated with *HFM1* gene mutations.
Discussion
This study connects *HFM1* gene variants to external genital malformations, expanding the spectrum of phenotypes related to *HFM1* mutations. Clinicians should consider the possibility of POI in 46 XX female infants with atypical genitalia and perform genetic testing for *HFM1* to avoid overlooking the diagnosis.

Efficacy of oral testosterone undecanoate in children with androgen insensitivity syndrome

Ying Liu[1], lele Li[2], chunxiu gong[2] & Zheng Yuan[2]
[1]Department of Pharmacy, Beijing Children's Hospital, Beijing, China; [2]Department of Endocrinology, Genetics, Metabolism, Beijing Children's Hospital, Beijing, China

Objective
To investigate the efficacy and safety of oral testosterone therapy in individuals diagnosed with androgen insensitivity syndrome (AIS).
Methods
A self-controlled study design was utilized, focusing on individuals with AIS who were genetically diagnosed at the Department of Endocrinology, Genetics, and Metabolism of Beijing Children′s Hospital. These patients underwent treatment involving the administration of testosterone. The primary observed indexes include the measurement of penis length, which should meet the minimal surgical standard or greater than or lower limit of normal. Secondary observed indexes include penile length standard deviation score (PL-SDS), an increase in penis longitude (ΔPL), medication dosage, the course of therapy, and safety indicators, among others. There were four courses of treatment. After each course, patients were evaluated to determine whether termination of treatment was appropriate. Patients who exhibited inadequate post-treatment penile length growth were advised to continue with further treatment. The statistical methodology included t-test, and a Wilcoxon rank sum test to describe efficacy and safety.
Results
Both penile length and PL-SDS interventions showed statistically significant gains when compared to the baseline performance of the 4 courses. The study involved the longitudinal monitoring of patients with the highest recorded age being 13.7 years. The weight, height, body mass index, bone age/age, cholesterol, hemoglobin and so on were all within the normal range. All patients were no changes in precocious puberty, pubic hair growth, aggressive behavior, vulvar skin darkening, diarrhea or other conditions.
Conclusions
The initial course of treatment for patients with PAIS demonstrates observable enhancements in penile length and PL-SDS. For patients with inadequate penile length growth, continued treatment in subsequent courses (such as the second, third, and fourth courses) is recommended toenhance outcomes gradually. Testosterone undecanoate was safe and effective for the majority of individuals with PAIS patients, with few adverse effects and good treatment tolerance.

Clinical profile and biomolecular assessment of a group of patients suspected 46 xy dsd in an african setting

Suzanne Sap[1], Ritha Carole Mbono[2], Gaelle Ntsoli[3], Marguerite EDONGUE HIKA[4], Adele Bodieu Chetcha[5], Ingrid Plotton[6] & Boniface Moiffo[4]
[1]University of Ebolowa, Peadiatrics, Mother and Child Center, Yaounde, Cameroon; [2]The University of Douala, Laquintinie Hospital, Department of Pediatrics, Douala, Cameroon; [3]Laquintinie hospital, Douala, Cameroon; [4]The University of Yaounde 1, Yaoundé, Cameroon; [5]Central Hospital Yaounde, Laquintinie Hospital, Yaoundé, Cameroon; [6]Service de médecine et de la reproduction, Hospices civils de Lyon, Université Claude Bernard Lyon 1, U1208, Lyon, France

Introduction
Aetiological diagnosis of patients with abnormal genitalia remains a big challenge in African context. Despite a proposed algorithm, difficulties related to arrival out of mini puberty (gonadotrophic axis then difficult to explore), unavailability of AMH dosage are some limiting factors for diagnosis of those suspected 46 XY DSD according to Hughes *et al* classification. We aim to explore clinical and biomolecular profile of this group f patients to better understand their aetiology in our context.
Methods
We did a retrospective observational study on a period of 11 years in the endocrinology and diabetology unit of the Mother and child center in Yaounde. We included all patients with a suspected 46 XY DSD according classification of Hughes *et al*. With limited resources, all patients with a least one palpable gonad was considered as "suspected 46 XY patient" (operational definition). Those with diagnosis of ovotesticular DSD after morphological exam were excluded from our analysis. We then explore their clinical profile, hormonal assay and when available biomolecular findings.
Results
We found 64 patients with our operational definition, ovotestis excluded. There were 3 missing files and we included 61 patients in our analysis. All the patients

were born at term. Two was reported to have acute foetal distress at birth. Most of the patients had a unique orifice 97.7%. The localisation of the orifice was penoscrotal in two third of patients realising a severe hypospadias. Both right and left gonads were reported palpable by hands of clinicians in 70% of patients. The localisation was mostly inguinal (incompletely descended). In two patients, a mullerian structure was found despite a clear description of two homogenous gonads by 3 senior radiologists. The karyotype was available for 27 patients from which, a clear anomaly was found in 9 (33%): 4 had PAIS, 3 mixed gonadal dysgenesis, one with 5alpha reductase mutation, one with SF1 mutation. For two third of patients, further analysis might be necessary.
Conclusions
Suspected 46 XY patients presents with severe hypospadias, with mostly 2 palpable gonads in the inguinal region. When biomolecular are performed, an aetiology is found in one third of the patients.

Demographic and psychosocial characterisation of transgender and gender-diverse youngsters referred to the danish gender identity service

Nanna Ravnborg[1,2,3], Mette Ewers Haahr[2,4], Anne Katrine Pagsberg[4,5], Katharina Main[1,3,4] & Annamaria Giraldi[2,4]
[1]Rigshospitalet, Copenhagen University Hospital, Department of Growth and Reproduction, Copenhagen, Denmark; [2]Mental Health Centre Copenhagen, Mental Health Services - Capital Region of Denmark, Sexological Clinic, Copenhagen, Denmark; [3]Rigshospitalet, University of Copenhagen, International Centre for Research and Research Training in Endocrine Disruption of Male Reproduction and Child Health (EDMaRC), Copenhagen, Denmark; [4]University of Copenhagen, Department of Clinical Medicine, Copenhagen, Denmark; [5]Mental Health Services - Capital Region of Denmark, Child and Adolescent Mental Health Centre, Copenhagen, Denmark

Background and aims
A considerable increase in referrals of adolescents to the Danish Gender Identity Service has been seen in recent years. Prior studies have suggested an elevated risk of internalising problems, a higher level of psychiatric morbidity along with higher suicidality rates among transgender and gender-diverse adolescents compared to cisgender peers. Therefore, it is important to understand the characteristics of youngsters experiencing gender incongruence to optimise the current assessment and treatment protocol and improve personalised care. We aim to describe the psychosocial profile of youngsters referred for evaluation of gender incongruence. We will describe the demographic characteristics, the history and development of gender identity and incongruence, as well as the development of sexuality. We will also examine the prevalence of psychiatric disorders, substance abuse, self-harm, and suicidal ideation.
Methods
This is a retrospective, observational study of a national cohort consisting of all children and adolescents under 18 years of age referred to the Danish Gender Identity Service from 2016 through 2022 (approximately 1200 individuals). We will use existing data from medical records obtained at routine visits from first assessment through repeated visits at the clinic. Data will be examined in subgroups according to sex assigned at birth, age of onset of gender incongruence, and treatment trajectory. Group comparisons will be performed using Student's T-test and Mann-Whitney/Wilcoxon tests as appropriate. The statistical software R will be applied for analysis and data representation.
Perspective
The evidence base for the current assessment and treatment protocol is sparse, although treatment options have existed for more than two decades in some countries. Large-scale population-based studies are needed to further improve healthcare for youngsters with gender incongruence. Thus, this study intends to provide better evidence for future assessment and treatment protocols to improve the well-being of transgender and gender-diverse youngsters.

5α-reductase type 2 deficiency- are there early predictors for gender identity outcome?

Luise Landreh[1], Michela Barbaro[2], Angelica Lindén-Hirschberg[3], Mats Holmberg[4] & Anna Nordenström[1]
[1]Pediatric Endocrinology Deppartment, Astrid Lindgren Children's Hospital, Karolinska University Hospital, Karolinska Institutet, Women's and Children's Health, Stockholm, Sweden; [2]Clinical Genetics, Stokholm, Sweden; [3]Endocrine Gynecology, Stockholm, Sweden; [4]ANOVA, Stockholm, Sweden

Background
5α-reductase type 2 deficiency (5αRD2) is a rare cause for 46, XY DSD. The enzyme catalyzes the conversion of testosterone (T) into dihydrotestosterone (DHT). In the fetus, T is responsible for the masculinization of the internal genitalia while DHT is needed for the masculinization of the external genitalia. During puberty, T facilitates changes in psychosocial behaviour, deepening of the voice, increase of muscular mass and the further masculinization of the external genitalia. Individuals with 5αRD2 present at birth with a wide clinical spectrum ranging from total female appearance to a nearly complete male phenotype with mild symptoms depending on the resting enzyme activity. During puberty, they often virilize both physically and psychologically. The first 5αRD2 studies describe a population in the Dominican Republic where affected individuals often changed gender identity after puberty from female to male, which resulted in a general recommendation for male gender identity. 5α-reductase 2 is encoded by the *SRD5A2* gene on chromosome 2. More than 100 different pathogenic variants of *SRD5A2* have been described, with no strong genotype-phenotype correlation. However, recent studies have suggested that the location of the mutation in the protein plays a role in the severity of the phenotype.
Methods
A cohort of 18 patients followed at pediatric endocrinology, endocrine gynecology and andrology departments is described according to their phenotype at diagnosis, genetics, hormonal profile and gender identity. The external genitalia score (EGS) was used to describe the genitalia phenotype.
Results
A wide range of phenotypes with 12 females and 6 males was observed. Treatment ranged from hypospadias operation and early treatment with DHT to treatment with estrogen or oral contraceptives. In some cases gonadectomy was performed in early puberty to prevent further masculinization. The genetic investigation showed different pathogenic variants, both homo- and heterozygous. The majority of the patients had a non-caucasian background. Late diagnosis, which could be caused by more female-looking genitalia (*i.e.* a more severe phenotype), seemed to more often lead to a female gender identity also after puberty.
Conclusions
The variation in gender outcome in the described cohort underlines the importance of patient-centered care, individual counseling for families with children born with 5αRD2 where the initial phenotype and genetics, including information about the expected enzyme activity, may provide guidance in clinical decisions.

Epidemiological, clinical and etiological aspects of acne in adult women

Malek Cherif[1], Meriem Amouri[1], Fatma Hammami[1], Rim Chaabouni[1], Emna Bahloul[1], Nabila Rekik[2] & Hamida Turki[1]
[1]Hedi Chaker University Hospital, Dermatology, Sfax, Tunisia; [2]Hedi Chaker University Hospital, Endocrinology, Sfax, Tunisia

Introduction and Objective
Traditionally considered as an inflammatory skin disorder of adolescence, acne can also affect adults, especially women. This study aims to analyze the epidemiological and clinical data of acne in adult women and to screen for hormonal imbalances in this population.
Materials and Method
We conducted a retrospective study (January 2022 - December 2023), enrolling all women aged 25 years or older who presented with acne. The diagnosis of polycystic ovary syndrome (PCOS) was made according to the revised Rotterdam criteria (2003).
Results
We included 107 women, with a mean age of 29 years. The acne either persisted since adolescence (18.7%) or appeared after the age of 25, either de novo (68.2%) or as a recurrence (13.1%). It was inflammatory (40.2%), comedonal (18.7%), or mixed (41.1%). The lesions were located on the face (96.3%), neck (8%), chest

(2.8%), and/or back (2.8%). Acne occurred in the context of hormonal imbalances in 31.8% of cases, including PCOS, which was suspected in 23 patients and confirmed in 16 cases (15%), hyperprolactinemia in 4 cases (3.7%), and hormonal contraception in 3 cases (2.8%) (hormonal intrauterine device, oral levonorgestrel, progestin implant). Acne was triggered or worsened by pregnancy in 3 cases and linked to the menstrual cycle in 1 case. Iatrogenic acne (8.4%) was induced by systemic ($n = 2$) or topical ($n = 3$) corticosteroids, azathioprine ($n = 1$), erlotinib ($n = 1$), teriflunomide ($n = 1$), and interferon beta ($n = 1$). Exogenous acne (40.2%) was induced by cosmetic products (20.6%), mask-wearing (maskne) (15.9%), and/or waxing (3.7%).

Conclusions

Our results are consistent with those of a Colombian study revealing a peak in late-onset acne among women aged 25 to 29 years. However, the prevalence of PCOS in our series is about half that of a Moroccan study (39% vs 15%). A lower demand for hormonal testing may explain this disparity. According to Dréno *et al*., adult female acne is predominantly mixed, but the involvement of the trunk is significantly less frequent in our study (48.4% vs 2.8%). Pregnancy can trigger or worsen acne due to global hypertestosteronemia. This condition may be attributed to an increase in Testosterone-Binding Globulin (TeBG) synthesis and elevated androstendione levels during pregnancy. Paroxysmal acneiform eruptions can be caused by glucocorticoids, androgens, halogens, lithium salts, vitamin B12, certain antidepressants, antiepileptics, immunosuppressants, and also epidermal growth factor receptor (EGFR) inhibitors. Comedogenic cosmetic products increases pore obstruction and bacterial proliferation.

A case report of aromatase deficiency

Ying Zhang[1] & Ruimin Chen[1]
[1]Fuzhou First General Hospital Affiliated with Fujian Medical University, Fuzhou Children's Hospital of Fujian Medical University, Fuzhou, China

Objective

This study describes the clinical characteristics of a child with aromatase deficiency.

Methods

Clinical data of a child with aromatase deficiency were collected, including physical examination, gonadal axis hormone levels, genetic testing results, and surgical treatment.

Results

The patient, socially identified as male, was admitted with the chief complaint of "abnormal external genitalia for 5 months." Physical examination revealed clear consciousness, no significant abnormalities in the heart or lungs, soft abdomen, and ambiguous external genitalia with clitoral hypertrophy resembling a penis, urethral opening at the scrotum, bifid scrotum resembling labia, and no visible vaginal opening. Auxiliary examinations showed a karyotype of 46,XX, negative SRY gene, anti-Müllerian hormone (AMH) 0.717 ng/ml, inhibin B 104 pg/ml, testosterone 8.6 ng/dl, estradiol 36.7 pg/ml, prolactin 16.00 ng/ml, luteinizing hormone (LH) 0.33 IU/l,human chorionic gonadotropin (hCG) <1.00 mIU/ml, follicle-stimulating hormone (FSH) 3.65 IU/l,dehydroepiandrosterone sulfate (DHEA-S) <15.0 µg/dl, and normal levels of cortisol, androstenedione, and adrenocorticotropic hormone (ACTH). Color Doppler ultrasound revealed a pelvic cyst measuring approximately 43.62.3 cm (likely ovarian in origin). The patient underwent laparoscopic gonadal exploration and biopsy, left ovarian cystectomy, cystoscopy, clitoral reduction, and vulvoplasty. Whole-exome sequencing identified compound heterozygous variants in the CYP19A1 gene (c.1352T>C and c.1304G>A), confirming the diagnosis of "aromatase deficiency." Postoperative pathology reported: (left ovary) serous cystadenoma; (right ovary) ovarian stroma and immature oocytes, consistent with benign malformation; (ovarian cyst) serous cystadenoma with a small amount of ovarian follicular cells.

Conclusion

This study reports a case of aromatase deficiency in a child presenting with an ovarian cyst. Surgical removal of the cyst revealed a serous cystadenoma on pathology.

Keywords

aromatase deficiency, CYP19A1 gene, ovarian cyst, serous cystadenoma, ambiguous genitalia.

When hyperandrogenism hides more: a sertoli-leydig cell tumor in a 16-year-old girl

Teodora Nastasa[1], Ilona Stafie[1], Andra Dorneanu[1], Maria-Christina Ungureanu[1,2] & Stefana Bilha[1,2]
[1]Saint Spiridon County Hospital, Iasi, Romania; [2]"Grigore T Popa" University of Medicine and Pharmacy, Endocrinology, Iasi, Romania

Introduction

The evaluation of secondary amenorrhea and progressive virilization in adolescent females requires a comprehensive approach to identify underlying causes of hyperandrogenism, from functional conditions to tumor-related causes, including adrenal and ovarian pathology. We present the clinical progression, diagnostic workup and successful management of a young patient with virilizing ovarian tumor, highlighting the importance of timely recognition and intervention.

Case Presentation

A 16-year-old, primigesta, primipara, known with nodular goiter, but no other significant personal or hereditary medical history, presented to our Endocrinology Department for secondary amenorrhea and progressive virilization over the previous year. Clinical examination revealed moderately severe hirsutism, widening of the biacromial diameter with an androgynous pattern of muscular hypertrophy, deepened voice, clitoromegaly and abdominal pain. Baseline and dynamic testing confirmed ovarian hyperandrogenism: baseline testosterone levels exceeding 5 times the upper limit of normal range [ULN], normal baseline DHEAS and 17-OH-progesterone levels, appropriate inhibition of cortisol, DHEAS and 17-OH-progesterone, but paradoxical increase in serum testosterone (7 x ULN) after the long Dexamethasone suppression test (0.5 mg every 6 hours, 5 days) which further increased (8X ULN) together with 17-OH-progesterone (5x ULN) after continuing with the short-acting GnRh analogue stimulation test. Abdominopelvic magnetic resonance imaging (MRI) revealed the right ovary replaced by a nodular mass measuring 43/29/44 mm, displaying heterogeneous tissue signal with an internal cystic component of 8 mm, diffusion restriction and heterogeneous gadolinium enhancement. A four-fold increase in alpha-fetoprotein (AFP), with normal levels of CA125, CEA and CA19-9, led to the diagnosis of virilizing ovarian tumor. Laparoscopic right adnexectomy was performed and histopathology confirmed a moderately-differentiated ovarian Sertoli-Leydig cell tumor (SLCT). Prompt diagnosis and surgical excision lead to an outstanding response, with restoration of menstrual cycles within weeks and clinical and biochemical resolution of hyperandrogenism within two months post-surgery. AFP returned to normal levels, with no ultrasonographic signs of residual disease.

Conclusions

Accounting for less than 0.5% of ovarian tumors, SLCTs do not usually associate with positive tumor markers, but may rarely produce AFP. When this occurs, they are the most common non-germ cell ovarian tumors associated with AFP secretion. Despite polycystic ovarian syndrome being the most common cause, a structured and thorough diagnostic approach in the evaluation of hyperandrogenism in adolescents is needed, especially when presenting with secondary amenorrhea and progressive virilization.

JOINT3505

The importance of the NR5A1 gene in sexual differentiation

Ariana Marques[1], Teresa Almeida Lopes[1], Joana De Beir[1], Joana Serra Caetano[1], Rita Cardoso[1] & Alice Mirante[1]
[1]ULS Coimbra, Pediatric Endocrinology, Diabetes and Growth Unit of the Pediatric Hospital of Coimbra, Coimbra, Portugal

Introduction

The NR5A1 gene plays a crucial role in gonadal development, sexual differentiation, and steroidogenesis. In the bipotential gonad, its interaction with SRY activates SOX9, promoting testicular differentiation and the formation of Sertoli cells, which activate the AMH gene, responsible for Müllerian duct regression. Sertoli cells induce the differentiation of Leydig cells, where NR5A1 activates the LH receptor (LHCGR) and INSL3, stimulating the production of testosterone and dihydrotestosterone - both essential for Wolffian ducts

differentiation and development of male external genitalia. Mutations in NR5A1 gene can result in a spectrum of phenotypes related to sexual differentiation (e.g., partial or complete gonadal dysgenesis, primary ovarian insufficiency, male infertility – oligo-azoospermia), reflecting its interaction with other key genes, such as GATA4, AMH, WT1, CBX2, and WNT4, affecting the regulatory network of gonadal development.
Case Report
A two-month-old infant was referred to the Endocrinology Clinic due to atypical external genitalia and micropenis. The child was born after an uneventful monitored pregnancy. Prenatal ultrasounds showed no abnormalities, and the fetus was designated as female. Delivery occurred by caesarean section at 42 weeks, with good neonatal adaptation. Due to atypical external genitalia, karyotyping revealed 46,XY and pelvic ultrasound identified testes near the scrotal sacs with no Müllerian structures. Male gender was assigned. At the two-month Endocrinology Clinic visit, the infant presented with penoscrotal hypospadias, micropenis, and testes located in the scrotum. Biochemical assessment excluded congenital adrenal hyperplasia and hormone levels were consistent with mini-puberty. The patient remained under follow-up, with serial ultrasounds consistently showing small testes with hyperechoic foci. At five years of age, molecular testing for androgen insensitivity was performed, but no mutations were identified. At 8 years, testosterone treatment (25 mg monthly for three months) was administered for micropenis, however no response was observed. Due to persistently low gonadotropin and testosterone levels, puberty induction with testosterone was initiated at 12 years, resulting in the development of pubic and axillary hair, penile growth, and the onset of acne. At 16 years, genetic testing identified a likely pathogenic variant, c.442_456del, p.(Glu148Glyfs*44), in heterozygosity, in exon 4 of the NR5A1 gene.
Conclusion
Testing for NR5A1 gene mutations should always be performed in cases of disorders of sexual differentiation, given the broad spectrum of associated phenotypes. Genetic diagnosis in these conditions enables optimised therapeutic management, clearer prognosis assessment, and genetic counselling for family members.

Increased alpha-glucosidase levels in sertoli cell-only syndrome: a report of three cases

Nada Hassairi[1], Najoua Lassoued[1], Houcem Elomma Mrabet[1], Adem Khedhr[2], Alaya Wafa[1] & Sfar Mohamed Habib[1]
[1]Taher Sfar University Hospital, Endocrinology Department, Mahdia, Tunisia; [2]Faculty of Medicine of Monastir, Family Medicine Department, Monastir, Tunisia

Background
Sertoli cell-only syndrome (SCOS) is one of the most common causes of non-obstructive azoospermia in infertile men. The definitive test for diagnosing SCOS is the testis biopsy. In this work, we present 3 cases of SCOS in which the alpha-glucosidase (α-GLUC) level was remarkably elevated.
Clinical Cases
Case 1: A 35-year-old male presented with primary infertility and secondary erectile dysfunction. Laboratory investigations revealed hypergonadotropic hypogonadism and total azoospermia. Testicular atrophy was confirmed on ultrasound and testicular biopsy confirmed the diagnosis of SCOS. α-GLUC levels was elevated. Genetic testing identified a partial AZFc microduplication on the Y chromosome. The karyotype was normal. **Case 2:** A 43-year-old male presented with severe osteoporosis, pathological fractures, bilateral gynecomastia, and infertility without erectile dysfunction. Azoospermia was confirmed, along with hypergonadotropic hypogonadism and bilateral testicular atrophy. Genetic screening was negative for Y-chromosome microdeletions. The karyotype was normal. A testicular biopsy revealed SCOS. α-GLUC levels was also elevated. **Case 3:** A 49-year-old male presented with primary infertility and normal erectile function. Laboratory investigations showed hyperprolactinemia without an identifiable cause, hypergonadotropic hypogonadism, and azoospermia. Testicular ultrasound confirmed bilateral testicular atrophy. A testicular biopsy confirmed the diagnosis of SCOS. The karyotype was normal. Genetic testing revealed a partial AZFc microdeletion on the Y chromosome. MRI of the hypothalamic-pituitary axis was normal. α-GLUC levels was elevated.
Discussion
SCOS also known as germ cell aplasia is characterized by azoospermia in which the seminiferous tubules of testicular biopsy are lined only with Sertoli cells. The exact diagnosis of SCOS is based on diagnostic testicular biopsy and histopathological examination. Seminal α-GLUC levels reflect the epididymal function. The diagnosis of SCOS was retained in these 3 patients thanks to the testicular biopsy. These 3 patients had an elevated α-GLUC level suggesting a possible relationship in the pathophysiology of SCOS that should be investigated by large-scale studies. Would this marker be useful in the diagnosis of SCOS in the future?.

Endocrine factors in the development of recurrent pregnancy loss clinical case

Khurshida Nasirova[1], Diyora Mukhammedaminova[1], Sevara Sadrieva[1] & Umida Mirzaeva[1]
[1]Tashkent Pediatric Medical Institute, Endocrinology, Tashkent, Uzbekistan

Introduction
Recurrent pregnancy loss (RPL) is a polyetiological complication of pregnancy, primarily caused by dysfunction of the reproductive system. Endocrine factors play a significant role in the etiology of spontaneous miscarriages. The prevalence of endocrine factors in recurrent pregnancy loss is approximately 17%. The most common hormonal disorders contributing to RPL include ovarian hypofunction, hyperandrogenism of various origins, thyroid hypofunction, hyperprolactinemia, and thyroid pathology.
Objective
Present a clinical case with RPL.
Materials and methods
The primary documentation has been reviewed: medical history, results of clinical, laboratory, and ultrasound examinations.
Results
In January 2023, a 28-year-old woman consulted an endocrinologist to identify possible endocrine causes of RPL. Medical history revealed an irregular menstrual cycle (2537 days). She had experienced four pregnancies: the first ended in preterm delivery at 30 weeks due to placental insufficiency, while the others resulted in spontaneous miscarriages at 9, 10, and 8 weeks. Complaints included fatigue, irritability, emotional instability, headaches, and menstrual irregularities. Hormonal studies were recommended. Test results obtained the following day revealed elevated prolactin levels (63.5 ng/ml) and TSH (8 mU/L), with T4 and T3 levels within the normal range. An MRI of the brain was subsequently recommended to rule out a prolactinoma. After thorough examinations, the patient was diagnosed with idiopathic hyperprolactinemia and subclinical hypothyroidism. Dopamine agonists and hormone replacement therapy were prescribed. Four months later, the patient became pregnant, and all medications were discontinued. However, signs of a threatened miscarriage appeared at 8 weeks. Hormonal analysis revealed elevated prolactin (200 ng/ml) and TSH (6 mU/l)levels, with a decrease in inhibin A (420 pg/ml). Treatment was resumed based on these findings. The patient was closely monitored throughout the pregnancy, with periodic assessments of prolactin, TSH, and inhibin A levels. Treatment was adjusted according to hormone levels. In 2024, the pregnancy concluded with a full-term delivery at 39 weeks without complications.
Conclusion
Elevated prolactin and TSH levels are associated with decreased inhibin A, indicating an increased risk of pregnancy loss. Inhibin A may be used as a predictor of RPL development linked to endocrine factors (e.g., hyperprolactinemia and hypothyroidism).

The relationship between indicators of leptin and anti-Muller hormone in women suffering from infertility and obesity

Sanobar Samijonova[1], Dilafruz Maksudova[1] & Khurshida Nasirova[1]
[1]Tashkent pediatric medical institute, Department of endocrinology, Tashkent, Uzbekistan

Relevance
In women of reproductive age with obesity, the interval from planning pregnancy to conception increases and as BMI increases, the fertility rate decreases. Obesity can have a significant impact on the reproductive function of women, since adipose tissue produces a large number of biologically active substances, and endocrine-metabolic and hormonal changes associated with excess fat play an undoubted role in dysfunction of the reproductive system. The purpose of the study: to study the relationship between leptin and anti-Muller hormone (AMH) in women of reproductive age suffering from infertility and obesity.
Materials and methods
The study included 55 women of reproductive age with obesity and infertility. The average age of the patients was 30.8 ± 5.9. The body mass index was examined and the baseline levels of the hormones AMH and leptin were determined.
Results
According to the results of the study, 35 women had class 1 obesity (30-34.9 kg/m^2) and 20 women had class 2 obesity (35-39.9 kg/m^2). The results showed a decrease in AMH levels of 1.03 ± 0.5 ($P = 0.004$) in patients with class 2 obesity. There was a significant moderate correlation between Leptin and body mass index ($r = 0.466$, $P < 0.0001$) and a significant moderate negative correlation between leptin and AMH ($r = -0.386$, $p = 0.004$) in the entire cohort of patients.
Conclusion
As a result of the study, it was revealed that the indicators of leptin and AMH reflect the relationship between reproductive disorders and obesity. The results obtained prove that with an increase in leptin levels, there is a decrease in AMH, which is the cause of endocrine infertility in women.

Unusual pulmonary embolism under testosterone replacement therapy in male hypogonadism: a case report

Hamza El Hadi[1], Silke Hoelscher[1], Jonel Trebicka[1] & Elena Vorona[1]
[1]Münster University Hospital, Department of Gastroenterology, Hepatology, Endocrinology, Infectiology, Münster, Germany

Background
Testosterone replacement therapy (TRT) is a well-established treatment for symptomatic hypogonadal men to maintain secondary sex characteristics and alleviate symptoms associated with testosterone deficiency. However, evidence regarding the potential risk of pulmonary embolism (PE) in hypogonadal male patients undergoing TRT remains scarce and controversial. We present a case of male patient with primary hypogonadism diagnosed with unusual bilateral pulmonary embolism (PE) during TRT.
Case report
A 50-year-old male with primary hypogonadism was referred to our endocrinology outpatient clinic for evaluation of unexplained fatigue and persistent exercise intolerance despite ongoing TRT. According to medical history, the patient attributed these symptoms to suboptimal testosterone levels and had increased the TRT dosage without consulting his doctor. Initial laboratory workup revealed significantly elevated hemoglobin and hematocrit levels alongside supraphysiological serum total testosterone concentrations. On physical examination, the patient was tachycardic but normotensive, with a normal respiratory rate and oxygen saturation on room air. Given his clinical presentation, Wells' criteria for pulmonary embolism stratified the patient as moderate risk. A D-dimer assay was markedly elevated, prompting an urgent computed tomography pulmonary angiogram (CTPA), which confirmed bilateral massive PE. Further investigations, including echocardiography, electrocardiography, and Doppler ultrasound of the lower extremities, were unremarkable. Accordingly, the patient was promptly initiated on a direct oral anticoagulant (DOAC) and transferred to a high-dependency unit for close monitoring.
Discussion and conclusion
The exact pathophysiological link between TRT and vascular events remains not fully elucidated. However, increasing body of evidence suggests that testosterone exerts erythropoietic stimulatory effects, leading to polycythemia, which may predispose patients to thromboembolic events. PE is a life-threatening condition, and its occurrence in males with hypogonadism under TRT represents a critical diagnostic challenge. This case highlights the need for awareness to early diagnosis of PE in hypogonadal men receiving TRT, particularly when unexplained symptoms such as fatigue and exercise intolerance arise. Further, we gave an evidence that PE in this patient population may mimic symptoms of testosterone deficiency and potentially leading to unwarranted dosage escalation and an increased risk of adverse vascular events. Therefore, regular clinical monitoring with individualized risk assessment are crucial in hypogonadal patients undergoing TRT to mitigate the risk of thrombotic complications.

A case of 46, xy dsd: pubertal virilization and gender identity in 17ßhsd3 deficiency

Emanuela Pignatone[1], Lara Devilli[1], Matteo Pontone[1], Laura Corbelli[1], Sara Barneschi[1], Gaia Varriale[2], Alessandra Bettini[3], Elena Andreucci[4] & Stefano Stagi[1,2]
[1]Department of Health Sciences, University of Florence, Florence, Italy; [2]Diabetology and Endocrinology Unit, Meyer Children's Hospital IRCCS, Florence, Italy; [3]Pediatric Psychology, Meyer Children's Hospital IRCCS, Florence, Italy; [4]SOC Genetica Medica, Meyer Children's Hospital IRCCS, Florence, Italy

Background
Inherited 17βhydroxysteroid dehydrogenase type 3 (17βHSD3) deficiency causes 46, XY disorders of sexual development (DSD) with extremely variable clinical presentation: from female genitalia appearance to ambiguous genitalia (AG). 17βHSD3 enzyme is primarily expressed in the Leydig cells where it catalyses the conversion of 4-androstenedione (δ4) into testosterone (T). The 17βHSD enzyme family includes 14 isoforms which are active in multiple tissues controlling final steps of androgen and estrogen biosynthesis. T/δ4 ratio and genetic testing are necessary for early diagnosis.
Case Report
A 16-year-old *girl* was referred to our clinic due to primary amenorrhea. Her mother was from Poland and her father from Italy. In her past medical story, no relevant information was reported. No prenatal investigations were performed during her gestation. At her physical examination AG were observed: a 5.0- cm phallus, palpable gonads were found in both inguinal canals and a single perineal urethral opening with a short vagina. She exhibited facial hair and pubertal development corresponding to Tanner stage B1 and PH5. Virilization had occurred during puberty. Weight was 74.8 kg and height 172.3 cm. Laboratory tests showed: total basal T 268 ng/dl, basal δ4 911 ng/dl, basal T/δ4 0.29 (similar after HCG stimulation), normal DHEAS, 19OHP and slightly increased FSH, LH, 17β-estradiol, DHT levels. Karyotype: 46XY in all metaphases. Abdominal MRI revealed gonads located in the inguinal canals, cavernous body and seminal vesicles; no uterus or ovaries were identified. *HSD17B3* gene sequencing showed the $c.277+4A>T$ homozygous mutation within intron 3 resulting in a splicing defect. She identified herself as female and after psychological evaluation, according to her parents, she decided to maintain the female gender. Bilateral gonadectomy, feminizing genitoplasty, vaginal dilatation, additive mammoplasty and facial sculpture were performed. She is now on hormonal replacement therapy with estrogens.
Conclusion
The clinical manifestations of our patient emerged during puberty and sex assignment was guided by her self-determination. Previous data reported that female-to-male gender assignment occurs in 39-64% if diagnosis is made after virilization. However, diagnosis during puberty has become rarer: 10% of cases according to a French study. Over the time, the initial decision regarding sex rearing has shifted to male gender assignment. Nonetheless, data remain inconsistent: early orchiectomy seems may allow retention of a female gender identity. The process of sex assignment, recognizing predictors of gender identity development, and determining the optimal timing for surgery remain challenging in these patients.

Clinical profile of turner syndrome patients in a tertiary endocrine center in Nepal

Ansumali Joshi[1], Srijana Karmacharya[1], Puspa Dahal[1] & Indu Rana[1]
[1]Kathmandu Diabetes and Thyroid Center, Kathmandu, Nepal

In Nepal, we have limited data regarding patients with Turner Syndrome, which is a rare chromosomal abnormality seen in females. We reviewed 16 cases of Turner Syndrome attending our endocrine center from July 2013 and Oct 2024. The mean

age was 7.06 ± 5.82 (range 8 - 30) years, weight was 38.12 ± 13.42(range 18-61) kg, height 131.21 cm ± 14.65 (range 104 - 153) cm and BMI was 20.96 ± 4.38 (range 16 - 30.4)kg/m^2. All patients presented with shunted growth. Primary amenorrhea was seen in 8 patients (50%), secondary amenorrhea in 3 patients (18.75%), delayed puberty in 13 patients (81.25%). 2 patients were 8 years old and 1 patient 11 years old. Only one was married and she was infertile. Webbed neck feature was noted in 10 patients (62.5%) and low set ear in 5 patients (31.25%). Madelung deformity was found in 2 patients (12.5%), cubitus valgus 12 patients (75%), kyphosis in 1 patient (6.25%) and broad chest in 8(50%) patients. One patient (6.25%) had hearing impairment and one (6.25%) had ear infection. Left renal agenesis was seen in 1(6.25%). Hypothyroidism was present in 7 patients (43.75%), hyperthyroidism in 1 patient (6.25%) and lymphedema in 1 patient (6.25%). Diabetes was not present in our patients while 1 patient (6.25%) had hypertension. None of our patients had cardiac problems. Mean FSH at presentation was 83.65 mIU/ml. Karyotyping was 45X0 in 10 patients (62.5%) and Mosaic in 6 patients (37.5%). Ultrasonography showed hypoplastic uterus in all patients. Growth hormone treatment was done in 4(25%) patients for the duration ranging from 6 months to 2 years. Hormone replacement therapy was initiated with estrogen only in 8(50%) patients and a combined estrogen & progesterone sequential regime in 8 (50%) patients. All estrogen were conjugated estrogen and progesterone was Medroxyprogesterone acetate. Combined oral contraceptive (COC) was not used in our patients.

Star protein deficiency in clinical practice: "a case series review"

Afaf Alsagheir[1], Abeer Alabduljabbar[2], Dania Farooq[3], Sara Abid[3], Sara Aljazaeri[3] & Raghad Alhuthil[2]

[1]Section of Pediatric Endocrinology, Department of Pediatrics, King Faisal Specialist Hospital and Research Centre, Riyadh, Saudi Arabia; [2]Department of Pediatrics, King Faisal Specialist Hospital and Research Centre, Riyadh, Saudi Arabia; [3]College of Medicine, Alfaisal University, Riyadh, Saudi Arabia

Background

Steroidogenic Acute Regulatory (StAR) protein deficiency is a rare autosomal recessive disorder disrupting steroid hormone production, leading to congenital adrenal hyperplasia (CAH) and variations in sexual development. Clinical presentations of StAR deficiency include electrolyte imbalances, ambiguous genitalia, adrenal and gonadal dysfunctions. Understanding the clinical and genetic spectrum of StAR deficiency is vital for accurate diagnosis, effective management, and genetic counselling.

Objectives

This case series provides detailed insights into the clinical presentation and genetic characteristics of StAR deficiency among seven patients diagnosed at King Faisal Specialist Hospital and Research Center (KFSH&RC) in Riyadh, Saudi Arabia.

Case presentation

Total of seven patients were born to consanguineous parents, predominantly first cousins. Patients were having 46, XY karyotype. And all patients exhibited congenital adrenal hyperplasia (CAH), The clinical presentations varied, with some patients showing bilateral inguinal gonads that were morphologically testicular, while others had completely feminized external genitalia or ambiguous genitalia. Most of the patients experienced symptoms of CAH like electrolyte imbalances and chronic salt-wasting. These symptoms were effectively managed using hydrocortisone and fludrocortisone. A notable finding they were having 46, XY karyotype with the StAR gene mutation, and all patients were phenotypically females.

Conclusions

These findings emphasize the importance of genetic counselling in consanguineous populations and highlight the need for continued research to address the complexities of StAR deficiency.

Italian survey on the endocrinological clinical approach to polycystic ovary syndrome

Olga Disoteo[1], Cecilia Motta[2], Chiara Sabbadin[3] & Renato Cozzi[4]

[1]Ospedale Sant'Anna, San Fermo della Battaglia (CO), Italy; [2]Azienda Ospedaliero Universitaria Sant'Andrea, UOC Medicina Specialistica Endocrino metabolica, Roma, Italy; [3]Azienda Ospedale Università Padova, UOC Endocrinologia, Padova, Italy; [4]ASST Grande Ospedale Metropolitano Niguarda, SC Endocrinologia, Milano, Italy

Introduction

Polycystic ovary syndrome (PCOS) is the most common endocrine disorder in reproductive-aged women, characterized by a range of clinical phenotypes that include reproductive, endocrine, and metabolic alterations.

Materials and Methods

We surveyed Italian Association of Clinical Endocrinologists members to examine PCOS diagnosis and management practices. The questionnaire included 4 demographic questions and 21 PCOS-related questions. Responses were collected anonymously via Lime Survey, preventing duplicate submissions. A total of 2412 members received an email with a link to the survey. Statistical analyses were performed using R software (version 3.4.3) with the EZR extension.

Results

503 out of 2412 physicians filled in the questionnaire, but 52 did not complete it fully. Thus, 451 participants (response rate 18.7%) were included in the analysis. Most respondents were female (62.5%) and over 55 years old (45.2%), Most endocrinologists (72.9%) see fewer than 5 patients per week with menstrual cycle issues, infertility, or hirsutism, while only 4% see more than 10 weekly. Patients with PCOS are 32.6% adolescents, 47.7% women of childbearing age, and 19% women of all ages, with no perimenopausal women. PCOS is confirmed in less than one-third of cases. 74.5% of respondents indicated that both endocrinologists and gynecologists had the expertise to manage PCOS, and most (56.3%) stated that they personally manage this condition from diagnosis to therapy 96.1% of respondents include pelvic US in diagnosing PCOS, mostly referring patients to gynecologists (78.5%) or radiologists (13.5%), with only 3.1% performing it themselves. All endocrinologists assess glucose metabolism: 30.2% using OGTT for all patients, 35.5% for at-risk patients, 30.4% considering fasting blood glucose and insulin, and 4.0% only fasting glucose. 61.0% believe diagnosing PCOS in adolescents is crucial if they show symptoms, 27.9% base it on symptom severity, and 11.1% say diagnosis can wait. Also, 67.2% consider patients' pregnancy desires critical in therapy decisions, with 28.8% referring to gynecologists for reproductive health (17.7%) or contraceptive counseling (11.1%). As for the concomitant presence of overweight/obesity, most manage this condition on their own (27.3%) or in collaboration with a dietitian (63.6%), whereas only a few (8.6%) refer the patient to another specialist.

Conclusions

The variability in PCOS diagnosis and management underscores the need for specialized, individualized care from a multidisciplinary healthcare team. A major pitfall identified in this survey is the assessment of IR during OGTT by most respondents, which is critical for prescribing metformin to about 40% of women with PCOS.

JOINT1346

Gynecomastia as a potential late effect of testicular lymphoma treatment: a case report

Petra Meliš[1], Mirna Hrabar[2], Katica Letinić Kravaršćan[1] & Srecko Marusic[1]

[1]University hospital Dubrava, Department for Endocrinology, Diabetes and Clinical Pharmacology, Zagreb, Croatia; [2]University hospital Dubrava, Zagreb, Croatia

Introduction

Gynecomastia, the benign proliferation of male breast tissue, is often associated with hormonal imbalances. This report describes a 72-year-old man who developed gynecomastia after being treated for an aggressive type of testicular B-cell non-Hodgkin lymphoma. It shows how cancer treatments can sometimes lead to hormone-related side effects.

Case Description

The patient presented with a six-month history of painful bilateral breast enlargement. His medical history included unilateral orchiectomy for testicular lymphoma, four cycles of R-CHOP chemotherapy, and one cycle of immunotherapy. He also underwent radiotherapy to the contralateral testis, thereby achieving complete remission. Tests showed low levels of LH, FSH, and testosterone, pointing to hypogonadotropic hypogonadism. There were no signs of high prolactin levels. Imaging studies ruled out testicular or adrenal masses.

Discussion

The patient's gynecomastia is likely a consequence of treatment-induced hypogonadotropic hypogonadism. Chemotherapy, immunotherapy, and radiotherapy can significantly disrupt hormonal balance. This case underscores the importance of

monitoring endocrine function in patients treated for testicular lymphoma, as gynecomastia may represent a rare but significant late effect of therapy.
Conclusion
Gynecomastia in this patient is attributed to treatment-induced hypogonadism following aggressive therapy for testicular lymphoma. There is a need for further research into the endocrine side effects of oncological treatments and long-term endocrine follow-up in cancer survivors.

Congenital adrenal hyperplasia due to 21-hydroxylase deficiency: a case report

Nada Ait Kassi[1], Khaoula Lakhdar[2], Habbadi Zineb[1], Fatima Toulali[1], Ghizlane Sabbar[1], Kaoutar Rifai[1], Hinde Iraqi[1] & Mohamed El Hassan Gharbi[1]
[1]Ibn Sina Hospital Mohamed V University, Endocrinology, Rabat, Morocco; [2]Ibn Sina Hospital Mohamed V University, Gynecology-Obstetrics and Endoscopy Department, Rabat, Morocco

Introduction
Congenital adrenal hyperplasia (CAH) due to 21-hydroxylase deficiency is a genetic disorder that impairs adrenal steroid synthesis, presenting with a spectrum of clinical manifestations and significant psychosocial challenges. The severity of the condition can vary widely, and its management involves not only addressing the hormonal imbalances but also the emotional and social difficulties faced by affected individuals, particularly during adolescence.
Case Presentation
We report the case of a 14-year-old female presenting with severe hirsutism, abnormal sexual development (PRADER stage 4), and metabolic risks. Diagnostic evaluation revealed classic 21-hydroxylase deficiency, confirmed by elevated 17 OH progesterone levels and bilateral adrenal hyperplasia. The patient was started on hydrocortisone therapy (20 mg/day), with a treatment plan that included both pediatric psychiatry and endocrinology support to address the psychosocial aspects of the condition.
Discussion
The management of CAH in adolescents requires a comprehensive approach that balances medical treatment with psychological care. Our case highlights the importance of individualized care plans that address both the physical and emotional aspects of CAH. The patient's family history of CAH further underscores the hereditary nature of the disorder, which can amplify psychosocial challenges. Early intervention, combined with multidisciplinary support, contributes significantly to managing symptoms and improving adherence to therapy.
Conclusion
This case illustrates that effective management of CAH in adolescents requires a holistic approach that includes pharmacological treatment alongside psychological and social support. Personalized care and close follow-up are essential to improving both the physiological and psychosocial aspects of this condition. Early diagnosis and a multidisciplinary approach are crucial in optimizing outcomes for patients with CAH.

Pure gonadal dysgenesis (46 XX type): 2 cases report

Fatiha Ettalibi[1], Sara Ijdda[2], Sana Rafi[1], Ghizlane El Mghari[1] & Nawal El Ansari[1]
[1]Mohammed VI University Hospital of Marrakesh, Department of Endocrinology, Diabetes, Metabolic Diseases, and Nutrition, Marrakesh, Morocco; [1]Mohammed VI University Hospital of Marrakesh, Department of Endocrinology, Diabetes, Metabolic Diseases, and Nutrition, Marrakesh, Morocco

Introduction
Pure gonadal dysgenesis is defined by the complete or nearly complete absence of ovarian tissue in phenotypic females. We report 2 cases of 2 young girls with a 46, XX karyotype associated with gonadal dysgenesis and no other associated organic abnormalities.
Case presentation
Case 2: 16-year-old girl with no significant medical history reffered for investigated of primary amenorrhea and delayed sexual development. Her height and BMI were within normal range, Tanner stage S1P1with external genitalia appearing normal for a child, without any sexual ambiguity or signs of hyperandrogenism. Hormonal tests showed a high follicle-stimulating hormone level (FSH: 52,58 mIU/ml), a low 17β-estradiol level (7 pg/ml) and normal levels of testosterone, prolactin, thyroid-stimulating hormone were reported, and bone age at 15 years. Her karyotype was 46, XX. At imaging (magnetic resonance imaging) the absence of individualisation of the 2 ovaries with major hypoplasia of the uterus measuring 20*8 mm were revealed. she had been commenced on hormone replacement therapy. **Case 1:** 17-year-old girl, without consanguinity, was admitted for primary amenorrhea with underdeveloped secondary sex characteristics Her height and BMI were normal, tanner stage S1P1, with normal childlike external genitalia, no sexual ambiguity, and no signs of hyperandrogenism. Hormonal testing revealed: FSH at 62 UI/ml, 17β-estradiol at 5 ng/ml, normal prolactin and thyroid-stimulating hormone, bone age were between 13 and 14 years. Pelvic MRI showed a hypoplastic uterus measuring 18.7 $\times$ 7.5 mm, with no individualization of the ovaries and no other malformations. A karyotype revealed two normal X chromosomes in all observed mitoses, and AMH $<$ 0.015 ng/ml. The patient was started on 17-beta estradiol treatment.
Discussion/conclusion
46, XX gonadal dysgenesis without the phenotype of Turner's syndrome is described as "pure" and it's an infrequent cause for primary amenorrhoea. Patients are born as phenotypic female. Pure gonadal dysgenesis (PGD) follows an autosomal recessive inheritance pattern, so genetic counseling is recommended. Management is based on hormone replacement therapy (HRT) to induce female pubertal development, promote uterine growth, and maintain bone health. Regarding fertility, the recommended option is the implantation of embryos fertilized with a donated oocyte.

Complexities of complete androgen insensitivity syndrome

Elene Asanidze[1], Jenaro Kristesashvili[2] & Ana Jibladze[2]
[1]University Geomedi, Tbilisi, Georgia; [2]Ivane Javakhishvili Tbilisi State University, Tbilisi, Georgia

Complete androgen insensitivity syndrome (CAIS) presents significant challenges in the accurate diagnosis and personalized management of individuals with a 46, XY karyotype who exhibit a female phenotype due to complete insensitivity to androgens. This retrospective case report analyzes the clinical data, genetic testing, hormonal profiling, and imaging studies of a patient who was initially misdiagnosed during hernioplasty and later misidentified as having Mayer-Rokitansky-Küster-Hauser syndrome. The report details the establishment of the correct diagnosis and implementation of a personalized management strategy that postponed gonadectomy until post-puberty. This approach included continuous monitoring and tailored estrogen replacement therapy, which facilitated informed patient decisions and comprehensive feminization while preventing the long-term consequences of estrogen deficiency. Supported by a literature review, this case report emphasizes the necessity of a multidisciplinary approach to managing CAIS, highlighting the importance of heightened awareness, accurate diagnostics, and personalized therapeutic plans to ensure holistic, patient-centered care.

Experiences in setting up a transitional care process in patients with differences in sex development and congenital adrenal hyperplasia in a tertiary care centre of a low-middle-income country

Janani Ilangamge[1], Chathupani Wettasinghe[2], Fathima Anverdeen[2], Dimuthu Muthukuda[3] & Sumudu Seneviratne[1]
[1]Faculty of Medicine, University of Colombo, Colombo, Sri Lanka; [2]Lady Ridgeway Hospital for children, Colombo, Sri Lanka; [3]Sri Jayewardenepura General Hospital, Sri Jayawardenapura, Sri Lanka

Introduction
Congenital adrenal hyperplasia (CAH) and differences in sex development (DSD) are complex medical conditions requiring lifelong care involving multiple

medical specialties at various stages of life. Transitional care refers to the smooth coordinated transfer of health care from more family-centered paediatric services to more individual-centred adult-care services, and involves meetings between paediatric and adult health care providers, patients and parents. Age of transition can vary from 14-21 years, based on the setting, health care services and socio-cultural aspects.
Method
This cross-sectional study assessed the recently established transitional process for patients above 16 years with CAH and DSD at an university pediatric endocrine unit. The transition process is currently coordinated by clinical-staff, and patients have been educated about its importance by the primary-clinician. Patient data were obtained from the unit-based patient registry (ethics-approval-EC–18-092), and follow-up phone call. Descriptive analyses were performed to determine patient characteristics and outcomes.
Results
The study involved 38 patients aged 16-26 years, with DSD ($n = 15$,39.4%) and CAH ($n = 23$, 60.6%), of whom 21(55.6%) were females, and 17(44.7%) were males. The majority ($n = 32$,84.21%) resided outside the district where the centre was located. Currently, 15 patients (39.5%, mean age:22.2years) have been transferred to adult-care while 17 (44.7%, mean age:17.2y) are currently undergoing the transitional process, and 6 (15.8 %, mean age:17y) are yet to start the transitional process. Among the 15 transferred to adult care, three(20%) hadn't yet engaged with adult-care services due to personal reasons and anticipatory anxiety, while another three(20%), who requested transfer to local hospitals (without specialized endocrine services) have returned due to lack of medication. Among those undergoing transition($n = 17$), seven-patients(41.2%) didn't initially turn up for their scheduled transition meetings citing personal reasons, leading to difficulties in rescheduling. Most patients undergoing transitional process or yet to start the process have requested to remain under paediatric care till completion of major school exams.
Conclusion
Patients appear to be experiencing anxiety/reluctance about transitioning to adult care, despite its importance. The process is also hindered by logistical issues with rescheduling and coordination of joint care meetings in low resource settings, and absence of specialized services and medicine in local hospitals. However, ways of overcoming the challenges identified are important for successful transition which is crucial for optimizing long-term patient care.

Clinical hyperandrogenism in obese and non-obese women with polycystic ovary syndrome

Emna Mraihi[1], Taieb Ach[2], Fatma Ben Abdessalem[1], Imen Halloul[2], Wiem Saafi[2], Hamza Elfekih[2], Ghada Saad[2] & Yosra Hasni[2]
[1]Faculty of Medicine Ibn Al Jazzar Sousse, University of Sousse, Sousse, Tunisia; [2]University Hospital Farhat Hached Sousse, Sousse, Tunisia

Introduction
Polycystic ovary syndrome (PCOS) is a multifaceted endocrinopathy characterized by a combination of reproductive, metabolic, and dermatological aspects. Among its defining features, clinical hyperandrogenism stands out as a hallmark manifestation, presenting with hirsutism, acne, and alopecia. While hyperandrogenism is observed in both obese and non-obese phenotypes of PCOS, the severity and presentation may vary between these groups. This study compares clinical hyperandrogenism in obese and non-obese PCOS women.
Subjects and Methods
This analytical cross-sectional study was conducted on 122 patients diagnosed with PCOS at the Endocrinology and Diabetology Department of FARHAT HACHED Hospital in Sousse from January to December 2024. Two groups were formed based on body mass index (BMI): the Obese PCOS (O-PCOS) group with a BMI above 25 kg/m^2 and the Lean PCOS (L-PCOS) group with a BMI below 25 kg/m^2. The study focused on various aspects of clinical hyperandrogenism. The severity of acne, hirsutism, and alopecia was assessed using the Global Acne Evaluation Scale, the modified Ferriman-Gallwey score, and Ludwig's classification of female hair loss.
Results
Among participants, 38 were classified as lean (31.14%), while 84 were categorized as obese (68.85%). The average age was 23.61 ± 4.97 years. Clinical hyperandrogenism was present in 89.3% of participants. Acne was the most frequent aspect, with a prevalence of 93.4%, followed by hirsutism (90.1%) and alopecia (35.2%). The mean ages of onset for these aspects were similar between O-PCOS and O-PCOS groups: 14.67 ± 4.99 years vs 13.45 ± 3.21 years for acne; 13.73 ± 2.85 years vs 12.96 ± 2.39 years for hirsutism; and 13.77 ± 2.48 years vs 12.54 ± 3.52 years for alopecia. Regarding severity, a higher prevalence of mild (31.6%) and severe cases (13.2%) of acne was observed in the L-PCOS group compared to O-PCOS ($P = 0.369$, $P = 0.135$ respectively). Mild and moderate cases of hirsutism were nearly equally distributed across both groups: fifty percent in each of the L-PCOS and O-PCOS patients exhibited mild hirsutism ($\boldsymbol{P < 10^{-3}}$), with 31.6% of the lean participants vs 35.7% of the obese showing moderate cases ($P = 0.198$). Alopecia presented similarly in both groups, with most cases classified as Grade 1 ($\boldsymbol{P = 0.041}$).
Conclusion
In conclusion, clinical hyperandrogenism is common in both lean and obese women with PCOS, with similar patterns of acne, hirsutism, and alopecia severity observed across these groups. These findings highlight the importance of comprehensive management of hyperandrogenism in all PCOS phenotypes, regardless of body weight.

Syndromic gonadal dysgenesis: a rare case of image syndrome

Hamdi Frikha[1], Nesrine Dhieb[1], Khouloud Boujelben[1], Yassmine Abdelkafi[1], Dhoha Ben Salah[1], Mouna Mnif[1], Mouna Elleuch[1] & Nabila Rekik Majdoub[1]
[1]Hedi Chaker University Hospital, Endocrinology, Sfax, Tunisia

Introduction
Gonadal dysgenesis (GD) is the leading cause of disorders of sex development (DSDs) in Western societies. However, syndromic forms of GD are extremely rare and challenging to diagnose. We report a rare etiology of syndromic GD: IMAGE syndrome.
Case report
A newborn with a 46,XY karyotype, born to non-consanguineous parents, presented with a salt-wasting crisis at day 7 of life, associated with severe intrauterine growth retardation (IUGR) and a birth weight of 1760 g. Clinical examination revealed a dysmorphic syndrome characterized by scaphocephaly, midface hypoplasia, and external genital anomalies (Quigley stage II/Prader stage IV, distal hypospadias, micropenis, and left testicular ectopia). Hormonal investigations showed peripheral adrenal insufficiency (both glucocorticoid and mineralocorticoid deficiency), partial hypergonadotropic hypogonadism with normal AMH levels, and bilateral adrenal hypoplasia on abdominal CT scan. Genetic analysis did not identify any mutations in the implicated genes (NR0B1, NR5A1, HSD3B2, POR). At 3 years of age, severe growth failure (-3 SD) prompted a stimulation test, which revealed complete growth hormone deficiency (GH peak = 0.29 ng/ml), despite a normal pituitary MRI. The combination of IUGR, adrenal hypoplasia, genital anomalies, and GH deficiency strongly suggested the diagnosis of "Intrauterine growth retardation, Metaphyseal dysplasia, Adrenal hypoplasia congenita, and Genital anomalies" (IMAGE) syndrome. Under hormone replacement therapy (hydrocortisone, fludrocortisone, and recombinant growth hormone), the evolution over 14 years was favorable: improved growth (-0.5 SD), spontaneous pubertal onset, no adrenal crisis, and good academic and social integration.
Discussion
IMAGe syndrome is a very rare condition caused by a mutation in the *Cyclin-Dependent Kinase Inhibitor 1C* (*CDKN1C*) gene. This ubiquitously expressed protein plays a fundamental role in the early stages of testicular development within the genital ridges. The clinical spectrum of IMAGe syndrome is broad and involves multiple organ systems. The dysmorphic syndrome includes facial and skeletal anomalies such as epiphyseal and metaphyseal dysplasia. Genital anomalies are generally mild, often limited to bilateral cryptorchidism and micropenis, as observed in our patient. Since *CDKN1C* is also expressed in the pituitary gland, IMAGe syndrome patients may present with varying degrees of pituitary hormone deficiencies, particularly affecting the somatotropic and gonadotropic axes. This could explain the complete GH deficiency and the moderately elevated gonadotropin levels observed in our patient.

From ovary to testis: a case of 46,XX ovotesticular DSD

Yassmine Mkhinini[1], Sana Kmiha[1,2], Saloua Ammar[3], Bochra Ben Rhouma[2], Rim Belhadj[1], Hajer Aloulou[1], Riadh Mhiri[3], Leila Keskes[2] & Thouraya Kammoun[1]

[1]Hedi Chaker University Hospital, Department of Pediatrics A, Sfax, Tunisia; [2]Faculty of Medicine of Sfax, University of Sfax, Laboratory of Human Molecular Genetics, Sfax, Tunisia; [3]Hedi Chaker University Hospital, Pediatric Surgery Department, Sfax, Tunisia

Introduction

46,XX ovotesticular disorder of sexual development (DSD) is a rare condition characterized by abnormal gonadal differentiation, with both testicular and ovarian tissue coexisting in the same individual. Typically, the testicular tissue is dysgenetic, while the ovarian tissue is normal.

Methods

We report the case of a 1-year-and-5-month-old child referred to our Pediatric Department A at Hedi Chaker University Hospital in Sfax for evaluation of DSD.

Results

The infant, assigned male at birth, presented with posterior hypospadias and left testicular ectopia. Born to non-consanguineous parents, the child was delivered at term with a birth weight of 3700 g, length of 48 cm, and head circumference of 34 cm. Psychomotor development was normal. On clinical examination, the child weighed 9 kg (−1.5 SD) and measured 79 cm (average height), with no dysmorphic features or limb abnormalities. The genital tubercle measured 2 cm, with penoscrotal hypospadias and a well-developed scrotum. A palpable right gonad (15 mm) was noted, while no gonad was identified on the left side. Hormonal testing at 18 months showed FSH at 1.8 mIU/ml, LH at 0.1 mIU/ml, testosterone at 0.03 ng/ml, DHT at 0.09 ng/ml, and low AMH at 16 ng/ml. Karyotyping revealed a 46,XX chromosomal pattern, and PCR analysis of the SRY gene was inconclusive, requiring FISH for further clarification. Abdominal ultrasound revealed a Müllerian cavity, a right testis in the distal inguinal canal, and no left gonad. Pelvic MRI confirmed the Müllerian cavity, a right testis, and a left oval structure suggestive of either an ovary or a polycystic testis. Surgical intervention included excision of the left gonad and Müllerian structures, along with a biopsy of the right gonad. Histopathological analysis confirmed the presence of an ovary on the left and a testis on the right. Following discussions with the parents, the child was raised as male. Androtardyl® treatment was initiated, with two injections showing a good response, followed by hypospadias repair. At 4 years and 9 months, the child was eutrophic, with a 5 cm phallus, a slightly posterior urethral meatus, a right testis in place, and an empty left scrotum.

Conclusion

46,XX ovotesticular DSD is a rare condition. Sex assignment can be challenging, and management requires a multidisciplinary approach.

Unilateral drug induced gynecomastia secondary to antiretroviral therapy in an HIV infected patient

Chayma Zouna[1], Nada Ait Kassi[1], Ghita Khamel[1], Zineb Habbadi[1], Fatima Toulali[1], Ghizlane Sabbar[1], Kaoutar Rifai[1], Hind Iraqi[1] & Mohamed Hassan Gharbi[1]

[1]CHU Rabat, Endocrinologie, Rabat, Morocco

Introduction

Gynecomastia has been described in HIV-infected men undergoing highly active antiretroviral therapy. However, data on the relationship between gynecomastia and a specific antiretroviral drug or hormonal abnormality are insufficient.

Observation

Patient aged 60 years with pulmonary tuberculosis treated 04 months ago. The patient has been treated for HIV infection for 06 months and is on combination antiretroviral therapy containing Efavirenz600mg/Emtricitabine200mg/Tenofovir disoproxil fumarate 245mg daily. Referred to our training for exploration of a left Gynecomastia with palpation of an indurated and nodular mass on the left side without axillary adenopathy with a normal contralateral examination as well as the External Genitalia with right and left testicle size measuring 3*4cm and penis size at 10cm. Mammary ultrasound showed glandular infiltration of the left breast with no individualized mass or collection, complemented by mammography finding a benign-looking left gynecomastia. Liver, kidney and thyroid tests were normal. Hormonal profile: Prolactin 4.7ng/ml Testosterone =4.78ng/ml Oestradiol=22.59pg/ml FSH =11.90mui/ml LH=8.79mui/ml Tumor markers AFP and BhCG negative Testicular ultrasound was normal except for a slight reduction in left testicular volume (38*16*29mm) compared with right (43*19*28mm). In view of the patient's severe discomfort, a local hormone treatment based on androstanolone gel 2.5% with daily cutaneous application was prescribed and the patient will be evaluated after 3 months.

Discussion

Gynecomastia is not uncommon in HIV-infected men on antiretroviral therapy, and is generally transient. Treatment with efavirenz and didanosine is associated with the development of gynecomastia. Underlying hypoandrogenism appears to contribute to the development of this disorder in these patients. Gynecomastia is initially unilateral, but progresses to bilateral but asymmetric disease in more than half of patients. In patients with persistent gynecomastia, testosterone has proved effective and safe when administered transdermally or intramuscularly over several weeks or months. Most cases developed within the first two years of treatment. Discontinuation of efavirenz had positive results, with most cases achieving complete resolution. Active screening and early discontinuation of efavirenz in patients who develop gynecomastia are recommended to improve quality of life and promote adherence to antiretroviral therapy.

Primary amennorhea caused by hyperandrogenism due to porto-systemic shunting

Mirjam van Albada[1], Ruben H. J. de Kleine[2], Valerie McLin[3] & Hubert van der Doef[4]

[1]University Medical Center Groningen, Beatrix Children's Hospital, department of pediatric endocrinology, Groningen, Netherlands; [2]University Medical Center Groningen, Department of surgery, Groningen, Netherlands; [3]University of Geneva Hospital, Department of Pediatrics, Geneva, Switzerland; [4]University Medical Center Groningen, Beatrix Children's Hospital, department of pediatric gastro-enterology, Groningen, Netherlands

Introduction

The liver plays a vital role in the endocrine system. In patients with portosystemic shunting, such as congenital portosystemic shunts or acquired portosystemic shunting because of collateral formation after portal vein thrombosis, several endocrine disturbances can occur. We present a case of a girl with primary amenorrhea after portal vein thrombosis.

Case report

A female,16 year of age, presented with primary amenorrhea and mild hirsutism. Height was 157 cm (-2,0 SD) and BMI 22,8 kg/m^2 (+0,7 SD). Her biochemistry showed hyperandrogenism with an androstenedione level of 19 nmol/l(1.35 – 7.82 nmol/l)and a testosterone level of 6.5 nmol/l(0.100 – 1.70 nmol/L), along with an LH to FSH ratio of 2.2 (LH 14,4 U/land FSH 6,6 U/l; PCOS-like fenotype). Her medical history included hematemesis at the age of 9 years due to esophageal varices, revealing an idiopathic portal vein thrombosis with porto-systemic shunting. She was also known to have mild primary hypothyroidism. In addition to hyperandrogenism, her biochemistry showed increased ammonia (176 µmol/l(15 - 45 µmol/L)), thrombocytopenia and mildly elevated bile salts. A retrograde portogram showed an intact portal bifurcation, after which a MesoRex bypass was performed successfully. This surgical procedure restored the portal flow from the mesentery to the liver, reconstituting the first pass mechanism. During follow-up, androstenedione and testosterone levels normalized (1.1 nmol/land 5.1 nmol/l,respectively), as did the LH to FSH ratio (LH 4,6 U/land FSH 6,2 U/l). Three months postoperatively, menarche occurred and her menses have remained regular since.

Conclusion

Loss of the liver's first pass metabolism due to a diverted portal flow can lead to several endocrine abnormalities, as illustrated in this case. Clinicians should be aware that porto-systemic shunting can mimic polycystic ovary syndrome (PCOS). More information on congenital portosystemic shunts can be found on the website from the International Registry of Congenital Porto-Systemic Shunts: https://ircpss.com.

JOINT2484

From prolactinoma suspicion to fmr1 premutation: a case of overlapping endocrine disorders

Rita Pinto Ribeiro[1], Patrícia Brito[1], Valentim Lopes[1], Olinda Marques[1] & Ana Margarida Monteiro[1]
[1]Braga Local Health Unit, Endocrinology Department, Braga, Portugal.

Introduction
Secondary amenorrhea is a relatively common health issue during reproductive years. Besides pregnancy, most common causes include polycystic ovary syndrome, premature ovarian insufficiency (POI), and hyperprolactinemia. POI affects approximately one in 100 females. Although most cases are idiopathic, FMR1 gene mutations should be sought in these patients due to the risk of X-fragile syndrome in future generations.
Case report
A 41-year-old female patient was initially referred to the Endocrinology Department at the age of 33 years due to bilateral galactorrhoea and elevated prolactin, which began two years postpartum (at 30 years), associated with oligomenorrhea. She was evaluated at a private consult and a short cycle of bromocriptine was done, with clinical resolution of the galactorrhoea. No analytical work-up from that period was available. At 31 years, she became pregnant again, but galactorrhoea returned one year postpartum. Testing showed a prolactin level of 95.45 ng/ml, but interpretation of the hypothalamic–pituitary–gonadal axis was limited by ongoing combined oral contraceptive (COC) use. Pituitary magnetic resonance (MRI) revealed a 5 mm lesion, suggesting a microadenoma. Upon referral, the patient was on COC and reported resolved galactorrhoea. She maintained clinical, analytical and imagiological vigilance. Stable imaging and no prolactin rise (maximum: 79.22 ng/ml) were seen during follow-up. At 38 years, after stopping COC, she developed secondary amenorrhea and hot flashes. Testing confirmed hypergonadotropic hypogonadism, with normal prolactin and thyroid function. Negative adrenal and thyroid autoantibodies, along with a normal karyotype, prompted FMR1 gene analysis, revealing a premutation with 70 CGG repeats—consistent with Fragile X-associated POI. The patient is currently on COC for contraceptive efficacy and awaits genetic counseling.
Conclusion
POI is a pathologic condition associated with health risks and negative impact on quality of life. Early diagnosis and systemic hormone therapy is imperative to treat hypoestrogenism symptoms and mitigate long-term health risks as osteoporosis and cardiovascular disease.

JOINT1412

Impact on fertility and bone mass of triptorelin and estradiol therapy in trans girls

Amaia Sánchez Arlegui[1], Claudia Cifuentes Zamalloa[1], Asier Peña Fuentes[1], Nancy Portillo Nájera[1], Gema Grau Bolado[1], Amaia Vela Desojo[1] & Itxaso Rica Echevarria[1]
[1]Cruces University Hospital, Barakaldo, Spain.

International guidelines recommend puberty blocking with GnRH analogs followed by Estradiol treatment (E2) for trans* girls who request medical therapy. There are still uncertainties about possible side effects, is recommended to consider fertility preservation before starting medication, and to periodically assess their bone mineral density (BMD). Besides genetic and hormonal factors, environmental influences on bone mass are crucial, particularly diet, calcium intake, weight, vitamin D levels and sports activity.
Objective
To study the impact of dual therapy on trans* girls in relation to inhibin B levels and BMD. To find out the proportion of minors participate in sports and its potential influence on bone mass acquisition.
Subjects and methodology
Retrospective study of 19 minors who started Triptorelin at an average age of 13.1 ± 1.6 years (65% Tanner III-IV) and E2 at 14.9 ± 1.08. Included variables: inhibin B, weight (SDS for age and gender identity), BMD in g/cm^2 and in SDS for gender identity and vitamin D levels. Scheduled sports activity data were collected (minimum of 2 hours/week). Variables before and during treatment were studied: Triptorelin (medium dose of 60 µg/k/28 days, started 29.1 ± 6 months prior) and transdermal E2 patches (75 mg/week received for 22.6 ± 9.5 months). SPSS V25 was used for statistical analysis. Non-parametric Wilcoxon test for related samples and Chi-Square for proportions.
Results
Initial data: Inhibin B 204 ± 49 pg/ml, Weight-SDS 0.07 ± 1.6, BMD L1L4 0.89 ± 0.16 g/cm^2 (SDS –1.1 ± 0.89), total body BMD 0.9 ± 0.11 g/cm^2 (SDS -0.23 ± 1.1) and vitamin D 21.9 ± 8.5 ng/ml. 23% (5/19) practice sports and 16% (3/19) visited the fertility clinic to request preservation. Inhibin B levels decreased with therapy. In a subgroup of 6 minors who had been on E2 treatment for 36 months, the decrease was even greater (196 ± 47 vs 87 ± 9.5 26). The weight-SDS increased slightly throughout the treatment. During the 2.5 years of combined therapy, BMD increased, the BMD-SDS values for gender in the lumbar spine showed no changes, and in the body, they decreased. Most of the minors did not engage in scheduled sports, and we could not associate this practice with the other variables studied.
Conclusions
Over the first 2.5 years of treatment with Triptorelin and Estradiol in trans* girls, there is a progressive decrease in Inhibin B levels that may compromise their fertility; however, only a minority seeks to preserve it. Most of them do not participate in sports and have low levels of vitamin D, factors that may negatively impact their bone health.

Premature ovarian insufficiency in a 26-year-old patient treated with hydroxyurea for sickle cell disease

Yosra Abderrahim[1], Bchir Najla[1], Dorra Dorraelguiche[1], Annam Benchhida[1], Arige Abid[1], Zouaoui Chadia[1] & Haroun Ouertani[1]
[1]Department of Endocrinology, Military Hospital of Tunis, Tunis, Tunisia.

Introduction
Reproductive function in women with sickle cell disease can be compromised by various mechanisms, including the direct impact of vaso-occlusive crises on the ovaries, endocrine dysfunction due to iron overload in chronically transfused patients, and iatrogenic factors such as hydroxyurea treatment. Several studies suggest that hydroxyurea may contribute to a decline in ovarian reserve. In this context, we report a case of premature ovarian insufficiency(POI) in a 26-year-old woman treated with hydroxyurea.
Case presentation
A 26-year-old female patient was referred to our department for secondary amenorrhea. The patient has a family history of homozygous sickle cell anemia in one sister and peripheral hypothyroidism in another. She has been treated for sickle cell disease since age 4 and has been on Hydroxyurea for several years, with infrequent need for transfusions and rare vaso-occlusive crises. Her menarche occurred at age 14, followed by 10 years of oligomenorrhea. Over the past year, she developed secondary amenorrhea, unresponsive to dydrogesterone, which had previously been effective. At presentation, she was receiving 500mg of Hydroxyurea twice daily and her hemoglobin was 9.8 g/dl. Hormonal tests revealed elevated FSH (144.34 mUI/ml), LH (80 mUI/ml), and low estradiol (24 ng/L), while thyroid hormones, prolactin, and testosterone were normal. AMH was < 0.05 ng/ml, confirming POI. Genetic testing showed a normal 46XX karyotype. Autoimmune screening showed a slightly positive TPO antibodies but negative anti-21 hydroxylase antibodies, making autoimmune ovaritis less likely given the strong suspicion of iatrogenic cause. Bone mineral density (BMD) tests revealed spinal and femoral osteopenia as a complication of hypogonadism. The patient was started on hormone replacement therapy, and her hematologist was consulted to explore alternative treatments to hydroxyurea in the hope of reversing ovarian function, although it seems very unlikely.
Discussion
Although several studies have reported a decline in ovarian function associated with hydroxyurea, its impact remains controversial. It is still unclear whether this decline can lead to ovarian insufficiency as severe as in our case or whether it is reversible after discontinuation of treatment. Further research is needed to clarify these effects. Meanwhile, these findings highlight the importance of considering fertility preservation for women of childbearing age before initiating hydroxyurea therapy.

The Puzzle Of 45,X/46,XY mosaicism (MGD): insights from an adult male case report

Amy Haeffner[1] & Sing Sim[1]
[1]University Hospitals Sussex NHS Foundation Trust, Brighton, United Kingdom.

Background
Mixed Gonadal Dysgenesis (MGD) describes individuals with a chromosomal mosaicism and underdeveloped gonads, often accompanied by impaired puberty,

fertility challenges and short stature. 45,X/46,XY mosaicism MGD has an estimated incidence of 5.6 per 100,000 liveborn males and median age at diagnosis is 29.1. MGD is associated with an increase in all-cause mortality and heightened risk of gonadal malignancy.
Case presentation
A 53-year-old biological male was referred to secondary endocrinology services with bilateral gynaecomastia and small testes, present since adolescence. Despite these findings, he reported normal libido, successful conception with three children, and no history of testicular infection, trauma, or steroid use. Historical sperm analysis suggested oligospermia. His past medical history includes ankylosing spondylitis (on etanercept), COPD, and benign prostatic hyperplasia. Clinical examination showed a weight of 92.6 kg, height 180 cm and BP 150/91 mmHg. He was well-virilized with male phenotypic features, bilateral gynecomastia, and small, lump-free testes. His blood tests revealed free testosterone of 134 pmol/l(163–473), total testosterone 12.2 nmol/l(6.68–25.7), LH 7.2 IU/l(1.7–8.6), FSH 13.5 IU/l(1.5–12.4), oestradiol 57 pmol/l(41–159), prolactin 167 mIU/l(86–324), cortisol 534 nmol/l(133–537), beta-HCG <0.1 IU/l,and alpha-fetoprotein 2.9 kU/L. Thyroid, renal, liver, and full blood count were unremarkable. Testicular ultrasound revealed bilateral small testes which were normal in shape and reflectivity with no visible mass or cysts. Serum PCR analysis confirmed a male sex chromosome complement with the SRY sequence on chromosome Y, excluding Klinefelter Syndrome. SNP array analysis revealed 27% monosomy X cells and 73% normal male cells, consistent with his clinical presentation of mosaicism, gonadal dysgenesis, and oligospermia. The patient has been referred for genetic counselling. A CT scan of the abdomen and pelvis is pending to evaluate for persistent Mullerian structures. He will undergo annual malignancy screenings, including testicular ultrasounds, due to the increased risk of gonadoblastoma (strongly linked to the presence of a Y chromosome).
Conclusion
This case underscores the rarity of late MGD diagnoses in older males and highlights the need for early investigations in disorders of sexual development. Awareness among paediatricians and general practitioners of MGD signs enables timely referral to specialists. While no standardized management pathway exists, early diagnosis reduces malignancy risks and addresses growth and sexual impairments. Management requires a multidisciplinary approach, including gender assignment, surgical interventions, hormone therapy, fertility considerations, and psychosocial support.

JOINT2045

Gender affirmation and hormonal health: the role of testosterone therapy in a non-binary cis woman with primary ovarian insufficiency

Sargunann Naidu Krishnasamy Naido[1] & Nashriq Khan Adam Khan[2]
[1]Whittington Health NHS, London, United Kingdom; [2]Norfolk and Norwich University Hospitals NHS Foundation Trust, Acute Medicine, Norwich, United Kingdom.

Introduction
Primary ovarian insufficiency (POI) complicates gender-affirming hormone therapy in non-binary individuals. Testosterone therapy, while effective for masculinization, may exacerbate POI-associated risks such as osteoporosis, cardiovascular disease, and endometrial hyperplasia. This case explores the challenges of testosterone therapy in a non-binary individual with cervical cancer and radiotherapy-induced POI.
Case Report
A 28-year-old non-binary individual (preferred pronouns: they/them) presented with severe hypothyroidism (Free T4 $<$ 2.0 pmol/l,TSH $>$ 100 mu/l)due to Hashimoto's thyroiditis, alongside fatigue, cognitive slowing, and paresthesia. Levothyroxine improved symptoms. The patient had a history of cervical cancer (FIGO Stage III) treated with surgery, chemotherapy, and radiotherapy, likely inducing POI (FSH 113.2 iu/l,LH 68.1 iu/l,Oestradiol $<$ 100 pmol/L). They had previously used testosterone for gender dysphoria but discontinued it due to cancer treatment. The patient had mental health conditions, including bipolar disorder, anxiety, and depression, aggravated by past trauma. They were uncertain about restarting testosterone therapy due to long-term health concerns. Options included testosterone for masculinisation or estrogen/progesterone for symptoms and bone protection. The patient decided to address thyroid health first and was referred to a London gender reassignment clinic.
Discussion
Testosterone therapy in non-binary individuals with POI presents a clinical dilemma. While it alleviates gender dysphoria and induces masculinization, POI increases risks of osteoporosis and cardiovascular disease due to estrogen deficiency. Testosterone may not provide equivalent skeletal or cardiovascular protection, and endometrial hyperplasia remains a concern in individuals with an intact uterus. This case highlights the need for individualized, multidisciplinary care. Shared decision-making is critical, particularly in the context of prior malignancy and complex mental health histories. Further research is needed to establish guidelines for testosterone use in non-binary individuals with POI.
Conclusion
Testosterone therapy in non-binary individuals with POI requires careful consideration of risks and benefits. While beneficial for gender affirmation, its potential harms in POI must be weighed against the individual's health status and goals. This case underscores the need for evidence-based guidelines to optimize care for this population.

Challenges in managing persistent hypercalcemia during pregnancy after failed surgical intervention: a multidisciplinary approach?

Roshan Shrestha[1], Lina Eltayieb[1], Ayesha Awan[1], Dalya Sadulah[1], Bashir Mahamud[1], Edward Lau[1], Furhana Hussein[1], Suzane Cadiz[1], Naing Myo Aung[1], Abisha Rameshkumar[1], Bhavini Bhatt[1], Chineze Otigbah[1], Min Sun[1] & Gideon Mlawa[1]
[1]Barking, Havering And Redbridge University Hospitals Nhs Trust, Endocrinology and Diabetes, London, United Kingdom.

Introduction
Hypercalcemia in pregnancy is a rare but significant condition with potential maternal and fetal complications, including nephrolithiasis, preeclampsia, and intrauterine growth restriction. Primary hyperparathyroidism, often caused by a parathyroid adenoma, is the most common etiology. However, its management is challenging due to imaging limitations and concerns about fetal safety. While parathyroidectomy is the definitive treatment, surgical timing must be carefully considered. Cinacalcet is an alternative, though its safety and efficacy in pregnancy remain uncertain. This case highlights the challaenges of managing refractory hypercalcemia in pregnancy, emphasizing the role of a multi-disciplinary team (MDT).
Case
A 42-year-old female was referred at 20 weeks of pregnancy due to cognitive impairment, chronic bone pain, fatigue, nausea, polyuria, and polydipsia. She had a history of hypercalcemia (corrected calcium 2.72–2.84 mmol/l)for 1–2 years, with investigations confirming primary hyperparathyroidism. Ultrasound revealed a 2.4 cm left parathyroid mass. She was started on cinacalcet but discontinued due to intolerance. Following MDT discussions, she underwent parathyroidectomy at 28 weeks, but postoperative calcium remained elevated (2.79 mmol/l)with unsuppressed PTH, indicating persistent disease. During pregnancy, from 32 weeks onward, she received weekly IV fluids and had regular calcium levels monitoring. She delivered via caesarean section, with the baby being small for gestational age. Postpartum imaging raised concerns about residual parathyroid tissue. Histology confirmed parathyroid tissue but lacked definitive evidence of an adenoma. A Sestamibi scan later suggested a large left inferior adenoma, though ultrasound findings were inconclusive. Cinacalcet was poorly tolerated, leading to gastrointestinal complications for which extensive investigations were done, which ruled out sinister pathology. Following MDT discussions, she was re-referred for surgical consideration and currently remains under endocrine team for follow-up of persistent hypercalcemia.
Discussion
Limited imaging options during pregnancy and incomplete surgical resection led to persistent disease. Medical therapy with cinacalcet was ineffective due to intolerance. Despite the attempted medical management and emergency parathyroidectomy, persistent hypercalcemia required ongoing MDT discussions. This case emphasizes the importance of individualized treatment plans and the complexities of managing refractory hyperparathyroidism in pregnancy.
Conclusion
This patient did not achieve normocalcemia and remained in borderline high calcium level despite the surgical intervention and was subsequently managed conservatively with medical therapy and close monitoring. MDT approach was required for further management and follow up to assess biochemical stability and to prevent further complications. The case highlights the need for careful MDT coordination to balance medical vs surgical management.

JOINT1270

Type 2 diabetes and hypogonadism: unveiling werner syndrome in a young adult

Kamar Ezzamene Mahmoud[1], Ines Bayar[1], Bilel Ben Amor[1], Sana Abid[1], Rihab Khochtali[1], Chanez Kalboussi[1], Héla Marmouch[1], Hanene Sayadi[1] & Inès Khochteli[1]
[1]Fatouma Bourguiba University Hospital Monastir, Department of Endocrinology and Internal Medecine, Monastir, Tunisia.

Introduction
Werner syndrome (WS), also known as adult progeroid syndrome, is a rare autosomal recessive disorder caused by a mutation in the WRN gene. It manifests as premature aging. Major clinical features include: Cutaneous aging characterized by thin, atrophic skin with chronic ulcerations, and early graying of hair and bilateral cataracts, often presenting at a young age. These manifestations are frequently associated with additional complications, such as type 2 diabetes mellitus (DM), hypogonadism, early-onset osteoporosis, premature atherosclerosis, and an increased risk of developing neoplasms (1).
Case presentation
We report the case of a 40-year-old male followed for type 2 DM and hypogonadism, which ultimately led to the diagnosis of WS, with a history of peripheral hypogonadism, diagnosed due to primary infertility, testicular hypotrophy on ultrasound and low testosterone levels. The patient has a history of surgery for bilateral cataracts at the age of 33. On examination, he exhibited a characteristic facial appearance, including a thin face with atrophic cheeks and a pointed nose, but without cutaneous ulcerations. He has gray hair since the age of 34. Given the association of these signs, we suspected WS despite the absence of a family history of premature aging and proceeded with genetic testing for the WRN gene mutation.
Discussion and Conclusion
Werner syndrome is associated with premature aging during the early third decade of life, and can be firstly recognized by a lack of growth spurt during adolescence leading to short stature in adulthood. Aging-related disorders like DM, osteoporosis, peripheral hypogonadism, atherosclerosis, and malignancies like thyroid carcinomas and melanomas, are common. Deep skin ulcers around Achilles tendons and elbows are rarer but pathognomonic. Hypogonadism is secondary to testicular atrophy. Treatment should be tailored to each patient's needs, with potential therapies including hormone replacement for hypogonadism and appropriate management of diabetes. Early diagnosis and multidisciplinary care are crucial to improving the quality of life and preventing further complications in these patients. The main cause of premature mortality in these patients are myocardial infarction and cancer (2).

Mixed gonadal dysgenesis: a case report and management approach

Sana Kmiha[1], Yassmine Mkhinini[1], Bochra Ben Rhouma[2], Marwa Bahloul[1], Mahdi Ben Dhaou[3], Riadh Mhiri[3], Leila Keskes[2] & Thouraya Kammoun[1]
[1]Hedi Chaker University Hospital, Department of Pediatrics A, Sfax, Tunisia; [2]Faculty of Medicine of Sfax, University of Sfax, Laboratory of Human Molecular Genetics, Sfax, Tunisia; [3]Hedi Chaker University Hospital, Pediatric Surgery department, Sfax, Tunisia.

Introduction
Disorders of sex development (DSD) encompass a wide range of congenital conditions involving atypical chromosomal, gonadal, or anatomical sex development. Mixed gonadal dysgenesis (MGD) is a rare form of DSD characterized by a mosaic karyotype and asymmetrical gonadal development. We report a case of a neonate diagnosed with MGD, detailing the clinical, hormonal, and imaging findings, as well as the management approach and follow-up.
Methods
We present the case of a neonate admitted to the Department of Pediatrics A at Hedi Chaker University Hospital for evaluation of a suspected disorder of sex development.
Results
A 3-day-old neonate was admitted for DSD evaluation. The pregnancy was uneventful. The neonate was born at term with a normal adaptation to extra-uterine life. Birth parameters were within normal limits: weight 3530g, height 49cm, and head circumference 34cm. There was no parental consanguinity. Examination of the external genitalia revealed pseudo-scrotal genital pads with transverse striation and a single orifice at the base of the bud. No palpable gonads were detected, and there were no signs of hyperpigmentation. Hormonal assays showed normal cortisol levels and normal 17-OHP, anti-mullerian hormone (AMH) was 17.3 ng/ml (normal range for males: 16.8-138) and Blood testosterone was 2.46 ng/ml. Blood karyotype revealed mixed gonadal dysgenesis: 45X [26]/46XY [7]. An abdominopelvic ultrasound revealed the presence of a uterus. Pelvic MRI confirmed a uterine structure without ovarian structures, an inguinal right testicle with an associated vaginal hydrocele, and a smaller left testicle. The biopsy of the gonads revealed the presence of testicular tissue. During follow-up, the patient demonstrated normal growth and psychomotor development. Management included feminizing urogenital surgery with endoscopic revision for bilateral orchiectomy, as the parents opted for a female gender assignment.
Conclusion
This case highlights the complexity of diagnosing and managing mixed gonadal dysgenesis. Early recognition through clinical, hormonal, and imaging evaluations is essential for appropriate gender assignment and surgical management. A multidisciplinary approach, including endocrinologists, pediatric surgeons, geneticists, and psychologists, is crucial to ensure the best long-term outcomes for affected individuals.

Molecular analysis of AMH and AMHR2 genes in four cases of persistent müllerian duct syndrome (PMDS)

Sana Kmiha[1,2], Bochra Ben Rhouma[2], Yassmine Mkhinini[1], Rim Belhadj[1], Hajer Aloulou[1], Hassen Kammoun[3], Leila Keskes[2] & Thouraya Kammoun[1]
[1]Hedi Chaker University Hospital, Department of Pediatrics A, Sfax, Tunisia; [2]Faculty of Medicine of Sfax, University of Sfax, Laboratory of Human Molecular Genetics, Sfax, Tunisia; [3]Hedi Chaker University Hospital, Genetic department, Sfax, Tunisia.

Introduction
Persistent Müllerian Duct Syndrome (PMDS) is a form of 46,XY disorder of sex development (DSD) characterized by the presence of Müllerian derivatives (uterus, fallopian tubes) in individuals with a 46,XY karyotype. It can result from mutations in the AMH gene, responsible for Müllerian duct regression, or the AMHR2 gene, encoding its receptor.
Methods
The mixed retrospective-prospective study included 46,XY DSD children with PMDS, followed at CHU Hédi Chaker in Sfax between 2008 and 2022. The clinical evaluation involved a review of medical history, hormonal assessment, and imaging of internal genital organs. Genetic analysis focused on the AMH and AMHR2 genes, with DNA extraction, PCR amplification, Sanger sequencing and next generation sequencing.
Results
We studied four children with genital development anomalies in whom ultrasound or surgical examination revealed the presence of Müllerian structures. All patients had a 46,XY karyotype. In two patients, specific mutations in the AMH and AMHR2 genes were found, confirming the diagnosis of PMDS. In a third patient, no mutations were detected, suggesting the possibility of an alteration in an unexplored region of the studied genes. In the fourth patient, genetic variations were also found, requiring further functional studies.
Conclusion
This study highlights the genetic diversity of PMDS and underscores the need for additional analyses to better understand the molecular mechanisms involved. We plan to further investigate the functional impact of the identified variants and expand our cohort to better characterize mutations within our population.

Morbid obesity in a patient with a Y chromosome microdeletion

Yesmine Elloumi[1], Wissal Abbes[1], Dhoha Ben Salah[1], Kouloud Boujelben[1], Hadjkacem Faten[1], Nadia Charfi[1], Mouna Mnif[1], Mohamed Abid[1], Mouna Elleuch[1] & Nabila Rekik Majdoub[1]
[1]Hedi Chaker University Hospital, Endocrinology Department, Sfax, Tunisia.

Background
Y chromosome microdeletions, specifically those occurring on the long arm (Yq) and within the AZF region, are a rare genetic cause of male infertility. These deletions typically result in the loss of one or more genes crucial for sperm production. While infertility is the primary consequence, an intriguing association with obesity has been observed in some cases.
Case report
A 29-year-old male with a family history of obesity was admitted to the Endocrinology department for morbid obesity. Physical examination revealed a blood pressure of 10/5 cmHg, faciotruncal obesity with a BMI of 61 kg/m^2, capillary fragility, and striae. Notably, the patient had an absent beard but preserved morning erections and libido. Genital examination showed testes measuring 3.2 and 3.4 cm in length with micropenis. No dysmorphic features were present. Laboratory results showed low testosterone levels at 0.51 ng/ml, LH and FSH levels at 4.8 mIU/ml and 12.3 mIU/ml respectively, and a normal prolactin level. Karyotyping revealed a deletion of the long arm of the Y chromosome.
Conclusion
Partial microdeletions of Yq may have side effects such as hypogonadism and obesity. These findings highlight the phenotypic variability associated with Yq microdeletions and emphasize the importance of comprehensive clinical evaluation in affected individuals.

Adoloscent girl with secondary amenorrhoea due to adult granulosa cell tumour - A rare presentation
Jananie Suntharesan[1], Lasika Liyanage[1], Mahendra Somathilaka[2] & Gihan Champika[3]
[1]Sirimavo Bandaranayake Specialized Children's Hospital, Department of Paediatric and Adolescents Diabetes and Endocrinology, Peradeniya, Sri Lanka; [2]Apeksha Hospital, The National cancer Institute, Maharagama, Sri Lanka; [3]Faculty of Medicine, University of Peradeniya, Department of Obstetrics and Gynecology, Peradeniya, Sri Lanka.

Introduction
Granulosa cell tumors (GCTs) are rare ovarian malignancies. In adolescents it is often missed or diagnosis is delayed due to their nonspecific presentation. This case report highlights the significance of a high index of suspicion and the role of tumor markers in identifying rare causes of secondary amenorrhea.
Case History
A 16-year-old female, previously healthy, presented with a two-year history of secondary amenorrhea. She had no abdominal pain or other associated symptoms her physical examination was unremarkable. Initial laboratory investigations revealed low follicle-stimulating hormone (FSH) levels with elevated inhibin B, raising suspicion of an ovarian tumor. Initial ultra sound pelvis was normal, however follow up ultrasound imaging confirmed the presence of a left-sided ovarian mass. The patient underwent a left-sided salpingo-oophorectomy. Histopathological examination confirmed the diagnosis of an adult-type granulosa cell tumor with a Ki-67 proliferation index of 67%, and tumor staging revealed pT1aN0Mx. Postoperative tumor markers, including inhibin A and inhibin B, normalized, along with normalization of luteinizing hormone (LH) and FSH levels. She resumed regular menstruation following surgery. The patient was subsequently treated with adjuvant chemotherapy to address the high recurrence risk associated with adult-type granulosa cell tumors.
Conclusion
This case highlights the importance of considering granulosa cell tumor in the differential diagnosis of adolescent girls presenting with secondary amenorrhea, especially when initial findings deviate from common conditions such as polycystic ovary syndrome (PCOS). Early identification of granulosa cell tumors is critical, as adult-type tumors are associated with a significant risk of recurrence and require comprehensive treatment, including surgery and chemotherapy. Clinicians should maintain a high index of suspicion and utilize tumor markers, including inhibin A and B, to identify rare underlying etiologies of amenorrhea. This case highlights the need for timely diagnosis and management of granulosa cell tumors to improve outcomes and the importance of long-term follow-up in these patients.

JOINT1952
Unusual case of hirsuitism following isotretinoin therapy for acne
Manjusha Rathi[1]
[1]Sandwell & West Birmingham Hospitals NHS Trust, Birmingham, United Kingdom.

Introduction
Hirsutism is the presence of terminal hair growth in females with a male distribution pattern. It is usually manifestation of hyperandrogenism in 80 % of the cases. Every effort should be taken to exclude polycystic ovary syndrome, endocrinopathies and rare causes before labelling it as idiopathic.
Case Report
42-year-old female was referred by dermatologist for investigation of hirsuitism. At age 40 years, during covid pandemic, she developed localised papulopustular acne which she felt was triggered by constant mask wearing. This was treated with isotretinoin between 2021 and early 2022. After stopping this therapy, she noticed localised excessive hair growth especially affecting her upper lip and chin area impacting her quality of life. She denied other symptoms of virilization, including change of voice or growth of hair in other locations. She was otherwise healthy with no significant past medical history. Her menstrual cycles have been regular, has 3 children (no concern related to fertility). She was not on any medication or oral contraceptive pill. On examination, her BMI 21.7 with evidence of significant localised hirsuitism affecting upper lip and chin area, with some pigmentation and bumps on skin due to regular plucking. Clinically she was euthyroid, no features of Cushing's or acromegaly. Investigations 9 am pituitary hormone profile, fasting blood glucose, HbA1c, Testosterone (Mass Spec) 1.04 (<1.89 nmol/l)Free Androgen Index (Mass Spec) 4.40 (0.73 - 6.16), DHEAS 2.93 (1.65 - 9.15 umol/l)Androstenedione 6.3 (0.9 - 7.5 nmol/L), SHBG 23.7 (20 - 155 nmol/l)were normal suggesting Isotretinoin exposure as a cause for hirsuitism.
Discussion
Isotretinoin is a synthetic vitamin A derivative used to treat nodulocystic resistant acne unresponsive to conventional treatments. While the exact mechanism of action is unknown, isotretinoin inhibits sebaceous gland function and keratinization. Most of its side effects of are self-limiting, treatable, and dose-dependent. Handful cases reported development of hirsuitism with menstrual irregularity following Isotretinoin therapy. However, to my knowledge this is the only case of isolated hirsuitism without menstrual irregularity. Studies examining the effects of oral isotretinoin on pituitary and adrenal hormones have yielded different results. It is hypothesised that isotretinoin may cause a decrease in SHBG levels and an increase in free androgens, thus leading to hirsutism and menstrual irregularity. This case highlights unusual cause of hirsuitism without menstrual irregularity. Further investigations are required to prove the mechanisms by which oral isotretinoin exerts its variable effects on the menstrual cycle, hirsutism, and hormones.

Clinical and diagnostic aspects of diminished ovarian reserve in women with thyroid hypofunction
Fotima Makhmudova[1] & Khurshidakhon Nasirova[1]
[1]Tashkent pediatric medical institute, Tashkent, Uzbekistan.

Introduction
The relevance of the problem, the relationship between reproductive function disorders and thyroid pathology is actively discussed in the scientific literature since thyroid diseases are one of the most common endocrinopathies in women of reproductive age.
Materials and Methods
we used medical databases on the Internet: Medline/PubMed, EMBASE, EBSCO, the Cochrane Library.
The results: The problem of the relationship between reproductive function disorders and thyroid pathology has become increasingly significant in recent years. This problem in women of reproductive age is currently of great theoretical and practical interest. In recent years, to examine the reproductive potential of women, the "ovarian reserve" has been assessed using certain indicators. According to Grigoryan O.R. *et al*.(2019), the vast majority of ovarian reserve indicators characterize the hormone-dependent stage of follicle growth. But discussions about the set and quantitative values of certain markers continue. Researchers from the Southwestern University of the Luzhou Clinic of China, who studied the relationship between ovarian reserve and thyroid function in women with infertility, conducted a retrospective analysis of data from 495 infertility patients who visited the clinic between January 2019 and December 2020. In this study, there was no significant correlation between ovarian reserve and thyroid function in women. A similar result was shown by a study conducted at the Center for Reproductive Medicine at the University Hospital of Brussels in 2015. The authors are Nikolaos P. *et al*. noted that this cross-sectional analysis could not demonstrate the relationship between autoimmune thyroiditis(AIT) and

ovarian reserve. Other researchers Michalakisetal., (2011) revealed results that contradict previous studies. The research showed that women with DOR had higher TSH levels compared to women with normal ovarian reserve, and suggest that thyroid disorders may be associated with ovarian reserve. This study demonstrated a very strong positive correlation between serum autoantibody levels and autoantibody levels in follicular fluid, prompted several researchers to suggest that thyroid diseases can indeed affect ovarian reserve. It should be emphasized that numerous works with similar results are presented in the world literature.

Conclusions

Thus, a review of the literature showed that this problem remains controversial and there are many unresolved issues. To solve them, further researches and presence of scholars of various profiles are needed.

Key words

ovarian reserve, thyroid hypofunction, infertility.

JOINT2628

Should all women with PCOS be treated for insulin resistance? absolutely, but we should know what PCOS is

Gyula Petrányi[1] & Maria Zaoura Petrányi[1]

[1]Petrányi & Zaoura Outpatient Clinic Limassol, Limassol, Cyprus.

The question was the title of a paper published in 2012*, a debate between pro: John C. Marshall and con: Andrea Dunaif reflecting the division in this important topic (not only in therapy). The polycystic ovary syndrome has a wrong and misleading name. It is the most common female endocrine disorder lasting throughout life, a combination of hyperandrogenism and ovarian dysfunction, with detectable insulin resistance in most cases (if we disregard the anovulation – polycystic ovary phenotype of the Rotterdam criteria). Further arbitrary phenotypes were formed with different therapy advice despite the symptoms change from time to time but the patient remains the same. The lack of a comprehensive view and the fragmented treatment options fail to achieve overall improvement of the patients. However, if we join the AES concept (a syndrome combining hyperandrogenism with ovarian dysfunction), this increases the homogeneity of the patients giving more chance to find a common treatment. The authors have been using metformin since the discovery of insulin resistance in PCOS, thus replacing the controversial combined contraceptive pill that reduces hyperandrogenism but maintains anovulation, the other fundamental problem in the syndrome. The metformin monotherapy era was followed by the combination of metformin + life-style changes, and most recently, vitamin D3 was added to the uniform treatment. All these metformin-based therapy variants have improved almost all symptoms including infertility. The metformin + life-style changes was better than metformin monotherapy but the recent addition of vitamin D doesn't seem more advantageous (detailed results will be presented during the congress). The authors' answer is yes: all women with PCOS should be treated for insulin resistance, and probably the 'male equivalents', too.

Isolated fsh deficiency in man with lujan-fryns syndrome (LFS)

Serafino Lio[1]

[1]Endocrine Section, Dpt Internal Medicine- Oderzo Hospital- Treviso ULSS 2, Oderzo-TV, Italy.

Lujan-Fryns Syndrome (LFS) is a rare neuro-rheumatological X-linked disorders with mild-moderate mental retardation, psychiatric disorders, marfanoid habitus, hypotonia, tall stature, craniofacial dysmorphism, hypernasal speech, normal sexual development and testis size.

Clinical case

Due to the finding of macrocrania, craniofacial dysmorphisms, normal stature growth, and mild learning and speech disorders an 8-year-old boy came to genetic counselling where a diagnosis of Lujan-Fryns syndrome with normal karyotype (46 XY) and exclusion of X-fragile syndrome in patient with pachydermioperiostosis and Raynaud's syndrome was made. At 21 years of age, she was also diagnosed with hypothyroidism from Hashimoto's thyroiditis (maternal family of thyroidopathy) and for which she is on L-Tyroxine therapy (with fluctuating dosage). Over the years, the patient has been followed for LFS by Geneticists and Endocrinologists with reported normal stature and pubertal growth and bone maturation, thyroid ultrasound picture compatible with autoimmune thyroiditis, testicular ultrasound in the normal range, brain and pituitary MRI also normal. as well as serum levels of prolactin, GH and IGF-I In March 2024, at the age of 33 years old, the patient was admitted to our department for the first time for group B Salmonella gastroenteritis. GH (0.61 ng/ml- reference limit (RF) 0.00-5.00), IGF-I (84 mg/dl -RF. 82-244), 8 o'clock Cortisol (15.8 mg/dl-RF 6.0-18.4), 8 o'clock ACTH (10.2 pg/ml-RF 0. 0-46); LH (0.3 mUI/ml-RF 1.3-8.6), total testosterone (1.15 ng/ml-RF 2.2-10.5), FSH (0.8 mUI/L-RF 12.4) were below normal and substantially confirmed 6 months later (LH 3.1 mUI/l,FSH 1.0 mUI/L), with normal serum levels of total and free testosterone (2.4 ng/ml -RF 2.2-10.5 and 7.6 pg/ml-RF 1.8-21.4, respectively). An LH-RH test (100 mg ev) was then performed, which revealed a normal LH response (baseline: 5.0 mUI/l,peak at 30': 17.7 mUI/l)and isolated FSH deficiency (baseline: 1.3 mUI/l,peak at 90': 2.2 mUI/L). Inhibin B assay was then performed, which was found to be normal (304.4 ng/L-RF 10-357). A spermiogram was not performed due to lack of parental consent.

Conclusions

1) to our knowledge this is the first described case of isolated FSH deficiency in LFS; 2) even with normal pubertal development and normal testicular volume in LFS it is useful in follow-up to evaluate the pituitary-gonadal axis.

JOINT636

Swyer syndrome in a young adult with type 1 diabetes presenting with primary amenorrhea: a case report

Alyssa Mariz Galicia[1] & Jerome Barrera[1]

[1]Zamboanga Doctors' Hospital, Department of Internal Medicine, Zamboanga City, Philippines.

Introduction

Primary amenorrhea signifies underlying genetic or endocrine abnormalities, with Swyer Syndrome, or 46, XY Complete Gonadal Dysgenesis, being a rare cause. Characterized by a female phenotype and male karyotype, it results from failed gonadal differentiation, leading to streak gonads, hypoestrogenism, and increased malignancy risk. This case exhibits a rare presentation of Swyer Syndrome in a young adult with Type 1 Diabetes Mellitus.

Case Presentation

A 31-year-old Filipino female presented to our Outpatient Clinic with primary amenorrhea. She denied family history of infertility, delayed puberty, or atypical genitalia. Patient's medical history revealed a diagnosis of Type 1 Diabetes Mellitus at the age of 22. During that time, laboratory findings demonstrated significant metabolic dysregulation, with a fasting blood sugar (FBS) of 279 mg/dl, indicative of marked hyperglycemia, and an HbA1C of 12.5%, reflecting prolonged poor glycemic control over preceding months. Additionally, serum C-peptide level of 0.11 nmol/lconfirmed severe insulin deficiency, characteristic of Type 1 Diabetes. Insulin therapy was promptly undertaken, and regular follow-up visits were done. Amenorrhea was unreported earlier due to stigma, cultural beliefs, financial constraints, and limited healthcare access. Physical examination revealed a female phenotype with normal external genitalia. Breast development and pubic hair growth corresponded to Tanner stage 2, but axillary hair was absent. These findings suggested significant delays in secondary sexual characteristics, prompting further investigation. Laboratory results showed hypergonadotropic hypogonadism, evidenced by elevated FSH (33.90 mIU/ml) and LH (12.93 mIU/ml), alongside a low estradiol level (10.57 pg/ml), pointing to ovarian insufficiency. Pelvic ultrasound demonstrated a hypoplastic uterus (4.6 × 2.3 × 1.6 cm), thin endometrium (0.2 cm), and a diminutive cervix (1.4 × 1.2 cm), without focal abnormalities. Bilateral ovaries were not visualized, indicating underdeveloped reproductive structures and necessitating further advanced imaging. Pelvic MRI corroborated ultrasound findings, revealing small uterus (2.2 × 3 × 0.7 cm), streak gonads, and a rudimentary vaginal canal. Chromosomal analysis confirmed the diagnosis of Complete Gonadal Dysgenesis or Swyer Syndrome with a 46, XY karyotype. The patient was advised to undergo prophylactic gonadectomy and hormonal replacement therapy but expressed reluctance due to cultural beliefs.

Conclusion

This case highlights the complexities of diagnosing and managing Swyer Syndrome, compounded by Type 1 Diabetes Mellitus. Early detection of primary amenorrhea and delayed puberty is essential for prompt intervention. A multidisciplinary approach is crucial for early recognition and priorities include reducing malignancy risk, and improving quality of life with hormonal therapy and psychosocial support.

Steroid metabolome signature of transgender and gender diverse treatment-naïve adolescents – 7-year experience in the first gender unit dedicated to youth in Poland

Aneta Gawlik-Starzyk[1], Wiktoria Kempińska[1], Aleksandra Antosz[1], Aleksandra Januszek-Trzciąkowska[1], Dorota Karbowska[1], Jakub Gawlik[2] & Tomasz Jakubowski[3]
[1]Faculty of Medical Sciences, Medical University of Silesia, Department of Pediatrics and Pediatric Endocrinology, Katowice, Poland; [2]The University Hospital, Kraków, Poland; [3]Upper Silesian Child Health Center, Public Clinical Hospital No. 6 of the Silesian Medical University, Institute of Psychology, University of Silesia, Katowice, Poland.

Introduction
There are many doubts around the etiology of gender incongruence and the increasing number of transgender and gender diverse children and adolescents (TGDC&A) seeking endocrine treatment.
Aim
We assume that based on urinary steroidal gas chromatography-mass spectrometry (GC-MS), we can look deeply at steroidogenesis in TGDC&A following the concept of delineating "steroid metabolomic signature".
Methods
This prospective study has examined consecutive series of 269 TGDC&A with mean/median age of 15.8/16.1 yrs diagnosed in accordance with WPATH SOC-8 in one university center between July/2017 and Sep/2024. Clinical and laboratory data was collected in unified medical records. Steroid metabolites in 24-h-urine samples were analyzed by quantitative targeted GC-MS.
Results
Urinary samples from 232 TGDC&A (194 RFAB-registered female at birth, 38 RMAB – registered male at birth) were analysed. The values of metabolites were assessed according to age/sex specific norms and presented as % of samples which are above or below norms (table present selected metabolites with important findings). RFAB patients with earlier gender dysphoria presented significantly lower concentration of androsterone and etiocholanolone (metabolites of DHEA, androstenedione and testosterone).
Conclusion
Transgender and gender diverse children and adolescents, mainly whose registered female at birth, present unique steroid metabolome signature. This needs further studies to explain whether these findings are useful, in some way, to explain etiology.

JOINT3648
From diagnosis to adulthood: navigating the complexities of a 46,XX SRY-positive male with DSD

Stefanie Gross[1], Camelia Procopiuc[1], Dana Dinu Dragasanu[1], Raluca Bocai[1] & Iuliana Gherlan[1,2]
[1]"C.I. Parhon" National Institute of Endocrinolgy, Bucharest, Romania; [2]Carol Davila University of Medicine and Pharmacy, Bucharest, Romania.

46,XX SRY-positive males are a rare DSD subset where individuals with a 46,XX karyotype develop a male phenotype due to SRY gene translocation, typically from the Y chromosome to the X chromosome. The SRY gene drives testicular development, but these individuals often exhibit mild genital ambiguity and are infertile due to missing Y-chromosomal genes needed for spermatogenesis. This case report describes the clinical management and long-term follow-up of an 18-year-old 46,XX SRY-positive male who has been under care at our clinic since the age of two. The patient initially presented with atypical external genitalia, including a mild hypospadias, a slightly bifid scrotum with an accentuated perineal raphe, and a normal penile length of approximately 4 cm. Firm gonads, each measuring around 1.5 ml, were palpable in the scrotal sacs but exhibited a tendency to ascend into the inguinal canal. No vaginal opening, excessive hair growth, or other abnormalities were observed. Genetic analysis revealed a 46,XX karyotype with a translocation of the SRY gene from the Y chromosome to the short arm of one X chromosome, confirmed via fluorescence in situ hybridization (FISH). Functional assessment of the gonads via an hCG stimulation test showed a rise in testosterone from baseline nondetectable levels to the low-normal range, confirming functional testicular tissue. In order to promote testicular descent and scrotal development, the patient was treated with hCG, resulting in favorable outcomes. Given the predominantly male phenotype and male psychosocial development, the decision to maintain male sex assignment was made. Over the years, the patient underwent priming with low-dose testosterone to support pubertal development and ensure the proper growth of secondary sexual characteristics, alongside regular hormonal monitoring and testicular ultrasounds to assess gonadal anatomy and exclude ovotestis. At age 16, testosterone therapy was discontinued while the patient was in a hypergonadotropic state. Despite normal external genitalia development to adult size, a spermogram revealed azoospermia, consistent with the expected infertility in 46,XX SRY-positive males. This case highlights the importance of a multidisciplinary approach in the diagnosis, treatment, and long-term management of individuals with DSD, emphasizing the role of genetic, endocrine, and psychosocial factors in guiding clinical decisions.

Primary amenorrhoea revealing prader-willi syndrome: a case report

Baltagi Myriam[1], Meriem Adel[1], Marwa Chiboub[1], Mariam Mestiri[1], Manel Jemel[1], Mediha Trabelsi[2] & Ines Kammoun[1]
[1]National Institute of Nutrition Tunisia, University of Tunis El Manar, Faculty of Medecine of Tunis, 1007, Tunisia., Endocrinology, Tunis, Tunisia; [2]Charles Nicolle Hospital, Genetics, Tunis, Tunisia.

Background
Prader-Willi syndrome (PWS) is a complex genetic disorder characterized by obesity, developmental delay, and hypogonadism. This case describes an adolescent with primary amenorrhea and a genetic profile compatible with PWS, but without SNRPN microdeletion.
Case Presentation
An 18-year, 9-month-old female was referred for primary amenorrhea. She had a history of morbid obesity since infancy, neonatal hypotonia, and delayed motor milestones (walking at 3 years). She was born at term with a birth weight of 3.25 kg, and obesity became evident at 1 year of age. Early hyperphagia and inappropriate feeding practices were noted. In the physical examination, the body mass index was 46 kg/m^{2}and the pubertal development according to the Tanner stage was S4P4. Pelvic ultrasound showed normal internal genitalia. Hormonal investigations revealed normal gonadotropins (FSH 4.41 mIU/ml, LH 5 mIU/ml), normal testosterone (0.14 ng/ml), normal thyroid function (TSH 0.8 mIU/ml, free T4 15 pmol/L), and prolactin 17 ng/ml. A progestogen challenge test was

negative. Genetic analysis revealed a profile consistent with PWS, although no microdeletion of the SNRPN locus was detected. She was started on estradiol and medroxyprogesterone to induce menstrual cycle and prevent complications such as osteoporosis. Follow-up is focused on optimizing endocrine and metabolic outcomes.

Conclusion

This case highlights the importance of considering PWS in patients with early-onset obesity, hypotonia, and endocrine abnormalities, even in the absence of classic genetic findings. Multidisciplinary care, including hormone replacement and nutritional management, is essential for managing the wide range of complications and improving long-term outcomes.

Impact of hysterectomy on ovarian function and woman health

Azizakhon Fakhriddinova[1], Zulaykho Shamansurova[1,2] & Durdona Samatova[3]

[1]Central Asian University, Endocrinology, School of Medicine, Tashkent, Uzbekistan; [2]Institute of Biophysics and Biochemistry at the National University of Uzbekistan, Metabolomics, Tashkent, Uzbekistan; [3]Republican Specialised Scientific Practical Medical Centre of Endocrinology, Tashkent, Uzbekistan.

Introduction

Hysterectomy is the most common non–obstetric surgery performed on women in late reproductive age in most countries of the world for the treatment of uterine cancer and various non-cancerous uterine conditions. Our aim to investigate the impact of hysterectomy on ovarian function, with a focus on hormonal changes and ovarian reserve by the data from the literature.

Material and Methods

For preparing our investigation we used data regarding clinical and lab data after hysterectomy from internet sourses such as PubMed, Web of Science, MedLine, Medscape, Scopus, Google Scholar.

Results

Elective bilateral salpingo-oophorectomy (BSO) in women under 50 is linked to a higher risk of coronary heart disease (CHD) and sexual dysfunction, and not recommended for women after 50. In contrast, for postmenopausal women, BSO can lower the risk of ovarian cancer without negatively affecting CHD, sexual function, hip fractures, or cognitive abilities. Taiwan National Health Insurance database indicated no significant difference in stroke risk between women who underwent hysterectomy. Whereas women who had hysterectomies before 45 showed a significantly increased risk of stroke. The same results were finds by a study from the Swedish Inpatient Registry. In the other prospective research on ovarian function study, premenopausal women who had a hysterectomy without bilateral oophorectomy faced nearly double the risk of ovarian failure compared to those who did not have a hysterectomy. After four years, 14.8% of women in the hysterectomy group experienced ovarian failure, reported a history of uterine fibroids. The risk was also notably higher in women who retained both ovaries. In the other study 20.6% women after hysterectomy were reached menopause during a five-year follow-up. Anti-Müllerian hormone (AMH) indicates ovarian follicular reserve. For women under 48, normal AMH level were predictive for reaching menopause within 12 months, whereas decrease in AMH levels raises the risk of early menopause. Due to the decreased follicles, the insufficient secretion of ovarian hormones contributed rise in FSH levels through negative feedback, the FSH/LH ratio rose significantly and become independent predictor of poor ovarian response and is linked to unfavorable outcomes in IVF treatment.

Conclusion

Hysterectomy affect the ovarian reserve which leads to early menopause, increased risk of CHD, stroke, fibroids, closely associated with patient age, disease, and the type of surgery, suggesting these factors should be considered in randomization stratification for future studies aimed at exploring possible effect modifications.

Effect of growth hormone to spinal growth and recombinant

Xuan Xu[1]

[1]Hunan Provincial People's Hospital, Changsha, China.

Growth hormone (GH) occupies a pivotal role in human growth and development. It not only promotes linear growth but also exerts profound influences on bone metabolism, bone dimensions, and bone mineral density (BMD) in pediatric and adolescent populations through the modulation of bone formation and resorption processes. Notably, the impact of GH on spinal growth has garnered considerable attention. Scoliosis, a complex three-dimensional spinal deformity characterized by lateral curvature of one or more vertebral segments, often accompanied by vertebral rotation and sagittal plane imbalance, poses a significant challenge. Among patients with growth hormone deficiency (GHD), the question of whether GH supplementation may contribute to the onset or progression of scoliosis remains a subject of debate. Recently, numerous scholars have conducted extensive research to explore the relationship between recombinant human growth hormone (rhGH) replacement therapy and scoliosis, yielding a range of findings, some of which are contradictory. This study aims to conduct an in-depth exploration of the effects of GH on spinal growth and to provide a comprehensive analysis of the potential association between rhGH replacement therapy and scoliosis. To achieve this, we will comprehensively review the impacts of GH and insulin-like growth factor 1 (IGF-1) on bone metabolism and bone mass, while also examining the consequences of GHD on bone health. By meticulously synthesizing existing research findings, we seek to elucidate with greater clarity the mechanisms through which GH regulates spinal growth and maintains spinal morphology. Furthermore, this study will specifically focus on the impact of rhGH replacement therapy on adolescent idiopathic scoliosis (AIS), with the objective of providing novel insights and guidance for the prevention and management of this condition. Through this comprehensive examination, we aspire to offer more refined diagnostic and treatment recommendations for patients with GHD and scoliosis.

Leg ulcer and klinefelter's syndrome: cause or coincidence? a case report

Rania Dassoufi[1], Ayoub Idrissi[2], Abainou Lahousssaine[2], Hamza El Jadi[2], Azzelarab Meftah[2] & Hicham Baïzri[2]

[1]Mohamed 6 University Hospital of Marrakech, Endocrinology-Metabolic Diseases-Nutrition Department, Marrakech, Morocco; [2]Avicenne Military Hospital- Marrakech- Morocco, Department of Endocrinology, Diabetes and Metabolism, Marrakech, Morocco.

Introduction

Leg ulcers are chronic cutaneous defects with no spontaneous cicatrization. Management is often multidisciplinary, involving plastic surgeons, dermatologists and vascular surgeons. The endocrinologist will be required in cases of diabetes or associated complicating endocrinopathy. We report through this observation a patient with recurrent bilateral venous leg ulcers, in whom Klinefelter's syndrome was confirmed.

Observation

49-year-old patient, followed in our training for a klinefelter syndrome. Having a history of profound venous thrombosis under a venous contension. A recurrence of venous ulcer was the main reason for this hospitalisation. Venous Doppler revealed bilateral ostial incontinence and multiplevaricose veins with incontinent perforators. Management was medical, with compression between 20 and 30 mmHg. Prevention includedmaintenance of effective contention with anticoagulation since surgery was not an option. The evolution was favorable after equilibration of diabetes, testosterone administration andoffloading mechanical tissue stress. We discuss through this case the physiopathology of lower extremity ulcers in Klinefelter'ssyndrom.

Discussion and Conclusion

Klinefelter's syndrome, first described in 1942 by Harry F. Klinefelter, is the most commoncongenital abnormality causing primary hypogonadism, occurring in 1 in 500 to 1 in 1000 livebirths. In a series of Klinefelter's patients observed for up to a 20-year period, the prevalence ofleg ulcers was 6–13%. The etiology of lower limb ulcers in these patients is multifactorial, with chronic venousinsufficiency, obesity, arteriopathy and, in particular, reduced fibrinolysis due to high levels of PAI-1, which may explain the thrombosis of cutaneous microvessels or venous thrombosis leading topost-phlebitic disease, as occurred in our patient. On the other hand, there is a loss of endothelial inflammatory control due to the decrease oftestosterone levels, as confirmed by the improvement under androgen therapy. This case illustrates an under- recognized complication of Klinefelter's syndrome. Thepathogenesis of ulcers in this endocrinopathy is unclear, but associations with abnormalities of fibrinolysis and prothrombotic states are reported.

A rare case of coexisting turner syndrome and mayer-rokitansky-küster-hauser syndrome

Edlira Hoxha[1] & Agim Gjikopulli[2]
[1]Specialty Polyclinic Nr.3, Tirana, University of Medicine, Faculty of Medicine, Tirana, Endocrinology department; Morphology department, Tirana, Albania; [2]"Mother Theresa" University Hospital Center, University of Medicine, Faculty of Medicine, Tirana, Pediatric hospital, Tirana, Albania.

Turner syndrome and Mayer-Rokitansky-Küster-Hauser (MRKH) are congenital conditions that affect female reproductive development. The presence of these two syndromes in a person is very rare in our clinical work, but they remain one of the most main causes of primary amenorrhea. So, Turner syndrome is responsible for short stature, gonadal dysgenesis and cardiovascular abnormalities. On the other part, MRKH is characterized by congenital aplasia of the uterus and upper two-thirds of the vagina. Our case is about a 14 year old female that came in the Specialty Polyclinic Nr.3 in Tirana with two main complaints, the absence of menstrual cycle (primary amenorrhea) and short stature. During the physical examination, was observed the lack of secondary sexual characteristics, webbed neck, short stature. *Hormonal analyses* revealed **hypergonadotropic hypogonadism**: LH 25.7mUI/ml [2.4-12.6]; FSH 94.8mUI/ml [3.5-12.5]; estradiol < 5 pg/ml [< 91 pg/ml]; Progesterone 0.073ng/ml [0.2-1.5]**, low value of GH and somatomedin C**: IGF-1 200ng/ml [191-496]; **subclinical hypothyroidism**:TSH 4.92 uUI/ml [0.51-4.3]. Karyotype examination showed the mosaicism pattern of Turner syndrome 45,X/47,XXX. Radiological examination like pelvic ultrasound and magnetic resonance (MRI) demonstrated ovary and uterus agenesia, also the absence of upper vagina. After these examinations and the multidisciplinary consultations, the patient was diagnosed with a rare combination of Turner syndrome and MRKH syndrome. The treatment consisted in the hormone replacement therapy like: somatotropin, gonadotropin and levothyroxine. In conclusion, reported cases with the combined presence of Turner and MRKH syndromes are unusual and rare. For appropriate diagnosis and treatment is necessary the multidisciplinary collaboration and management, including endocrinologist, pediatrician endocrinologist, gynecologist, geneticist and psychological care.

An atypical case of premature pubarche

Laura Corbelli[1,2], Alessio Rossi[1,2], Sara Soldovieri[1,2], Emanuela Pignatone[1,2], Sara Barneschi[1,2] & Stefano Stagi[1,2]
[1]Department of Health Sciences, University of Florence, Florence, Italy, Florence, Italy; [2]Diabetology and Endocrinology Unit, Meyer Children's Hospital IRCCS, Florence, Italy, Florence, Italy.

Introduction
Premature pubarche is defined as the development of pubic hair before the age of 8 in girls and 9 in boys. It is an expression of premature adrenarche, which refers to an early increase in adrenal androgen secretion, a phenomenon that normally precedes gonadal maturation by one to two years. Premature pubarche can be classified as idiopathic or due to underlying conditions such as adrenal hyperplasia or exposure to exogenous androgens.
Case Presentation
A 6-year-and-10-month-old girl was referred for the onset of secondary sexual characteristics, presenting with pubertal development P =(Tanner pubic hair stage) 2, B (Tanner breast stage) 1-2 on the left, B1 on the right. Laboratory tests showed prepubertal basal LH and increased DHEAS (82.00 µg/dl); FSH, cortisol, insulin, fT4, TSH, IGF-1, δ4-androstendione were within normal limits. ACTH stimulation test demonstrated normal 17-OH-progesterone levels. Pelvic ultrasound revealed a transitional-type uterus and ovarian volume at the upper limit for her age. GnRH stimulation test was performed showing prepubertal LH values (peak LH 3 mU/ml) without inversion of the FSH/LH ratio and in line with prepubertal estrogen levels (< 5 pg/ml). Bone age was advanced (9 years and 6 months). Growth was between the 90th and 97th percentile above the genetic target, but when corrected for bone age, it fell within the genetic target range. After 6 months, the breast bud regressed and pelvic ultrasound confirmed a transitional-type uterus and ovarian volume at the upper limit for her age. At the next visit, the girl presented pubertal development P3 B2 on the right and B1 on the left. ACTH stimulation test and a triptorelin test were repeated and remained normal. Hormonal evaluations continued to indicate a prepubertal status and tumor markers (CA 19.9, CEA, CA125, alpha-fetoprotein) were negative, but an increase in DHEAS (140.00 µg/dl) was noted. Bone age remained advanced by 2 years. Based on clinical history, the diagnostic tests performed and the blood test results, a diagnosis of atypical premature pubarche was established.
Discussion and Conclusions
Unlike typical cases of premature pubarche, which often progress slowly without significant clinical consequences, atypical cases present with more pronounced signs of androgen excess, such as accelerated growth, acne, and advanced bone age. These patients may require extensive evaluation to rule out underlying conditions. Long-term follow-up is crucial to monitor potential metabolic or endocrine complications, including hyperandrogenism, polycystic ovary syndrome, and metabolic syndrome.

Aromatase defficiency: a rare cause of female ambiguous genetalia

Saleha Babli[1], Areej Alaman[1], Modhi Alsubie[1] & Wael Alzahrani[1]
[1]Prince Sultan Military Medical City, Riyadh, Saudi Arabia.

Introduction
Aromatase deficiency results from autosomal recessive inheritance of mutations in the CYP19A1 gene. It gives rise to ambiguous genitalia in 46,XX fetuses. At puberty, affected girls have hypergonadotropic hypogonadism, do not develop secondary sexual characteristics, and exhibit progressive virilization **Case:** 16 years old girl who was referred to a urologist in our institution at the beginning of 2020 (she was 12 years old then) as a case of ambiguous genitalia for genital construction surgery. She is a product of full term normal vaginal delivery, no history of maternal virilization during pregnancy. Ambiguous genitalia was diagnosed at birth, her chromosomal analysis confirmed 46 XX genetic sex. No genital constructive surgery done at early life, the parent raise her as a girl and they lost follow up. When she was 12 years old the mother seeks medical advice due to primary amenorrhea Unfortunatly she lost follow up due to Covid pandemic. Presented again in 2022. **Family history:** Parents are first degree relatives History of one female maternal cousin with ambiguous genitalia **Examination:** Height: 160cm (on the 25 percentile) Weight 65 kg (above 90 percentile) She has hirsutism with Acanthosis nigricans No breast development **Genitalia Examination:** Clitromegaly Fusion of labioscrotal fold **Laboratory investigations:** Estradiol less than 18 pmol/l(22-2-5) LH 18.3 IU/l(1.0-11.1) FSH 30 IU/l(0.87—8.8) Total testesteron 0.76 nmol/l(0.069-2.71) Free testesteron index 1.56 (0.5-6.5) DHEAS 4.1 micmol/l(1.7-9.9) Pelvic US The uterus and ovaries are not clearly visualized. **Pelvic MRI** A thin vertically oriented fluid filled structure is noted behind the urinary bladder, It measured 2.3x.2.2 cm and is thought to be mullerian duct remnant. No normal vaginal wall or lumen could be visualized. There are two oval structures identified in the lower part of the pelvis, measure 1.2 x0.8 cm in the right and 1.9x0.8 on the left thought to be ovaries, few tiny bilateral follicles are present largest measures 3.1mm. **Examination under anesthesia:** Common urogenital sinus 3 cm with 2 opening. Short vagina with underdeveloped wall The distance from external common urogenital opening till vaginal opening is 3.5 cm (high confluence) **Genetics study showed:** A homozygous pathogenic variant was identified in the CYP19Ai gene. Patient was started on oral estrogen Follow up MRI showed increase in the size of vagina and uterus so the patient was planned for genital constructive surgery.
Conclusions
This is a case of aromatase deficiency with late diagnosis at adolescent.

Warthin-like subtype of papillary thyroid cancer – a single-center experience, preliminary report

Olga Wajtryt[1], Elwira Bakuła-Zalewska[2], Jacek Gałczyński[1] & Marek Dedecjus[1]
[1]Maria Sklodowska-Curie National Research Institute of Oncology, Department of Endocrine Oncology and Nuclear and Nuclear Medicine, Warsaw, Poland; [2]Maria Sklodowska-Curie National Research Institute of Oncology, Department of Pathology, Warsaw, Poland.

Introduction
Papillary thyroid cancer of the Warthin type (WLPTC) is a rare subtype of papillary thyroid cancer named for its similarity to Warthin's tumor of the salivary glands. Histopathologically, it is characterized by the formation of

papillary like structures, the presence of oxyphil cells, and lymphocytic infiltration. WLPTC has been shown to occur more frequently in women, especially in the 4th decade of life, and is often associated with autoimmune thyroid disease.
Aim of the Study
A retrospective review of data from 30 patients with WLPTC diagnosed from 2021 to 2025 was performed. The aim of the analysis was to characterize the patients, including demographic data, histopathological findings, and treatment course. In the group of 30 patients, the majority were women (n = 26, 86%) and the remainder were men (n = 4, 14%). The mean age of the patients was 46 ± 11 years, with a median of 49 years. According to the TNM classification, the distribution was as follows: pT1a in 13 patients (43%), pT1b in 12 patients (40%), and pT2 in 5 patients (16%); no nodules were larger than 4 cm. Multifocality was observed in 24 cases (80%), and coexisting subtypes—classic, follicular, oncocytic, and hobnail—were identified. Lymph node metastases were confirmed in the central compartment (pN1a in 5 of 29 cases, 17%) and in the lateral compartment (pN1b in 1 of 29 cases, 3%). No distant metastases were found. In 18 cases (60%), the nodule was found to be intrathyroidal; in 5 cases (17%), there was extension into the capsule; and in 7 cases (24%), microscopic extrathyroidal extension was observed. Angioinvasion was present in 5 cases (17%). Coexisting autoimmune thyroiditis was found in 26 cases (86%). According to the AJCC 8th edition classification, 100% of the patients were classified as Stage I. Based on the ATA 2015 risk stratification: 9 out of 29 patients (31%) were assessed as low risk, and 20 out of 29 patients (69%) as intermediate risk. In our group, 29 out of 30 patients (96%) received radioactive iodine (RAI) treatment; the response to treatment was excellent in 26 cases (90%), with 1 case showing a biochemically incomplete response, while 3 patients are awaiting results.
Conclusions
The Warthin subtype, although very characteristic, is rarely diagnosed. It is associated with autoimmune thyroiditis, exhibits a clinical course like other papillary carcinoma subtypes, and has a good prognosis that also depends on the coexisting subtype.

Serum proteomic analysis reveals insights into the mechanism of action of teprotumumab, an insulin-like growth factor-1 receptor inhibitor, in patients with chronic thyroid eye disease (TED)

Peng Li[1], Michael Karon[1] & Monica Gavala[1]
[1]Amgen Inc., Thousand Oaks, United States.

Background
TED is a heterogenous disease, with symptoms that can burden daily life. Patients with chronic TED may be particularly challenging to diagnose and treat. Insulin-like growth factor-1 receptor (IGF-1R) plays a key role in TED pathogenesis. Teprotumumab, a fully human monoclonal IGF-1R inhibitor antibody, recently demonstrated proptosis improvement in a trial of patients with chronic, low disease activity TED. This trial represents a significant step for a population traditionally treated with decompression surgery and recalcitrant to pharmacotherapy. To further understand teprotumumab's impact on biomarkers and signaling pathways, we examined serum proteomics to elucidate global pathways impacted by teprotumumab in chronic TED.
Methods
Patients in the trial (NCT04583735) had clinical activity score (CAS) ≤1 and TED duration 2-10 years. Serum samples were collected from placebo ($n = 20$) and teprotumumab ($n = 41$) patients at baseline and weeks 3, 12 and 24 and analyzed on the Olink Explore 3072 platform. Serum IGF-1 levels were analyzed with the R&D Quantikine assay.
Results
In samples from teprotumumab-treated patients, drug target engagement was validated and confirmed through the IGF-1 immunoassay. Modulation of IGF-1 pathways (i.e., soluble IGF-1R, and insulin-like growth factor binding proteins [IGFBPs] 1-3) was also observed post-teprotumumab treatment in the Olink assay. Additionally, teprotumumab treatment inhibited key proteins that are elevated in tissues of TED patients. These included proteins involved in collagen formation and extracellular matrix (ECM) production, such as COL1A1, OMD, and MMP1; decreased by 2.07, 1.82 and 1.60-fold compared to placebo after 24-week treatment, respectively.
Conclusion
Previous studies have demonstrated that collagen accumulation results in expansion of the ECM that causes destructive tissue remodeling,[1,2] a hallmark of TED. Our findings underscore the pivotal role of IGF-1R activation in TED and confirm target engagement and modulation with teprotumumab in these patients with low CAS, chronic TED. Global proteins associated with the disease were altered by teprotumumab, particularly in pathways related to IGF-binding and ECM which ultimately may lead to disease modification. These insights strengthen our understanding of teprotumumab's therapeutic mechanisms and its role in the management of chronic TED.

Comparison of hematologic and autoimmune status of patients with Graves' disease and autoimmune thyroiditis during surgical treatment

Farida Saidova[1], Jale Aslanova[1], Rasim Huseynov[1], Nizami Muradov[1], Shahla Alakbarova[1] & Aygun Mayilova[1]
[1]Scientific Center of Surgery named after M.A.Topchubashov, endocrine surgery, Baku, Azerbaijan.

The purpose
of the study was to compare the hematological and immunological parameters of patients with Graves' disease (GD) and autoimmune thyroiditis (AIT) when performing different volumes of surgical intervention.
Material and Methods
On 28 patients with GD and 36 patients with AIT with anemia performed total thyroidectomy (TT) and subtotal thyroidectomy (ST). HCB, RBC, HCT, MCV, MCH, MCHC, serum iron (Fe) and ferritin (Fr) were determined. Immune status was assessed by the level of CD3+, CD4+, CD8+, CD4+/CD8+, CIC, erythrophagocytosis, TRAb, TPOAb.
Results and discussion
Before surgery, more pronounced changes are observed in the group of patients with AIT statistically significant changes are noted in the level of MCV, MCH, Fe, Fr in comparison with the corresponding indicators of the group of patients with GD. Immune disorders expressed in immunodeficiency of the cellular component of immunity and activation of the humoral component, are observed in both groups of patients, only the level of CD4+ helper cells is significantly lower in patients with AIT ($P < 0.05$). A year after ST, hematological disorders worsened in both groups of patients compared to controls. At the same time, in terms of the values of HGB, RBC and HCT indicators, both groups differ significantly from each other and more pronounced changes are observed in individuals with GD. A deterioration is also observed among indicators of immune status (CD3+, CD4+, CD4+/CD8+, CIC) and are more pronounced in patients with AIT ($P < 0.05$). A year after TT, hematological parameters improved significantly in patients of both groups and were practically no different from the control group. Only the hematocrit level in individuals with AIT (37,9± 0,4%)still differs from the corresponding indicator for controls and patients with GD ($P < 0.05$). By this time, the immunological parameters of both groups had approached the control ones.
Conclusions
Although GD and AIT are autoimmune diseases with different clinical presentations and different mechanisms for the development of anemia, the results obtained are unidirectional. Performing TT in patients with GD and AIT with anemia leads to the cessation of the autoimmune process and improvement of hematological parameters against the background of euthyroidism, achieved through levothyroxine replacement therapy. The preservation of thyroid tissue during ST in both groups of patients apparently contributes to the further aggravation of autoimmune disorders and deterioration of hematological parameters, despite the euthyroid hormonal background of the patients.

The role of procalcitonin and ProGRP in the follow-up of medullary thyroid carcinoma

Andreia Martins Fernandes[1], Micaela Batista[1], Leandro Augusto Silva[1], Ana Rita Elvas[1], Joana Couto[1], Raquel G. Martins[1], Jacinta Santos[1], Teresa Martins[2], Nuno Cunha[3] & Fernando Rodrigues[1]
[1]Portuguese Oncology Institute of Coimbra, Endocrinology Department, Coimbra, Portugal; [2]Portuguese Oncology Institute of Coimbra, Coimbra,

Portugal; [3]Portuguese Oncology Institute of Coimbra, Laboratory Medicine Department, Coimbra, Portugal.

Introduction
Calcitonin (Ctn) and carcinoembryonic antigen (CEA) are the primary tumour markers for medullary thyroid carcinoma (MTC) follow-up. Procalcitonin (ProCtn) and Progastrin-releasing Peptide (ProGRP) have been suggested as complementary markers for MTC, but the available data are still limited.
Aims
To evaluate the performance of ProCtn and ProGRP in post-surgical follow-up of MTC.
Materials and methods
Ctn, ProCtn, and ProGRP levels were measured at the last follow-up in a total of 85 patients: 21 controls with non-MTC thyroid disease and 64 patients with surgically treated MTC.
Results
In the control group, all patients had normal Ctn, ProCtn and ProGRP levels. Among the 64 patients with MTC, 35 (54.7%) were female, with a median age at diagnosis of 60 years. 46 patients had sporadic MTC and 18 hereditary MTC. The median follow-up time was 93.7 months. At the end of the follow-up, 25 patients (39.1%) showed no evidence of disease, 27 (42.2%) presented with biochemical evidence, and 12 (18.8%) exhibited structural evidence. ProCtn and Ctn ($r = 0.939$) and ProGRP and Ctn ($r = 0.781$) values were strongly correlated ($P < 0.001$). Median ProCtn and ProGRP values differed across the groups - no evidence of disease, biochemical evidence, and structural evidence - at 0.06 ng/ml, 0.7 ng/ml, and 9.8 ng/ml for ProCtn, and 40.2 pg/ml, 62.6 pg/ml, and 536.6 pg/ml for ProGRP, respectively ($P < 0.001$). No patients with structural disease had normal Ctn levels. Among those with elevated Ctn levels of ≤ 150 pg/ml, 10/20 (50%) had normal ProCtn, and 14/18 (77.8%) had normal ProGRP. None of the patients with elevated Ctn and normal ProCtn or ProGRP levels showed evidence of structural disease. The most accurate ROC-derived cut-off values for identifying structural disease were settled at 138.4 pg/ml for Ctn [AUC: 0.94 (95%CI 0.88-1), $P < 0.001$] with 91.7% sensitivity, 82.7% specificity, 55% positive predictive value (PPV), and 97.7% negative predictive value (NPV); at 1.76 ng/ml for ProCtn [AUC: 0.96 (95%CI 0.9-1), $P < 0.001$] with 90.9% sensitivity, 87.8% specificity, 62.5% PPV, and 97.7% NPV; and at 161.4 pg/ml for ProGRP [AUC:0.98 (95%CI 0.94-1), $P < 0.001$] with 88.9% sensitivity, 97.9% specificity, 88.9% PPV, and 97.9% NPV.
Conclusions
ProCtn and ProGRP strongly correlate with Ctn in MTC follow-up. The established cut-off values for Ctn and ProCtn demonstrate excellent sensitivity and NPV in detecting structural disease, while ProGRP provides high specificity, PPV, and good sensitivity. These findings suggest that they may be promising complementary markers, but further research is needed to validate their clinical utility.

JOINT2711

Resection of the thyroid isthmus as a surgical treatment method for well-differentiated thyroid cancer in selected patients

Mariia Berlovich[1] & Petr Nikiforovich[1]
[1]Endocrinology Research Centre, Moscow, Russian Federation.

Introduction
We present a study aimed at exploring the advantages and disadvantages of isthmusectomy (IE), as well as determining the indications and limitations for its application. Considering the relatively favorable prognosis associated with well-differentiated thyroid cancer (WDTC), there is growing interest in minimizing the extent of invasive procedures and the risk of surgical complications. Currently, there are no recommendations regarding the extent of thyroid resection for tumors confined to the isthmus. However, scientific evidence supports IE as a potentially safe and effective method.
Materials and Methods
A retrospective analysis was conducted to evaluate the treatment outcomes of 32 patients who underwent internal excision for tumors confined to the isthmus at the Endocrinology Research Centre (median age: 47years [25;70], 78.13% under 55 years). Demographic data, clinical and pathological characteristics of tumors based on ultrasound findings, results of fine needle aspiration biopsy (FNAB), and morphological examination (ME) of postoperative specimens were recorded. In cases with confirmed malignancy staging was performed according to the American Joint Committee on Cancer (AJCC) system (8th edition) and risk stratification for recurrence.
Results
FNAB results confirmed malignant thyroid tumors in 11 patients (34.4%) (Bethesda VI), in 8 patients (25,0%) a Bethesda V, in 13 patients (40.6%) a Bethesda IV. Histologically, WDTC was confirmed in 22 patients, all staged as I: T1a (50.0%), T1b (40.9%), T2 (9.1%). The mean tumor size was 15 mm [6;32]. ME revealed metastases in adjacent lymph nodes (LN) (N1a) in 2 patients, each measuring less than 1 cm, with fewer than 5 affected LN. 21 patients (95.5%) with confirmed WDTC were at low risk, while 1 patient (4.5%) was classified as high risk for disease recurrence. Papillary thyroid cancer was confirmed in 21 patients, with high-grade differentiated thyroid carcinoma diagnosed in 1 patient who subsequently underwent total thyroidectomy. Regarding early postoperative complications, only one patient experienced transient hypocalcemia. The median follow-up period was 18 months [8;34] with no reported recurrences of the disease. Patient observations are ongoing.
Conclusions
The findings indicate the potential of IE as a surgical treatment for lesions confined to the isthmus, provided that an appropriate assessment of the characteristics of the detected lesion and the overall health status of the patient is conducted at the preoperative stage. The implementation of IE into surgical practice may lead to a reduction in the risks of typical postoperative complications associated with this localization, such as recurrent laryngeal nerve injury, hypoparathyroidism, and hypothyroidism.

Medullary thyroid carcinoma: a 15-year case series

Andreia Martins Fernandes[1], Leandro Augusto Silva[1], Ana Rita Elvas[1], Joana Couto[2], Raquel G. Martins[1], Jacinta Santos[1], Teresa Martins[1] & Fernando Rodrigues[1]
[1]Portuguese Oncology Institute of Coimbra, Endocrinology Department, Coimbra, Portugal; [2]Portuguese Oncology Institute of Coimbra, Coimbra, Portugal.

Introduction
Medullary thyroid carcinoma (MTC) accounts for up to 5% of thyroid carcinomas and can exhibit variable clinical behaviour. Nearly 25% are associated with multiple endocrine neoplasia type 2 syndrome (MEN2) or familial isolated MTC.
Objectives
To evaluate the characteristics and clinical evolution of patients with MTC followed at our institution.
Methods
Retrospective analysis of the medical records of patients diagnosed with MTC between 2009 and 2024.
Results
Seventy-six patients were identified (55.3% women), with a mean age at diagnosis of 61 ± 14.1 years. Preoperative diagnosis was established in 32.9% ($n = 25$) of patients. At diagnosis, staging was as follows: stage I ($n = 32$), II ($n = 15$), III ($n = 6$), IVa ($n = 15$), and IVc ($n = 8$). Germline pathogenic *RET* variants were identified in 14 of 67 patients (20.9%), while somatic variants were identified in 8 of 15 patients (53.3%). Surgery was performed in 94.7% ($n = 72$), including hemithyroidectomy (n = 8), total thyroidectomy (TT) ($n = 20$) - 7 with two-staged surgeries, TT with bilateral recurrent dissection ($n = 29$), and TT with bilateral recurrent + lateral neck dissection ($n = 15$). The median tumour size was 14 mm, with 25 of 67 patients (37.3%) presenting microcarcinomas. R0 resection was achieved in 52 of 62 patients (83.9%). Vascular invasion was observed in 12 of 50 cases (24%), while extrathyroidal extension was observed in 12 of 63 cases (19%). Local cervical recurrence occurred in 18.8% ($n = 13$) (median time post-surgery: 6.5 months), treated surgically in 9 cases; the remaining patients were kept under surveillance. Additional therapy was performed in 13.2% of patients ($n = 10$): 9 had radiotherapy (cervical, $n = 6$; bone, $n = 3$), and 3 received tyrosine kinase inhibitors. Median follow-up was 67.5 months (IQR 24.8 – 121). At the most recent evaluation, 46.1% ($n = 35$) of patients were disease-free, 30.3% ($n = 23$) had biochemical evidence of disease, and 23.7% ($n = 18$) had structural disease (locoregional, $n = 4$; distant, $n = 14$ - bone ($n = 7$), liver ($n = 5$), lung ($n = 8$)). Among those with structural disease, 72.2% ($n = 13$) showed disease progression. A total of 21.1% of patients ($n = 16$) died, with 10 of these deaths attributed to MTC. Median overall survival was 66.5 months (IQR 25.5 – 119.3).
Conclusions
The importance of long-term follow-up is emphasized due to the possibility of recurrence or disease progression. Genetic testing is essential not only for individual prognosis but also for familial genetic counselling, in addition to enabling targeted systemic therapy when indicated.

Cardiovascular and metabolic markers after thyroid cancer treatment: a fine balance of long-term outcomes

Miruna-Viorela Nacu[1], Carmen Sorina Martin[1,2], Marian Andrei[1], Gabriella-Patricia-Victoria-Helen Bicknell[2], Carmen Barbu[1,2] & Simona Fica[1,2]
[1]Elias Emergency University Hospital, Department of Endocrinology, Diabetes Mellitus, Nutrition and Metabolic Disorders, Bucharest, Romania; [2]Carol Davila University of Medicine and Pharmacy, Department of Endocrinology, Diabetes Mellitus, Nutrition and Metabolic Disorders, Bucharest, Romania.

Introduction
Differentiated thyroid carcinoma (DTC), although the most common endocrine malignancy, has a better overall survival rate than most malignancies. It has been presumed that intermediate and high-risk tumors require long term suppression with thyroid hormones in order to prevent thyroid stimulating hormone (TSH) tumor growth. Given the interplay between cardiovascular system, metabolic parameters and thyroid hormones, long term subclinical or overt hyperthyroidism might additionally impact negatively the survival of these patients. Moreover, radioactive iodine therapy (RAI) can also play a role in the development of cardiovascular pathology of these patients. Not enough studies investigate this fine balance and current recommendations are based on moderate quality evidence with heterogenous data.
Objective
We performed a retrospective observational study in order to investigate the relationship between cardiovascular and metabolic profiles of patients with DTC who underwent total thyroidectomies in our hospital from 2010-2024. Mean follow-up time was 5.34 years (SD = 4.76).
Results
A total of 144 patients were included, median age at diagnosis 52.5 years (IQ $r =$ 22), 88.19% females. Papillary thyroid cancer accounted for 93.62% of cases and 72.83% were stage I. Fifty-five (38.19%) were under suppressive therapy (defined as TSH < 0.5 uUI/ml) and 64.58% underwent RAI treatment with a median of 50 (IQ $r = 125$) mCi doses. We compared metabolic profiles of TSH-suppressed and non-suppressed groups, which were similar in terms of age, BMI and gender. We found no statistically significant differences between glycemia, HbA1c, lipid profiles, systolic and diastolic blood pressure and heart rate in these two groups. Fibrinogen levels were higher (363.83 +/- 71.69 mg/dl vs 319.77 +/- 51.08, one-sided p = 0.029) in patients with suppressed TSH. Same analysis was performed with respect to RAI treatment and higher heart rate was found in patients who received RAI therapy ($P = 0.014$). Not enough patients developed cardiovascular pathologies after DTC treatment in order to achieve statistical significance.
Conclusion
More studies with longer follow-up periods that also investigate cardiovascular and metabolic outcomes are needed in order to assess and customize life-long management of patients with DTC. The possible low-grade inflammation and elevated heart rate could be indicative of future cardiometabolic negative outcomes in these patients.

The value of intraoperative frozen section in surgical management of thyroid nodules

Rachida Bouattay[1], Linda Misbah[1], May Ferjani[1], Khaled Harrathi[1] & Jamel Koubaa[1]
[1]ENT and Head and Neck Department, University Hospital of Fattouma Bourguiba, Monastir, Tunisia.

Introduction
Nodular thyroid pathology poses the problem of its histological nature on which the therapeutic approach depends. Intraoperative frozen section, by giving the rapid diagnosis of benignity or malignancy, conditions the immediate surgical procedure. The aim of this work is to study the sensitivity and specificity of intraoperative frozen section in thyroid pathology and to identify its limits.
Materials and Methods
This is a retrospective study having collected over a period of two years, 120 patients operated on for thyroid pathology. The average age was 46 years (range 15 to 84 years). A female predominance was noted with a sex ratio of 0.17. Preoperative thyroid cytology was performed in 9 cases. The tumors were benign in 77 cases (64.2%) and malignant in 43 cases (35.8%). We compared the results of intraoperative frozen section with the definitive histological examination.
Results
The intraoperative frozen section concluded to a benign lesion in 90 cases (75%), a malignant lesion in 29 cases (24.1%). It was doubtful in one case (0.9%). The doubtful case corresponded to a malignant lesion on the definitive histological examination. No false positive (FP) was reported. The sensitivity of the extemporaneous examination for all histological types was 69% and the specificity was 100%. The predictive positive value was 100% and the predictive negative value was 85.5%. The diagnostic efficiency was 88.3%.
Conclusion
The reliability of the intraoperative frozen section of the thyroid is widely demonstrated. Our study showed a perfect specificity of this examination; however the difficult interpretation of thyroid lesions of follicular architecture and microcarcinomas explains a sensitivity of 69%.

Radioiodine-refractory differentiated thyroid cancer in children and adolescents: a retrospective single-center study

Konstantin Slashchuk[1], Maria Reinberg[1], Alena Kharlova[1], Mariia Berlovich[1], Petr Nikiforovich[1], Marina Sheremeta[1], Michail Degtyarev[1], Olga Chikulaeva[1], Elena Nagaeva[1], Dmitry Brovin[1], Valentina Peterkova[1], Natalia Mokrysheva[1] & Ivan Dedov[1]
[1]Endocrinology Research Centre, Moscow, Russian Federation.

Introduction
Differentiated thyroid cancer (DTC) in pediatric patients is rare but often aggressive, with a high prevalence of regional and distant metastases. Tailored management strategies are particularly critical for radioiodine-refractory (RAIR) cases, which represent 10–30% of all DTCs. Current RAIR classification systems lack pediatric-specific criteria, necessitating new frameworks to address the unique clinical course and therapeutic needs of this population.
Objectives
To evaluate outcomes in pediatric DTC patients treated with surgery and radioiodine (RAI) therapy, with a focus on RAIR cases and those presenting with advanced disease. Additionally, to propose a new RAIR classification based on iodine avidity and therapeutic outcomes.
Materials and Methods
A retrospective review of medical records for 278 pediatric DTC patients treated between 2008 and 2022 was conducted. Patients underwent surgery followed by RAI therapy, with follow-ups every 3 to 6 months. Advanced cases were identified by high-risk presentation and resistance to RAI therapy. Kaplan-Meier analysis was used to assess progression-free survival (PFS). Cox regression adjusted for age, sex, and interaction terms was performed to evaluate predictors of outcomes.
Results
Among 278 patients, 39 (14%) had advanced disease. In this subgroup, 4 achieved remission, 29 had disease stabilization, and 6 experienced biochemical or structural progression, with one patient requiring lenvatinib therapy. The PFS rate among RAIR patients was 84.62%, with an overall 5-year survival rate of 100%. Patients with RAI-non-avid metastases exhibited poorer outcomes in terms of PFS and remission probability.
Conclusions
This study highlights the need for personalized therapeutic approaches for pediatric DTC patients. A new classification system categorizing RAIR cases based on iodine avidity and therapeutic outcomes should be proposed. This framework aims to guide treatment and follow-up strategies, potentially informed by the molecular and genetic distinctions between iodine-avid and non-avid subgroups. Patients with non-avid metastases demonstrated worse prognoses, underscoring the importance of tailored interventions.

The role and limitations of fine-needle aspiration cytology in thyroid nodule diagnosis

Malika El Omri[1], Nawress Thabet[1], Habib Rouatbi[1], Mouna Belakhdher[1], Jihene Houas[1], Monia Ghammam[1], Abir Meherzi[1], Hamza Elfekih[2], Wassim Kermani[1] & Mohamed Abdelkafi[1]

[1]Farhat Hached Hospital, Department of ENT and Head and Neck Surgery, Sousse, Tunisia; [2]Farhat Hached Hospital, Department of Endocrinology, Sousse, Tunisia.

Background
Fine-needle aspiration cytology (FNAC) is the gold standard for evaluating thyroid nodules, offering a minimally invasive and ultrasound-guided approach to distinguishing benign from malignant lesions. This technique plays a critical role in optimizing patient management by guiding therapeutic decisions and minimizing unnecessary surgeries.
Objective
To assess the diagnostic accuracy of FNAC in the management of thyroid nodules and identify its limitations.
Methods
This retrospective cross-sectional study analyzed FNAC results from patients who underwent thyroid nodule surgery at our ENT Department over a five-year period (January 2018 – December 2022).
Results
A total of 333 patients were included, with a mean age of 47.45 years and a strong female predominance (male-to-female ratio of 1:5.8). The primary mode of detection was a palpable cervical mass (57.35%), while 15.6% were incidental findings. Multinodular goiters were more prevalent (61.6%) than solitary nodules (38.4%). Ultrasound classification revealed that 52% of nodules were categorized as **EU-TIRADS <4**, while 48% were classified as **EU-TIRADS ≥ 4**. FNAC was performed on 75 patients (22.5%). The results were distributed as follows: 14.7% non-diagnostic (Bethesda I), 44% benign (Bethesda II), 10.7% atypia/follicular lesion of undetermined significance (Bethesda III), 6.6% follicular neoplasm/-suspicious for follicular neoplasm (Bethesda IV), and 24% suspicious for malignancy (Bethesda V). No cases were classified as Bethesda VI (malignant). Final histopathological analysis confirmed benign pathology in 48 cases, with FNAC correctly identifying 23 (TN = 47.9%). Among 27 malignant cases, FNAC correctly diagnosed 17 (T P = 70.8%). The overall diagnostic efficacy of FNAC was 53.3%.
Conclusion
FNAC remains a crucial diagnostic tool for thyroid nodules, but its performance can be enhanced through systematic ultrasound guidance to reduce false-negative rates. Optimizing this technique within a multidisciplinary framework would refine diagnosis and improve patient management.

JOINT2364

A problem necessitating a reemphasized solution: a case of hypothyroidism presenting as a new pericardial effusion in a patient with helicobacter pylori infection treated with proton-pump inhibitor

Carlo Casipit[1] & Bruce Casipit[1]
[1]Jefferson-Einstein Hospital, Philadelphia, United States.

Background
Oral Levothyroxine (LT4) is the primary treatment for hypothyroidism and requires an acidic gastric pH for absorption. On the other hand, Proton Pump Inhibitors (PPIs) are the most effective treatment for gastric acid suppression. Simultaneous use of LT4 and PPI can be challenging even for experienced physicians.
Case Presentation
A 70-year-old female with Hypothyroidism and Helicobacter pylori infection, who is compliant with her Levothyroxine and Pantoprazole, presented to the hospital with a 3-week onset of fatigue and chest pain. She denied lethargy, constipation, cold intolerance, weight gain, or any bleeding. Vital signs showed T 36.8C, HR 63bpm, and BP 110/60mmHg. Physical examination showed intact sensorium, no thyromegaly, edema, murmurs, or abnormal lung and abdominal findings. Diagnostic tests were remarkable for TSH 31.33 mIU/l(0.5-5 mIU/L), FT4 0.6 ng/dl (0.8-1.8 ng/dl), normal Troponin, EKG with low voltage QRS, chest X-ray showed cardiomegaly, echocardiogram showed new pericardial effusion without tamponade. The cardiology team suggested no urgent intervention. The endocrinology team increased her levothyroxine dose; the pharmacy was consulted for an LT4 liquid or gel formulation however, it was unavailable. Her Pantoprazole was switched to Famotidine which was administered 4 hours after LT4. Her symptoms improved, and she was discharged with strict follow-up for thyroid function testing and a repeat echocardiogram.
Discussion
PPIs suppress gastric acid for 48 hours due to their irreversible binding to H-K ATPase on parietal cells. Previous studies showed that using PPI in the morning or night while on LT4 causes an almost equal degree of TSH elevation. Alternatively, since Histamine 2 Receptor Blockers (H2RB) suppress acid secretion for only 4 hours, LT4 can be given 4 hours after H2RB administration. Increasing LT4 doses may be considered but can predispose patients to side effects. Interestingly, LT4 gel capsules and liquid formulations do not require acidic pH for absorption and are unaffected by PPI. Rectal and IV LT4 are options for acute needs but are tedious for maintenance administration.
Conclusion
Patients on LT4 requiring concurrent acid suppression can benefit from H2RB and Gel coated or liquid formulations of LT4. Patients should be re-educated regarding the need for strict outpatient follow-up with close monitoring of thyroid function tests.

Thyroid nodules in acromegaly: a study of 78 cases

Soukaina Lahlou[1], Nassim Essabah Haraj[1], Siham El Aziz[1] & Asma Chadli[1]
[1]CHU Ibn Rochd, Clinical Neurosciences and Mental Health Laboratory, Department of Endocrinology, Diabetology, Metabolic Diseases and Nuttition, Casablanca, Morocco.

Introduction
Acromegaly is a condition often associated with thyroid diseas. The aim of this study was to analyze the incidence of thyroid nodules, including thyroid cancer, in patients with acromegaly.
Material and Patients
This is a retrospective descriptive study involving 78 acromegalic patients hospitalized in the endocrinology department of CHU Ibn Rochd in Casablanca from January 2005 to December 2024. All patients underwent a morphological thyroid assessment. Statistical analysis was performed using Excel.
Results
The average age of the patients was 48 years (range: 18-72), with a male-to-female ratio of 0.33. The average duration of the disease was 8 years. The average IGF-1 level was 582 ng/ml, which is 2.62 times the normal value. Thyroid morphological abnormalities were found in 52 patients. A multinodular goiter was discovered in 85.7% of patients, while 14.3% of patients had a single nodule. The nodule size was less than 10 mm in 71% of the patients and greater than 10 mm in 22% of the patients. Among these nodules, 46.8% were classified as EUTIRADS 3 and 23,4 % were EUTIRADS 4. Therefore, 39% of our patients underwent fine needle aspiration and 23.4% returned a category 3 result according to the Bethesda classification. Additionally, three cases of papillary thyroid carcinoma were diagnosed.
Conclusion
This study highlights the high prevalence of thyroid abnormalities, particularly multinodular goiter, in patients with acromegaly. The majority of thyroid nodules were classified as moderate to high suspicion of malignancy. underscoring the need for careful monitoring and early diagnosis of thyroid cancer in acromegalic patients. These findings emphasize the importance of regular thyroid assessments in this patient population.

Report of two cases of thyroid hormone resistance syndrome with developmental disorders in young children

Linying Liao[1,2] & Xingxing Zhang[1]
[1]The Second Xiangya Hospital of Central South University, Department of pediatrics, Changsha, China; [2]The Second Xiangya Hospital of Central South University, Changsha, China.

Thyroid hormone resistance syndrome (RTH) is a rare endocrine disease mainly caused by thyroid hormone receptor (THR) deficiency, characterized by elevated free thyroid hormones (FT3, FT4) and unsuppressed thyroid stimulating hormone (TSH). In this study, we report two cases of RTH in young children, both with developmental disorders. Child 1 was a 4-year-old boy who presented to the clinic with language delay, global developmental delay, mental retardation, and thyroid function showing elevated FT3 and FT4 and normal or elevated TSH. Genetic testing revealed a de novo heterozygous mutation in the thyroid hormone receptors beta (THRB) gene c.1373T>C, resulting in a change in amino acid at

position 458 of THRB from valine to alanine (p.Val458Ala) in the form of generalized thyroid hormone resistance (GRTH). Child 2 was a 2-year-old boy who presented to the clinic with abnormal thyroid function, characterized by growth retardation, severe low body weight, and emaciation, accompanied by tachycardia as a symptom of thyrotoxicosis. Genetic testing revealed a de novo heterozygous mutation in the THRB gene c.959G > A, resulting in a change in amino acid 320 of THRB from arginine to histidine (p.Arg320His), which was considered to be a selective pituitary thyroid hormone resistance (PRTH) type. We used β-blockers to control symptoms in child 2 with hyperthyroidism and developed individualized nutritional support programs for two children with growth and developmental disorders.The clinical manifestations of thyroid hormone resistance syndrome are complex, and early genetic testing can help reduce misdiagnosis and underdiagnosis. Its treatment is symptomatic and inappropriate methods such as antithyroid drugs, thyroidectomy and ablation therapy should be avoided.

Keywords
thyroid hormone resistance syndrome;thyroid hormone receptors beta;children;-developmental disorders;genetic testing.

An unusual case of a patient alternating from hypothyroidism to hyperthyroidism following COVID-19 infection

Evangelia Pissadaki[1], Vasiliki Daraki[1], Vasiliki Venetsanaki[1], Rodanthi Vamvoukaki[1], Panagiotis- Nikolaos Tsakalomatis[1], Fotis Mermigkas[1], Maria Sfakiotaki[1], Grigoria Betsi[1] & Paraskevi Xekouki[1]
[1]University General Hospital of Heraklion, Department of Endocrinology Diabetes and Metabolic Diseases, Crete, Greece.

Introduction
Hashimoto's thyroiditis and Graves' disease are the most prevalent autoimmune thyroid disorders. Antibodies targeting the TSH receptor (TRAbs) may be either stimulatory (TSAbs), leading to hyperthyroidism, or blocking (TBAbs), resulting in hypothyroidism. In rare instances, patients may switch from TSAb to TBAb or vice versa, thereby exhibiting alternating hyper- and hypothyroidism. Although the shift from hyperthyroidism to hypothyroidism is commonly observed in clinical practice, progression from hypothyroidism to hyperthyroidism is notably uncommon. Herein, we describe a patient who presented initially with severe hypothyroidism and subsequently transitioned to hyperthyroidism following COVID-19 infection.
Case Presentation
A 57-year-old Caucasian female, smoker, with no previous history of thyroid disease, presented to the emergency department with profound fatigue, lethargy, weight gain, and diffuse edema. The patient reported mild proximal muscle weakness, hoarseness, and memory disturbances. Her medical history included obesity, hyperlipidemia, hypertension, and nephrolithiasis. On physical examination, she appeared myxedematous, with generalized edema, psychomotor retardation, hoarseness, and bradycardia. Laboratory investigations revealed markedly elevated TSH (83.93 μIU/ml), reduced free T4 (<0.42 ng/dl), high anti-TPO antibodies (>1,000 IU/ml), and elevated CPK (1106 U/L). Treatment with liquid levothyroxine was initiated, which resulted in rapid clinical improvement. Subsequently, the patient contracted COVID-19 infection and after a 13-day hospitalization, she was discharged with further clinical and biochemical improvement. One month later, at outpatient follow-up, she was euthyroid and in stable condition. However, two months post-COVID-19 infection, she developed clinical features indicative of hyperthyroidism, including weight loss, palpitations, nervousness, and fatigue in the absence of neck pain, tenderness, or fever. Laboratory evaluation showed a suppressed TSH level (0.011 μIU/ml; normal range: 0.25–3.43 μIU/ml). Despite the reduction of her levothyroxine dosage, her symptoms persisted. A subsequent workup revealed further TSH levels reduction <0.0083 μIU/ml, with normal FT3 and FT4 levels. Notably, thyroid-stimulating immunoglobulins (TSI) were tested positive, prompting initiation of thiamazole therapy alongside continued levothyroxine treatment, following a "block and replace" strategy. Under this combined regimen, the patient remains asymptomatic, euthyroid, and in good overall health.
Conclusions
This case underscores a rare instance of hypothyroidism transitioning to hyperthyroidism, highlighting the potential for alternating stimulatory and blocking TSH receptor antibodies. These findings may be particularly relevant following COVID-19 infection, suggesting that viral infections may trigger or exacerbate underlying autoimmune processes. Further research is warranted to elucidate the immunological mechanisms contributing to this unusual thyroid function shift and optimize management strategies for similar complex cases.

Chemotherapy-induced hypothyroidism: a crucial diagnostic challenge

Karimi Meryem[1], Hajar Azagouagh[1], Nouhaila Essafir[1], Fatima Toulali[1], Kawtar Rifai[1], Hinde Iraqi[1] & Mohamed El Hassan Gharbi[1]
[1]CHU Ibn Sina, Rabat, Morocco.

Introduction
Severe hypothyroidism is a rare but possible endocrine complication following chemotherapy. It may be linked to an autoimmune thyroiditis triggered by cytotoxic agents. This poster presents a case of severe thyroid dysfunction in the context of post-chemotherapy follow-up for Ewing's sarcoma.
Clinical Case
We report the case of a 24-year-old patient followed for Ewing's sarcoma of the jaw, who underwent surgery, followed by a pulmonary metastatic relapse. The patient had surgery and adjuvant chemotherapy, and was referred for exploration of thyroid hypermetabolism discovered during a PET scan performed as part of the staging assessment. Laboratory tests revealed a TSH > 100 μUI/ml and positive anti-thyroglobulin antibodies, compatible with severe hypothyroidism. A cervical ultrasound showed signs of thyroiditis. Management consisted of introducing hydrocortisone at 10 mg/day for 5 days, followed by a gradual introduction of levothyroxine to an optimal replacement dose. Clinical and biological monitoring allowed for gradual improvement in hormonal parameters and symptoms.
Scientific Discussion
Although chemotherapy is necessary to treat aggressive malignant conditions, it can trigger thyroid inflammation through immune mechanisms, notably by the production of anti-thyroid antibodies such as anti-thyroglobulin and anti-thyroid peroxidase antibodies, which damage the gland and induce hypothyroidism. It can also have a direct toxic effect due to the use of certain chemotherapy agents, such as alkylating agents and anthracyclines. Management of this condition relies on thyroid hormone replacement with levothyroxine, with a cautious approach depending on the severity of the dysfunction.
Conclusion
Hypothyroidism is a recognized complication of chemotherapy, often under-diagnosed. This case highlights the importance of screening for thyroid dysfunction in patients who have received treatments likely to affect thyroid function, particularly aggressive treatments like alkylating agents, and especially when atypical symptoms or suggestive imaging findings are present. Prompt and appropriate management helps prevent complications and significantly improves the patients' quality of life.

Hyperthyroidism and pregnancy: specificities of the first trimester

Zineb Dhaimi[1], Bensbaa Salma[1], Nassim Essabah Haraj[1], Siham El Aziz[1] & Asma Chadli[1]
[1]CHU Ibn Rochd, Laboratory of Neuroscience and Mental Health Faculty of Medicine and Pharmacy, Hassan II University – Casablanca, Morocco, Department of Endocrinology, Diabetology, and Metabolic Diseases, Casablanca, Morocco.

Introduction
Hyperthyroidism is a common endocrinopathy during pregnancy, often presenting as transient gestational hyperthyroidism in the first trimester. If uncontrolled, it poses a risk of maternal and fetal complications, potentially threatening vital prognosis.
Study Objective
Evaluate the clinical and therapeutic profile of first-trimester hyperthyroidism in pregnancy.
Materials and Methods
A prospective study was conducted in our Department, including 168 patients diagnosed with hyperthyroidism in the first trimester (January 2019 to September 2024). Statistical analysis was performed using SPSS software.
Results
The average age was 26 years, with a mean gestational age of 11 weeks. A personal history of thyroid disease was reported in 16 patients. The predominant symptom was pregnancy-related vomiting, present in 98% of the patients. The mean ultrasensitive TSH was 0.04 mIU/l,the mean free T4 (T4L) was 12 ng/l,ranging from 1.1 to 11 times the normal values, and the mean free T3 (T3L) was 5.7 ng/l,ranging from 1.1 to 3 times the normal values. Graves' disease was identified in four patients, and toxic goiter in five. Sixty-five percent of patients were treated with synthetic antithyroid drugs and beta-blockers, 16% with beta-

blockers alone, 7.5% with beta-blockers and corticosteroids, and 2.5% with synthetic antithyroid drugs alone. For the remaining patients, simple monitoring was implemented. Symptoms of hyperthyroidism disappeared in 75% of patients, with normalization of thyroid function by 16 weeks of gestation. As for obstetric complications, 2 fetal deaths were recorded.
Conclusion
This study demonstrated that The most common cause of Hyperthyroidism in the First Trimester is transient gestational hyperthyroidism. Antithyroid drugs (ATDs) were reserved for severe forms With a favorable outcome in the majority of patients After adequate care.

Synchronous papillary thyroid cancer and malignant neoplasms: Hodgkin lymphoma and nasopharyngeal carcinoma

Malika El Omri[1], Nawress Thabet[2], Mouna Belakhdher[1], Jihene Houas[1], Abir Meherzi[1], Monia Ghammam[1], Hamza Elfekih[3], Wassim Kermani[1] & Mohamed Abdelkafi[1]
[1]Farhat Hached Hospital, Department of ENT and Head and Neck Surgery, Sousse, Tunisia; [2]Farhat Hached University Hospital, ENT Department, Sousse, Tunisia; [3]Farhat Hached Hospital, Department of Endocrinology, Sousse, Tunisia.

Objectives
Papillary thyroid carcinoma (PTC) is the most common type of thyroid cancer. Its co-occurrence with Hodgkin's lymphoma (HL) and nasopharyngeal undifferentiated carcinoma (UCNT) is extremely rare. The aim of this study is to investigate the clinical characteristics and treatment challenges associated with this unusual situation.
Methods
We conducted a retrospective analysis of three cases of synchronous tumours involving the thyroid gland, which were reported in our department.
Results
This report presents the cases of three female patients aged 27, 51, and 70 years, respectively. One patient presented with fever and night sweats, another with a suspicious thyroid nodule, and the third with multiple cervical lymph nodes and unilateral epistaxis. Physical examination revealed cervical lymphadenopathies in all three cases, an indurated thyroid nodule in one case, and a suspicious tumoral process in the nasopharynx in another case. All patients underwent a neck ultrasound. Two patients underwent a body scan in addition to a nasopharyngeal scan. All patients underwent a thyroid fine needle aspiration, with one patient also receiving a nasopharyngeal biopsy and two patients receiving an adenectomy. The diagnosis of papillary thyroid carcinoma (PTC) was made in two cases with Hodgkin's lymphoma (HL) and in one case with undifferentiated carcinoma (UCNT). Initially, all three patients underwent total thyroidectomy with lymph node dissection. Subsequent treatment for the other neoplasms after surgery included chemotherapy for the two cases of Hodgkin's lymphoma and radiotherapy associated with chemotherapy for the undifferentiated carcinoma of the nasopharynx. The radioactive iodine treatment was delayed following the management of synchronous cancer.
Conclusion
the synchronous occurrence of differentiated thyroid cancer and malignant tumors presents a significant diagnostic and treatment challenge. It is important to note that the presence of a suspicious lymph node in papillary thyroid carcinoma may indicate the presence of other concurrent head and neck malignant tumors.

Recurrent thyroid-associated ophthalmopathy in hashimoto's thyroiditis: a case report

Kenan Sakar[1], Aslınur Akıncı Altundal[2], Müjdat Karabulut[3] & Gulhan Akbaba[1]
[1]Faculty of Medicine, Mugla Sitki Kocman University, Department of Endocrinology and Metabolic Diseases, Mugla, Türkiye; [2]Faculty of Medicine, Mugla Sitki Kocman University, Mugla, Türkiye; [3]Faculty of Medicine, Mugla Sitki Kocman University, Department of Ophthalmology, Mugla, Türkiye.

Introduction
Thyroid-associated ophthalmopathy (TAO) is predominantly linked to Graves' disease, manifesting in approximately 25-50% of such patients. However, its association with Hashimoto's thyroiditis (HT) is rare, with only isolated reports in the literature. The presence of recurrent TAO in HT is even more uncommon and presents unique diagnostic and therapeutic challenges. This case highlights recurrent moderate-to-severe TAO in a patient with HT, requiring systemic corticosteroid therapy.
Case Presentation
An 80-year-old female with a 15-year history of hypothyroidism secondary to HT, diabetes mellitus, and hyperlipidemia presented with progressive orbital symptoms, including erythema, swelling, diplopia, and burning sensations. Examination revealed bilateral proptosis (Hertel: 22 mm in the right eye, 23 mm in the left eye), conjunctival hyperemia, and a Clinical Activity Score (CAS) of 5/7, indicating active and moderate-to-severe TAO. The patient was receiving treatment with levothyroxine (75 µg/day), rosuvastatin (10 mg/day), and linagliptin (5 mg/day). Laboratory investigations demonstrated normal TSH (1.22 mIU/L), normal free T3 (4.05 pmol/L), normal free T4 (16.9 pmol/L), and significantly elevated thyroid receptor antibody (TRAb) (19.97 IU/L). Anti-thyroid peroxidase (Anti-TPO) and anti-thyroglobulin (Anti-Tg) antibodies were positive. Orbital magnetic resonance imaging (MRI) revealed no evidence of compressive optic neuropathy. The patient received a cumulative dose of 4.5 g of methylprednisolone over 12 weeks. Following treatment, the CAS decreased to 1/1, and the ophthalmopathy became inactive. However, 11 months after completing therapy, ocular symptoms recurred, with a CAS of 4/4 and an increased bilateral Hertel measurement of 24 mm. Thyroid function tests revealed TSH: 16 mIU/l,normal free T4 levels, and an elevated TRAb level of 27 IU/L. The levothyroxine dosage was increased and a 6-week course of methylprednisolone therapy was planned for active ophthalmopathy.
Conclusion
The pathogenesis of TAO in HT remains poorly understood, it may involve a different immunopathogenic mechanism, primarily mediated by TRAb and local inflammatory cytokines. Recent case reports have highlighted instances of TAO in patients with Hashimoto's thyroiditis, even in the absence of TRAb. Corticosteroids are the first-line therapy for active disease. Our patient received a cumulative dose of 4.5 g of methylprednisolone over 12 weeks, leading to a temporary resolution of symptoms. However, relapse occurred 11 months post-treatment, requiring a second cycle of steroid therapy. Optimizing thyroid hormone replacement is crucial in hypothyroid TAO cases, as untreated hypothyroidism may exacerbate orbital inflammation. In summary, while TAO is uncommon in HT, clinicians should remain vigilant for ocular manifestations in these patients.

Hormonal effects of the thyroid gland in breast cancer chemotherapy

Makhbuba Azimova[1] & Khurshidakhon Nasirova[1]
[1]Tashkent Pediatric Medical Institute, Tashkent, Uzbekistan.

Breast cancer (BC) is the most common malignancy among women and a leading cause of mortality worldwide. Its rising prevalence makes it a significant public health concern. Despite extensive research, the potential link between thyroid dysfunction and BC remains controversial. The thyroid gland regulates metabolism, immune response, and cell growth, potentially influencing cancer progression. However, studies provide conflicting evidence regarding whether thyroid diseases, such as hypothyroidism, hyperthyroidism, and autoimmune disorders, contribute to BC development or progression. Understanding the impact of thyroid function on BC patients undergoing chemotherapy is crucial for improving treatment strategies and patient outcomes.
Purpose
this study aims to assess thyroid function in BC patients undergoing chemotherapy and its changes during treatment.
Material and Methods
By measuring key thyroid biomarkers and analyzing their variations, the research seeks to determine whether thyroid dysfunction plays a role in BC progression or is a consequence of chemotherapy. Additionally, it examines the relationship between thyroid hormone levels and lymph node involvement, a critical prognostic factor. The study included 86 BC patients and 30 healthy controls. Assessments included:

- Measurement of thyroid-stimulating hormone (TSH), triiodothyronine (T3), thyroxine (T4), and anti-thyroid peroxidase antibodies (anti-TPO).
- PET-CT analysis of 18-FDG uptake in the thyroid gland.
- Evaluation of lymph node involvement via clinical and radiological data.
- Statistical analysis using SPSS v.19, with $P < 0.05$ considered significant.

The results. BC patients exhibited significant differences in thyroid function compared to the control group:.

- Lower TSH (1.72 $\pm$ 0.89 vs. 2.1 $\pm$ 0.74 µIU/ml, $P = 0.042$).
- Lower T3 (1.23 $\pm$ 0.34 vs. 1.56 $\pm$ 0.41 nmol/l,$P = 0.035$).

• Higher T4 (17.8 ± 3.5 vs. 14.2 ± 3.1 pmol/l,$P = 0.028$).
• Higher anti-TPO (64.5 ± 20.3 vs. 48.1 ± 18.7 IU/ml, $P = 0.017$)
No significant thyroid function differences were found between invasive and ductal BC. However, lymph node involvement varied significantly ($P = 0.018$), suggesting a possible link between thyroid function and tumor aggressiveness.
Conclusion
BC patients show significant thyroid hormone alterations, indicating a possible interplay between thyroid function and BC. However, no direct causative link is established. Chemotherapy may contribute to thyroid imbalances. Autoimmune thyroid involvement warrants further study. Routine thyroid monitoring in BC patients could help prevent complications. Further large-scale research is needed to clarify these findings and optimize treatment strategies through a multidisciplinary approach involving oncologists and endocrinologists.

Surgical treatment of grave's disease in children: a report of five cases

Nawress Thabet[1], Malika El Omri[2], Linda Misbah[2], Mouna Belakhdher[2], Jihene Houas[2], Abir Meherzi[2], Monia Ghammam[2], Hamza Elfekih[3], Wassim Kermani[2] & Mohamed Abdelkafi[2]
[1]Farhat Hached University Hospital, ENT Department, Sousse, Tunisia; [2]Farhat Hached Hospital, Department of ENT and Head and Neck Surgery, Sousse, Tunisia; [3]Farhat Hached Hospital, Department of Endocrinology, Sousse, Tunisia.

Objective
To analyze the epidemiological and clinical features of children who underwent thyroid surgery for Grave's disease at our departmet and to evaluate the indications and outcomes of surgical treatment.
Materials and Methods
This retrospective study includes five pediatric cases of thyroid surgery performed between 2010 and 2022 for Grave's disease.
Results
The mean age was 16.8 years (10-17 years), and all patients were female. The average time from diagnosis to surgery was 20.3 months. At diagnosis, 60% of patients had multinodular goiters, while 40% had diffuse and homogeneous goiters. Median FT4 and TSH levels were 12.8 pmol/land 0.05 mU/l,respectively. Surgical indications included thyroid nodules (60%, with compression in one case), resistance to medical treatment (20%), and severe ophthalmopathy (20%). Total thyroidectomy was performed in all cases, with no malignancy detected. Postoperative complications were minimal, with only one case of transient hypocalcemia.
Conclusion
Total thyroidectomy is a safe and effective treatment for pediatric Grave's disease, particularly in cases of treatment resistance or severe manifestations. When performed by experienced surgeons, it provides definitive management with a low risk of complications.

Primary hyperparathyroidism in a 12-year old girl caused by an ectopic mediastinal adenoma: a case report

Geeske Muehlschlegel[1], Franka Hodde[1], Marie Ritter[1], Johanna Weekes[1], Thomas Musholt[2] & Clemens Kamrath[1]
[1]Centre of Paediatrics and Adolescent Medicine, Division of Paediatric Endocrinology and Diabetology, University Hospital Freiburg, Freiburg, Germany, Freiburg, Germany; [2]Centre of General Surgery, Division of Oncologic and Special Visceral Surgery, University Hospital Mainz, Mainz, Germany, Mainz, Germany.

Background
We describe the case of a 12-year-old girl who presented with the incidental laboratory finding of primary hyperparathyroidism.
Case Presentation
The girl had an elevated calcium level in a laboratory test done by her paediatrician to check for a suspected viral infection. As calcium and parathyroid hormone (PTH) levels were repeatedly elevated, she was referred to our centre for further diagnosis. The athletic girl presented without symptoms and had all laboratory signs of primary hyperparathyroidism including elevated serum levels of calcium (3.10 mmol/l[reference range: 2.10-2.55]) and PTH (120 pg/ml [17-74]) and hypercalciuria (Ca/creatinine 0.73 mmol/mmol Crea [<0.61]). Renal ultrasonography showed no evidence of nephrocalcinosis. Cervical sonography failed to identify a suspected site of adenoma in loco typico. PET-CT showed an ectopic adenoma in the mediastinum close to the thymus tissue (Figure). Family history of endocrine neoplasia was negative, genetic testing for MEN-1 and MEN-2 was initiated, results are still awaited. The resection was successfully performed via lateral thoracoscopy, requiring one-lung ventilation.
Conclusions
This is a rare case of primary hyperparathyroidism due to ectopic parathyroid adenoma in a 12-year-old girl. Primary hyperparathyroidism is rare in children with a prevalence of 2–5 cases/100,000. Hyperparathyroidism due to an ectopic adenoma is even rarer in children, with very few cases reported in the literature. Ectopic parathyroid glands are the result of abnormal migration of the parathyroid gland during development. Because of the line of migration from the angle of the mandible to the mediastinum, they are often located in the anterior mediastinum, embedded in the thymus.

Fahr's syndrome: the hidden neurological face of hypocalcemia

Inass Chaari[1], Eléazar Niyogushima[1], Rania Dassoufi[1], Ayoub Idrissi[1], Abainou Lahousssaine[1,2], Hamza El Jadi[1,2], Azzelarab Meftah[1,2] & Hicham Baïzri[1,2]
[1]Avicenna Military Hospital, Endocrinology, Diabetology and Metabolic Diseases, Marrakech, Morocco; [2]Biosciences and Health Research Laboratory, Faculty of Medicine and Pharmacy, Cadi Ayyad Marrakech university, Marrakech, Morocco.

Introduction
Fahr's syndrome is a rare anatomoclinical entity whose primary etiology is either primary or postoperative hypoparathyroidism. It is characterized by bilateral and symmetrical intracerebral calcifications, mainly located in the basal ganglia, and is most often associated with disturbances in phospho-calcium metabolism.
Case Report
We report the case of a 29-year-old female patient with a history of total thyroidectomy in 2015, who presented to the emergency department with tonic-clonic seizures. Laboratory tests revealed hypocalcemia at 1.27 mmol/l(normal range: 2.25–2.60). Renal and hepatic function tests were normal, and the electrocardiogram showed no abnormalities. Brain CT imaging revealed bilateral and symmetrical intracerebral calcifications in the basal ganglia, supporting the diagnosis of Fahr's syndrome. Further investigations showed hyperphosphatemia at 2.38 mmol/l(normal range: 0.8–1.45) and a markedly reduced parathyroid hormone (PTH) level of less than 4 pg/ml (normal range: 12–72). Magnesium levels were also low. The diagnosis of Fahr's syndrome was established, and the patient was started on replacement therapy with calcium, vitamin D, and magnesium, along with an anticonvulsant. After three months, clinical and biochemical improvement was observed.
Discussion
Fahr's syndrome is classically defined by the triad of symmetrical basal ganglia calcifications, neuropsychiatric symptoms, and parathyroid gland dysfunction. The pathophysiological mechanisms underlying intracerebral calcifications in Fahr's

syndrome remain poorly understood. Most authors suggest a metabolic disorder of oligoglial cells, leading to mucopolysaccharide deposits and secondary vascular, perivascular, and calcified lesions. These calcifications predominantly affect the small blood vessels of the basal ganglia. Clinically, they often manifest as neuropsychiatric disturbances. Fahr's syndrome generally has a favorable prognosis, and correcting phosphocalcium metabolism disorders frequently leads to significant improvement.
Conclusion
In cases of phosphocalcium metabolism disturbances, particularly in the presence of associated endocrine disorders, intracerebral calcifications should be systematically investigated. Treatment is based on correcting phosphocalcium metabolism abnormalities.

Do patients with Ehlers–Danlos syndrome and a history of fractures have abnormal thyroid hormone profiles?

Jakub Podstawka[1,2], Ivan Rychlik[3], Jan Domański[1,2], Aleksandra Żuk - Łapan[1,2], Bernadetta Kałuża[1,2] & Edward Franek[1,4]
[1]Department of Internal Medicine, Endocrinology, and Diabetology, National Medical Institute of the Ministry of the Interior and Administration, Warsaw, Poland; [2]Students Scientific Group of the Medical University of Warsaw at the Department of Internal Medicine, Endocrinology, and Diabetology, National Medical Institute of the Ministry of the Interior and Administration, Warsaw, Poland; [3]Department of Internal Medicine, Third Faculty of Medicine, Charles University, and Královské Vinohrady University Hospital, Prague, Czech Republic; [4]Department of Human Epigenetics, Mossakowski Medical Research Institute, Polish Academy of Sciences, Warsaw, Poland.

Background
Joint hypermobility and instability are among the key risk factors for fractures in patients with Ehlers–Danlos syndrome (EDS). Abnormalities in thyroid hormone profile may be associated with the condition of bones and predisposition to fractures. The purpose of this study was to assess thyroid hormone profiles in patients with hypermobile or classical EDS and a history of fractures.
Material and Methods
The study involved a prospective assessment of 30 female patients with either hypermobile or classical EDS. The patients were divided into two groups. Group 1 comprised patients with no history of fractures ($n = 13$), and group 2 comprised patients with a history of fractures ($n = 17$). All patients underwent an assessment of thyroid hormones and parameters of calcium of phosphate metabolism.
Results
The assessed groups showed no differences in terms of such parameters as thyroid stimulating hormone (TSH) (1.691 ± 0.772 vs. 2.439 ± 1.644, $P = 0.209$ [μIU/ml]), free triiodothyronine (fT3) (3.542 ± 0.802 vs. 3.262 ± 0.495, $P = 0.516$ [pg/ml]), free thyroxine (fT4) (1.335 ± 0.15 vs. 1.354 ± 0.276, $P = 0.630$ [ng/dl]), anti-thymocyte globulin (ATG) (25.623 ± 29.141 vs. 41.312 ± 63.209, $P = 0.99$ [IU/ml]), or anti-thyroid peroxidase (ATPO) (49.385 ± 139.919 vs. 26.259 ± 31.054, $P = 0.902$ [IU/ml]) levels. There was no significant correlation between fractures and TSH (Spearman's R 0.237, $P = 0.207$), fT3 (Spearmans R -0.124, $P = 0.513$), fT4 (Spearman's R -0.496, $P = 0.624$), ATPO (Spearman's R 0.029, $P = 0.878$), or ATG (Spearman's R 0.029, $P = 0.878$) levels.
Conclusions
Positive history of fractures in patients with EDS is not associated with thyroid hormone profile abnormalities.

JOINT134

A single-center experience with papillary thyroid carcinoma arising from a thyroglossal duct cyst

Andreia Martins Fernandes[1], Leandro Augusto Silva[1], Ana Rita Elvas[1], Joana Couto[1], Raquel G. Martins[1], Jacinta Santos[1], Teresa Martins[1] & Fernando Rodrigues[1]
[1]Portuguese Oncology Institute of Coimbra, Endocrinology Department, Coimbra, Portugal.

Introduction
The thyroglossal duct cyst is a congenital cyst that arises during the embryological development of the thyroid, resulting from incomplete obliteration of the thyroglossal duct. Malignant transformation is rare (<1%), with papillary thyroid carcinoma being the most common malignancy encountered. Treatment remains controversial, particularly concerning the need for additional interventions following Sistrunk's procedure, such as total thyroidectomy, lymph node dissection, and radioiodine therapy.
Aims
To assess the experience of our center in the management of papillary carcinoma arising from a thyroglossal duct cyst.
Materials and Methods
A retrospective study of patients diagnosed with papillary carcinoma arising from a thyroglossal duct cyst, followed at our center between 1987 and 2023.
Results
A total of 10 patients were included in the study, with a predominance of females ($n = 6$). The median age at diagnosis was 59 years. All patients initially presented with a painless cervical mass. In 9 cases, the diagnosis was established postoperatively. Seven patients underwent Sistrunk procedure, while 3 underwent cyst excision. Total thyroidectomy was performed in all cases, with 3 patients undergoing the procedure during the same surgical time and 7 in a subsequent operation. During total thyroidectomy, prophylactic central compartment lymph node dissection was performed in 4 patients, and 1 of these also underwent lateral cervical lymph node dissection due to the presence of lymphadenopathy. Papillary carcinoma was concurrently identified in the thyroidectomy specimen in 5 patients; 4 of these were microcarcinomas, and the remaining had a tumor measuring 12 mm. Lymph node metastases were identified in 3 patients. Nine patients received radioactive iodine therapy. An excellent response was observed in 9 patients, while 1 patient remains under surveillance with a biochemical incomplete response, exhibiting a stable thyroglobulin level of less than 1.8 ng/ml. The median follow-up period was 131 months.
Conclusions
Currently, there are no universally accepted guidelines for the management of papillary carcinoma arising from a thyroglossal duct cyst. While fine-needle aspiration cytology is commonly used, its diagnostic accuracy is limited, with the majority of diagnoses being confirmed postoperatively through histopathological examination. The diagnosis of papillary thyroid carcinoma originating from a thyroglossal duct cyst requires a thorough evaluation of both the thyroid gland and bilateral cervical lymph nodes. Regarding treatment, the favorable outcomes observed in our cohort suggest that an overly aggressive approach may not be necessary in most cases. Instead, an individualized treatment strategy, tailored to each patient's specific risk factors, may be more appropriate.

Steroid-responsive encephalopathy in graves' disease: a rare case of neuropsychiatric symptoms in thyroid autoimmunity

Teresa Guimaraes[1,2], Fátima Santos[1] & Jorge Herbert[1]
[1]Unidade Local de Saúde Tâmega e Sousa, Penafiel, Portugal; [2]Unidade Local de Saúde Tâmega e Sousa, Critical Care Medicina, Penafiel, Portugal.

Introduction
Graves' disease is an autoimmune syndrome primarily characterized by hyperthyroidism, which can also present with goiter, ophthalmopathy, and myxedema. Hyperthyroidism results from thyrotropin receptor antibodies (TRAb) that stimulate thyroid hormone production. While steroid-responsive encephalopathy associated with autoimmune thyroiditis (SREAT) is often linked to Hashimoto's thyroiditis, its occurrence in Graves' disease is rare. SREAT typically presents with confusion, altered consciousness, and seizures, and may involve autoimmune vasculitis rather than abnormal thyroid hormone levels. We report a rare case of SREAT in a patient with Graves' disease, presenting with severe neuropsychiatric symptoms.
Methods
A 48-year-old woman presented to the emergency department with disorientation, disinhibition, speech impairment, inability to walk, and visual hallucinations. Her history included depression, anxiety, and recent hyperthyroidism diagnosis.
Results
Extensive diagnostic testing revealed elevated thyroid hormones, suppressed TSH, high anti-TPO antibodies, TRAb, and TSI, leading to a diagnosis of SREAT associated with Graves' disease. Treatment with high-dose intravenous methylprednisolone, followed by oral corticosteroid tapering, resulted in complete neurological and psychiatric recovery.
Conclusions
This case underscores the importance of recognizing SREAT in patients with Graves' disease and neuropsychiatric symptoms. Prompt diagnosis and corticosteroid therapy can lead to full recovery, highlighting the need for clinical awareness of this rare condition. Further research is essential to improve diagnostic precision and treatment protocols for SREAT in thyroid autoimmunity.

Routine clinical analysis of BRAFV600E and TERT promoter variants in advanced thyroid carcinomas

Sorina Schipor[1], Octavian Alexandrescu[1,2], Sorin Dutulescu[2,3], Andrei Muresan[1], Dana Manda[1], Dumitru Ioachim[1], Dana Terzea[1], Carmen Cristea[1] & Mihai-Constantin Ceausu[1,2]
[1]"C. I. Parhon" National Institute of Endocrinology, Bucharest, Romania; [2]"Carol Davila" University of Medicine and Pharmacy, Bucharest, Romania; [3]"Prof. Dr. Matei Bals" National Institute for Infectious Diseases, Bucharest, Romania.

Background
Papillary thyroid carcinoma (PTC) is the most common type of thyroid cancer, generally characterized by a good prognosis. However, a small percentage of PTCs demonstrates a higher aggressiveness and poor outcomes. Recent WHO 2022 classification of thyroid tumors introduced a group of differentiated high-grade thyroid carcinomas (DHGTC), along with poorly differentiated thyroid cancer (PDTC) and anaplastic thyroid carcinomas (ATC) as advanced thyroid cancers. Due to the heterogeneity of diagnostic criteria and the rarity of the disease, molecular characterization of these tumors is needed.
Objectives
This is a single-center study investigating the presence of BRAFV600E and *TERT* promoter variants C228T and C250T in a group of patients routinely investigated for these genetic markers.
Materials and methods
All cases were successfully investigated by Sanger sequencing for the BRAFV600E, C228T and C250T *TERT* promoter variants using genomic DNA extracted from formalin-fixated paraffin-embedded (FFPE) tumor material.
Results
We included in the analysis a group of 23 patients (18-83 y) tested from 2023 to 2024 due to an adverse course of disease (loco-regional or distant metastases, radioiodine treatment resistance, high-risk histopathological features). After histopathological characterization, there were 13 DHGTC, 1 iefvPTC (invasive encapsulated follicular variant of papillary thyroid carcinomas), 4 PDTCs and 3 ATCs. We also included 2 patients with invasive PTC, molecularly tested in their nodular metastasis. The overall occurrence of BRAFV600E variant was 19/23 cases (82,6%). C228T was identified in 5/23 cases (21.7%). We did not identify C250T variant in any cases. Simultaneous presence of BRAFV600E and C228T was observed in 5 cases (3 PDTCs and 2 DHGTC). The co-occurrence of the variants was observed in patients older than 45 y.o, except for one patient of 32 y.o, with nodular metastasis and invasive PTC. Another patient had both variants in microPTC, coexisting with a medullary thyroid carcinoma on the same lobe.
Conclusions
A proper molecular stratification is crucial to select the group of patients at high risk of unfavorable PTC course and simultaneously to avoid overtreatment in low-risk cases.

Thyroid cancers in children: pathological and therapeutic specificities

Malika El Omri[1], Nawress Thabet[2], Linda Misbah[1], Mouna Belakhdher[1], Jihene Houas[1], Abir Meherzi[1], Monia Ghammam[1], Hamza Elfekih[3], Wassim Kermani[1] & Mohamed Abdelkafi[1]
[1]Farhat Hached Hospital, Department of ENT and Head and Neck Surgery, Sousse, Tunisia; [2]Farhat Hached University Hospital, ENT Department, Sousse, Tunisia; [3]Farhat Hached Hospital, Department of Endocrinology, Sousse, Tunisia.

Introduction
Thyroid cancers in children are rare but often present with distinct clinical features, including higher rates of malignancy and advanced disease at diagnosis.
Objective
To analyze the clinical, paraclinical and therapeutic characteristics of pediatric thyroid cancers.
Methods
A retrospective review of children under 18 years of age who underwent surgery for thyroid nodule between January 2000 and December 2024 was conducted.
Results
Among 4920 surgeries for thyroid disease, only 29 cases (0.6%) involved children, with a mean age of 14.4 years. Most patients presented with anterior cervical swelling (82.7%), with a mean symptom duration of 11 months. Ultrasonography revealed single thyroid nodules in 58.6% and multinodular goiters in 41.4%, with malignancy suspected in 17.2%. Fine-needle aspiration cytology was performed in seven cases, confirming papillary thyroid carcinoma (PTC) in two patients. Surgical indications included compressive symptoms (51.7%), nodules >3 cm (38%), Bethesda IV cytology (6.9%), and suspected metastasis (3.4%). Total thyroidectomy (was performed in 27.6%, while hemithyroidectomy was performed in 44.8%. Lymph node dissections were performed in 27.6% of cases. Histopathological examination revealed benign lesions in 86.2% of cases, including multinodular goiters, adenomas, and lymphocytic thyroiditis. PTC was diagnosed in four patients (13.8%), with advanced disease (lung metastases) in one case. Complications occurred in 48.3% of cases, primarily transient hypoparathyroidism (41.3%). Radioactive iodine therapy was administered in PTC cases, with favorable outcomes and no recurrence reported after follow-up of 15 months.
Conclusion
Thyroid cancers in children are rare, with most lesions being benign. However, papillary thyroid carcinoma can occur, often at advanced stages. Early detection and tailored treatments, including surgery and radioactive iodine, are essential. Despite challenges, outcomes are generally favorable with multidisciplinary care.

JOINT2105

Relationship between high bone turn over and tsh receptor antibodies in patients newly diagnosed with Graves' disease

Wafa Ben Hilel[1], Imen Rojbi[1], Asma Krir[2], Sabrine Mekni[1], Sawsen Essayeh[1], Rihab laamouri[1], Karima Khiari[1] & Ibtissem Ben Nacef[1]
[1]Charles Nicolle Hospital, Endocrinology, Tunis, Tunisia; [2]Pasteur Institute, Clinical Biochemistry and Hormone Laboratory, Tunis, Tunisia.

Background
Graves' disease is the most common etiology of hyperthyroidism which is a cause of secondary osteoporosis. Thyrotropin (TSH) is known to affect directly the bone metabolism through the TSH receptor and TSH receptor antibodies (TRAb) may have an important role in bone turn-over. This study aimed to determine the correlation between TRAb and bone remodeling markers (BRMs) in patients newly diagnosed with Graves' disease.
Patients and methods
We performed a cross-sectional study at the endocrinology department of Charles Nicolle Hospital in Tunis, Tunisia including newly diagnosed patients with Graves' disease from Juin to Decembre 2023. Subjects with co-morbidities (hyper or hypoparathyroidism, inflammatory bowel disease, malabsorptive disorder, renal disease, chronic liver disease, Cushing's disease, hypogonadism), pregnant, breast-feeding or menopausal women or history of drug use (steroid, bisphosphonates, calcium or vitamin D) were not included in the study. BRMs involving total alkaline phosphatase (ALP), osteocalcin (OSC) and Carboxy-terminal telopeptide of type I collagen (CTX-I) were assessed in Clinical Biochemistry and Hormone Laboratory of Pateur Institute.
Results
Our study population consisted of 34 patients newly diagnosed with Graves' disease with a higher prevalence of female subjects (76,5%). Mean age of participants was 38,5 $\pm$ 10,4 years. Mean level of free thyroxine (FT4) and TSH were respectively 3,5 $\pm$ 1,9 ng/dl [NR: 0,7–1,8 ng/dl] and 0,02 $\pm$ 0,01 mUI/l[NR: 0,4 – 4 mUI/L]. Mean level of TRAbs was 20,4 $\pm$ 12,6 UI/l[NR: $<$ 2UI/L]. Elevated levels of ALP, osteocalcin, and CTX-I were observed in 24,2 %, 42,4%, and 45,5 % of patients, respectively, based on laboratory reference ranges. TRAb levels were positively and significatively correlated to PAL ($P = 0,01$) and osteocalcin ($P = 0,03$). Although TRAb levels vary in the same direction as CTX levels, this association wasn't significant ($P > 0,05$). Receiver operating characteristic (ROC) analysis identified a significant TRAb cut-off value for predicting elevated ALP and osteocalcin levels. The ROC-determined cut-off was 44 UI/l,with a sensitivity of 66.7% and a specificity of 87.5% for predicting elevated ALP. The same cut-off value predicted elevated osteocalcin with a sensitivity of 83.3% and a specificity of 44.4%.
Discussion and Conclusion
This study reveals a positive correlation between TRAb and BRMs in patients newly diagnosed with Graves' disease. This suggests a detrimental impact of TRAb on bone metabolism in the context of hyperthyroidism. Importantly, normalization of the autoimmune abnormality occurs significantly later than the restoration of euthyroidism, with TRAb levels gradually disappearing over an extended period.

Thyroglossal duct cysts: diagnosis and management

Mehdi Ferjaoui[1], Misbah Linda[1], Meriem Grassa[1], Nawres Bouaziz[1], Rachida Bouatay[1], Amel El Korbi[1], Nawres Kolsi[1], Khaled Harrathi[1] & Jamel Koubaa[1]
[1]Fattouma Bourguiba University Hospital, Monastir, Tunisia.

Introdution
Thyroglossal duct cysts (TGDCs) are the most common congenital midline neck masses in the pediatric population. TGDCs result from incomplete involution of the thyroglossal duct, which guides the descent of the thyroid gland from the base of the tongue to the thyroid. There are several indications for their removal, including recurrent infections, sinus formation and risk of malignancy. This article reviews the clinical presentation, diagnosis, and surgical management of TGDCs in children.
Material and method
This is a retrospective study conducted in the ENT department at Fattouma Bourguiba Hospital in Monastir over a four-year period, from January 2021 to December 2024, involving 45 cases of thyroglossal duct cysts.
Observation
The mean age was 6.37 years, with extremes ranging from 3 to 15 years, and the sex ratio was 0.83 (20 males/24 females). One child had previously undergone surgery for hydrocele. These children presented with cervical swelling that had developed since birth, with a history of infection in 9 cases. On examination, an infrahyoid swelling ranging from 0.5 to 4 cm was noted, mobile on tongue protrusion and swallowing, with the presence of a fistula and serous discharge in 9 cases. Ultrasound findings were consistent with a thyroglossal duct cyst in all 45 cases. Surgical excision using the modified Sistrunk procedure was performed in all cases with an uneventful postoperative course.
Conclusion
A persisting thyroglossal duct may lead to cysts or fistulas. The most common method of treatment is complete resection through the Sistrunk procedure. This technique effectively removes the cysts and reduces recurrence rates.

JOINT1557

Long-term follow-up of nodular goiter – experience in fukushima area of north-east Japan

Takao Kunori[1] & Hiroshi Yoshida[1]
[1]Iwaki-city medical center, Department Surgery, Iwaki-city, Japan.

Background
Benign thyroid nodules (NOD) has been generally considered to have no operative indication. However, long-term course is still unclear. In the present study, we reviewed 18 years' NOD cases, including a year of nuclear power plant accidents (NPP, 2011), to find out its natural course.
Patients and Methods
6,553 Japanese patients (2007-2024), who live in iodine rich lands of Fukushima, visited our thyroid clinic; mean age, 60 (female, 81%). Follow-up study was performed in 1,551 patients (4,883 times; 0- 18 years). Assays: Serology was performed for thyroid peroxidase antibody (TPO), anti-thyroglobulin antibody (TgAb), thyroid stimulating hormone receptor antibody (TRAb) and, in some patients, thyroid stimulating hormone antibody (TSAb). Hormonal assay was performed for free thyroxine (F-T4), free triiodo-thyronine (F-T3), thyroid stimulating hormone (TSH) and thyroglobulin (Tg). Cytology of NOD: Fine needle aspiration cytology (FNA); class 1 (normal), 7.3%; class 2 (benign), 42%; class 3 (malignancy not ruled out), 2.3%; class 4 (suspicious), 0.2%; class 5 (malignant), 3.0%; Solid 57%,?Cyst?43%. Changes of NOD: Enlargement rates of nodules (VR%, size%) were calculated from a formula; current VL(volume) /initial VL and size/initial size (of FNA nodules).
Results
1) VR%: 24% down and(vs) 12% (46% no change: 1-year), 20% vs 15% (56%: 2-year). 16% vs 13% (49%: 3-year), 28% vs 11% (52%: 5-year) and 9.7% vs 5.3% (74%: 10 year). 2) Factors related with VR% (over 10 years): 3 factors had significant; thyroglobulin (Tg) as a UP factor, Tg/VL and age as DOWN factor. 3) Prediction of VR% after 5 years: a) Size at first visit: Increased size was 50% in 10-15 mm (initial size), whereas unchanged (60%) or decreased (27%) in 20-29mm. b) Tg: Tg/VL was associated with TgAb. 4) Influence of NPP accidents: There was no influence to statistics of NOD.
Discussion
A half of NOD remained unchanged/reduced. Up VL (200%-) generally observed in small NOD. Long term follow-up seemed not always necessary if FNA confirmed benign. Significance of autoantibodies was unclear. However, we do not know if these results are also applied to non-Japanese people.

Vitamin D supplementation to prevent post-thyroidectomy hypocalcemia

Jeresa Willems[1], Daan van Twist[1], Annette Pijnenburg[2], James van Bastelaar[2], Marco Medici[3], Robin Peeters[3] & Roderick Tummers - de Lind van Wijngaarden[1]
[1]Zuyderland Medical Center, Internal Medicine, Heerlen/Sittard-Geleen, Netherlands; [2]Zuyderland Medical Center, Surgery, Sittard-Geleen, Netherlands; [3]Erasmus Medical Center, Internal Medicine, Rotterdam, Netherlands.

Background
Hypocalcemia is a common complication of thyroidectomy, often necessitating hospitalization for calcium supplementation. Previous studies yielded contradictory results on whether cholecalciferol prevents postoperative hypocalcemia, and most were conducted in non-Western countries with different dietary habits and baseline vitamin D levels. Therefore, we aimed to investigate the effect of preoperative cholecalciferol on post-thyroidectomy hypocalcemia in a Dutch population.
Methods
Patients who underwent thyroidectomy between 2023-2025 received 100,000 IU cholecalciferol one week preoperative ('vitamin D group') and were compared to a historical cohort (2019-2022) who did not receive cholecalciferol supplementation ('control group'). Outcomes included incidence of post-thyroidectomy hypocalcemia (<2.00 mmol/L,24h,48h,72h, >72h postoperative), need for postoperative supplementation, time until normocalcemia, length of hospital stay, and hospital readmission.
Results
Fifty patients received preoperative cholecalciferol and were compared to 154 control patients (82.8% female, median age: 55 years [IQR:43-66]). Hypocalcemia occurred less frequently in the vitamin D group (cumulative incidence: 16.0% vs. 35.1%, $P = 0.01$ for biochemical and 12.0% vs. 24.0%, $P = 0.07$ for symptomatic hypocalcemia). Preoperative cholecalciferol supplementation was associated with a reduced risk of hypocalcemia (OR 0.27,95%CI:0.11-0.68, $P = 0.005$). Furthermore, the vitamin D group demonstrated a lower need for postoperative supplementation (32.0% vs. 53.9%, $P = 0.007$) and faster recovery to normocalcemia (0[0-2] vs. 3[0-11] days, $P = 0.002$). No differences were observed in length of hospital stay and hospital readmissions.
Conclusion
A preoperative dose of 100,000 IU cholecalciferol was associated with a significant reduction in post-thyroidectomy hypocalcemia. With a number needed to treat of 5 patients to prevent one case of hypocalcemia, this inexpensive and safe intervention could be considered for routine use in patients undergoing thyroidectomy.

Trends of thyroglobulin and dynamic risk stratification in thyroid nodule cancer without radioiodine ablation

Pablo Fernández Velasco[1], Lucia Estévez Asensio[1], Beatriz Torres Torres[1], Daniel De Luís Román[1] & Gonzalo Díaz Soto[1]
[1]Hospital Clinic Universitario de Valladolid, Endocrinología y Nutrición, Valladolid, Spain.

Objective
To analyze the progression of plasma thyroglobulin (Tg) levels and dynamic risk stratification (DRS) in patients diagnosed with differentiated thyroid cancer (DTC) without radioactive iodine treatment in a thyroid unit.
Materials and Methods
A prospective study was conducted on all patients who underwent thyroidectomy or hemithyroidectomy with a diagnosis of DTC and did not receive radioactive iodine treatment between 2020 and 2024. Clinical, biochemical, and imaging data were collected at diagnosis and during follow-up.
Results
A total of 66 patients without radioactive iodine treatment were evaluated (80.3% women, mean age 55.6 ± 11.7 years, 72.7% were diagnosed incidentally and an

average DTC follow-up of 2.0±1.3 years). The most common DTC subtype was classic papillary carcinoma in 42.4% of cases. Total thyroidectomy was performed in 75.8% of patients, while 24.2% underwent hemithyroidectomy. The mean tumor size was 8.0±7.2 mm (30.3% of cases >1 cm). Histopathological characteristics included multifocality in 31.8% of cases, bilaterality in 21.2%, and capsular invasion in 18.2%. The tumor stage was I, with all patients classified as having a low risk of recurrence. When evaluating DRS (Momesso *et al.*) in the total cohort three months after surgery, 39.3% of patients had an indeterminate response (IR), 57.1% had an excellent response (ER), and 3.6% had a biochemical incomplete response. At the end of the mean follow-up, 60.5% had an ER, while 39.5% had an IR (P <0.05). However, there were no significant differences in Tg levels during follow-up, either in the overall sample (1.5±2.3 vs. 1.3±1.2, not significant) or by type of surgery. Among those patients who underwent total thyroidectomy, 88% had Tg <1 ng/ml, whereas 100% of those who underwent hemithyroidectomy had Tg <30 ng/ml. When correlating baseline circulating Tg levels with those from the last follow-up visit, a strong positive correlation was observed (r = 0.916, P <0.001). However, no correlation was found with TSH levels. Finally, when analyzing initial DRS in total thyroidectomy patients in relation to different clinical and histopathological characteristics, no significant differences were found in age, sex, or histological features predicting disease progression, except for a larger tumor size in the IR group (8.7±4.9 vs. 6.4±3.2 mm, P <0.05).

Conclusions

A total of 60.5% of patients exhibited an ER from diagnosis, maintaining stability during follow-up despite not receiving radioactive iodine treatment. DRS was associated only with tumor size and not with other clinical or histological features. Baseline circulating Tg levels correlated with final Tg levels.

Growth profiles in children with congenital primary hypothyroidism before and after the relaunching of newborn screening programme in dr soetomo hospital

Rayi Kurnia Perwitasari[1,2,3], Yuni Hisbiyah[1,2,3], Nur Rochmah[2,3] & Muhammad Faizi[2,3]

[1]Pediatric Subspecialty (Consultant) program, Faculty of Medicine, Universitas Airlangga, Surabaya, Indonesia; [2]Department of Child Health, Faculty of Medicine, Universitas Airlangga, Surabaya, Indonesia; [3]Department of Child Health, Dr. Soetomo General Academic Hospital, Surabaya, Indonesia.

Background

Congenital hypothyroidism (CH) is a common endocrine disease that can cause significant developmental delays and growth failure. The thyroid hormone is essential for adequate growth and development, especially throughout foetal life and early infancy. Newborn screening (NBS) programs have markedly enhanced the early identification and treatment of congenital hypothyroidism. The Indonesian Ministry of Health has relaunched NBS program by the end of 2023. The aim of this study is to compare the growth profile at birth, at the first time of diagnosis, and after treatment of the children with CH who were diagnosed without screening and who were diagnosed through the screening program.

Methods

15 children who had been diagnosed with CH before the relaunching of the NBS program (non-NBS group) and 6 children who were diagnosed by the NBS program (NBS group) were included. fT4, TSH, weight, and height data were obtained from the medical record. Weight and height were transformed into z-scores standard deviation (SDS) according to the WHO growth chart. The data were processed with independent t-test using RStudio, with P < 0.05 considered significant.

Results

The mean age of diagnosis in the non-NBS group was 877 days, and in the NBS group was 24.6 days old. Average fT4 in the non-NBS group is 0.233 ng/dl, and in the NBS group is 0.52 ng/dl. The mean of the TSH level in the non-NBS group is 322.78 mLu/l,and in the NBS group, it is 228.9 mLu/L. There are no differences between birth weight SDS and birth length SDS between the non-NBS group vs. the NBS group (-0.11 vs. -0.92; P = 0.16) and (-0.14 vs. -0.41; P = 0.56), respectively. There are differences in weight SDS between the non-NBS group vs. the NBS group (-2.73 vs. -0.37; P < 0.01) and no differences in height SDS (-2.72 vs. -0.51; P = 0.08). Even after both groups were adequately treated, there are still differences in weight SDS and height SDS in the non-NBS group vs. the NBS group (-2.14 vs. -0.6; P < 0.05) and (-2.5 vs. -0.25; P < 0.05).

Conclusions

Primary congenital hypothyroidism is initially asymptomatic, the diagnosis can be delayed without screening, and the child may be exposed to hypothyroid conditions for a long time, leading to growth failure. Early diagnosis and treatment of congenital hypothyroidism are essential for improving growth and developmental outcomes. The optimal growth potential can be achieved through continuous monitoring and appropriate management.

JOINT2431

A case with TSHB gene mutation presenting with neuromotor retardation

Sibel Baykut[1,2], Yasemin Denkboy Öngen[1] & Erdal Eren[1]

[1]Uludag University, Pediatric Endocrynology, Bursa, Türkiye; [2]Uludag University, Bursa, Türkiye.

Introduction

Pathogenic variants in the TSHB gene are known to cause severe isolated central congenital hypothyroidism (CH). Mutations in this gene are associated with congenital central hypothyroidism, secondary hypothyroidism, and Hashimoto's thyroiditis. We present the clinical, biochemical, and genetic features of a patient with a central CH phenotype.

Case

A 9-year-old female patient demonstrated delayed developmental milestones, with head control achieved at 9 months and the ability to walk at 2 years of age. She was born with right femoral agenesis and underwent prosthetic surgery at the age of 2. Additionally, she has sensorineural hearing loss and intellectual disability. During the investigation, at the age of 1.5 years, laboratory findings revealed Free T4: <0.4 ng/dl and TSH: 3.25 µU/ml. As a result, L-thyroxine treatment was initiated. The parents are consanguineous (second-degree relatives) . The other two siblings are healthy and alive, and there is no similar medical history in the family. Karyotype analysis revealed a normal female karyotype (46, XX). A homozygous pathogenic variant, c.205C>T (p.Gln69*), in the TSHB gene (NM_000549.4) was identified. Sanger sequence analysis revealed that parents were heterozygous. Microarray: arr(1-22)x2,(X)x2, normal Pituitary MRI was normal, and all other pituitary hormones, including prolactin (PRL), were secreted at normal levels. Following the initiation of L-thyroxine therapy, the patient showed positive improvements in neuromotor development.

Conclusion

Isolated TSH deficiency is not detected by routine neonatal TSH-based screening, which represents a significant clinical challenge. In particular, infants presenting with neuromotor retardation in neurology clinics should have thyroid function evaluated, including Free T4 and Free T3 levels. In this case, delayed diagnosis and treatment of profound central hypothyroidism contributed to neurodevelopmental delays.

JOINT2676

Harmonization of thyroid function test measurements across multiple immunoassay platforms for a common reference interval

Kyu Won Cho[1], So Young Kang[2], Min Young Lee[2], Myeong Hee Kim[2] & Woo In Lee[2]

[1]Kyung Hee University Hospital at Gangdong, Seoul, South Korea; [2]Kyung Hee University College of Medicine, Seoul, South Korea.

Background

Thyroid function tests (TFTs) are among the most frequently performed immunoassays in clinical laboratories. However, the lack of standardized reference materials and methods has led to significant variability in results among different manufacturers, making standardization challenging. Additionally, reference intervals (RIs), which are essential for accurate interpretation, vary across analytical methods. This study aims to establish a common RI applicable across multiple automated immunoassay platforms using percentile transformation.

Methods

We analyzed randomly selected samples covering a wide concentration range (TSH: 283 samples, T3: 265 samples, fT4: 283 samples) from Kyung Hee University Hospital at Gangdong. These samples were tested on the three most widely used automated immunoassay analyzers in South Korea (Abbott Alinity i, Beckman Coulter DxI 800, and Roche cobas e801) to measure TFT values simultaneously. Using percentile transformation, regression analysis was conducted to derive recalibration equations. These equations were applied to TFT measurements from 120 healthy individuals, each tested on all three platforms. Healthy individuals were selected based on normal blood test results from a health screening center, absence of

suspected thyroid disease on ultrasound, and negative anti-thyroglobulin antibody (Anti-TG) test and anti-thyroid peroxidase antibody (Anti-TPO) tests. RIs were determined using the nonparametric percentile method (2.5th–97.5th percentiles). The final common RI was derived by integrating the recalibrated results from all three platforms, ensuring a common RI across different methods.
Results
Recalibration effectively minimized method-dependent discrepancies in RI values. The common TSH RI (0.51–4.08 μIU/ml) reduced inter-method variability, narrowing the differences observed across method-specific RIs: Abbott (0.52–4.08), Beckman Coulter (0.49–4.27), and Roche (0.50–3.99). For triiodothyronine (T3), the common RI (0.71–1.41 ng/ml) significantly reduced variations among Abbott (0.84–1.40), Beckman Coulter (0.78–1.47), and Roche (0.65–1.27), demonstrating the most pronounced improvement. Similarly, for free thyroxine (fT4), the common RI (0.84–1.42 ng/dl) narrowed the gap between platform-specific values: Abbott (0.83–1.39), Beckman Coulter (0.83–1.32), and Roche (0.97–1.46). Among the three markers, T3 exhibited the greatest reduction in variability after recalibration, while TSH and fT4 also showed notable improvements in cross-platform consistency.
Conclusions
Harmonization of TFT results using recalibration equations successfully minimized inter-method variability, enabling the establishment of a common RI. This approach improves result interpretation across immunoassay platforms and ultimately enhances clinical decision-making. Future research should validate the RI in independent populations, assess its clinical applicability, and evaluate its stability across different platforms to ensure reliability and facilitate widespread adoption.

Characteristics of papillary thyroid carcinoma in men

Majda El Baidouri[1], Nassim Essabah Haraj[1], Siham El Aziz[1] & Asma Chadli[1]
[1]CHU Ibn Rochd, Clinical Neurosciences and Mental Health Laboratory, Faculty of Medicine and Pharmacy, Hassan II University, Casablanca, Morocco, Department of Endocrinology, Metabolic Diseases, and Nutrition, Casablanca, Morocco.

Introduction
Papillary thyroid carcinoma is the most common type of thyroid cancer. Although it is more prevalent in women, its occurrence in men is often associated with a poorer prognosis.
Objective
In this context, we conducted a descreptive study aiming to highlight the clinical and histoprognostic characteristics of papillary carcinoma in men.
Materials and Methods
Our study included all male patients followed in the endocrinology department of Ibn Rochd University Hospital in Casablanca for thyroid carcinoma between 2000 and 2024.
Results
The study population comprised 59 patients, with an average age of 50 years (mean age: 50 $\pm$ 14.5 years). The follicular variant of papillary carcinoma was the most frequently observed in 35% of patients. Six percent of the patients presented with poor prognostic variants, primarily the oncocytic variant in two cases. Thyroid carcinoma was associated with other neoplasms in 6% of cases. It was unifocal in 71% of patients. Regarding recurrence risk, 5% were at high risk, and 20% at intermediate risk. Lymph node dissection was performed in 13% of cases, with positive findings in three patients. Vascular emboli were present in 16% of cases, and 11% exhibited thyroid capsule invasion. Radioiodine therapy was indicated for 62% of patients. Two patients had secondary metastases, and three retained residual tumor tissue.
Conclusion
Papillary thyroid carcinoma generally has a favorable prognosis. However, its association with the male sex may be linked to a less reassuring prognosis, with a higher frequency of radioiodine therapy and a risk of residual tumor.

Endocrine surveillance: detecting recurrent graves' disease in ectopic thyroid and primary hyperparathyroidism post-radioiodine treatment

Paula Sprovera[1], Catarina Saraiva[1], Carolina Monteiro Antunes[1], Catarina Gama[1], Bruna Pimentel[1] & Margarida Oliveira[1]
[1]Egas Moniz Hospital - ULSLO, Endocrinology, Lisbon, Portugal.

The occurrence of Graves' disease in ectopic thyroid tissue following total thyroidectomy is a rare event, as is the coexistence of Graves' disease and primary hyperparathyroidism. While both conditions are relatively common in endocrinology practice, their concurrent presentation is unusual, raising the possibility of an association with prior radioiodine (RAI) therapy. RAI-induced hyperparathyroidism has an average latency period of 24 years, with this period decreasing as the patient's age at the time of RAI treatment increases. This case report describes the rare occurrence of recurrent Graves' disease in ectopic thyroid tissue, complicated by primary hyperparathyroidism, in a patient with a history of RAI treatment.
Case Report
A 47-year-old woman with a history of Graves' disease initially presented with an enlarged, nodule-free goiter. Following unsuccessful thionamide treatment, she underwent total thyroidectomy for compressive symptoms and subsequently developed hypothyroidism. Four years later, a progressively enlarging mass appeared in the right anterior neck. Elevated and rising levels of thyroid-stimulating immunoglobulin and thyroid-stimulating hormone receptor antibodies were observed, necessitating levothyroxine dose reduction and eventual cessation due to subclinical hyperthyroidism. Ultrasound revealed a 3 cm, hyperechogenic, hypervascularized nodule in the infrahyoid region. A subsequent scintigraphy confirmed hyperfunctioning ectopic thyroid tissue in this location. Following 10 mCi of I-131 RAI therapy, hyperthyroidism resolved, and cervical ultrasound remained stable for eight years. At that point, an hypoechoic nodular lesion was detected in the right inferior thyroid bed, accompanied by hypercalcemia (11.7 mg/dl), elevated PTH (180 pg/ml), and normal vitamin D levels. Parathyroid scintigraphy confirmed hyperfunctioning parathyroid tissue in the right suprasternal region. The patient underwent right parathyroidectomy, resulting in resolution of hypercalcemia and hyperparathyroidism.
Conclusion
Recurrent Graves' disease due to hyperfunctioning ectopic thyroid tissue after total thyroidectomy is a rare phenomenon. Remnant or ectopic thyroid tissue can become hyperfunctional in the presence of thyroid-stimulating hormone receptor antibodies, leading to growth and presenting as a mass. This case highlights also the rare coexistence of Graves' disease and primary hyperparathyroidism, potentially associated with prior RAI treatment. Post-RAI treatment, we recommend periodic serum calcium level monitoring every 3–5 years. This case emphasizes the importance of long-term follow-up and vigilant surveillance for new or emerging endocrine abnormalities, including hyperparathyroidism, even years after initial therapies.

JOINT3972

Synchronous medullary and papillary thyroid carcinoma: a clinical case

Patricia Ferreira[1,2], P. Andrea-Ferreira[3], Jorge Pinheiro[4,5] & Elisabete Rodrigues[1,2,5]
[1]Serviço de Endocrinologia, Diabetes e Metabolismo, ULS São João, Porto, Portugal; [2]Faculdade de Medicina da Universidade do Porto, Porto, Portugal; [3]Serviço de Cirurgia Endócrina, ULS São João, Porto, Portugal; [4]Serviço de Anatomia Patológica, ULS São João, Porto, Portugal; [5]ENDO-ERN, Amsterdam, Netherlands.

Introduction
Thyroid carcinomas represent the most common endocrine malignancies, with papillary thyroid carcinoma (PTC) accounting for the majority of cases. Medullary thyroid carcinoma (MTC), arising from parafollicular C cells, is less frequent and follows a distinct clinical course. The coexistence of MTC and PTC in the same patient is an unusual finding with significant implications for diagnosis, genetic screening, and treatment. Understanding the interaction between these malignancies is crucial for optimizing outcomes.
Case Presentation
A 70-year-old male, ex-smoker with a history of arterial hypertension, and coronary artery disease was under investigation for a stable pulmonary nodule. During the work-up a PET DOTA-NOC scan revealed intense radiotracer uptake in the superior pole of the right thyroid lobe, with no uptake in the pulmonary nodule, prompting referral to endocrinology for further evaluation. Biochemical evaluation revealed normal TSH, high calcitonin (285pg/ml; N: $<$9.52) and CEA (5.3ng/ml; N:0-3) levels. Urinary metanephrines were normal. Cervical ultrasound showed two EU-TIRADS 4 thyroid nodules, on the right with 15x8x14mm and on the left with 10x8x11mm. FNA of the right nodule was consistent with medullary thyroid carcinoma. In this context, the patient underwent total thyroidectomy with central compartment neck dissection. Histopathology disclosed a 9mm MTC confined to the thyroid (pT1aN0R0) and

two out of seven central lymph nodes with PTC metastasis, the largest with 3mm and extranodal extension. After full inclusion of the surgical specimen an incidental 3mm PTC was identified in the left lobe (pT1aN1aR0, ATA high risk). Postoperatively, calcitonin levels declined to 1.6 pg/ml, indicating a favorable response. The patient is currently awaiting genetic testing and is scheduled to undergo radioiodine therapy with 150mCi for the PTC.
Discussion
The synchronous occurrence of medullary and papillary thyroid carcinomas is rare, accounting for approximately 19% of all MTC cases and 0.28% of all PTC cases. While MTC originates from parafollicular C cells and is frequently associated with RET mutations, PTC arises from follicular cells and commonly harbors BRAF or RAS mutations. The coexistence of these two malignancies raises questions about potential shared pathogenic mechanisms. Classic genetic alterations found in isolated MTC and PTC do not seem to play a role in synchronous cases, suggesting independent oncogenic pathways. Although the simultaneous presence of these malignancies does not appear to significantly alter their individual clinical behaviors, accurate diagnosis remains challenging. This underscores the need for thorough biochemical and histopathological evaluation to ensure proper management and follow-up.

JOINT3862

Evaluation of the relapse rate in patients with graves disease and its relationship to the great score

Sara Hami Gil[1], Jose Alvaro Romero Porcel[1], Jose Antonio Ariza Jimenez[2], Ana-Belen Ariza-Jimenez[3] & Maria Victoria Cózar León[1]
[1]Hospital Universitario Virgen de Valme, Endocrinology and Nutrition, Sevilla, Spain; [2]Hospital Universitario Costa del Sol, Endocrinology and Nutrition, Marbella (Málaga), Spain; [3]Hospital Universitario Reina Sofia, Instituto Maimonides de Investigación Biomédica de Cordoba. Cordoba University., Pediatric Endocrinology, Cordoba, Spain.

Introduction
Antithyroid drugs are the first step of treatment in patients with Graves' Basedow Disease (GBS). A treatment duration of 12 to 18 months is recommended, however, the relapse rate is high (up to 60% in some series); different authors recommend longer treatments. Vos *et al*. propose a scale (GREAT-Score), which classifies patients into 3 groups according to the risk of recurrence (class-1 lower risk, class-3 higher risk), taking into account age, analytical parameters (T4l, TRAb) and goitre.
Objective
To evaluate relapse in hyperthyroid patients after treatment, according to the duration of treatment and the GREAT-Score.
Material and Methods
Retrospective observational study in patients with GBS diagnosed between June/2020 and December/2020 and their relationship with GREAT Score, with a follow-up of 36 months.
Results
A sample of 54 patients was presented, 76% were women; mean age was 47+/-14.5 years, 33.3% smokers, clinically, nervousness, weight loss, palpitations and ophthalmopathy (67.3%, 46.2%, 29.6, 1.9%, respectively). Regarding the GREAT-Score, 48% were Class 1, 41% Class 2 and 11% Class 3. 59.3% were treated with Carbimazole, 40.7% with Thiamazole. Duration of treatment was less than 12 months in 18.5% of the sample, between 12-18 months in 38.9%, between 18-24 months in 35.2% and above 24 months in 7.4%. 93.8% had no side effects, with hypothyroidism and elevated transaminases (4.2%, 2.1%, respectively). The analytical values (median-ranges) at diagnosis were: TSH 0.01µIUI/ml(0.01-0.01), T4l 3.2ng/dl(1.97-4.58), T3l 9.59pg/ml(5.33-21), TRAb 6. 83U/L(4.04-13.30); at the end of treatment: TSH 1.78µIUI/ml(1.02-2.83), T4l 1.19ng/dl(1.03-1.31), T3l 3.1pg/ml(2.76-3.44), TRAb 1.65 U/L(0.8-1.23). Overall relapse was 46.3%, (66.7% smokers); relapse according to GREAT-Score was 42.3% in Class1 and 50% in class2-3. Relapse according to treatment duration was 60% in those with a duration of less than 12 months, 38% in those with a duration of 12-18 months, 50% in those with a duration of 18-24 months and 25% in those with a duration of 24-30 months.
Conclusions
Relapse in GBS after ATD is high, patients with GREAT-Score class2-3 had a higher relapse than those with class1, and treatment over 24 months had a lower relapse than those with shorter duration. It would be interesting to establish risk profiles (GREAT-Score) prior to pharmacological treatment, thus being able to select those patients who may benefit from longer treatment.

Celiac disease in patients with thyroid disorders: clinical features, diagnosis, and management

Raida Ben Salah[1], Faten Hadj Kacem[1], Nabila Rekik[1] & Zouheir Bahloul[1]
[1]University of Sfax, Internal Medicine, Sfax, Tunisia.

Introduction
Celiac disease and thyroid disorders are both common autoimmune conditions, but their coexistence is less frequently discussed. While both diseases share certain clinical features, their diagnosis can be challenging when they occur together. This study aims to describe the clinical features, diagnostic approaches, and management of patients with celiac disease and thyroid disorders.
Methods
We reviewed the medical records of patients diagnosed with both celiac disease and thyroid disorders at our hospital.
Results
The patients included four women and one man, with a mean age of 22.4 years at the onset of celiac disease (range: 10-39 years). We analyzed the clinical presentation, thyroid function tests, serology, and endoscopic findings. The diagnosis of celiac disease was confirmed by positive anti-transglutaminase antibodies and gastroscopy. The management strategy involved initiating a gluten-free diet for all patients. Among the five patients, thyroid disorders included patent hyperthyroidism in one case, mild hyperthyroidism in one case, hypothyroidism in two cases, and euthyroid thyroidopathy in one case. Celiac disease preceded thyroid dysfunction in three patients, with an average delay of 44 months (range: 24-84 months). In two patients, the diagnosis of celiac disease was concurrent with the thyroid disorder. Clinically, three patients presented with significant weight loss, while one patient had chronic diarrhea. Laboratory findings revealed iron deficiency anemia, malabsorption syndrome, and positive anti-transglutaminase antibodies in three patients. Three patients underwent gastroscopy, which showed typical findings of celiac disease, including flattened and scalloped duodenal folds without mosaic pattern in two cases and a mosaic pattern in one case. All patients were placed on a gluten-free diet, leading to favorable clinical outcomes.
Discussion
Although intestinal absorption disorders can occur in both hyperthyroidism and hypothyroidism independently of celiac disease, celiac disease must be considered in patients presenting with signs of malabsorption. Prompt diagnosis and gluten-free dietary intervention are critical to preventing complications. Recent studies suggest that screening for autoimmune thyroid disorders in patients with celiac disease could be beneficial. The overlapping clinical features of these diseases—such as weight loss, diarrhea, muscle weakness, anxiety, hair loss, and infertility—can complicate diagnosis, especially when hypothyroidism masks some symptoms of celiac disease.
Conclusion
The coexistence of celiac disease and thyroid disorders is relatively common and can complicate diagnosis due to overlapping symptoms. Early recognition of celiac disease in patients with thyroid dysfunction is essential for proper management and to avoid long-term complications.

A decade of thyroid orbitopathy research in albania: a retrospective study from a tertiary referral center

Marjeta Kermaj[1], Megi Lekbello[1], Dorina Ylli[1] & Agron Ylli[1]
[1]U.H.C "Mother Tereza", U.M.T, Endocrinology, Tirana, Albania.

Introduction
Thyroid Orbitopathy (TO), also referred to as Graves' Orbitopathy (GO), is a complex and impactful complication of Graves' disease (GD). Limited data from Albania highlight the need for a deeper understanding of its presentation and management.
Aim
This 10-year retrospective study conducted at a tertiary referral center in Albania analyses the clinical features, diagnostic challenges, and treatment approaches for GO to enhance disease understanding and improve management strategies.
Methods
Data were systematically collected from 178 patients referred for GO evaluation and treatment over a decade. Patient demographics and clinical characteristics were documented using the European Group on Graves' Orbitopathy (EUGOGO) protocol. Cases were categorized as bilateral (asymmetric or symmetric) or unilateral GO, and clinical features were analyzed to identify distinguishing patterns.

Results
Among 178 patients with GO, the mean age was 44.9 ±14.9 years. Bilateral GO was most common (72.5%), followed by unilateral (17%) and unilateral-to-bilateral (10.5%). Asymmetric GO was observed in 30.9% of bilateral cases. GO onset was often concurrent with GD, with female predominance (72.5%). Mild GO was present in 48%, while 52% had moderate to severe forms. Local treatment was effective for mild cases, while 80% of moderate/severe cases responded positively to intravenous glucocorticoids. Hypothyroidism was a significant risk factor for GO activation.
Conclusion
Clinical management should prioritize the overall presentation of GO, emphasizing individualized treatment approaches. Hypothyroidism was identified as a key risk factor for GO activation, highlighting the need for careful thyroid function management to mitigate disease progression.

Prevalence of thyroid nudules in children with idiopathic prcocious puberty or early and fast puberty

Yanhong Li[1], de-lu chen[1], liu-lu xie[1], jun zhang[1] & qiu-li chen[1]
[1]The First Affilated Hospitl of Sun Yat-Sen University, pediatric endocrinology, Canton, China.

Background and Objectives
The aim of the study is to investigate the prevalence of thyroid nodules in children and adolescents with idiopathic central precocious puberty or early and fast puberty.
Methods
From 2020 to 2024, 645 children were diagnosed idiopathic central precocious puberty or early and fast puberty in our center, and accepted thyroid ultrasound examination were enrolled in our study. Results of ultrasound inspections as well as thyroid function were analyzed, and compared with 314 children who had underlying thyroid diseases.
Results
Among 645 children with idiopathic central precocious puberty or early and fast puberty, 254 (39.4%) had thyroid nodules, however, only 85 (27.1%) thyroid nodules were detected in 314 children with underlying thyroid diseases ($P < 0.05$). In children with idiopathic central precocious puberty or early and fast puberty, thyroid nodules were mostly bilateral (70.4%), only 29.6% were unilateral. Ti-RADS showed that 174 cases were grade 1, 60 cases were grade 2, 3 were grade 3, 1 grade 4 and 1 grade 5. Thyroid function was normal, no hyperthyroidism or hypothyroidism was observed. anti-Thyroid antibodies were negative.
Conclusion
Unexpectedly detected thyroid nodules were more than expected in children with idiopathic central precocious puberty or early and fast puberty. The nodular were mostly bilateral. Thyroid ultrasound may be considered in such children and furthe investigations are needed.
Key words
thyroid, central precocious puberty, early and fast puberty, children.

Influence of aromatase inhibitors on thyroid function in postmenopausal women with early-stage breast cancer: a prospective controlled study

Djordje Marina [1], August Nielsen[2], Kristian Buch-Larsen[1], Michael Andersson[3], Åse Krogh Rasmussen[1] & Peter Schwarz[1]
[1]Rigshospitalet, Department og Nephrology and Endocrinology; Endocrinology Research Unit, Copenhagen, Denmark; [2]Rigshospitalet, København S, Denmark; [3]Rigshospitalet, Department of Oncology, Copenhagen, Denmark.

Purpose
Aromatase inhibitors are frequently used in adjuvant therapy for both early- and advanced-stage breast cancer. While the common side effects of these treatments are well-documented, their impact on thyroid function has not been systematically assessed and remains unclear. This study aimed to evaluate thyroid function in postmenopausal women with estrogen receptor-positive early-stage breast cancer one and two years after starting aromatase inhibitors.
Methods
This prospective controlled study involved 59 postmenopausal women with early-stage breast cancer and 39 healthy controls. All participants underwent chemotherapy and were treated with aromatase inhibitors, with 35 patients also receiving locoregional radiotherapy. The primary outcomes included the evaluation of thyroid hormones and thyroid-binding globulin post-chemotherapy, as well as at one-year and two-year follow-ups after initiating aromatase inhibitors. Secondary outcomes included thyroid autoantibodies and body mass index.
Results
No significant differences in thyroid parameters were observed between patients and healthy controls before chemotherapy. During treatment with aromatase inhibitors, free thyroxine levels increased at both follow-up visits ($P < 0.01$) and total thyroxine levels increased at the two-year visit ($P = 0.02$). In contrast, triiodothyronine levels decreased at both visits ($P < 0.01$ and $P = 0.03$). There were no changes in thyroid-stimulating hormone or thyroid-binding globulin, but albumin levels increased after one year ($P < 0.01$). Weight changes were insignificant, and the prevalence of autoimmune thyroiditis was low ($\leq 15\%$). No differences in thyroid function were detected between women treated with locoregional radiotherapy and those who were not.
Conclusions
This study suggests that, despite statistically significant changes in peripheral thyroid hormones, no obvious clinically important effects were observed in patients with early-stage breast cancer during the two years of treatment with aromatase inhibitors. These changes were not associated with thyroid autoimmunity, non-thyroidal illness, radiotherapy, or high-dose corticosteroids. To our knowledge, this study provides the longest follow-up of thyroid hormones and thyroid-binding globulin in this specific patient group, focusing on the effects of aromatase inhibitors on thyroid function. Further research is needed to understand better the long-term impact of aromatase inhibitors on thyroid function in this population.

Thyroid hormone levels and echocardiographic changes in subclinical hypothyroidism: a correlation study

Valentina Velkoska Nakova[1,2], Brankica Krstevska[3], Elizabeta Srbinovska Kostovska[4], Cvetanka Volkanovska Ilijevska[5], Natasha Nedeska Minova[6] & Hristina Camoska Sesoska[1,7]
[1]Faculty of Medical Sciences, Goce Delcev University, Stip, Stip, Macedonia; [2]Clinical Hospital Stip, Stip, Macedonia; [3]Internal Medicine Center 'Srce', Skopje, Macedonia; [4]Medical Faculty, Ss. Cyril and Methodius University in Skopje, University Clinic of Cardiology, Skopje, Macedonia; [5]Medical Faculty, Ss. Cyril and Methodius University, University Clinic of Endocrinology, diabetes and metabolic disorders, Skopje, Macedonia; [6]General City Hospital 8th September, Skopje, Macedonia; [7]Institute for Cardiovascular Diseases, Ohrid, Macedonia.

Objective
Overt hypothyroidism has been linked to alterations in cardiac output and diastolic dysfunction. Moreover, subclinical hypothyroidism (SCH) exhibits changes in echocardiographic parameters when compared to healthy individuals. This study investigates the correlation between thyroid hormone values and echocardiographic parameters in patients diagnosed with SCH.
Methods
In fifty-four patients with newly diagnosed ScH who met the criteria for levothyroxine treatment, blood tests and echocardiographic studies were conducted at enrollment and again after five months of maintaining a euthyroid state.
Results
TSH negatively correlated with EF, E/A, GLS, S/TDI (r=-0.15, r=-0.14, r=-0.26, r=-0.22, $P < 0.05$, respectively), and positively correlated with E/e 'sep. ($r = 0.14$, $P < 0.05$). FT4 negatively correlated with E/e'sep., IVRT, MPI (r=-0.17, r=-0.21, r=-0.19, $P < 0.05$, respectively), and positively correlated with E/A, GLS, S/TDI ($r = 0.18$, r=-0.18, $r = 0.19$, $P < 0.05$, respectively). FT3 negatively correlated with A dur (r=-0.39, $P < 0.01$), and positively correlated with EF and s/d ($r = 0.18$, $r = 0.22$, $P < 0.05$). Using a general linear model with univariate analysis, we found that TSH had a statistically significant independent influence on EF, LVEDd, IVRT, MPI, GLS, and S/TDI. FT4 significantly influenced EF, LVEDd, LVEDvol, E/A, A dur, Ar dur, MPI, GLS, s/d, and S/TDI, while FT3 had a significant impact on EF, LVEDd, IVCT, MPI, and GLS ($P < 0.05$). After substitution therapy, there was a statistically significant improvement in parameters indicating diastolic dysfunction (A dur: 112.18 ± 17.2 vs. 107.25 ± 14.4 msec and E/e' sep.: 7.62 ± 2.29 vs. 6.60 ± 2.06, $P < 0.01$), as well as in global and longitudinal left ventricular function (MPI: 0.47 ± 0.08 vs. 0.43 ± 0.07 and GLS: -19.55 ± 2.3 vs. -20.07 ± 2.7, $P < 0.05$).

Conclusion
Thyroid hormones directly influence specific parameters used to assess global and longitudinal systolic and diastolic left ventricular function in patients with ScH, and the most of them are reversible with levothyroxine treatment.
Keywords
subclinical hypothyroidism, echocardiography, left ventricular function.

Effectiveness of antithyroid therapy on TH1, TH17, and TH22 lymphocytes in pediatric Graves' patients
Artur Bossowski[1], Aleksandra Starosz[2], Karolina Stozek[1], Filip Bossowski[3], Marcin Moniuszko[1 2] & Kamil Grubczak[1 2]
[1]Medical University in Bialystok, Department of Pediatric Endocrinology and Diabetes with a Cardiology Unit, Bialystok, Poland; [2]Medical University in Bialystok, Department of Medical Immunology, Faculty of Medicine, Bialystok, Poland; [3]Medical University in Bialystok, Department of Paediatrics, Endocrinology and Diabetes with a Cardiology Divisions, Bialystok, Poland.

Graves' disease is the leading cause of autoimmune hyperthyroidism. Thyroid hormones are an essential element of the endocrine system, playing a pivotal role in the body's development, especially important in children with intensified growth. Disturbance within thyroid tissue certainly affected the whole body. Nowadays, numerous research studies indicate different factors contributing to the onset of the disease; however, the exact pathomechanism of Graves' disease is still not fully understood, especially in the context of immune-related processes. Th1, Th17, and Th22 effector lymphocytes were found to be crucial participants in the disease outcome, as well as in autoimmune diseases. Here, our study aimed at assessing selected effector T lymphocytes, Th1, Th17, and Th22, in newly diagnosed pediatric Graves' disease patients, together with their association with thyroid-related parameters and the potential outcome of disease management. We indicated significant increases in the frequencies and absolute numbers of selected effector lymphocytes in Graves' disease patients. In addition, their mutual ratios, as well as Th1/Th17, Th/Th22, and Th17/Th22, seem to be significant in those diseases. Notably, low Th17/Th22 ratio values were distinguished as potential prognostic factors for normalizing TSH levels in response to methimazole treatment. To sum up, our research determines the crucial contribution of Th1, Th17, and Th22 cells in the pathogenesis of Graves' disease. Moreover, the mentioned subset of T cells is highly likely to play a substantial role in the potential prediction of therapy outcomes.

Paresthesia as a rare symptom of thyrotoxicosis following parathyroidectomy
Maria Luís Mazeda[1], Bruna Silva[1], Catarina Cidade-Rodrigues[1], Vânia Gomes[1], Vânia Benido-Silva[1], Catarina Chaves[1], Catarina A. Pereira[1], Ana Saavedra[1], Claudia Machado[1], Margarida Almeida[1] & Filipe M Cunha[1]
[1]ULS Tâmega e Sousa, Penafiel, Portugal.

Hypocalcemia induced paresthesia is a common complication in patients undergoing parathyroidectomy to treat primary hyperparathyroidism (PHPT). Rarely, paresthesia can be a symptom of thyrotoxicosis. Palpation thyroiditis can occur following parathyroidectomies. It causes thyrotoxicosis in 30-40% of cases and is often asymptomatic. We present a case of patient with post-parathyroidectomy parestehesia, with normal calcemia, as a symptom of thyrotoxicosis due to palpation thyroiditis. A 51-year-old woman with a previous history of urinary calculi and osteopenia. She was diagnosed with PHPT (PTH 108 pg/ml, corrected total calcium 10.9mg/dl, phosphate and 24h urinary calcium of 474mg) a she had an abnormal left inferior parathyroid in the Tc99m sestamibi scan and ultrasound. Her pre-operative thyroid function was normal. She underwent a left inferior parathyroidectomy and discharged with calcium carbonate/cholecalciferol 1250mg/400IU daily. Two days after the procedure the patient presented to the emergency department with oral and acral paresthesia, nausea and headache. No history of recent upper respiratory tract infection, exposure to iodinated radiocontrast agents, or amiodarone use. She had a normal calcemia (PTH 18 pg/ml, serum corrected total calcium 10.2mg/dl, ionized calcium 1.27 mmol/land normal phosphate) and thyrotoxicosis (TSH 0.04 mU/l,free T4 1.62 ng/dl and free T3 3.36 ng/dl). TSH receptor (TRA), thyroperoxidase (TPOA), and thyroglobulin (TgA) antibodies were normal. The diagnosis of thyrotoxicosis due to palpation thyroiditis was made. She started propranolol 10mg tid. Her thyroid function normalized and her symptoms improved within 2 months. This is a rare case of symptomatic thyrotoxicosis caused by palpation thyroiditis in a patient that underwent parathyroidectomy for a PHPT. Operative thyroid manipulation or trauma with rupture of thyroid follicles is the most suggested mechanism. It is a self-limited condition with thyroid function normalizing within a few weeks to months. In addition, the presenting symptom was much more common in hypocalcemia a much more frequent complication of parathyroidectomy. Thyrotoxicosis is rarely associated with paresthesia, however in this case the symptoms were probably a result of the effects of thyroid hormones on the peripheral nerves. So, it is important to be aware, that in this context, not all paresthesia is a result of hypocalcemia. At 2-month follow up, the patient was asymptomatic and thyroid function studies normalized. PTT may be underestimated due to lack of symptoms and lack of routine testing, so it is important to be aware of biochemical or clinical evidence of thyrotoxicosis in the early postoperative period after parathyroidectomy.

Recent advances in the treatment of goiterous hypothyroidism in infants and children
Aml Sabt[1], Ashraf Soliman[2], Nada Alaaraj[2], Ahmed Elawwa[2], Noor Hamed[2], Fawzia Alyafei[2], Shayma Ahmed[2] & Noora AlHumaidi[2]
[1]Sidra Medicine, Doha, Qatar; [2]Hamad Medical Corporation, Doha, Qatar.

Background
Goiterous hypothyroidism in infants and children is a critical endocrine disorder with diverse etiologies, ranging from congenital defects to autoimmune thyroiditis. Recent advancements in treatment have improved outcomes, particularly through novel therapeutic strategies and early interventions.
Objective
To summarize and analyze the recent advances in the treatment of goiterous hypothyroidism in infants and children, with a focus on novel therapies, their outcomes, and associated advancements.
Methods
A comprehensive review of studies published between 1996 and 2024 was conducted. Key studies were identified based on their focus on novel treatments, including liquid levothyroxine formulations, intra-amniotic therapy, precision medicine, and surgical interventions. Data on study characteristics, findings, and therapeutic outcomes were extracted and organized chronologically.
Results
The review encompassed 17 studies, highlighting significant advancements in treatment approaches:.
- Liquid and Soft Gel Levothyroxine: Improved bioavailability and absorption, particularly in cases of malabsorption or drug interferences, ensuring better thyroid hormone control and growth outcomes (Fallahi *et al*., 2017).
- Intra-Amniotic Thyroxine Therapy: Demonstrated efficacy in reducing fetal goiter size and improving neonatal thyroid function, especially in cases of maternal Graves' disease or dyshormonogenesis (Kobayashi *et al*., 2017; Miyata *et al*., 2007).
- Precision Medicine: Genetic insights have enabled targeted therapies for thyroglobulin (TG) and thyroid peroxidase (TPO) mutations, improving treatment of congenital goiter and dyshormonogenesis (Rodrigues *et al*., 2021).
- Screening and Early Treatment: Expanded newborn screening has enabled timely levothyroxine initiation, preventing neurocognitive deficits and supporting normal growth (Wassner & Brown, 2015).
- Surgical Interventions: Total thyroidectomy has improved outcomes in patients with large, resistant goiters, resolving compressive symptoms and enhancing quality of life (Li *et al*., 2020).
- High-Dose Levothyroxine: Early initiation in severe congenital hypothyroidism improved developmental milestones and normalized cognitive function (Dubuis *et al*., 1996).

Conclusions
Recent advancements in treatment emphasize the critical role of early diagnosis and tailored therapies. Intra-amniotic thyroxine, liquid levothyroxine formulations, and genetic insights have significantly improved outcomes in fetal and pediatric hypothyroidism. Future research should focus on long-term outcomes and the integration of precision medicine into routine care.

Keywords

Assessment of subacute thyroiditis progression using shear wave elastography

Stefania-Alexandra Bunceanu[1], Andreea Bena[2], Luciana Moisa Luca[1], Monica Latia[1] & Dana Stoian[2]
[1]Department of Doctoral Studies, 'Victor Babes' University of Medicine and Pharmacy, Timi?oara, Romania; [2]Second Department of Internal Medicine, 'Victor Babes' University of Medicine and Pharmacy, Timisoara, Romania.

Introduction
Subacute thyroiditis (SAT) is a self-limiting inflammatory disorder of the thyroid gland, characterized by cervical pain and transient thyroid dysfunction due to follicular destruction. The assessment of thyroid elasticity through shear wave elastography (SWE) may offer significant insights into the progression of the disease and assist in clinical decision-making.
Objective
This study aimed to evaluate the diagnostic efficacy of SWE elastography in forecasting the resolution of SAT and its relationship with clinical parameters and thyroid function.
Materials and Methods
Thirty-eight patients (78.9 % female) were enrolled in this study. Evaluations encompassed conventional ultrasound, shear wave elastography (SWE), assessment of biological markers (including TSH, FT4, and inflammatory markers), as well as clinical evaluations focusing on pain and lateral cervical inflammatory symptoms.
Results
Out of the 38 patients assessed, all exhibited clinical symptoms indicative of SAT. Conventional ultrasound findings demonstrated hypoechogenicity in 100% of cases. SWE elastography revealed an initial mean elasticity index (EI) that was elevated in all patients, with a median value of 115 kPa (range: 100–121 kPa). The EI progressively decreased to 54 kPa at one month, 24.3 kPa at three months, and 11.9 kPa at six months. Initial TSH levels were 0.05 μIU/ml, increasing to 0.1 at one month, 0.54 at three months, and 2.5 μIU/ml at six months. The erythrocyte sedimentation rate (ESR) declined from 95.7 mm/h initially to 7.2 mm/h at the six-month evaluation. Significant correlations were noted between EI and ESR ($r = 0.812$, $P < 0.0001$), EI and TSH ($r = -0.419$, $P = 0.005$), as well as EI and clinical symptoms ($r = 0.798$, $P < 0.0001$). These findings indicate that EI serves as a robust predictor of disease progression, which can inform both initial and ongoing therapeutic strategies.
Conclusion
SWE elastography proves to be a valuable instrument for monitoring the progression of SAT. The elasticity index demonstrates a strong correlation with clinical and biochemical parameters, establishing it as an important predictor of disease resolution and a guide for therapeutic management.

Non-autoimmune subclinical hypothyroidism associated with variants in the PAX8 gene: presentation of two patients

Núria González-Llorens[1], María Antolín Mate[1], Judith Gonzalez Morla[2], María Hernandez Herrero[3], María Clemente León[1], Núria Camats-Tarruella[1] & Diego Yeste Fernández[1]
[1]Vall d'Hebron University Hospital, Barcelona, Spain; [2]Hospital de Palamós, Palamós, Spain; [3]Joan XXIII University Hospital, Tarragona, Spain.

Introduction
The transcription factor PAX8 is essential for thyroid development and function, acting as a key regulator in gene transcription. More than 50 variants in the PAX8 gene have been identified, which can be de *"novo"* or autosomal inheritance. These variants are associated with a wide range of clinical phenotypes, ranging from mild forms of hypothyroidism to more severe situations, such as congenital hypothyroidism accompanied by structural thyroid malformations. In some cases, these variants are also associated with renal or urogenital tract anomalies. We present two clinical cases of non-autoimmune subclinical hypothyroidism with *PAX8* gene varians.
Clinical Patients description: Patient 1: A 5-year-old male with normal neonatal growth and a history of treated cryptorchidism presented with weight gain and asthenia. Laboratory results showed thyroid-stimulating hormone (TSH) levels of 37.2mUI/ml and thyroxine (T4) levels of 0.94ng/dl in two occasions with negative antibodies, diagnosing non-autoimmune subclinical hypothyroidism (NASHT). Levothyroxine treatment was initiated, and thyroid ultrasound was normal. High-throughput sequencing of a gene panel revealed a heterozygous variant in the *PAX8* gene (c.80C>T p.(Pro27Leu)), classified as a variant of uncertain significance (VUS). The patient's mother has a history of hypothyroidism, but family segregation analysis was not possible. At age 15, due to poor treatment adherence, lab results showed TSH of 52.2mUI/ml and T4L of 0.68 ng/dl. At age 18, the patient weighs 129 kg, is 183 cm tall, and has a BMI of 38.5. He continues treatment with levothyroxine 250 mg/day (0.5 mg/kg). Patient 2: A 6-year-old male diagnosed with NASHT, with TSH of 7mUI/ml, T4 of 0.83ng/dl, and negative thyroid antibodies. Levothyroxine was started at an external center. Thyroid ultrasound showed a reduced size for his age (3rd percentile). Molecular study revealed a pathogenic heterozygous variant in the *PAX8* gene (c.1033_1036dupTTTC), inherited from the mother, causing a premature stop codon. At 13 years old, prepubertal, he is on 50 mg/day of levothyroxine (1.4 mg/kg/day).
Conclusions
These cases highlight the importance of PAX8 in thyroid function, showing that PAX8 gene variants can lead to a broad spectrum of clinical manifestations, including NASHT. Functional studies are needed to confirm the role of VUS variants in the *PAX8* gene in thyroid gland formation and function.

Hypothyroidism manifesting as delusional ideas of persecution: a case report

Chanez Kalboussi[1], Sana Abid[1], Ines Bayar[1], Rihab Khochtali[1], Kamar Ezzamene Mahmoud[1], Bilel Ben Amor[1], Ekram Hajji[1], Héla Marmouch[1], Hanene Sayadi[1] & Inès Khochteli[1]
[1]Fattouma Bourguiba Hospital, Internal Medicine and Endocrinology, Monastir, Tunisia.

Introduction
Clinical manifestations of hypothyroidism includeS fatigue, weight gain, constipation, and myoxodema. Psychiatric symptoms can also be prominent and they were described as myxoedematous madness(1). They include depression, cognitive impairment and, in rare cases, psychotic features. We report here the case of a 49-year-old man presenting with delusional ideas of persecution, a manifestation of hypothyroidism, highlighting the challenges of diagnosing psychiatric symptoms as part of an endocrine disorder.
Case Presentation
He was a 48-year-old male without family history of psychiatric disorders. He was admitted for patent hypothyroidism complicated by rhabdomyolysis and acute renal failure, 8 months after receiving radioactive iodine therapy (RAI) for Graves' disease. He presented with generalized fatigue, myalgias, weight gain, and somnolence. On examination, he exhibited generalized myxedema, psychomotor slowing. He also described persecutory delusions, in which he believed that medical team and patients hospitalized next to him, were conspiring against him. Biochemical results confirmed severe hypothyroidism with a TSH of 87 and FT4 of 0.7. With the improvement of thyroid function, the persecutory delusion is resolving and further psychiatric evaluation is planned.
Discussion
Hypothyroidism is often accompanied by psychiatric symptoms, but the onset of delusions—particularly persecutory delusions—is rare (2) and may be confused with primary psychiatric disorders. In this case, the origin of the delusions were quite easy due to the contexte of severe hypothyroidism but it might be challenging in further situations (3). This case underscores the importance of considering endocrine disorders, such as hypothyroidism, when evaluating psychiatric symptoms, especially in patients with known thyroid dysfunction. Specific hormone replacement therapy is essential in managing both the physical and psychiatric components of the disease.
Conclusion
This case highlights the need for clinicians to be aware of the varity of psychiatric manifestations of hypothyroidism, including rare symptoms such as delusional ideas of persecution. Delusions in hypothyroid patients may resolve with appropriate thyroid hormone replacement, and recognizing this association can prevent unnecessary psychiatric interventions and improve patient outcomes.

Association of plasma thyroxine levels with cognitive disorders in early-onset schizophrenia and other psychosis spectrum disorders

Yesim Saglam[1], Cagatay Ermis[2], Deniz Tanyolac[1], Ahmet Oz[3], Serkan Turan[4], Huseyin Anil Korkmaz[5] & Gul Karacetin[1]
[1]University of Health Sciences, Bakirkoy Prof Dr Mazhar Osman Research and Training Hospital for Psychiatry, Neurology and Neurosurgery, Istanbul, Türkiye; [2]Queen Silvia Children's Hospital, Gothenburg, Sweden; [3]Istanbul University-Cerrahpasa, Istanbul, Türkiye; [4]Bursa Uludağ University Faculty of Medicine Hospital, Bursa, Türkiye; [5]University of Health Sciences, Izmir Faculty of Medicine, Department of Pediatrics, Izmir, Türkiye.

Objective
We aimed to evaluate the relationship between thyroid hormone levels and neurocognitive functions in patients with schizophrenia and other psychosis spectrum disorders (SSD).
Method
A total of 135 patients with early-onset SSD were included in the study. The patients were diagnosed according to the Diagnostic and Statistical Manual of Mental Disorders-5 with schizophrenia ($n = 88$), schizophreniform ($n = 24$), schizoaffective disorder ($n = 7$), and other non-affective psychotic spectrum disorders ($n = 16$). Of the patients, 74.3% ($n = 101$) were within the first year of the disease duration, while 25.7% ($n = 34$) were within the first two years of the disease. A percentage of % 62.0 ($n = 85$) of our patients were experiencing their first episode of psychosis. The participants underwent a cognitive assessment. Blood samples were collected to measure serum levels of thyroid-stimulating hormone (TSH), free thyroxine (fT4), and free triiodothyronine (fT3). Subgroup analyses were conducted based on the severity of the psychosis.
Results
We found a significant interaction between The Rey Auditory Verbal Learning Test (RAVLT-learning), RAVLT-cue call, Wechsler Memory Scale (WMS), The controlled oral word association test (COWAT), Categorical fluency, Auditory Consonant Trigrams (ACT), The Trail-Making Test-A (TMT-A), global cognition, and fT4 levels. We did not find any association between all cognitive scores and fT3 and TSH levels. The correlation between fT4 levels and global cognition was significant for patients with mild to extreme illness severity ($r = 0.41$, $P < 0.001$), but not significant for those with residual/minimal to mild illness ($r = 0.15$, $P = 0.261$). Accordingly, hierarchical regression analyses were performed to estimate global cognition scores, including subsamples with minimal to mild illness and youth with mild to extreme psychosis (Table 3). Education, age, sex, substance use, and daily antipsychotic dose were first entered into the models, yielding significance for both the model containing patients with minimal to mild severity as well as the model of patients with mild to extreme disease severity. When plasma fT4 levels were added in a second step, the model containing patients with minimal to mild disease severity did not provide a significant R^2 change ($\Delta R^2 = 0.03$, $p = 0.127$), while it was significant in those with mild to extreme psychosis severity ($\Delta R^2 = 0.10$, $p = 0.002$).
Conclusions
Serum fT4 levels were associated with the performance across various cognitive domains in cases of early-onset psychotic disorders. This correlation was accentuated among patients with higher illness severity. Future studies could focus on the effects of specific pathways that can affect the course and progression of psychosis.

Evaluation of clinical findings, laboratory results, and radiological features in pediatric patients followed up for thyroid dysfunction

Aylin Bağcı[1], Erdal Kurnaz[2] & Şenay Savaş Erdeve[2]
[1]Department of Pediatrics, Etlik City Hospital, University of Health Sciences, Ankara, Turkey, Ankara, Türkiye; [2]Department of Pediatric Endocrinology, Etlik City Hospital, University of Health Sciences, Ankara, Turkey, Ankara, Türkiye.

Objective
This study analyzed the laboratory findings and diagnostic distribution of patients with thyroid function test abnormalities referred to our clinic.
Materials and Methods
In this study, 310 cases with abnormal thyroid function tests referred to our clinic between October 1, 2022, and May 31, 2023, were retrospectively evaluated. Patient data were obtained retrospectively from our hospital's medical records. The cases' demographic, clinical, and laboratory data were analyzed to investigate the final diagnostic distribution.
Results
The study included 310 patients, of whom 64.8% ($n = 201$) were female, with a median age of 10 years (ranging from 5 to 13 years). All cases had undergone evaluation by other departments before presenting to the pediatric endocrinology clinic. While some patients had previously visited a single center, others had consulted multiple centers. Among the reasons for their initial visits to these centers, 39.4% of the cases ($n = 122$) had undergone routine check-ups, during which abnormal thyroid function test results led to their referral to our clinic. Before being referred to our clinic, 24.2% of the cases ($n = 75$) had been evaluated due to abnormal thyroid function test results detected during screening. Additionally, 2.9% of the cases ($n = 9$) had presented due to obesity, 2.6% ($n = 8$) due to palpitations, 2.3% ($n = 7$) due to constipation, and another 2.3% ($n = 7$) due to short stature. Furthermore, 26.5% of the cases ($n = 82$) had been evaluated for various other complaints, including increased hair loss, recent weight loss, decreased appetite, fatigue, and chest pain. All patients were referred to our tertiary pediatric endocrinology clinic due to abnormal thyroid function test results. The final diagnostic distribution of these cases in our hospital showed that 31.3% ($n = 97$) were diagnosed with Hashimoto thyroiditis, while 22.3% ($n = 69$) had congenital hypothyroidism. Euthyroidism was identified in 17.4% ($n = 54$) of the cases, whereas 13.2% ($n = 41$) were diagnosed with subclinical hypothyroidism. Central hypothyroidism was found in 9.4% ($n = 29$) of the cases. Additionally, 3.5% ($n = 11$) of the patients were diagnosed with Graves' disease, and 2.9% ($n = 9$) had hashitoxicosis. Moreover, 13 cases were found to have isolated TSH elevation due to excess weight or obesity. Relevant cases received necessary treatments, while others were placed under follow-up.
Conclusion
Thyroid dysfunction in childhood is a common condition that may require early diagnosis and prompt treatment, as in congenital or acquired hypothyroidism, or it may stem from a condition that necessitates clinical follow-up.

Effectiveness and outcome of fixed 600 Mbq radioactive iodine activity in the treatment of benign thyroid disease

Cristina Edward[1], Man Wai Cheng[2] & Isha Malik[1]
[1]Manchester University NHS Foundation Trust, Manchester, United Kingdom; [2]Manchester University NHS Foundation Trust, Manchester, United Kingdom.

Objective
This study aimed to evaluate the effectiveness and thyroid status outcomes following the introduction of a fixed radioactive iodine (RAI) dose of 600 Mbq in patients diagnosed with hyperthyroidism.
Methods
A retrospective review was conducted involving 92 patients treated for hyperthyroidism after the implementation of the fixed 600 Mbq RAI dose. The analysis focused on primary diagnoses, biochemical outcomes, and the duration of hypothyroidism development in patients post-RAI, as well as the initiation of levothyroxine therapy.
Results
Among the 92 patients studied, 67 were diagnosed with Graves' disease and 25 with multinodular goitre (MNG). The cohort comprised 72% females and 26% males, with an average age of 54.8 years. The overall cure rate was 89%, surpassing the 83.5% cure rate reported in previous studies involving variable doses of RAI. Antithyroid medication (ATD) was discontinued in 91% of Graves' patients on average 11.3 weeks after RAI, compared to 84% of MNG patients who ceased ATD therapy an average of 11.7 weeks post-RAI. The average time to hypothyroidism development was 13.38 weeks for Graves' patients and 22.1 weeks for those with MNG. In patients with Graves' disease, 84% initiated levothyroxine therapy, while only 40% of MNG patients required thyroxine supplementation post-RAI.

Conclusion
The overall cure rate was 89%, indicating a significant improvement over variable dose RAI outcomes documented in other studies, with 91% of Graves' patients and 84% of MNG patients discontinuing ATD therapy on average 11.3 and 11.7 weeks post-RAI, respectively. The administration of 600 Mbq RAI is associated with a lower incidence of hypothyroidism requiring thyroxine supplementation in patients with MNG, and hypothyroidism develops later compared to those with Graves' disease. As previously known, RAI for toxic MNG is an effective treatment that can result in euthyroidism, with fewer patients requiring levothyroxine replacement. We intend to use the results to implement a streamlined outpatient follow-up approach, where thyroid function tests can be organized at 6 weeks via a virtual clinic, with the first face-to-face appointment scheduled between 11 to 12 weeks, thus reducing the need for earlier and more frequent appointments. This approach may potentially enhance patient care by improving access, increasing time efficiency, enabling early detection of complications, and boosting patient satisfaction.

Metabolically associated fatty liver disease in woman with hypothyroidism

Zulaykho Shamansurova[1,2] & Dilbar Abdurazakova[3]
[1]Central Asian University, Endocrinology, School of Medicine, Tashkent, Uzbekistan; [2]Institute of Biophysics and Biochemistry at the National University of Uzbekistan, Metabolomics, Tashkent, Uzbekistan; [3]Andijan State Medical Institute, Andijan, Uzbekistan.

Introduction
Metabolically associated fatty liver disease (MAFLD) frequent condition in people with obesity and lipid abnormalities. Hypothyroidism associated with fat abnormalities and predisposed to weight gain. We aimed to investigate frequency of fatty liver disease among women with hypothyroidism.
Material and Methods
105 women in age 45-59 who lived in Andijan city which is iodine deficiency area BMI blood serum T3, T4, TSH, ALT, AST, bilirubin, total cholesterol (TCh), triglycerides (TG), LDLP, HDLP level were measured, aterogenic index were calculated. MAFLD degree were were detected by ultrasound.
Results
Obesity were determined by BMI and showed 1st degree in 38.2%, 2nd degree in 20.5%, 3rd degree in 7.8% of woman. Hypothyroidism were detected in 45.5% women. Blood TCh, TG, LDLP, HDLP and atherogenic index, blood ALT, AST level were higher than those without hypothyroidism. Interestingly in 41% of women with hypothyroidism were detected MAFLD in ultrasound. In patients who followed thyroid hormone replacement therapy MAFLD were lower than those who non-adhered which suggested about linkage between MAFLD and thyroid state.
Conclusion
MAFLD is a frequent clinical future in patients with hypothyroidism and depends from thyroid state. Adequate hormone replacement therapy can prevent MAFLD in patients with hypothyroidism.

P63 immunohistochemical peculiarities under autoimmune thyroiditis vs papillary thyroid carcinoma (PTC)

Tamuna Gvianishvili[1] & Liana Gogiashvili[2]
[1]Ivane Javakhishvili Tbilisi State University, Alexandre Natishvili Institute of Morphology, Clinical and Experimental Pathology, Tbilisi, Georgia; [2]Ivane Javakhishvili Tbilisi State University, Alexandre Natishvili Institute of Morphology, Department of Clinical and Experimental Pathology, Tbilisi, Georgia.

Background
Hashimoto thyroiditis, which is classified as an autoimmune disorder affecting the thyroid gland, has been considered as a lesion preceding and predisposing to papillary thyroid carcinoma (PTC) by several authors. In contrast, the other clinical type of thyroid autoimmune disease - the Riedel's thyroiditis has not been evidenced to be a pre-cancer lesion.
Materials and Methods
This hypothesis encouraged us to undertake the morphological and immunohistochemical comparative assessment of these two types of thyroiditis (RT and HT) utilizing the diagnostic value p63 immunohistochemistry in thyroid pathology. The surgical specimens of the thyroid gland, obtained from 36 patients were studied in total, including Riedel's thyroiditis ($n = 5$), Hashimoto's thyroiditis ($n = 24$) and papillary thyroid carcinoma ($n = 7$) as a control group.
Results and Discussion
Obtained results showed that autoimmune thyroiditis types are characterized by histological and immunohistochemical heterogeneity, however, pathological alterations in both processes (RT, HT) specifically demonstrated progressive involution of glandular tissue and replacement with rigid tissue, sometimes, scar fibrosis. Positive p63 expression were highly specific for papillary carcinoma in the setting of HT, which was not characteristic for the Riedel's thyroiditis specimens.
Conclusion
According to biomolecular research data, we could not exclude dysplastic and neoplastic transformation in progenitor cells within the parenchyma of Hashimoto's thyroiditis vs Riedel's autoimmune thyroiditis.

Papillary thyroid microcarcinomas detected by nuclear medicine imaging methods do they have a worse prognosis?

Seda Hanife Oğuz [1], İpek Çınar[2], Banu Ertürk[1], Gürsan Kaya[3], Murat Fani Bozkurt[3] & Alper Gürlek[1]
[1]Hacettepe University School of Medicine, Department of Internal Medicine, Division of Endocrinology and Metabolism, Ankara, Türkiye; [2]Hacettepe University School of Medicine, Department of Internal Medicine, Ankara, Türkiye; [3]Hacettepe University School of Medicine, Department of Nuclear Medicine, Ankara, Türkiye.

Background
Studies have suggested that papillary thyroid carcinomas incidentally detected by nuclear medicine imaging techniques may have a worse prognosis compared to those identified by other methods. However, it remains unclear whether this observation applies to papillary thyroid microcarcinomas (PTMCs).
Aim
To compare the prognostic differences among PTMCs detected by nuclear medicine imaging (e.g., 18F-FDG PET, technesium-99m-MIBI), incidental PTMCs, and non-incidental PTMCs using pathological tumor characteristics.
Methods
Patients diagnosed with PTMC in Hacettepe University School of Medicine between 2008 and 2020 were categorized into three groups: (1) PTMCs detected by nuclear medicine imaging methods ($n = 24$), (2) incidental PTMCs ($n = 251$), and (3) non-incidental PTMCs ($n = 132$). Tumor pathology characteristics, including multifocality, extrathyroidal extension, vascular invasion, and lymph node involvement were analyzed. Logistic regression analysis was performed to assess the association between detection method and tumor aggressiveness, adjusting for potential confounders such as age at diagnosis.
Results
Patients with PTMCs detected by nuclear medicine imaging were significantly older at diagnosis (54.7 ± 11.7 years) compared to incidental PTMCs (51.0 ± 11.4 years) and non-incidental PTMCs (47.1 ± 11.8 years) ($P = 0.001$). Tumor size was also significantly different among groups ($P < 0.0001$), with nuclear medicine-detected PTMCs (4.8 ± 2.5 mm) and non-incidental PTMCs (5.3 ± 2.3 mm) being larger than incidentally detected PTMCs (3.4 ± 2.4 mm). Logistic regression analysis showed that PTMCs detected by nuclear medicine imaging were significantly more likely to be bilobar compared to incidentally detected PTMCs (OR: 4.59, 95% CI: 1.55-14.58, $P = 0.006$). The rate of cervical lymph node metastasis was markedly higher in PTMCs detected by nuclear medicine imaging compared to both incidentally detected PTMCs (OR: 41.13, 95% CI: 9.33-191.20, $P < 0.0001$) and non-incidental PTMCs (OR: 3.82, 95% CI: 1.16-12.58, $P = 0.027$). However, there were no significant differences among the groups in terms of extrathyroidal extension or vascular invasion.
Conclusions
Although nuclear medicine-detected PTMCs were larger in size and associated with a significantly higher rate of cervical lymph node metastasis and bilobar involvement compared to incidental PTMCs, other aggressive pathological features did not significantly differ. These findings suggest that PTMCs identified by nuclear medicine imaging may have distinct biological behavior, warranting further investigation to determine their true prognostic implications.

Corneal ulcer, a rare complication of hashimoto's thyroiditis

Ahmed Boukhalfa[1], Sara Ijdda[1], Sana Rafi[1], Ghizlane El Mghari[1] & Nawal El Ansari[1]

[1]Cadi Ayad University, Mohamed VI University Hospital Center, Department of Endocrinology, Diabetes, Metabolic Diseases and Nutrition, Marrakesh, Morocco.

Introduction

Ophthalmic involvement in autoimmune thyroid diseases such as Graves' disease is well known, while Hashimoto's thyroiditis has rarely been implicated in the development of occular manifestations. Corneal ulceration is a serious complication that can jeopardize the visual prognosis. We report a clinical observation of an association between Hashimoto's thyroiditis and corneal ulcer to describe this rare complication.

Clinical Case

Forty three years-old female patient, treated for hashimoto's thyroiditis for 12 years on levothyroxine 100mg/d. The patient reported the onset of ocular redness aggravated by visual fog for 2 months. Workup noted whit cell blood at 7150/mm^3, CRP at 55 mg/land TSH us at 18 uUI/ml. Fundus showed a visual acuity of 6/10 on the right and counting fingers at 0.5 m on the left, conjunctival hyperhemia with axial opacity and punctiform corneal perforation measuring 1*1 mm in the left eye. The patient was put on systemic corticosteroids with analgesic treatment. The evolution was marked by regression of local inflammatory signs. The patient was scheduled for amniotic membrane transplantation.

Discussion

Ophthalmological involvement is generally frequent in basedow's disease, where it can occur in around 25-50% of cases, whereas this prevalence is only 2% in Hashimoto's thyroiditis (1). Ocular lesions can occur at any time during the course of thyroid disease, sometimes 10 or even 20 years after the diagnosis of autoimmune thyroid disease (2). The pathogenesis of thyroid ophthalmopathy is based on the development of antibodies directed against both the thyroid gland and the orbit. Immunological mechanisms are represented by orbital infiltration by T lymphocytes recognizing orbital antigens and periocular muscles (3,4), secretion of cytokines and water-attracting glycosaminoglycans, and transformation of orbital fibroblasts into adipocytes, resulting in exophthalmos and inflammation of the eyeball with, in some cases, corneal fragility responsible for epithelial perforation. The presence of anti-TPO antibodies (in 90% of cases) testifies to their involvement in this pathogenesis (5,6).

Conclusion

Ocular complications in autoimmune thyroid disease (AITD) are a rare but sometimes serious entity that can be vision-threatening. They should therefore be screened in any patient being treated for an AITD.

Acute thyrotoxic crisis with cardiothyreosis: management challenges in the face of carbimazole-induced hepatic cytolysis

Ilham Midhat[1], Sana Rafi[1], Sara Ijdda[1], Ghizlane El Mghari[1] & Nawal El Ansari[1]

[1]Mohammed VI University Hospital of Marrakesh, Department of Endocrinology, Diabetes, Metabolic Diseases and Nutrition, Marrakesh, Morocco.

Introduction

Acute thyrotoxic crisis (ATC) is an exceptional form of life-threatening thyrotoxicosis. Its diagnosis is not easy to make, given its multisystemic and non-specific clinical manifestations. Its treatment requires specialized and urgent care, given the risk of single or multiple organ failure. We report the case of a patient with CAT complicated by cardiothyreosis.

Case report

Patient aged 30, known to have undocumented thyreopathy for 4 years, initially put on Carbimazole 20mg/d, taken irregularly then stopped for a period in view of hepatic cytolysis, then restarted 10 days ago in view of a normal hepatic workup. She presented to the emergency department with stageVI dyspnoea, palpitations, thermophobia and asthenia, in a context of significant weight loss. The workup revealed peripheral hyperthyroidism with TSH at 0.004 µUi/ml, T4L > 64.3 pmol/land T3L at 17.7 pmol/l,with negative antibodies. the electrocardiogram showed supraventricular tachycardia at 220 bpm, with significant hepatic cytolysis. The patient underwent emergency conditioning, then was slowed by B-blockers (Propanolol) combined with an antiarrhythmic, and because of the hepatic cytolysis, which contraindicating the start of synthetic antithyroid drugs (ATDs), the patient had received corticosteroid therapy, combined with rehydration according to cardiac tolerance, and anticoagulation. And then, she underwent emergency plasmapheresis. The evolution was marked by a good clinico-biological improvement, electrocardiogram abnormalities and thyroid balance after the plasmapheresis session. Then, She underwent radical surgery after clinical stabilization and euthyroidism, with a simple postoperative course.

Discussion

ATC represents a veritable life-threatening emergency. Although rare, its mortality rate remains high (around 15%), mainly due to the onset of multivisceral failure. It is defined by an exacerbation of all the manifestations of thyrotoxicosis: fever, tachycardia, agitation, vomiting, dehydration, neuro-psychiatric disorders. Cardiothyreosis, is the most serious clinical presentation, occurs preferentially in the elderly. There are many causes, the most common being Graves' disease, toxic goiter and amiodarone therapy. It is characterized by a drop in peripheral vascular resistance, an increase in resting heart rate, left ventricular contractility, blood volume and cardiac output. The most frequent and earliest sign is tachycardia, as well as atrial fibrillation, ventricular arrhythmias, pulmonary hypertension, orthostatic hypotension, right-predominant heart failure and coronary insufficiency.) In addition to specific treatments such as ATDs, radioactive iodine and surgery, the therapeutic arsenal includes symptomatic treatments: β-blockers as first-line therapy, digitalis, electrical cardioversion, even hemodynamic assistance and plasmapheresis.

Vesicular thyroid carcinomas

Meryem Chakir[1], Nassim Essabah Haraj[1], Siham El Aziz[1] & Asma Chadli[1]

[1]UHC Ibn Rochd, Casablanca, Morocco.

Introduction

Follicular or vesicular cancers account for 5 to 10% of differentiated thyroid cancers (DTC) and are therefore the second most common cause of endocrine tumors after papillary thyroid cancer. They can be minimally or massively invasive, making them a more aggressive histological type compared to papillary carcinoma.

Objective

The objective of our study is to describe the clinical and evolutionary characteristics of vesicular thyroid tumors.

Materials and Methods

This is a retrospective descriptive study involving 34 patients treated in our service, between 1986 and 2024, diagnosed with vesicular thyroid carcinoma. Statistical analysis was performed using SPSS software.

Résults

The average age of our patients was 51.6 years. All the patients in our study were women. The most common presenting feature was the presence of an isolated goiter (67%), followed by an isolated thyroid nodule (8%). Bone metastases led to the diagnosis in one patient. One patient consulted for a nasal voice with progressive worsening and was diagnosed with carcinoma on an ectopic lingual thyroid. All our patients underwent total thyroidectomy, and lymph node dissection was indicated in only one patient. Radioactive iodine treatment was administered to 85% of the patients. All the carcinomas in our series were unifocal. Tumor size ranged from 0.5 cm to 7.5 cm. The development of locoregional and distant metastases (bone, lungs) was observed in one and two patients, respectively. Two patients developed ductal breast carcinoma during the follow-up. A complete remission was observed in 53% of the patients.

Conclusion

Our study reveals a female predominance of follicular thyroid carcinomas, with the majority of cases presenting as an isolated goiter. The overall prognosis is generally favorable, and the risk of local or distant recurrence is the key factor in guiding treatment.

Sclerotherapy of cystic formations of the thyroid and parathyroid glands

Pamputis Sergey[1], Vasiliy Semikov[2] & Yuriy Aleksandrov[3]

[1]Yaroslavl State Medical University, Surgery, Yaroslavl, Russian Federation; [2]I.M. Sechenov First Moscow State Medical University (Sechenov

University), Surgery, Moscow, Russian Federation; [3]Yaroslavl State Medical University, Surgery, Yaroslavl', Russian Federation.

Cystic formations of the thyroid and parathyroid glands are a common pathology due to the widespread use of ultrasound examination of the neck organs. True cysts of the thyroid (TC) and parathyroid glands (PC) are hormonally inactive and often have small sizes. But large cysts (10%) have clinical manifestations (pressure on the surrounding neck organs). The attitude towards this pathology is ambiguous - from radical removal to passive observation. Complications of TC and PC can be malignant transformation, ruptures and bleeding. We analyzed 96 clinical cases of TC (78) and PC (18). The size of the cysts varied from 20 to 114 mm, and the volume - from 6 to 360 ml (on average - 42.1 $\pm$ 24.2 ml). An algorithm of actions for this pathology is proposed. The first method of detecting cysts is ultrasound, which allows you to identify a cyst and measure its size. Initially, a complete cyst aspiration is performed for cytological examination and determination of TG and PTH levels. For punction TC the aspirate was yellow or brown, transparent or cloudy; for punction PC was colorless, transparent. The laboratory criteria are the levels of TG and PTH in the aspirate. If a high level of TG and a low level of PTH are detected in the TC, then obtaining the results of Bethesda 4,5,6 in the tissue component of the TC is the basis for surgical intervention. Bethesda 1,2 was the basis for the observation. PC were characterized by high levels of PTH (from 1218 to 3070 pg/ml; average 2012.5$\pm$946.7 pg/ml) and low levels of TG. The method of choice for their treatment is mainly observation. The recommended period of ultrasound examination is 3,6,12 months. If the contents accumulate in the cysts with a volume of up to 10 ml, repeated aspiration of the contents with subsequent ultrasound control is possible. In case of repeated accumulation of contents in thyroid cysts with a volume of more than 10 ml, sclerotherapy is preferable. Compression syndrome served as the basis for surgical intervention for TC in 3 cases, simultaneous operations were performed in 9 cases: in 6 cases – with a multi-node toxic goiter, in 3 - with thyroid cancer. When choosing methods of treatment for thyroid cysts, it is necessary to be guided by the fact that the treatment method should be as safe and minimally invasive as possible.

Ultrasound support of diapeutic interventions in thyrioid pathology

Yuriy Aleksandrov [1], Mikl Mogutov[1] & Maria Belyakova[1]
[1]Yaroslavl State Medical Univercity, Surgery, Yaroslavl, Russian Federation.

Diapeutic manipulations involve simultaneous diagnostic and therapeutic actions. With regard to the thyroid, it's a combination in the hands of a specialist of non-invasive diagnostic ultrasound and invasive interventions, such as FNAB, sclerotherapy, laser destruction, radiofrequency ablation and HIFU performed under ultrasound control. The evaluation of ultrasound examination protocols of the thyroid in 1235 patients were analyzed. Ultrasound protocols included an assessment of echogenicity, structure, and size of the gland itself, as well as the identification of focal formations (in 1,041 patients; 84.3%), which were described according to the TI-RADS criteria adopted in the clinic (echogenicity, structure, evenness and clarity of contours, shape, vascularization, presence of Halos, calcifications, signs of invasiveness). In order to form surgical tactics, the number of formations, their size, volume and localization were evaluated. At an early stage, TAPB was used for diagnosis under ultrasound control (988 patients; 80.0%). Performing this diapeutic manipulation allowed us to identify a group of patients with tumors (categories Bethesda IV, V, VI) (143 people; 11.6%) who underwent traditional surgical treatment. Ultrasound monitoring was recommended for a significant number of patients (756 people; 61.2%). Minimally invasive therapeutic manipulations were used in 89 patients (7.2%) in the treatment of thyroid nodules belonging to the Bethesda II category: in 14 people (1.1%) it was sclerotherapy, in 10 patients (0.8%) high-intensity focused ultrasound (HIFU) was performed, in 65 people (5.3%) laser destruction. All patients gave informed consent to undergo diapeutic manipulations. All diapeutic manipulations were performed under the supervision of ultrasound on an outpatient basis by a team of specialists, which included a surgeon and a specialist in radiation diagnostics. They did not require special training and were well tolerated by patients. The analysis of the results showed that minimally invasive diapeutic manipulations in most cases are the final method, leading to an improvement in the patient's quality of life and even to a complete cure of the patient. They are the method of choice for severe patients and patients who refuse surgical treatment. In these situations, the treatment was palliative. Minimally invasive therapeutic manipulations can precede open surgery, significantly reducing the size of focal formations. Ultrasound diapeutics, which makes it possible to provide significant assistance both in making a diagnosis and in the subsequent treatment of patients with focal thyroid pathology, is the prerogative of a surgeon who has special training in ultrasound diagnostics, and not a radiologist.

Prevalence of thyroid autoimmunity and by age, sex, geographic region, and socioeconomic status among 1.7 million chinese adults

Dan Shen[1], Sailimai Man[1 2 3], Xiaochen Yang[2 4], Canqing Yu[1 3 5], Liming Li[1 3 5], Bo Wang[2 3 6] & Jun Lv[1 3 5]
[1]School of Public Health, Peking University, Department of Epidemiology and Biostatistics, Beijing, China; [2]Meinian Institute of Health, Beijing, China; [3]Peking University Health Science Center Meinian Public Health Institute, Beijing, China; [4]School of Public Health, Peking University, Department of Social Medicine and Health Education, Beijing, China; [5]Key Laboratory of Epidemiology of Major Diseases (Peking University), Beijing, China; [6]Peking University Center for Public Health and Epidemic Preparedness & Response, Beijing, China.

Background
Thyroid autoimmunity (TAI) is among the most common autoimmune disorders, and it has been linked to an elevated risk of numerous autoimmune and non-autoimmune diseases. However, current estimates of TAI prevalence are limited due to small sample size or single jurisdiction data. This study aimed to investigate the prevalence of TAI in Chinese population and how it varies by age, sex, geographic region, and socioeconomic status.
Methods
The Meinian Health Check-up database was used in this nationwide, large-scale, cross-sectional study. The study included 1,758,425 individuals aged $\geq$18 years who had health check-ups between 2017 and 2023 and collected blood samples for thyroid function and thyroid antibody tests. TAI was defined as positivity for thyroid peroxidase antibody (TPOAb) and/or thyroglobulin antibody (TgAb). Sample weights based on the 2020 Chinese census were assigned to account for the unequal sample distributions across provinces and to adjust for age and sex proportions. Weighted prevalence with a 95% confidence interval (CI) was computed using the Taylor Series Linearization method.
Results
Among the overall study population (mean age 44.7$\pm$12.8 years; 60.0% female), the weighted prevalence of TAI was 23.5% (95% CI 21.7%-25.3%). Near half (46.3%) of those with TAI had positive results for both TPOAb and TgAb, 30.6% were TPOAb+ only, and 23.1% were TgAb+ only. Most of TAI (70.8%) had normal thyroid function, while 22.0% had hypothyroidism. The prevalence of TAI increased with age, peaked at the age of 50 to 59 years, and declined thereafter. Overall, females had more than double the prevalence compared to males (33.6% [32.3%-35.0%] vs. 14.1% [12.8%-15.3%]), with a similar pattern across each age group. Geographically, TAI was most prevalent in the northern (26.5% [24.3%-28.6%]) and central (26.7% [24.1%-29.2%]) regions of China, followed by the eastern region (25.7% [22.6%-28.8%). No significant difference was observed for the prevalence of TAI between coastal and non-coastal region. A socioeconomic gradient was also identified, with individuals resided in higher gross domestic product level cities having a lower prevalence of TAI.
Conclusions
TAI was common in the Chinese population and varied by age, sex, geographic region, and socioeconomic status. A notable proportion of individuals with TAI had normal thyroid function, suggesting that many cases may go undetected without routine assessment. These findings highlight early detection may be useful in preventing the progression to overt thyroid dysfunction and reducing the broader burden of autoimmune disorders.

EP1488

JOINT2281

A case of post-operative graves disease

Tea Khurodze[1], vitali vashakidze[1], Basa Gegeshidze[1], Ana Pruidze[1] & Sopo Javelidze[1]
[1]David Tvildiani Medical University, Tbilisi, Georgia.

Background
Graves disease is one of the most common thyroid pathologies with multiple risk factors that may present with various clinical manifestations. Because of the small

number of cases, there is ongoing debate whether postoperative GD can be associated with previous autoimmunity exacerbated by exogenous stress or new onset improper response of the immune system after partial thyroidectomy. Theory suggests that during surgery, injured thyroid follicular cells release THS-R which are picked up by APC that induces Th2 humoral response. Risk factor of this phenomenon might be genetic predisposition to autoimmunity.
Case Presentation
A 23 years old Caucasian female admitted to the hospital with the complaints of general weakness, palpitation, sleep disturbances, hand tremor, headache, irregular menstrual cycle, increased appetite and sweating. 3 years ago, a patient was diagnosed with a dynamically growing nodule measuring 38 mm with euthyroid state confirmed by laboratory tests. Fine-needle aspiration excluded malignancy. The patient underwent hemithyroidectomy (histomorphology confirmed a nodular goiter). Postoperatively, subclinical hypothyroidism was identified, and levothyroxine therapy was initiated, however, the patient stopped taking medication. In family history, mother has hypothyroidism and Sjogren's disease. On physical examination, there was a tremor of the outstretched hands, moist and warm skin, slight exophthalmos, and a positive Graphe's sign. Initial lab tests revealed thyrotoxicosis: TSH – 0.09 MKU/ml, FT4 – 24.28 pmol/l; FT3 – 7.61 pmol/l,Thyreoglobulin – 26.910 ng/ml (3.5-7.7) anti-TSH-R – 6.5 IU/l(normal range $<$ 1.0). Moreover, an ultrasound revealed a coarse-grained left thyroid lobe in the size of 4.7cc with irregular echogenicity. Color Doppler imaging demonstrated enhanced blood flow in the parenchyma. Scintigraphy revealed increased uptake of Tc-99m in the remnant left lobe of the thyroid gland. Based on these findings, a diagnosis of Grave's disease was made. The patient was started on methimazole and Beta-blocker with symptomatic and laboratory improvement.
Conclusion
This is a rare case of new onset Graves disease after partial thyroidectomy. Case highlights importance of post-surgical follow-up and screening including TFTs. In the presence of Hyperthyroidism after lobectomy, Grave's disease should be considered in broad differential diagnosis. Even though it indicates possible improper immune response to released TSH-R during the surgery, further research is needed to understand pathophysiology of association between GD and thyroid surgery.

AI chatbots vs endocrinologists in clinical decision-making in thyroid nodule and papillary thyroid carcinoma management

Grigoris Effraimidis[1], Athanasios Kasotas[2], Eleni Sazakli[3], Olga Karapanou[4], Katerina Saltiki[5] & Marina Michalaki[3]
[1]Faculty of Medicine, School of Health Sciences, University of Thessaly, Department of Endocrinology and Metabolic Diseases, University General Hospital of Larissa, Larissa, Greece; [2]Department of Endocrinology and Metabolic Diseases, University General Hospital of Larissa, Larissa, Greece; [3]Faculty of Medicine, School of Health Science, University of Patras, Patras, Greece; [4]Endocrine Department, NIMTS Veteran's Hospital, Athens, Greece; [5]Endocrine Unit, Department of Clinical Therapeutics, National and Kapodistrian University, Athens, Greece.

Introduction
The management of thyroid nodules and papillary thyroid carcinoma (PTC) varies widely, influenced by evolving guidelines and clinical judgment. With advancements in artificial intelligence (AI), chatbots like ChatGPT, Copilot and Gemini have emerged as potential decision-making supporting tools.
Aim
This study aims to compare clinical decision-making patterns among endocrinologists and AI chatbots responses.
Methods
A web-based survey was distributed to the members of the Hellenic Endocrine Society (HES), presenting 12 clinical scenarios addressing management strategies for solitary thyroid nodules and PTC across various risk profiles (EU-TIRADS 4 and 5 nodules and very-low, low, and low-to-intermediate risk PTCs). Participants selected one of four management strategies for each scenario. ChatGPT, Copilot and Gemini answered the 12 scenarios at two time points: April 2024 (T1 – survey end) and January 2025 (T2). AI chatbots responses were compared with the recent American and European Thyroid Association guideline recommendations, as well as with endocrinologists' responses.
Results
A total of 201 endocrinologists (25% of HES members) participated in the survey. Between T1 and T2, ChatGPT, Copilot and Gemini altered their responses for 8/12, 6/12 and 7/12 scenarios, respectively. At T1, ChatGPT and Copilot aligned with 33% and 58% of guideline recommendations, increasing to 66% for both at T2. Conversely, Gemini's alignment remained at 17% at both time points. Agreement between the AI chatbots responses and the predominant choices among endocrinologists was as follows: at T1, ChatGPT matched the endocrinologists' prevailing choice in 2 (17%), Copilot in 1 (8%) and Gemini in 3 out of 12 scenarios (25%). By T2, agreement rates improved to 5/12 (42%) for ChatGPT, 4/12 (33%) for Copilot, and 6/12 (50%) for Gemini. Finally, the mean percentage of survey respondents whose answers corresponded to answers provided by AI chatbots was calculated. At T1, ChatGPT had a 24% agreement rate, Copilot 24% and Gemini 37% (noted 1 and 2 questions were excluded for Copilot and Gemini as the chatbots could not provide any recommendation). At T2, these rates increased to 34%, 30% and 43% for ChatGPT, Copilot and Gemini, respectively.
Conclusion
This study highlights the evolving role of AI chatbots in clinical decision-making for thyroid nodules and PTC. Over time, the alignment of AI responses with clinical guidelines and endocrinologists' choices improved, suggesting their potential utility in supporting clinical decisions. Further research is needed to optimize AI integration into clinical practice and ensure consistency with evolving medical guidelines.

HPA axis integrity after Iv methylprednisolone for active moderate-to-severe thyroid eye disease

Athanasios Kasotas[1], Grigoris Effraimidis[2] & Alexandra Bargiota[2]
[1]University General Hospital of Larissa, Department of Endocrinology and Metabolic Diseases, Larissa, Greece; [2]Faculty of Medicine, School of Health Sciences, University of Thessaly, Department of Endocrinology and Metabolic Diseases, University General Hospital of Larissa, Larissa, Greece.

Introduction
Only five small studies have evaluated the effects of supraphysiologic intravenous methylprednisolone (IVMP) therapy on hypothalamic-pituitary-adrenal (HPA) axis suppression in patients with active moderate-to-severe thyroid eye disease (TED). The standard IVMP regimen consists of 4.5 g administered over 12 weeks (0.5 g weekly for six weeks, followed by 0.25 g weekly for another six weeks).
Aim
To investigate the impact of IVMP therapy on HPA axis function in patients with moderate-to-severe TED.
Methods
This study included adults ($>$18 years) with active moderate-to-severe TED followed at the Department of Endocrinology and Metabolic Diseases, University General Hospital of Larissa, Greece, (April 2008–July 2024). HPA axis function was assessed using the standard-dose Synacthen test (250 μg synthetic ACTH) 7–10 days after IVMP completion. Serum cortisol levels were measured at baseline and 30- and 60-minutes post-ACTH injection. Adrenal sufficiency was defined as a peak cortisol level $\geq$18.1 μg/dl (500 nmol/L). Patients receiving glucocorticoids of any route of administration beyond the IVMP regimen or with conditions affecting cortisol-binding globulin were excluded.
Results
Of 127 enrolled patients, 115 were analyzed. the test could not be performed in 12 patients due to drug unavailability ($n = 9$), severe infection ($n = 2$), or incorrect dosing ($n = 1$), leaving 115 patients for analysis. All patients were euthyroid at the time of testing (FT4 range: 0.96–1.67 ng/dl; reference range: 0.93–1.7 ng/dl). Baseline cortisol levels were $\geq$18.1 μg/dl in 13% of patients, while 93% and 100% achieved $\geq$18.1 μg/dl at 30- and 60-minutes post-ACTH injection, respectively, indicating intact adrenal function. Notably, all patients with baseline cortisol $<$5.5 μg/dl achieved peak cortisol levels $\geq$18.1 μg/dl.
Discussion
Consistent with prior small studies, our findings in a large cohort confirm no evidence of HPA axis suppression following IVMP therapy for TED. Routine HPA function evaluation may not be necessary for TED patients receiving IVMP.

Differentiated high-grade thyroid carcinoma (DHGTC) and poorly differentiated TC (PDTC): diagnostic and therapeutic challenges in the precision medicine era - report of two cases

Aikaterini Kapama[1], Kyriakos Vamvakidis[2], Athanasios Karampeazis[3], Sofia Tseleni-Balafouta[4], Pantelis Constantoulakis[5] & George Simeakis[6]

[1]Department of Endocrinology, Diabetes and Metabolism, European and National Expertise Center for Rare Endocrine Disorders, Evangelismos General Hospital, Athens, Greece; [2]Department of Endocrine Surgery, Henry Dunant Hospital Center, 11526 Athens, Greece, Athens, Greece; [3]Oncology Unit - 401 General Military Hospital of Athens, Athens, Greece; [4]National and Kapodistrian University of Athens, Athens, Greece; [5]Genotypos-Science Labs, Athens, Greece; [6]Thyroid Cancer Outpatient Clinic - Endocrine Dept. 401 General Military Hospital of Athens, Athens, Greece.

Background
DHGTC and PDTC are rare, aggressive forms of TC with intermediate prognosis, thus posing significant therapeutic challenges.
Case-report-1
A 59-year-old male underwent total thyroidectomy with neck dissection and internal jugular vein thrombectomy due to a rapidly growing neck mass. Histopathological report revealed PDTC-70% with DHGTC foci-30%, 20/40 infiltrated lymph nodes (LNs) and tumor thrombus. Tumor molecular analysis (TMA) (AmoyDx® HANDLE Classic-NGS-Panel) revealed a *PTEN*-InDel (Intron 6, c.634 + 1G > C, p.?). Preoperative whole-body CT-scans performed due to elevated Tg:962.3ng/ml, revealed no distant metastases. However, a post-operative (4-weeks after CT-scans) 18FDG-PET CT-scan showed hypermetabolic activity in: thyroid bed, cervical/mediastinal LNs, sternum manubrium, and in a single lung nodule. Diagnostic (5mCi-^{131}I) whole-body scan (WBS) showed no uptake in the lung or sternum. Radiotherapy was delivered to the manubrium (total dose:40Gy). In chest CT-scan 75-days after 18FDG-PET, disease progression was documented with a more than double increase in the size of the lung node, slight increase in cervical LNs and rising Tg:6851.49ng/ml. Systemic treatment (ST) with lenvatinib-20mg daily, pembrolizumab-200mg Q3W and denosumab-120mg once per month, was initiated. 90-days after, mixed response was documented by 18FDG-PET (regression of lung, sternum, and LNs metastases), three new small suspicious bone lesions (right acetabulum, left hip-bone, C7-vertebra) and a lesion invading the cricoid cartilage, while Tg decreased:394.24ng/ml.
Case-report-2
A 73-year-old female with a history of large, multifocal, locally invasive papillary TC and negative for distant metastases post-therapy ^{131}I-WBS underwent revision surgery due to disease persistence. Histopathological report revealed widely invasive DHGTC with PDTC foci, which was in concordance with the revised by an expert pathologist first report. Chest CT-scan revealed multiple cannonball lung metastases while brain-MRI revealed 10 metastatic lesions; Tg:6325.17ng/ml. TMA revealed a *BRAF*V600E mutation. Stereotactic radio-surgery was performed to brain metastases (maximum dose:24Gy) with a lesion volume decrease up to 75% within two-months. ST treatment with dabrafenib 75mg-bid was initiated and a mixed response in lung was documented within 3-months while increased Tg:15679.18ng/ml, implied possible re-differentiation. Nevertheless, structural progression was documented after one-month with subsequent Tg decrease:10111.02ng/ml and Trametinib-2mg daily was added to the treatment. Mixed response in lung was documented within 2-months with increased Tg:20159.66ng/ml. Albeit mixed response, the patient succumbed to complications from lung metastases.
Conclusion
PDTC and DHGTC are rare, aggressive types of TC requiring a multidisciplinary approach. When and where to perform locoregional therapies in combination with the type of ST according to TMA is of paramount significance towards appropriate therapeutic management and precision medicine implementation.

Hypothyroidism in infants and young children: diagnostic challenges and clinical manifestations

Ayesha Abdul Razzaq[1,2], Rehmana Waris[1], Aimen Waris[3] & Aqeela Ayub[3]
[1]Children Hospital, PIMS, Islambad, Pakistan; [2]Children Hospital, PIMS Islamabad, Islamabad, Pakistan; [3]Holyfamily Hospital, Rawalpindi, Pakistan.

Objectives
The incidence of pediatric hypothyroidism is rising with nearly 1 in 257 infants affected each year in our country. Disease is usually diagnosed late due to vague symptoms. Current study is conducted to identify the symptoms which should alert the physicians and help in reaching correct diagnosis.
Study design
This is a observational and prospective study.
Place and duration of study: It was conducted at Children Hospital, Pakistan Institute of Medical Sciences from March 2023 to March 2024.
Methods
Children aged 5 years or below with low serum T4 and raised TSH levels were included in study. Data was analyzed by applying appropriate statistical tests via SPSS.
Results
In newborns to infants up to 3 months of age, the most common symptoms are prolonged jaundice, feeding difficulties, and constipation. Between 3 months to 1 year, constipation, hypotonia, and coarse facies become the predominant features. From 1 to 5 years, the most frequently observed signs include hypotonia, coarse facies, short stature, and periorbital puffiness. The most common clinical manifestation across all age groups is hypotonia (75.4%), followed by coarse facies (64.9%) and constipation (64.9%). Other notable features include periorbital puffiness, feeding difficulties, prolonged jaundice, short stature, developmental delay, umbilical hernia, wide anterior fontanelle, and in some cases, goiter.
Conclusion
Hypothyroidism in children is challenging to diagnose due to its nonspecific symptoms, which often overlap with other conditions. The prevalence of this condition in the pediatric population within our region highlights the need for prompt and efficient diagnosis and management. Special attention should be given to infants presenting with persistent jaundice, feeding difficulties, or poor weight gain. Beyond infancy, clinical signs such as hypotonia, coarse facial features, delayed development, and poor growth should raise suspicion for hypothyroidism. Early recognition and treatment are crucial to prevent long-term complications, including developmental delays and cognitive impairment.
Key Words
Hypothyroidism, persistent Jaundice, generalized hypotonia, coarse facies, Constipation.

JOINT3406

Graves' disease in monozygotic twins: a case report and literature review

Marwa Ibrahim[1] & Khalid Hussain[1]
[1]Sidra Medicine, Endocrine and Diabetes, Doha, Qatar.

Background
Graves' disease (GD) is an autoimmune disorder that leads to hyperthyroidism, primarily due to the activation of the thyroid gland by thyrotropin receptor antibodies (TRAb). GD in children is rare, and its occurrence in monozygotic twins is even more uncommon. This case explores the potential genetic and environmental factors contributing to GD in twins.
Case Presentation
A 3-year-old female (a preterm product of an IVF, part of a monozygotic twin). was otherwise healthy except for mild eczema. She presented with six months history of intermittent loose stools, mild abdominal discomfort, and later, increased appetite, hyperactivity, insomnia, and palpitations. Clinical evaluation revealed tachycardia (HR 150-160 bpm), elevated Free T4 (> 65 pmol/L), and suppressed TSH (< 0.01 mIU/L), confirming hyperthyroidism. Thyroid antibody testing was positive for Anti-TG Ab (232 IU/L), Anti-TSHR Ab (27.5 IU/L), and elevated TPO antibodies (213 kIU/L). Goiter grade I in examination. Neck ultrasound showed a mildly enlarged thyroid with hyperemia. The patient was treated with carbimazole and propranolol, leading to gradual improvement. The second twin, despite positive thyroid antibodies (TSHR Ab < 0.8, TPO 51, Anti-TG Abx 647 IU/ml), remain euthyroid.
Literature Review
Graves' disease (GD) in monozygotic twins is rare, with few cases reported, especially in this age group. Genetic factors, including shared HLA alleles and thyroid-specific antibodies, may predispose twins to autoimmune thyroid disorders. A 2019 study by Smith *et al*. described a case where one twin developed GD while the other remained euthyroid, despite both having thyroid antibodies, highlighting the complex interaction between genetic predisposition and environmental factors like infections, stress, or maternal thyroid dysfunction. Del Giudice *et al*. (2018) found that monozygotic twins are at a higher risk for GD than dizygotic twins, emphasizing the role of genetics. However, environmental triggers may determine whether one twin develops the disease while the other stays asymptomatic.

Discussion
The presence of thyroid antibodies in the second twin, despite euthyroid status, suggests an increased future risk for GD. The published Literature supports the observation that elevated TRAb levels can precede clinical disease and may serve as a biomarker for early intervention. This case underscores the importance of monitoring for GD in siblings with positive thyroid antibodies, especially in the context of family history..
Conclusion
This case of monozygotic twins with divergent thyroid outcomes underscores the complex interplay of genetic and environmental factors in autoimmune thyroid disease. Early detection and monitoring of at-risk individuals are crucial.

The value of ultrasound features and elastography in the diagnosis of medullary thyroid carcinoma

Monica Latia[1], Andreea Bena[2], Stefania Bunceanu[1], Luciana Moisa-Luca[1] & Dana Stoian[2]
[1]Victor Babes University of Medicine and Pharmacy, Department of Doctoral Studies, Timisoara, Romania; [2]Victor Babes University of Medicine and Pharmacy, Discipline of Endocrinology, Second Department of Internal Medicine, Timisoara, Romania.

Introduction
Medullary thyroid carcinoma (MTC) is a rare thyroid malignancy with distinct histological characteristics, making its diagnosis via conventional ultrasound (US) challenging. Although malignancy risk stratification benefits from features like hypoechogenicity, irregular margins, and microcalcifications, their specificity for MTC remains under debate. This study evaluates the potential of combining elastographic stiffness measurements with US features to improve diagnostic accuracy in MTC.
Materials and Methods
This study analyzed 20 histopathologically confirmed MTC cases. Conventional US was used to assess nodule features indicative of malignancy, including hypoechogenicity, inhomogeneity, a taller-than-wide shape, irregular margins, microcalcifications, an interrupted thyroid capsule, and suspicious cervical lymphadenopathy. Shear Wave Elastography (SWE) (Aixplorer Mach 30) quantified nodule stiffness, with a mean elasticity index (EI) cut-off of 30 kPa used to suggest malignancy.
Results
The median patient age was 53.5 years, with a female predominance (70%, 14/20). The median nodule volume was 0.55 ml. All nodules were solid and hypoechoic, with 80% (16/20) showing inhomogeneous echotexture. Seven nodules had a taller-than-wide shape, and eight demonstrated irregular margins. No cases showed an interrupted capsule, while suspicious lymph nodes were detected in three cases on US. Microcalcifications were noted in 35% (7/20) of nodules, and 60% (12/20) were classified as high-risk according to TIRADS. SWE revealed increased stiffness in 75% (15/20) of nodules. The median EI was 35.5 kPa, with a maximum of 58.8 kPa. Coexisting autoimmune thyroiditis was present in 40% (8/20) of patients.
Conclusions
Integrating elastographic stiffness measurements with conventional US features enhances the diagnostic precision for MTC. SWE, in particular, serves as a reliable, non-invasive adjunct in differentiating malignant from benign thyroid nodules, emphasizing its clinical utility in routine practice.

Keywords
medullary thyroid carcinoma, ultrasound, elastography, shear wave elastography, diagnostic imaging.

The quest for reliable biomarkers: circulating free DNA in thyroid cancer

Ali Al Jumaah[1,2], Shailesh Gohil[1,2], Narendra Reddy[1,2], Jacqui Shaw[1] & Miles J Levy[1,2]
[1]University of Leicester, Leicester, United Kingdom; [2]University Hospitals of Leicester NHS Trust, Leicester, United Kingdom.

Introduction
Thyroid cancer (TC) is the most common endocrine malignancy. The overall 5-year survival is in excess of 85%, especially in well-differentiated papillary type. Despite the very good prognosis, 20% of patients would have recurrence. Currently, surveillance consists of serial thyroglobulin, calcitonin and CEA, imaging and biopsies. All of which have limitations from poor sensitivity to risk of malignancy and invasiveness. Circulating Cell-free DNA (cfDNA) is a liquid biopsy that detects circulating DNA fragments in plasma. It is simple, non-invasive and has shown promising results in other cancers, such as breast and colon.
Aim and Objectives
We hypothesise that cfDNA can be used as a surveillance tool in TC, by plotting serial cfDNA levels against the clinical course of TC.
Methods
Eighty-two plasma samples were collected from 23 patients during follow up at different stages of TC (pre-op, post-op, post RI/chemo, remission, stable disease, residual disease, progression/mets). cfDNA was extracted using QIAamp® circulating NA kit (Qiagen). Total cfDNA and fragment length distribution was determined using 4200 TapeStation (Agilent Technologies).
Results
Participants characteristics are summarised in table 1. The lowest cfDNA concentration was 87ng/ml and the highest was 1430ng/ml. The mean value of cfDNA in each stage of the disease is shown in tablet 2. Papillary TC produced mean cfDNA concentration of 276.4ng/ml, compared to in 230.4ng/ml Follicular, 232.2ng/ml in Medulary and 298.2ng/ml in Anaplastic type. Interestingly, the highest cfDNA concentration was extracted from post-op plasma sample and the 2nd highest was from plasma sample taken during remission.
Discussion
Our results showed that cfDNA levels did not track disease activity although cfDNA was detected in patients with anaplastic and poorly-differentiated TC. The role of cfDNA in non-aggressive tumours without metastases is less clear and larger-scale studies are required to examine cfDNA role in surveillance of TC.

Table 1: Participants and tumour characteristics *TC: Thyroid Cancer.*

Autoimmune thyrogastric syndrome: clinical features, diagnosis, and management

Raida Ben Salah[1], Faten Hadj kacem[1], Sameh Marzouk[1], Nadia Charfi[1] & Zouheir Bahloul[1]
[1]University of Sfax, Internal Medicine, Sfax, Tunisia.

Introduction
Autoimmune thyrogastric syndrome is a rare condition characterized by the co-occurrence of autoimmune thyroid disease and gastric disorders, often associated with autoimmune gastritis. The syndrome can lead to both thyroid dysfunction and digestive symptoms, presenting diagnostic challenges due to the overlap of clinical manifestations. The aim of this study is to explore the clinical features, diagnostic approaches, and outcomes of patients diagnosed with autoimmune thyrogastric syndrome.
Methods
We conducted a retrospective analysis of patients diagnosed with autoimmune thyrogastric syndrome at our institution. Clinical data, including thyroid function tests, gastric biopsy results, and serological markers (such as anti-thyroid antibodies and anti-intrinsic factor antibodies), were collected. Additionally, we assessed patients' clinical outcomes following treatment with thyroid hormone replacement therapy and vitamin B12 injections. Gastroscopy was performed to assess the presence of autoimmune gastritis and other gastric abnormalities.
Results
A total of 12 patients (9 women, 3 men) were included in the study. The mean age at diagnosis was 48.5 years (range: 35-70 years). Of these patients, 10 had autoimmune hypothyroidism, 2 had hyperthyroidism, and 9 were diagnosed with autoimmune gastritis. Positive anti-thyroid peroxidase antibodies were found in 10 patients, and anti-intrinsic factor antibodies were present in 7 patients. Gastroscopy revealed signs of atrophic gastritis in 8 cases, with villous atrophy observed in 4 cases. After treatment with thyroid hormone replacement and vitamin B12 supplementation, 8 patients showed significant improvement in both thyroid function and gastrointestinal symptoms, while 3 patients had partial improvement. One patient did not show any significant clinical response.
Conclusion
Autoimmune thyrogastric syndrome is an uncommon but important condition that involves both thyroid and gastric autoimmune dysfunction. Early recognition and appropriate treatment, including thyroid hormone replacement and vitamin B12 supplementation, are essential for managing symptoms and improving patient outcomes. Clinicians should consider the possibility of this syndrome in patients presenting with symptoms of both thyroid and gastric disorders, particularly when autoimmune gastritis is suspected. Further studies are needed to better understand the pathophysiology and optimal management strategies for this syndrome.

Dozens of doubts: a series of atypical presentations of medullary thyroid carcinoma running title: atypical presentations of medullary thyroid carcinoma

Sanja Medenica[1], Ananda Mohan Chakraborty[2], Ana Ostojic[3], Liza Das[2], Uma Nahar Saikia[4], Rajender Kumar[5], Debajyoti Chatterjee[4] & Pinaki Dutta[2]
[1]University of Montenegro, Department of Endocrinology, Podgorica, Montenegro; [2]PGIMER, Chandigarh, Department of Endocrinology, Chandigarh, India; [3]University of Montenegro, Department of Pulmonary Medicine, Podgorica, Montenegro; [4]PGIMER, Chandigarh, Department of Histopathology, Chandigarh, India; [5]PGIMER, Chandigarh, Department of Nuclear Medicine, Chandigarh, India.

Medullary thyroid carcinoma (MTC), originating from parafollicular C cells, accounts for 5- 10% of thyroid malignancies but is responsible for 15% of thyroid cancer-related mortality. This case series reviews 12 atypical presentations of MTC, highlighting significant diagnostic and therapeutic challenges. About 80% of MTC cases are sporadic, while 20% are hereditary, often linked to multiple endocrine neoplasia (MEN) syndromes. The predominant clinical manifestations include neck swelling, diarrhoea, and metastatic symptoms. In our cohort of 80 MTC patients, we identified 5 with considerable diagnostic ambiguity and with management complexities due to therapy-related complications. Notably, we observed cases with coexisting conditions such as chondrosarcoma, concurrent carcinoma prostrate, and ectopic Cushing's syndrome, complicating the clinical picture. We also had one female subject who have presented at the age of 16 years with negative RET mutation. One patient demonstrated a rare association with Marfanoid habitus linked to a RET mutation. One of them presented with metachronous VHL spectrum (Pheochromocytoma, pancreatic cysts and clear cell subtype of renal cell carcinoma) disease with MTC. one each presented with bowel perforation in an area uninvolved by metastatic process attributed to Lenvatinib treatment and glomerulonephritis due to tyrosine kinase inhibitor. This series underscores the necessity for comprehensive evaluation and individualized management strategies in MTC cases. Cases and figures will be elaborated during presentation. Given the potential for diverse clinical presentations and complications, our cases highlight the importance of awareness among healthcare providers regarding the varied manifestations of MTC, which can obscure diagnosis and complicate treatment.

JOINT1873

Low risk of malignancy in thyroid nodules at our centre

Marta Carrasco Marín-Blasco[1], Laia Capdevila Torrents[1], Fernando Herrerías González[2], Alba Dalmau Vila[1], Carolina López Cano[1] & Ferran Rius Riu[1]
[1]Hospital Universitari Arnau de Vilanova de Lleida, Endocrinology and Nutrition, Lleida, Spain; [2]Hospital Universitari Arnau de Vilanova de Lleida, General Surgery, Lleida, Spain.

Objectives
To evaluate the results of cytology tests performed at our centre, correlate them with ultrasound characteristics and, in cases with surgical indication based on cytology results (Bethesda IV-VI), compare them with final pathological findings.
Patients and Methods
The EU-TIRADS classification was used for ultrasound characteristics, and the Bethesda system was used for cytology results. We analysed the results of 1,236 valid cytology samples recorded in our database from 20 June 2019 to 24 May 2024. Of the 93 nodules classified as Bethesda IV-VI, pathological findings were reviewed for the 87 that underwent surgery.
Results
The distribution of Bethesda categories was as follows: 938 nodules (75.9%) were Bethesda II, 202 (16.3%) Bethesda III, 26 (2.1%) Bethesda IV, 37 (3%) Bethesda V, and 33 (2.7%) Bethesda VI. Among EU-TIRADS 3 nodules, 19 out of 666 (2.9%) were Bethesda IV-VI; among EU-TIRADS 4, 36 out of 576 (6.3%); and among EU-TIRADS 5, 38 out of 257 (14.8%). Malignancy was confirmed in 62 out of 87 (71.3%) surgically treated cases: 5 out of 23 (21.7%) Bethesda IV nodules were malignant, 28 out of 36 (77.8%) Bethesda V nodules, and 32 out of 32 (100%) Bethesda VI nodules. For EU-TIRADS 3, 666 cytology tests were performed, with 5 (0.75%) confirmed malignancies; for EU-TIRADS 4, 576 tests with 25 (4.3%) malignancies; and for EU-TIRADS 5, 36 out of 257 (14%) malignancies.
Conclusions
The results indicate lower-than-expected rates of suspicious cytology and confirmed malignancy. Given the low malignancy rates across all ultrasound risk categories, we believe this may reflect a lower risk of malignancy in our population. The findings also support less aggressive surgical approaches or follow-up for nodules with Bethesda IV cytology in our patients.

Peculiarities of diagnostic gluten intolerance in ukrainian patients with autoimmune thyroiditis

Oksana Khyzhnyak[1], Myroslava Mykytyk[1], Olga Oleksyk[2,3], Roman Nikolaiev[1], Arsen Bilanin[4] & Svitlana Opalenyk[3,5]
[1]V. Danilevsky Institute for endocrine pathology problems NAMS of Ukraine, Department of Clinical Endocrinology, Kharkiv, Ukraine; [2]Zakarpatska Endoclinica, Uzhhorod National University, Uzhhorod, Ukraine; [3]Uzhhorod National University, Uzhhorod, Ukraine; [4]Zakarpatska Endoclinica, Uzhhorod, Ukraine; [5]Zakarpatska Endoclinica, Uzhhorod, Ukraine, Uzhhorod National University, Uzhhorod, Ukraine.

The prevalence of celiac disease (CD) in patients with chronic autoimmune thyroiditis (AIT) is estimated to be between 2 and 7.8%.
The aim of the study is to determining the frequency of combined autoimmune pathology - AIT and CD, including gluten intolerance without CD in Ukrainian patients.
Materials and methods
173 patients (three age groups: I – 5-20, II - 21-45, III – 46-60 yrs) with AIT and anti-thyroid peroxidase (ATPO) blood level exceeding 500 μIU/ml were examined: $n = 35$ M/138 F. Thyroid status was assessed using TSH and fT4 levels. Ultrasound diagnostics were also used to visualize the thyroid gland. Statistical processing of the results was performed using Package for Social Sciences v.16.0 (SPSS Inc, Chicago, Il, USA).
Results and discussion
It was found that 32.4% ($n = 56$) patients of all age had a high titer of anti-tissue transglutaminase antibody IgG (tTG) or anti-gliadin antibody IgG (AB AGA). In the I group a positive titer tTG IgG was in 14.3%, AGA IgG in 17.9%, in the II group – in 10.5% and 27.6%, respectively; in the III group – in 5.8% and 23.2%, respectively. Simultaneously positive titer of tTG and AGA IgG and IgA was only in 4 patients (2.3%), which in the presence of pronounced activity of antithyroid immunity, moderate hypothyroidism, as well as erased gastrointestinal symptoms and other nonspecific extraintestinal clinical signs, allows with a high degree of probability to establish the diagnosis of "CD" in these patients. In patients with only one elevated indicator - AGA IgG, it is possible to diagnose "Gluten intolerance without CD". Given the low frequency (2.9%) of high titer tTG IgA, the use of these indicators as a screening examination of patients with AIT is not advisable. Analysis of the dependence of the level of AGA IgG on the activity of thyroid autoimmunity revealed a positive correlation ($r = 0.83$, $P = 0.01$) with the level of ATPO, i.e., with high levels of ATPO, the frequency and severity of the immune response to the pathological effects of gluten increases.
Key words
autoimmune thyroiditis, celiac disease.

Unusual presentation of hypothyroidism: pericardial effusion is not always due to cardiac cause
Dina Fawzy[1] & Dina Mammdouh[1]
[1]Pediatric Endocrinology and Diabetology Unit, Alexandria University, Pediatric Endocrinology and Diabetology Uni, Alexandria, Egypt.

Background
Pleural and pericardial effusion is a rare complication of severe hypothyroidism in children but can be present in 10 to 30 % of adults. Most pediatric cases have been in children with Down syndrome, Pericardial effusion in hypothyroidism is due to the increased capillary permeability, albumin distribution volume and reduced lymph drainage in pericardial cavity. Its presence in mild cases of hypothyroidism is uncommon although it can be seen in severe, long-standing hypothyroidism. The management of pericardial effusions is with thyroid replacement with or without an intervention to drain the fluid. Several studies have shown successful management of hypothyroid-induced pericardial effusion with echocardiographic tamponade physiology, but not clinical cardiac tamponade, to be treated effectively with levothyroxine alone.
Case presentation
A 12-year-old Down syndrome female, presented to our ER with complaints of dyspnea. The condition started one week before admission with orthopnea, the child started to sleep only on sitting 45 degrees position + progressively increasing dyspnea for 5 days at start on effort then one day before admission she developed dyspnea at rest. She is a known case of Down Syndrome karyotyping + echo showing VSD 8 mm at one month old with no follow up Her Examination: HR 100 bpm – BP 100/70 mmHg, RR 30 cycles/min Temp. 36.4°c, her anthropometric measurements: Height 150 cm (-0.68 SD), Weight 68 kg(+ 1.9 SD), BMI 30.2 (98th percentile), cardiac examination: Heart distant heart sound with murmur at mitral area, general examination: facial features of down syndrome, bilateral Lower limbs edema up to sacrum, Neck showed goiter with resonant sternum. She withdrew routine labs + TSH and freeT4 for screening of hypothyroidism. Till results revealed she did echocardiogram showed VSD 10 mm and moderate pericardial effusion with clear fluid.
TSH more than 1500 microIU/ml**, Free T4 0.6** ng/dl **The child received l troxin 50 mic/day + lasix IV + ACE Inhibitor**
Follow up after one week echocardiogram showed mild pericardial effusion + VSD
Follow up after 2 weeks: TSH 30 free T4 0.98, no pericardial effusion.
Conclusions
Hypothyroidism is one of the uncommon etiology causing pericardial effusion. Even though it occurs in long-standing myxedema, it can occur in mild cases too, which when unnoticed can be fatal. Since with early cardiac assessment and adequate thyroid replacement therapy, the pericardial effusion due to hypothyroidism can be reversible, it needs to be identified and managed early.

JOINT2759 Assessing sensitivity of thyroglobulin measurement in neck node fine needle washout for diagnosis of thyroid cancer metastasis: use of node dissection and 131I scintigraphy as reference standards
Romain Vankemmel[1], Christine Do Cao[2], Miriam Ladsous[2], Samuel Boury[3], Camille Marciniak[4], Sebastien Aubert[5], Georges Lion[6], Pascal Pigny[1] & Benoit Soudan[1]
[1]Lille University Hospital, Department of Biochemistry and Hormonology, Metabolism, Nutrition and Oncology, Lille, Francexb; [2]Lille University Hospital, Department of Endocrinology, Diabetology and Metabolism, Lille, France; [3]Lille University Hospital, Department of Radiology, Lille, France; [4]Lille University Hospital, General and Endocrine Surgery Department, Lille, France; [5]Lille University Hospital, Department of Pathology, Lille, France; [6]Lille University Hospital, Nuclear Medicine Department, Lille, France

Background
Detecting cervical node metastasis prior to surgery in patients with differentiated thyroid cancer is essential for guiding the extent of thyroid surgery and neck dissection. Guidelines recommend performing thyroglobulin measurement in fine needle washout to improve the sensitivity of ultrasound (US)-guided fine needle cytology for the diagnosis of neck node metastasis. The choice of 1 ng/ml of thyroglobulin as cut-off value for diagnosing metastasis remains controversial. Confirmation of the metastatic disease by node dissection is not feasible in many cases, thus leading to a risk of misclassifying the patients' status. In those cases, US node features are used to evidence patients' status at later stage. However, cervical lymph node metastases usually remain stable for years after thyroidectomy, and US node features suggestive of malignancy often lack sensitivity.
Objective
To assess sensitivity of thyroglobulin measurement in fine needle washout for the diagnosis of thyroid cancer node metastasis.
Methods
For this retrospective monocentric study, data on eligible patients attending our onco-endocrinology from 2011 to 2024 were collected using electronic records. Inclusion criteria were: completion of presurgical fine needle puncture of suspicious lymph nodes; subsequent thyroglobulin measurement in the needle washout; subsequent thyroidectomy; eligibility for 131I therapy after thyroidectomy. Diagnostic accuracy was assessed using a composite reference standard: histopathological lymph node examination if the node was dissected, or presence of 131I uptake on postablation scintigraphy if the node was not.
Results
A total of 537 patients were screened for eligibility. For 63 patients, metastatic status of punctured lymph node was confirmed by neck node dissection report or by 131I scintigraphy. For 14 patients, the punctured lymph node was free of metastasis. Area under the ROC curve (AUC) was 0.91 (95% confidence interval 0.85 - 0.98). Sensitivity of thyroglobulin measurement in needle washout was 87 % (95% confidence interval 76.9 - 93.4) for the threshold of 1 ng/ml.
Conclusions
Thyroglobulin measurement in fine needle washout efficiently detects neck node metastasis of differentiated thyroid cancer. We use 131I scintigraphy combined with histopathological records as a reference standard for assessing diagnostic accuracy. More studies estimating sensitivity of this diagnostic test are needed to help clinicians in the therapeutic choice. Local registration: DEC24-307

Thyroid disease related to the SARS-CoV-2 virus

Ifigenia Kostoglou-Athanassiou[1], Lambros Athanassiou[2], Xenia Poimenidi[1] & Panagiotis Athanassiou[3]
[1]Asclepeion Hospital, Voula, Department of Endocrinology, Diabetes and Metabolism, Athens, Greece; [2]Asclepeion Hospital, Voula, Department of Rheumatology, Athens, Greece; [3]St. Paul's Hospital, Department of Rheumatology, Thessaloniki, Greece

The SARS-CoV-2 virus affects the respiratory system and causes pneumonia. However, it also affects other organ systems. As the COVID-19 pandemic swept over humanity it became apparent that it may affect the thyroid gland, as various cases of subacute thyroiditis started to emerge in relationship with the COVID-19 infection. The aim was to describe cases of thyroid disease observed and followed-up over a period of 4 years in a tertiary care facility.

Methods

Over a period of 4 years 6 cases of thyroid disease were diagnosed and follow-up in a tertiary care facility. These 2 cases of subacute thyroiditis, in 2 female patients, aged 45 and 48 years, respectively, 30 and 15 days after a mild COVID-19 infection, 1 case of subacute thyroiditis after the mRNA vaccine in a male patient aged 51 years, 1 case of Graves' disease after a COVID-19 infection in a female patient aged 33, 1 case of disease aggravation after a COVID-19 infection in a previously quiescent case of Graves' disease in a female patient aged 48 years and 1 case of hypothyroidism due to Hashimoto thyroiditis 6 weeks after a COVID-19 infection in a female patient aged 56 years.

Results

The patients who developed subacute thyroiditis after a SARS-CoV-2 infection were dealt with by prednisolone administration. However, in one of the patients the disease recurred, and steroids were administered. After remission the patient developed subclinical hypothyroidism and thyroxine was administered. Two years later both patients need 50 μg thyroxine daily to remain euthyroid. The patient who developed subacute thyroiditis following vaccination against COVID-19 received prednisolone and following tapering he is euthyroid. In the patient who developed Graves' disease and also developed thyroid ophthalmopathy, antithyroid medication was administered followed by subtotal thyroidectomy and ophthalmopathy is stable. The patient who had recurrence of Graves' disease is now stable on treatment with unimazole and thyroxine on a block and replace regimen. The patient who developed hypothyroidism is stable thyroxine. It appears that the SARS-CoV-2 virus affects the thyroid gland. It is related to the development of subacute thyroiditis, Hashimoto's thyroiditis, painless thyroiditis and Graves' disease as well as exacerbation of previously quiescent Graves' disease. It appears that thyroid cells express the ACE2 enzyme which acts as a receptor for the virus. However, as by now almost the entire population has been infected by COVID-19, thyroid disease in the context of the SARS-CoV-2 infection is relatively uncommon.

Post-alemtuzumab thyroid autoimmunity remitting after commencement of ocrelizumab in patients with multiple sclerosis

Paraskevi Kazakou[1], Dimitrios Tzanetakos[2], Stavroula Paschou[1], Chrysoula Michaletou[3], Maria Anagnostouli[3], Constantinos Kilidireas[3], Evangelia Zapanti[4] & Panos Stathopoulos[3]
[1]Endocrine Unit and Diabetes Centre, Department of Clinical Therapeutics, Alexandra Hospital, School of Medicine, National and Kapodistrian University of Athens, Athens, Greece; [2]Second Department of Neurology, School of Medicine, National and Kapodistrian University of Athens, "Attikon" University Hospital, Athens, Greece; [3]Multiple Sclerosis & Demyelinating Diseases Unit, 1st Department of Neurology, Eginition Hospital, School of Medicine, National and Kapodistrian University of Athens, Athens, Greece; [4]Department of Endocrinology, Alexandra Hospital, Athens, Greece

Objective

Immune reconstitution therapies (IRT), which include antibody-based cell-depleting therapies targeting CD52+ (alemtuzumab) or CD20+ (rituximab, ocrelizumab) leukocytes, are approved for the treatment of multiple sclerosis. Autoimmune thyroid disease (AITD) is the most common adverse effect of alemtuzumab treatment; Graves' disease (GD) being the most prevalent manifestation followed by Hashimoto Thyroiditis (HT).

Patients

We present nine clinical cases of secondary AITD induced by alemtuzumab (five cases of GD and four cases of HT) in which remission of thyroid autoimmunity was achieved after the initiation of ocrelizumab and in one case after commencement of rituximab and ocrelizumab subsequently.

Results

The five patients who developed GD post-alemtuzumab were initially treated with antithyroid drugs (ATD) and continued on "block and replace" treatment; two of them developed a fluctuating course between hyperthyroidism and hypothyroidism. Since the start of ocrelizumab all five patients have experienced an improvement in the course of GD with continuous decrease of thyroid-stimulating immunoglobulin (TSI) levels. In three patients GD resolved and ATD were stopped. The other two patients are currently under medical treatment in a dose reducing regimen. Similarly, thyroid autoimmunity with positive autoantibodies [anti-thyroglobulin (anti-Tg) and anti-thyroperoxidase (anti-TPO) antibodies] in all four patients who developed HT is under remission.

Conclusion

These cases highlight the possibility of remission of post alemtuzumab thyroid autoimmunity, especially GD, after ocrelizumab treatment with avoidance of further medical or surgical treatment.

T cell gene expression differences between ATA+ infertile euthyroid and ATA+ hypothyroid patients

Viktória Temesfői[1,2], Péter Kaltenecker[1,2], Anna Nörenberg[1,2], Tímea Serény-Litvai[1,2], József Kun[2,3], Péter Urbán[2,3], Attila Gyenesei[2,3] & Emese Mezősi[2,4]
[1]Szentágothai Research Centre, University of Pécs, Pécs, Hungary; [2]National Laboratory on Human Reproduction, University of Pécs, Pécs, Hungary; [3]Hungarian Centre for Genomics and Bioinformatics, Szentágothai Research Centre, University of Pécs, Pécs, Hungary; [4]1st Department of Medicine, Clinical Center, Medical School, University of Pécs, Pécs, Hungary

Autoimmune thyroiditis – background

Hashimoto's thyroiditis is marked by the presence of autoantibodies (ATA) targeting thyroid peroxidase (anti-TPO) or thyroglobulin (anti-Tg), along with immune cell infiltration into the thyroid gland, resulting in chronic inflammation. Together with the impairment of central and peripheral tolerance, autoreactive $CD4^+$ and cytotoxic T cells play a crucial role in the pathogenesis and maintenance of the disease. Chronic inflammation ultimately leads to diminished thyroid function and an increase in thyroid-stimulating hormone (TSH) levels. ATA positivity does not necessarily result in hypothyroidism; yet, the clinically insignificant disease is a substantial risk factor for fertility and pregnancy complications even with a functionally intact thyroid gland and normal TSH levels.

How infertility is linked to autoimmune thyroiditis – hypotheses

Systemic immune disfunction affecting reproductive organs and maternal-fetal tolerance associated with ATAs present at reproductive sites. Relative insufficiency of the thyroid gland during pregnancy characterised by elevated TSH levels, as the thyroid gland fails to meet increasing hormonal demands.

Comparisons and results

We analyzed the gene expression patterns of total peripheral T cells (polyA, bulk mRNA) from ATA+ infertile euthyroid, ATA+ hypothyroid patients, and age-matched healthy controls (three individuals in each group). In the hypothyroid group, NF-κB, p53, TNF, cell proliferation, IL-17 signaling and migratory pathways were upregulated compared to both ATA+ euthyroid and healthy individuals, and members of the CXC chemokine subfamily exhibited elevated expression alongside inflammatory cytokines, such as IL-1α, IL-1β. Euthyroid ATA+ individuals showed no relevant alterations in their T cell gene expression profile relative to the healthy group, suggesting that discernible functional differences at the level of T cells emerge only when the thyroid gland is compromised, and fertility issues most likely have an underlying cause that is not necessarily present at T cell gene expression levels. Furthermore, while the impacted pathways were largely analogous in comparison of the hypothyroid vs. healthy, as well as between the hypothyroid vs. euthyroid ATA+ groups, minor differences were noticeable, including the HIF1 signaling pathway, indicating a transition to anaerobic metabolism only subsequent to thyroid dysfunction.

Genetic testing in medulary thyroid cancer in a tertiary center in Romania

Stanescu Laura-Semonia[1], Bratu Gratiela[1], Sofia-Maria Lider-Burciulescu[1,2], Andrei Muresan[1], Dumitru Ioachim[1], Ruxandra Dobrescu[1] & Corin Badiu[1,2]
[1]"C. I. Parhon" National Institute of Endocrinology, Endocrinology 4, Bucharest, Romania; [2]"C Davila" University of Medicine and Pharmacy, Endocrinology, Bucharest, Romania

This is a single-center study of 106 subjects who were tested for germline RET mutations at our center. Among those, 97 were diagnosed with MTC and 9 had genetically positive family history and underwent screening. A total of 74 patients underwent complete RET gene testing on exons 5, 8, 10, 11, 13, 14, 15, 16 and on the rest of 32 patients targeted analysis was performed. We identified a germline RET variant in 40 of 106 (37.7%) patients from 9 families; 8/40 (20%) were initially considered sporadic cases based on the negative family history for MTC or MEN2 related pathologies and from the 32 patients with positive family history, 9 were index cases and 23 relatives. Considering the identified mutations, when classified in ATA risk categories, 20/40 (50%) patients harboured a "high risk" (H) level mutation and 20/40 a "moderate risk" (MOD) level mutation. ATA H risk RET mutations: 20/20 (100%) with C634Trp/Phe/Arg mutations; 15/20 (75%) patients underwent thyroid surgery and were dignosed with MTC. Median (min-max) age at surgery was 37.4 (21-56) years. ATA MOD risk RET mutations: 8/20 (40%) patients with C618Arg mutation, 8/20 (40%) patients with C620Arg mutation and 4/20 (20%) with V804Met mutation; 16/20 (80%) patients had total tiroidectomy with median age (min-max) at surgery of 36 (10-68) years. As for genotype-phenotype correlation in MEN2 syndrome, 10/20 (50%) patients with a codon 634 mutation and 4/8 (50%) with a codon 618 mutation presented PHEO; in our cohort, no patient with codon 620 and 804 presented PHEO until the end of follow-up. Of all PHEO patients, 6/14 (42.8%) had bilateral disease with the median age of 9.6 years between left and right disease. Primary hyperparathyroidism (HPTH) was diagnosed in 6/20 patients, all with mutation in codon 634 and the median age was 43 years. Out of 66 cases tested negative for germline RET mutation, ten cases with advanced, metastatic MTC underwent RET somatic testing using fresh or formalin-fixed, paraffin-embedded primary tumor/metastasis tissue. From them, 8/10 (80%) patients tested positive for Met918Thr mutation and two cases harbored Cys634Arg mutation. Mutational screening is mandatory in all patients with extended MTC, being crucial in selecting targeted treatment with TKI inhibitors and predicting responsiveness to therapy.

10 years of experience in providing surgical care to children with nodular and diffuse toxic goiter

Eugenia Globa[1], Oleksandr Tovkai[1], Volodymyr Palamarchuk[1] & Oleksandr Nechai[1]
[1]Ukrainian Scientific and Practical Center of Endocrine Surgery, Transplantation of Endocrine Organs and Tissues of the Ministry of Health of Ukraine, Kyiv, Ukraine

Aim
To study the structure of thyroid diseases in children who required surgical treatment, analysis of their gender and age distribution, features of the preoperative, intra- and postoperative course in case of thyroid nodules (TN) and diffuse toxic goiter (DTG), to determine the frequency of early and late complications, disease recurrences and their further treatment.
Materials and methods
This retrospective cohort study included 456 children (under 18 years of age) who underwent thyroidectomy at the Center between 2013-2022. According to the results of clinical and laboratory data and final pathohistological examination, all patients were divided into 3 groups: thyroid cancer ($n = 241$), TN ($n = 151$) and DTG ($n = 64$). In the preoperative period, the duration of the disease, patients' age, sex distribution, thyroid function, the results of instrumental examinations (thyroid ultrasound, FNAB with cytological assessment according to Bethesda) were investigated in patients with TN and DTG. In patients available for further postoperative follow up, the postoperative thyroid function, frequency of early and late complications and further treatment were studied.
Results
Among all thyroid diseases that required surgical intervention, thyroid cancer (52.8%) and female gender (75%) prevailed. The mean age of the operated children was 14.4 ± 2.5 years. TN were significantly more frequent in pubertal age group ($P < 0.05$). The mean duration of the disease before surgery in case of TN was shorter than in DTG ($P < 0.001$). Thyroidectomy was most often done in DTG, and hemithyroidectomy (HT) and/or HT+ lymphadenectomy (LD) in case of TN. In 21.3% of patients with TN after HT/HT+LD, euthyroidism was achieved. In patients with DTG in the late postoperative period, persistent hypoparathyroidism was the only and most frequent complication ($n = 2$, 12.5%). In contrast, in TN in the late postoperative period, 7 patients (10%) were diagnosed with a relapse of the disease, which occurred more often in younger children (13.0 [13.0; 14.0] years) compared to the group without relapse ($P = 0.01$). Treatment of relapse included follow-up in the majority of patients with TN (71.4%).
Conclusions
Thyroid cancer predominated in the structure of thyroid diseases requiring surgical intervention. Persistent hypoparathyroidism was the only complication in the treatment of patients with DTG. Considering the preservation of euthyroidism in 21.3% of patients with TN after HT/HT+LD, broader use of organ-preserving surgery should be considered, with further evaluation of postoperative hormone replacement therapy.

Iratherapy and graves' disease: about 20 cases followed

Redhouane Longo[1] & Mourad Benrabah[1]
[1]Regional University Military Hospital, Oran, Algeria

Introduction
Graves'disease is one of the usual indications of iratherapy in the Nuclear Medicine service whose main population followed to our service is young (20-40 years), addressed after failure of medical treatment (Carbimazol).
Objective
Highlight the effectiveness of Iratherapy as the most used therapeutic weapon in the young population.
Materiels and Methods
The files have been collected since 2021 and the information is transmitted on a sheet with the following criteria: Age/Number of cures/Recurrence/result (Hypothyroidism or euthyroidism) then statistical analysis of the sample.
Results
The majority of patients treated for Graves' disease by iratherapy in our department, had a remission of their pathology with hypothyroidism as major side effect, rarely an euthyroidism. Recurrence after the first treatment is $<10\%$, which required the administration of 2 to 3 additional treatments.
Discussion
The effectiveness of irathatherapy is no longer to be demonstrated in the literature and in current practice, and the results in our patients treated at our service confirm this trend. Resistance to iratherapy; requiring a 2nd, 3rd cure; is related to an increased volume of the thyroid gland at the time of administration of iodine 131; Patients with failed irathérapie are referred for surgery.
Conclusion
Iratherapy is an effective therapeutic weapon for Graves' disease, to be preferred among the young and professionally active population with a very low recurrence rate.

Hashimoto's thyroiditis or graves' disease? a case of thyroid autoimmune disease with oscillating thyroid function

Alberto Arbex[1], Ivana Magalhaes[2], Amanda Montenegro[2], Mariana Arbex[1], Gustavo Arbex[1] & Renata Bussuan[2]
[1]Grossenwiehe Medical Clinic, Endocrinology, Flensburg, Germany; [2]AFYA Medical School, Endocrinology, Rio de Janeiro, Brazil

Introduction
Thyroid autoimmune diseases are characterized by a wide spectrum of clinical manifestations ranging from hypothyroidism to hyperthyroidism. This case highlights the diagnostic and therapeutic challenges of managing a patient with suspected overlapping autoimmune thyroid conditions.
Case Presentation
A 45-year-old woman was initially diagnosed with hyperthyroidism in 2008. Laboratory findings included TSH 0.004 μIU/ml (reference range: 0.35–4.94) and positive thyroid peroxidase antibodies (anti-TPO >600 U/ml). Thyroid

scintigraphy revealed a warm nodule in a normocaptating gland. Tapazole was prescribed but not initiated. She lost follow-up and returned one year later with hypothyroidism (TSH 5.208 µIU/ml). Levothyroxine therapy was initiated and titrated to 50 mg/day, achieving euthyroid status. During pregnancy, the levothyroxine dose was increased to 88 mg/day. The patient remained stable until 2019, when progressive thyroid function normalization allowed dose reduction, culminating in levothyroxine discontinuation in January 2020. Three months later, without levothyroxine, she developed hyperthyroidism symptoms, including tachycardia and insomnia. Laboratory tests showed TSH <0.02 µIU/ml, elevated free T4 (1.52 ng/dl), anti-TPO 692.59 U/ml, and TSH receptor antibodies (TRAb) 8.99 U/l (reference <0.55). Thyroid ultrasound revealed gland enlargement (volume: 11.8 cm^3) with an increased Doppler flow. An antithyroid medication was not initiated, and six months later, thyroid function spontaneously normalized (TSH 1.01 µIU/ml, free T4 0.75 ng/dl). The patient remains asymptomatic under regular follow-up.

Discussion

This case demonstrates the diagnostic complexity of thyroid autoimmune diseases, presenting features of both Hashimoto's thyroiditis and Graves' disease. The oscillation between hypothyroidism and hyperthyroidism, presence of positive anti-TPO, anti-TG, and TRAb, and the spontaneous normalization of thyroid function suggest a potential overlap syndrome. Factors contributing to disease variability, including immune modulation and external factors, need further investigation.

Conclusion

The clinical features underscores the importance of continuous follow-up and individualized management in patients with autoimmune thyroid disease. Oscillating thyroid function challenges the diagnosis and requires a multidisciplinary approach to optimize patient outcomes and prevent complications.

Myxedema coma triggered by a urinary tract infection: a case report

Afrah El Kaissi[1], Hajar Srifi[2], Jade Issouani[2] & Ahmed Anas Guerboub[2]
[1]CHU Ibn Sina - Rabat, Endocrinology, Rabat, Morocco; [2]Hôpital Militaire d'Instruction Mohamed V - Rabat, Endocrinology, Rabat, Morocco

Introduction

Myxedema coma (MC) is a rare but severe endocrine emergency caused by a significant depletion of thyroid hormones, which can be triggered by various factors, including infections (1,2). Early diagnosis and prompt management are crucial for improving prognosis and reducing mortality (3). We report a case of MC precipitated by a severe urinary tract infection.

Case Report

A 78-year-old female with hypertension and chronic kidney failure (CKD) was admitted for septic shock of urinary origin. Upon admission, she presented with coma, hypothermia, bradycardia, hypoventilation, and generalized myxedema. The electrocardiogram showed right bundle branch block with diffuse low voltage. Laboratory tests revealed severe hypothyroidism (TSH $>$ 200 mU/l, FT4 $<$ 0.42 pmol/l, FT3 1.4 pg/ml), cortisol level of 155 ng/ml, and acute decompensation of CKD. Transthoracic echocardiography showed a mildly hypertrophied left ventricle with good kinetics. Management included continuous cardiorespiratory, hemodynamic, and thermal monitoring, along with antibiotic therapy, urgent hemodialysis, and thyroid hormone replacement with L-thyroxine (LT4) via nasogastric tube, starting with a loading dose followed by maintenance. Hydrocortisone hemisuccinate was also administered. The patient initially showed improvement in heart rate but died 2 days later due to multivisceral failure.

Discussion & Conclusion

MC is an acute decompensation of prolonged hypothyroidism, potentially fatal, characterized by cognitive impairment, hypothermia, bradycardia, hypoglycemia, and renal and respiratory insufficiency (1,4). It can be triggered by various factors such as cold exposure, infections, trauma, or anesthesia (1). Management requires continuous monitoring of vital signs and urgent administration of L-T4 (200 to 400 mg IV). Hydrocortisone is also administered to prevent adrenal crisis (1). T4-T3 combination therapy may be considered, as the conversion of FT4 to FT3 can be impaired in severely decompensated patients or those on steroid therapy, although this approach remains controversial (5).

Toxic thyroid nodule and anterior pituitary insufficiency: a rare association

Hajar Azagouagh[1], Anas Abdenabi[1], Meryem Karimi[1], Fatima Toulali[1], Kaoutar Rifai[1] & Hinde Iraqi[1]
[1]CHU Ibn Sina, Rabat, Morocco

Introduction

The association between a toxic thyroid nodule and anterior pituitary insufficiency is rare and presents a diagnostic challenge. We report a case illustrating this unusual clinical situation, characterized by thyrotropic insufficiency with suppressed TSH but low FT4, associated with corticotropic insufficiency due to granulomatous thickening of the pituitary stalk.

Case Report

A 75-year-old female with no significant medical history presented with symptoms of hyperthyroidism (palpitations, weight loss) for four years. Initial cervical ultrasound revealed a left sub-total lobar thyroid nodule measuring 25×9 mm (EU-TIRADS 3), with a benign cytology result. She was started on carbimazole (10 mg/day) and beta-blockers. Thyroid scintigraphy confirmed a left quasi-total lobar toxic nodule. However, thyroid function tests showed a suppressed TSH (0.24 µUI/ml) with paradoxically low FT4 (0.74 ng/dl), suggesting thyrotropic insufficiency. Pituitary MRI revealed thickening of the pituitary stalk of granulomatous origin. An anterior pituitary function assessment showed low 8 AM cortisol levels (98 ng/ml), requiring hydrocortisone replacement therapy (10 mg/day).

Discussion

The association between a toxic thyroid nodule and thyrotropic insufficiency is uncommon and poorly documented in the literature. Typically, a toxic nodule leads to primary hyperthyroidism, characterized by suppressed TSH with elevated FT4 and/or FT3. In this case, the hormonal discrepancy (suppressed TSH with low FT4) suggested thyrotropic insufficiency, confirming hypothalamic-pituitary involvement. Thyrotropic insufficiency is a rare condition (prevalence: 1/16,000 to 1/80,000). It can result from infiltrative pituitary lesions, such as granulomatous hypophysitis. Granulomatous hypophysitis, particularly in sarcoidosis or tuberculosis, can lead to multiple anterior pituitary deficiencies, notably corticotropic and thyrotropic insufficiency. In our case, the thickening of the pituitary stalk suggests a granulomatous disease, although initial investigations were negative. Further diagnostic workup, including salivary gland biopsy and angiotensin-converting enzyme dosage, is ongoing to assess for sarcoidosis. Regarding management, appropriate hormonal replacement therapy is crucial. The treatment of the toxic nodule relies on radioiodine therapy, which is particularly suitable for elderly patients refusing surgery.

Conclusion

This case highlights a rare association between a toxic thyroid nodule and thyrotropic insufficiency, altering the typical biochemical profile of a toxic nodule. It underscores the importance of investigating pituitary involvement in cases of hormonal discordance and considering a granulomatous etiology when structural abnormalities of the pituitary stalk are present.

Challenges in the diagnosis of thymic hyperplasia-associated myasthenia gravis in the setting of coexisting Graves' disease

Yotsapon Thewjitcharoen[1], Veekij Veerasomboonsin[2] & Thep Himathongkam[1]

[1]Vimut-Theptarin Hospital, Theptarin Diabetes, Thyroid, and Endocrine Center, Bangkok, Thailand; [2]Vimut-Theptarin Hospital, Radiology, Bangkok, Thailand

Background
Recognizing thymic hyperplasia secondary to Graves' disease (GD) is important for avoiding unnecessary investigations and surgeries. However, other causes of thymic hyperplasia or *de novo* thymic abnormalities after euthyroidism especially the presence of massive thymic hyperplasia should be investigated. The clinical features of myasthenia gravis (MG) and thyroid eye disease (TED) may be similar and thymic hyperplasia may occur in both conditions. This could be a diagnostic dilemma as to whether a conservative approach or investigations should be pursued. Thymectomy in patients with nonthymomatous MG could improve clinical outcomes and reduce the need for immunosuppressive therapy. Herein, we report an interesting case of the coexistence of severe TED and MG with the presence of thymic hyperplasia.
Clinical case
A 40-year-old Thai woman diagnosed with severe TED requiring orbital decompression and intravenous methylprednisolone presented with left eye ptosis and chewing weakness for 1 month. She denied limb muscle weakness, hoarse voice, or difficulty breathing. Her previous history included hypothyroidism after thyroidectomy for GD 18 months earlier. At the initial diagnosis of GD, laboratory tests were notable for highly elevated serum thyrotropin receptor antibody at 25.5 IU/l and then gradually declined to 13.2 IU/l at 6 months after thyroidectomy (reference range is 0 to 1.75 IU/l). Anti-acetylcholine receptor antibody was positive confirming the diagnosis of MG. A chest computed tomography scan showed a $10\times9\times1.6$ cm thymic enlargement. No mediastinal widening on previous chest X-ray (CXR) at the time of thyroidectomy was found. Therefore, thymic hyperplasia-associated MG was suspected and the patient underwent video-assisted thoracoscopic thymectomy. The pathologic results revealed non-neoplastic thymic tissue with focal thymic epithelial hyperplasia. At 1 year later, her symptoms have much improved and she was prescribed only oral azathioprine 50 mg/day without prednisolone. Strabismus and eyelid surgeries had been performed after inactive TED.
Conclusion
Our case highlighted a diagnostic dilemma as to whether a thymectomy is necessary for thymic enlargement in the setting of coexisting GD and MG. Previous CXR and clinical course of hyperthyroidism are important to differentiate between thymic hyperplasia secondary to GD and thymic hyperplasia-associated MG. While thymic hyperplasia secondary to GD is typically benign and improves with the regular treatment of GD, thymic hyperplasia-associated MG might need further investigations and treatments.

Pre-operative lugol's iodine treatment in the management of patients undergoing thyroidectomy for graves' disease: is there an impact?

Rachida Bouattay[1], May Ferjani[1], Linda Misbah[1], Khaled Harrathi[1] & Jamel Koubaa[1]
[1]ENT and Head and Neck Department, University Hospital of Fattouma Bourguiba, Monastir, Tunisia

Introduction
Graves' disease is a predominantly female autoimmune disorder of the thyroid gland. It is characterized by a diffuse goiter and biological hyperthyroidism, often accompanied by exophthalmos. Although medical treatments exist for Graves' disease, surgical excision of the thyroid gland offers a definitive treatment. Preoperative preparation with Lugol's iodine is still controversial. The aim of our study is to highlight the benefits of preoperative treatment with Lugol's iodine in the management of patients undergoing thyroidectomy for Graves' disease.
Patients and methods
This is a retrospective study that collected records of patients hospitalized for surgical management of Graves' disease over an eleven-year period.
Results
Our series included 51 patients, 38 women (75%) and 13 men (25%) with a mean age of 39.41 years and extremes of 14 to 69 years. The goiter was multi-nodular in 23 patients (45%), homogeneous in 22 cases (43%) and nodular only in 12% of patients. Surgery was indicated in cases of resistance to medical treatment (84%), poor compliance (8%) and associated thyroid carcinoma (6%). Forty-nine patients (96.1%) underwent preoperative preparation with potassium iodide (Lugol's solution 2%) at a dose of 07-10 drops*3/day (over a period of 07 to 10 days). All our patients underwent total thyroidectomy. The operative difficulties were mainly the dissection of the recurrent nerves and the parathyroid glands made difficult by the hypervascularization of the gland and the bleeding during the procedure. Postoperative complications included transient hypocalcemia in 21 patients (41.17%), transient dysphonia in 3 patients (5.88%), and hematoma in 2 patients (3.92%).
Conclusion
Total thyroidectomy is the procedure of choice for the definitive cure of Graves' disease. Postoperative complications are frequent and not negligible, hence the need for preoperative medical preparation. Both the American Thyroid Association and the European Thyroid Association recommend the use of Lugol's solution in the preparation of patients undergoing surgery, but their recommendations are based on low-quality evidence.

Autoimmune thyroid disease: a continuum oscillating between hypothyroidism and hyperthyroidism: a case report

Najoua Lassoued[1], Mariam Akacka[1], Meryem Etteyeb[1], Houcem Elomma Mrabet[1], Mohamed Bentraya[1], Alaya Wafa[1] & Zantour Baha[1]
[1]University Hospital Taher Sfar Mahdia, Mahdia, Tunisia

Introduction
Autoimmune thyroid disorders can present atypical evolutions making their management complex. We report the case of a young patient presenting an unusual alternation between phases of hyperthyroidism and hypothyroidism.
Observation
A 26-year-old patient presented with primary hypothyroidism in the 4th month of her pregnancy, treated with L-thyroxine. She consulted 6 months after giving birth for asthenia, palpitations, and tremors. The biological assessments showed a suppressed TSH and elevated FT4. Anti Thyroid peroxidase antibodies and Anti-TSH receptor (ATSHR) antibodies were positive. L-thyroxine was interrupted and treatment with thiamazole was started. Three years later, biological hypothyroidism was objectified leading to the discontinuation of thiamazole. The patient presented at 12 weeks of pregnancy. She was still in clinical and biological euthyroidism. ATSHR antibodies had returned negative. Six months after delivery, a thyroid assessment revealed the reappearance of hyperthyroidism. A thyroid scintigraphy was performed, showing normal and homogeneous thyroid uptake. The diagnosis of autoimmune thyroid disease with swing antibodies was retained and the decision was to put the patient on low-dose thiamazole each time she presented a phase of hyperthyroidism.
Discussion
The initial positivity of ATSHR antibodies points towards Graves' disease, but a normal scintigraphy does not support this diagnosis, nor does the evolution with oscillation between hyperthyroidism and hypothyroidism. This oscillation could be related to a dynamic evolution of autoimmunity, with fluctuations of ATSHR antibodies between stimulating and blocking forms. There is also evidence that Graves' disease and Hashimoto's thyroiditis may be different manifestations of a continuous spectrum of autoimmune thyroid diseases.

Thyroid disorders in autoimmune polyendocrinopathy

Dhoha Ben Salah[1], Oumaima Dimassi[1], Khouloud Boujelben[1], Ameni Ben Abdallah[1], Faten Haj Kacem Akid[1], Nadia Charfi[1], Mouna Mnif[1], Mohamed Abid[1], Mouna Elleuch[1] & Nabila Rekik Majdoub[1]
[1]Department of Endocrinology Hedi Chaker Hospital, Sfax, Tunisia

Objective
To evaluate the characteristics of autoimmune thyroid diseases (AITD) occurring within the context of autoimmune polyendocrinopathy (APE).
Patients and Methods
This was a retrospective study including 41 patients diagnosed with APE involving AITD, hospitalized in the Endocrinology Department of Hedi Chaker University Hospital, Sfax, between 2009 and 2019.
Results
The mean age at diagnosis was 32.6 ± 15.3 years, with a female predominance. Hashimoto's thyroiditis was identified in 33 cases, while Graves' disease was present in 8 cases. The most common association was with type 1 diabetes (68.3%), followed by Addison's disease (36.6%). Other associated autoimmune conditions included primary ovarian insufficiency, autoimmune hypophysitis, celiac disease, chronic mucocutaneous candidiasis, myasthenia gravis, vitiligo,

and hypoparathyroidism, each occurring in one case. AITD was classified within APE type 3 in 22 cases, APE type 2 in 16 cases, and APE type1 in one case. Additionally, chromosomal anomalies, specifically trisomy 21, were observed in two cases. The first clinical manifestation was type 1 diabetes in 48.8% of cases, AITD in 29.3%, and Addison's disease in 14.6%.
Conclusion
AITD is an organ-specific autoimmune disorder that can coexist with systemic autoimmune diseases, suggesting a shared immune mechanism. This expands the spectrum of multiple autoimmune syndromes, necessitating vigilant clinical and biological monitoring, particularly for thyroid function.

Optimizing thyroid surgery: the critical role of intraoperative histological examination

Malika El Omri[1], Nawress Thabet[1,2], Habib Rouatbi[1], Mouna Belakhdher[1], Jihene Houas[1], Monia Ghammam[1], Abir Meherzi[1], Hamza Elfekih[3], Wassim Kermani[1] & Mohamed Abdelkafi[1]
[1]Farhat Hached Hospital, Department of ENT and Head and Neck Surgery, Sousse, Tunisia; [2]Farhat Hached University Hospital, ENT Department, Sousse, Tunisia; [3]Farhat Hached Hospital, Department of Endocrinology, Sousse, Tunisia

Background
In thyroid nodular pathology, intraoperative histological examination is a crucial diagnostic tool that helps guide surgical decision-making.
Objectives
To assess the accuracy and effectiveness of intraoperative histological examination in the management of thyroid nodules and to highlight its benefits and limitations as a real-time diagnostic tool during surgery.
Methods
This retrospective cross-sectional study analyzed 333 intraoperative histological examinations performed on thyroidectomy specimens at our ENT Department over a five-year period (January 2018 – December 2022).
Results
I this study the mean age of 47.45 years, with a strong female predominance (male-to-female ratio of 1:5.8). The most common reason for discovery was a palpable cervical mass (57.35%), while incidental detection via ultrasound accounted for 15.6%. Ultrasound findings revealed that multinodular goiters were more prevalent (61.6%) than solitary nodules (38.4%). Malignant tumors were diagnosed in 21.3% of cases, with the majority being papillary carcinoma (87.3%), followed by follicular carcinoma (9.8%), medullary carcinoma (1.4%), and anaplastic carcinoma (1.4%). Intraoperative examination identified 61 malignant cases, 259 benign cases, and 13 uncertain cases. When compared to the final histopathological examination across all histological types, intraoperative examination demonstrated a diagnostic accuracy of 93%, with a sensitivity of 85.9%, specificity of 100%, positive predictive value (PPV) of 100%, and negative predictive value (NPV) of 96%. The Youden index was 0.86. The sensitivity of intraoperative examination varied by histological type. It showed strong concordance with the final pathology report in 90.3% of papillary carcinomas and 100% of medullary and anaplastic carcinomas, but only 42.8% of follicular carcinoma cases. The rate of secondary surgical interventions following final histological examination was 3% (10 cases).
Conclusion
Intraoperative histological examination plays a pivotal role in the surgical management of thyroid nodules, offering rapid and precise diagnosis that optimizes surgical decision-making and minimizes the need for reoperations. Its high specificity and sensitivity enhance patient care by ensuring appropriate surgical intervention.

Secondary hyperparathyroidism and papillary carcinoma of the thyroid: about a case

Nawres Bouaziz[1], Rachida Bouatay[1], Misbah Linda[1], Nour Bziouich[1], Mahdi Ferjaoui[1], Amel El Korbi[1], Nawres Kolsi[1], Khaled Harrathi[1] & Jamel Koubaa[1]
[1]Fattouma Bourguiba University Hospital, Monastir, Tunisia

Introduction
Secondary hyperparathyroidism (SHPT) and coexisting papillary thyroid carcinoma (PTC) have been reported in sporadic cases and studies are scarce. The mechanism linking these two pathologies remains unclear. As a minimally invasive approach to parathyroidectomy has replaced bilateral neck exploration, a thorough preoperative thyroid evaluation is necessary to identify concomitant papillary carcinoma. We aim to report a case associating secondary hyperparathyroidism and thyroid papillary carcinoma.
Case report
This is a case of a 36-year-old woman with chronic renal failure, not on haemodialysis for IgA nephropathy, who was referred for hyperparathyroidism with a parathyroid hormone level of 334 pg/l and a calcemia of 2.08 mmol/l. Neck ultrasound showed a right lobar thyroid nodule of 19*13*10 mm, EUTIRADS 5 grade, with no pathological parathyroid gland. This was supplemented by a parathyroid scintigraphy, which showed no evidence of a pathological parathyroid gland. Fine needle aspiration of the thyroid nodule was inconclusive. The patient underwent a right thyroid lobectomy. Intraoperative frozen section analysis revealedtwo foci of papillary thyroid carcinomameasuring 1.4 cm and 1.7 cm, necessitating completion thyroidectomy and right recurrent mediastinal dissection. A subtotal parathyroidectomywas also performed. The final histopathological examination confirmed the PTC in the right lobe of thyroid, without lymph node involvement and parathyroid hyperplasia. The patient was therefore referred to nuclear medicine department for additional treatment with radioactive iodine.
Discussion/Conclusion
The prevalence of thyroid papillary carcinoma is high in patients with secondary hyperparathyroidism, compared with thyroidpapillary carcinoma in the general population. Most thyroid papillary carcinomas with SHPT are occult thyroid carcinomas and present no significant difference in terms of tumor pathological features and prognostic staging. It is necessary for surgeons to perform more adequate preoperative examination and be more careful during surgery to avoid missing the coexistence of thyroidpapillary carcinoma in patients with secondary hyperparathyroidism. Disclosure of interest: none declared

Association of graves' disease and differentiated thyroid cancer: a report of two cases

Oumayma Zarrouk[1], Ezzine Abir[2], Hajer Boudriga[2], Rakia Ghanem[2], Dardouri Teheni[2], Sihem Mensi[2], Yosra Hasni[1] & Kaouther Chatti[2]
[1]University Hospital of Farhat Hached, Endocrinology Departement, Sousse, Tunisia; [2]University Hospital of Sahloul, Department Of Nuclear Medicine, Sousse, Tunisia

Introduction
The presence of hyperthyroidism is no longer considered a protective factor against the development of thyroid cancer. The coexistence of differentiated thyroid cancer and Graves' disease(GD) is a well-documented but rare phenomenon, with reported prevalence rates ranging from 0.1% to 9.8% in the literature. We present two cases of female patients with hyperthyroidism secondary to GD who were subsequently diagnosed with differentiated thyroid cancer.
Case Reports
Case 1: A 49-year-old female patient with a two-year history of GD was managed with antithyroid drugs (ATD). She developed drug-induced cholestasis as a side effect of ATD therapy. Clinical examination revealed bilateral firm cervical lymphadenopathies. Cervical ultrasound demonstrated a nodular thyroid structure, with the largest nodules located in the upper right lobe(14 mm)and the mid-left lobe, classified as EU-TIRADS IV. Due to ATD intolerance and the presence of cervical lymphadenopathies, the patient underwent total thyroidectomy with bilateral mediastino-recurrent lymph node dissection (MRLD). Histopathological analysis identified three foci of papillary thyroid carcinoma (PTC) without lymph node involvement. Postoperatively, the patient received an ablative dose of radioactive iodine (100 mCi), achieving a favorable biochemical and morphological response. **Case 2:** A 68-year-old female patient with GD exhibited resistance to medical treatment with ATD. A radical surgical approach was pursued, and she underwent total thyroidectomy with bilateral MRLD. Histopathological examination revealed a 2 cm papillary thyroid carcinoma in the right lobe and a 3 cm thyroid tumor with malignant potential in the left lobe. The tumor was classified as pT2NxMx. She received ablative therapy with 30 mCi of radioactive iodine, resulting in a good therapeutic response.
Conclusion
The pathogenesis underlying the association between GD and thyroid cancer remains incompletely understood. Cervical irradiation is a recognized risk factor

for thyroid cancer, as it induces nuclear modifications that may initiate tumorigenesis. Additionally, it may contribute to the development of hyperthyroidism. Damaged thyroid cells with reduced hormone production may be subjected to increased thyrotropic stimulation, potentially promoting tumor proliferation. Furthermore, antithyroid therapy has been implicated in this association, as it normalizes previously suppressed TSH levels, which may facilitate tumor growth. Dobyns *et al*. reported a higher incidence of thyroid cancer in patients treated medically for hyperthyroidism compared to those managed with radioiodine therapy or surgery. The possibility of thyroid cancer in patients with GD should not be overlooked. A malignancy workup should be considered, and a diagnostic approach similar to that for any thyroid nodule should be applied. Early detection and appropriate management are crucial for optimizing outcomes in these patients.

A challenging case of amiodarone induced thyrotoxicosis

Hasan Jamjoom[1]
[1]Imperial College NHS trust, London, United Kingdom

Introduction

Amiodarone induced thyrotoxicosis (AIT) is characterized by thyroid over-activity in context of current/recent amiodarone use. It is sub-divided mainly into 2 types; Type 1 AIT occurs due to amiodarone's high iodine content causing increased thyroid hormone production, whereas Type 2 AIT is a form of destructive thyroiditis resulting in excessive thyroid hormone release. Distinguishing these sub-types is based on biochemical and radiological parameters, which helps guide treatment.

Case-report

A 69-year-old gentleman with known chronic renal impairment, ischemic heart disease with moderate left ventricular impairment, severe aortic stenosis, a previous out of hospital cardiac arrest, and a long-standing amiodarone use history presented in cardiogenic shock and type 2 respiratory failure. He was intubated and taken to the intensive care unit where he was noted to be thyrotoxic with a TSH of <0.01, T4 of >64, and T3 of 10.9, which was believed to be contributing to his initial presentation. He was commenced on Propylthiouracil (PTU) 200 mg TDS and prednisolone 40 mg daily. TSH receptor antibody titre was 0.4 U/l (range <0.4) and a thyroid doppler USS showed absence of hypervascularity consistent with Type 2 AIT. Following brief improvement, thyroid hormones incremented further, prompting a change of PTU to carbimazole 20 mg TDS. During this time the patient was extubated and transferred for an inpatient Transcatheter aortic valve insertion (TAVI) for aortic stenosis. He however remained thyrotoxic, therefore the prednisolone dose was escalated to 60 mg daily. The admission was complicated by urosepsis and a hospital acquired pneumonia, which drove further relapse in thyroid status. Total thyroidectomy was considered however deemed risky given the patients' cardiac background. A combination of PTU 200 mg TDS, carbimazole 20 mg TDS, and prednisolone 60 mg daily was utilized, and over the coming weeks, T3 and T4 levels steadily declined, allowing the TAVI to proceed. Subsequently PTU and carbimazole were gradually discontinued, and prednisolone was weaned to 40 mg daily. Thyroid function improved revealing a TSH of 0.04, T4 of 16.9, and T3 of 3.7.

Discussion

A combination of steroids and anti-thyroid drugs are typically used in AIT as diagnostic obscurity/overlap often exists. Due to amiodarone's long half-life, AIT may occur months after discontinuation, and therefore discontinuing amiodarone acutely can not only be challenging from a cardiac standpoint, but may offer little immediate benefit from a thyroid perspective. Total thyroidectomy may be considered in cases of treatment resistant AIT however this was deemed risky in our case given the patient's cardiac background.

Apalutamide-induced severe hypothyroidism in a patient treated with levothyroxine: new data on the impact of apalutamide on thyroid hormone metabolism

Florie Quattochi[1], Grunenwald Solange[1], Pierre-Louis Toutain[2] & Philippe Caron[3]
[1]CHU Larrey, Department of Endocrinology and Metabolic diseases, Toulouse, France; [2]The Royal Veterinary College, Department of Comparative Biomedical Science, Hatfield, United Kingdom; [3]CHU Larrey, Department of Endocrinology and Metabolic diseases, Toulouse, France

Apalutamide is a selective antagonist of the androgen receptor, increasingly used in the treatment of prostate cancer. In the SPARTAN and TITAN trials, an increased risk of subclinical or severe hypothyroidism was reported, much higher in patients treated with levothyroxine prior to apalutamide than in untreated patients. Apalutamide is suggested to cause hypothyroidism by inducing UDP-glucuronosyltransferase activity leading to reduced exposure to levothyroxine, but other mechanisms can be considered in patients treated with levothyroxine. A 65-year-old man underwent total thyroidectomy for Graves' disease followed by 150 µg/day levothyroxine supplementation with normal TSH level (3.9 mU/l). Eight months later, apalutamide (240 mg/day) associated with triptorelin (GnRH agonist intramuscular injections every 3 months) treatment was started for his metastatic prostate cancer. After one month of apalutamide treatment, follow-up of the patient revealed increased TSH (47.9 mU/l) level, and the dosage of levothyroxine was gradually increased to normalize TSH level. In this patient treated with levothyroxine (275 µg/day, 3.25 µg/kg/day) and refractory hypothyroidism (TSH = 38 mU/l, Free T4 = 7.9 pg/ml), a levothyroxine absorption test was performed: after a fast overnight, the patient intake orally 1000 µg levothyroxine, blood samples were drawn for TT4 determinations at baseline and then every 2 hours during 24 hours. Percentage absorption of levothyroxine was calculated using the formula: increment TT4 (µg/dl) $\times$ 10 $\times$ 0.442 $\times$ BMI $\times$ 100/ total administered levothyroxine. After 1000 µg levothyroxine intake, TT4 presented a rise from 5.8 µg/dl at baseline toward peak level at 2 hours (8.1 µg/dl) with percentage of absorption at 27.1% (normal $>$ 60%) demonstrating significantly reduced T4 absorption. Then TT4 declined at 5.7 µg/dl after 16 hours followed with a TT4 rise toward second peak level at 20 h (8.5 µg/dl): increased UDP-glucuronosyltransferase activity with T4 enterohepatic circulation and secondarily intestine T4 absorption likely explaining this second peak of T4 concentration. No adverse events were observed during the test. In conclusion, apalutamide treatment worsened hypothyroidism via decreased levothyroxine absorption and increased T4 clearance in this patient, explaining the higher prevalence of refractory hypothyroidism in levothyroxine-treated patients during apalutamide treatment.

Acute suppurative thyroiditis due to internal fistula: a paediatric case report

Michaela Nikolaou[1], Sophia D Sakka[1], Georgia Panagiotou[2], Ekaterini Dokou[2] & Christina Kanaka Gantenbein[1]
[1]Division of Endocrinology, Diabetes and Metabolism 'Aghia Sophia' Children's Hospital ENDO-ERN center for Rare Paediatric Endocrine Diseases, First Department of Pediatrics Medical School, National and Kapodistrian University of Athens, "Aghia Sophia" Children's Hospital, Athens, Greece; [2]2nd Department of Pediatrics, "Aghia Sofia" Children's Hospital, Athens, Greece

Introduction

Acute suppurative thyroiditis (AST) is a rare but serious bacterial infection of the thyroid gland, accounting for 0.1%-0.7% of thyroid diseases, mainly affecting children and linked to congenital anomalies like pyriform sinus fistulas. These fistulas can serve as a pathway for infection, potentially leading to abscess formation and spreading to adjacent tissues, which renders early diagnosis crucial. Mortality rates range from 3.7%-9%, highlighting the need for prompt treatment. This study reports a rare case of AST caused by a fistula originating from the thyroid gland and extending to the arytenoid fossa.

Case report

A $2\ ^{10/12}$-year-old girl with a known thyroid nodule on the left lobe presented with fever for 4 days and painful anterior neck swelling. Palpation revealed a 4×3 cm anterior left sided neck mass with tenderness and erythema of the overlying skin. Laboratory tests showed elevated white blood cell count (25,840/µL), C-reactive protein (CRP) of 146 mg/l and erythrocyte sedimentation rate (ESR) of 85 mm/hr. Thyroid-stimulating hormone (TSH) was 3.51 mIU/l and free-T4 was 1.50 ng/dl (normal range 0.74-1.6). Thyroid ultrasound revealed an isoechoic nodule (42x19x25 mm), occupying almost the entire left thyroid lobe and reactive local lymph nodes. Antibiotic therapy with Cefotaxime and Clindamycin was initiated. ENT examination revealed no signs of an abscess. Fever subsided after four days of intravenous treatment, and neck swelling began to resolve. The patient completed a 10-day course of antibiotics. A follow-up thyroid ultrasound,

performed two weeks later, revealed an enlarged nodular area of the left lobe with heterogeneous echotexture, cystic regions, and multiple reactive lymph nodes, consistent with suppurative thyroiditis. This was caused by a fistula originating from the thyroid gland and extending to the arytenoid fossa, confirmed by MRI of the cervical area. Following consultation with both ENT and paediatric endocrinology specialists, conservative 6monthly follow up was suggested. This decision was based on the absence of further episodes of thyroiditis and the lack of indications for surgery.

Conclusions

Acute suppurative thyroiditis is a rare but potentially life-threatening condition if untreated, mainly due to underlying conditions or congenital abnormalities, such as pyriform sinus fistula. Lack of awareness contributes to the delay in adequately treating this rare entity and to frustrating relapses. Treatment typically involves surgery and antibiotics, but recent studies suggest that less invasive approaches may also lead to favourable outcomes. This underscores the importance of balancing expert opinion with evidence-based practices in managing this endocrine emergency.

"Predictive value evaluation of preoperative sonographic risk stratification in patients with differentiated thyroid cancer: a feasibility study for a prospective clinical trial"

Maciej Bulwa[1], Magdalena Kolton[1], Malgorzata Haras-Gil[1], Agata Wilk[1], Barbara Jarzab[1], Daria Handkiewicz-Junak[1] & Jolanta Krajewska[1]
[1]Maria Sklodowska-Curie National Research Institute of Oncology Gliwice Branch, Nuclear Medicine and Endocrine Oncology Department, Gliwice, Poland

Introduction

Preoperative risk stratification in differentiated thyroid cancer (DTC) remains a considerable challenge for endocrinology. Sonographic evaluation of the tumor before surgery may help with optimal planning of the thyroid surgery extent. However, no data are available for the estimation of its sensitivity and specificity. Thus, we plan to perform a prospective clinical trial to define the accuracy of preoperative sonographic differentiation between low risk and higher risk DTC. For the appropriate planning, we first performed a retrospective study to determine the sonographic features necessary for the preoperative diagnosis of low-risk DTC. We found that there was a possibility to apply sonographic diagnosis. This study was reported during ECE 2024. Based on the univariate analysis of feature sensitivity, we prepared a multifeature predictive classifier (MPC), which requires a prospective validation in our clinical trial.

Aim

The primary objective of the study is to evaluate the preoperative sonographic criteria based on MPC in a prospective clinical trial. During the trial, the thyroid tumor with DTC suspicion or DTC diagnosis will be evaluated by sonography to calculate MPC, in aim to allow planning lobectomy for low-risk thyroid cancer. For adequate trial planning, we needed to estimate the following data: 1. what is the predictive positive value of MPC, compared to a single ultrasonographic feature? 2. How many patients should be recruited? 3. How long will the trial last?

Methods

On the basis of our retrospective results, we plan to evaluate the predictive value of selected sonography features: lesion diameter, its ill-defined or irregular margins and vascularity in CD option. On the basis of these sonographic results, the MPC will be calculated, and its positive predictive value will be evaluated in the context of postoperative histopathological stratification.

Results

In our center, the proportion of low risk to higher risk patients is 65% and 35%. We expect that the trial should give at least 10% difference between positive predictive values (PPV of MPC), compared to the ultrasonographic criteria specified above. Thus, we should recruit 1000 patients with intermediate or high risk DTC during the trial. Taking into account the numbers of patients coming to our center in 2019 -2021, we expect that the trial will last circa 32 months.

Conclusions

The results of our analysis indicate that the planned clinical trial is feasible in our center.

Utilization of blood cell-derived parameters in the diagnosis of subacute thyroiditis during pregnancy

Ahmet Kursat Soyer[1], Fatma Neslihan Cuhaci Seyrek[2], Kubra Durmus Demirel[1], Abbas Ali Tam[2], Oya Topaloglu[2], Reyhan Ersoy[2] & Bekir Cakir[2]
[1]Ankara City Hospital, Endocrinology and Metabolism, Ankara, Türkiye; [2]Ankara Yıldırım Beyazıt University Faculty of Medicine, Endocrinology and Metabolism, Ankara, Türkiye

Introduction

Subacute thyroiditis (SAT) is extremely rare during pregnancy. In this group, the inability to use thyroid scintigraphy and radioactive iodine uptake may present challenges in confirming the diagnosis of SAT. While blood-cell-derived parameters have been employed in the differential diagnosis of SAT and Graves' disease (GD) in various studies, to the best of our knowledge no studies have been conducted specifically in pregnant patients in the literature.

Methods

The study included 4 pregnant women with SAT and 9 pregnant women with GD. Pre-treatment blood-cell-derived parameters and thyroid function tests were retrospectively compared between two groups.

Results

All SAT cases presented with typical symptoms, ultrasonographic findings of SAT and elevated acute phase reactant levels. All GD cases exhibited typical symptoms, disease course and 7/9 (77.7%) patients have found positive for thyroid-stimulating hormone receptor antibodies (TRAB). There was no difference between the groups in terms of age and gestational week. We found

Anti-thyroglobulin (IU/ml)	1 (0,2-1,5)	1,3 (0,5-234)	0,373
Anti-thyroid peroxidase (U/ml)	35,5 (5,74-78)	89 (30-2965)	0,076

Data were expressed as median, minimum, and maximum values; *SAT,* subacute thyroiditis*; GD,* Graves' disease; *LUC,* large unstained cells; *PLR,* platelet-to-lymphocyte ratio*; NLR,* neutrophil-to-lymphocyte ratio; *SIRI,* systemic inflammation-response index; *SII,* systemic immune-inflammatory index; *PIV*, pan-immune inflammation value

that thyroid stimulating hormone (TSH) levels, neutrophil count, and systemic immune-inflammatory index (SII) were significantly higher and percentage of large unstained cells (LUC%) was significantly lower in pregnant women with SAT compared to those with GD.
Conclusions
TSH, SII levels, LUC percentage and neutrophil count may serve as valuable tools in the differential diagnosis of thyrotoxicosis during pregnancy.

JOINT2110

Adherence to levothyroxine treatment among patients withhypothyroidism and evaluation of depressive stratus andfactors related with non-adherence

Ceyda Dinçer Yazan[1], Onur Elbasan[1] & Dilek Gogas Yavuz[1]
[1]Marmara University Faculty of Medicine, Endocrinology and Metabolism, Istanbul, Türkiye

Introduction
Hypothyroidism is a common clinical problem requiring life-long treatment and follow-up. Even though the management of hypothyroidism is generally straightforward, several studies shown that a large percentage of patients are over or under-treated and the drug adherence is also sub-optimal. The aim of this study was to evaluate drug adherence and factors associated with non-adherence, determine the attainement of the euthyroidism and evaluate the depressive status.
Method
300 patients treated for hypothyroidism at least for one year were included. Patients were administered eight-item Modified Morisky Medication Adherence Scale (MMAS-8), a structured self-reporting medication adherence measure to identify the behaviour of patients with regard to prescribed medications. They were evaluated for the medication use habits, comorbidities and drugs used together with levothyroxine, nutritional habits. Beck depression scale was applied to all patients.
Results
According to MMAS-8 scale, 29.67% of the patients have low drug adherence, 36.67% have moderate adherence and 33.67% of the patients have good drug adherence. Male and female patients have similar MMAS-8 scores. The mean age of the low adherent group was lower significantly ($P = 0.009$). TSH levels of the patients with good adherence was lower than moderate and low adherence groups significantly ($P > 0.001$). 99.33% of the patients were taking levothyroxine at morning before breakfast. 17.33% of the patients were having breakfast within 30 minutes after taking the levothyroxine, 38.67% were having breakfast within 30-60 minutes. 12.67% of the patients were taking together with another medication. The MMAS-8 score was not associated with etiology of hypothyroidism and education background. 32.67% of the patients have moderate or severe deppression. There was no relation between MMAS-8 score and Beck depression score when evaluated by cathegorisation but the depression scores of the good adherent patients was lower significantly ($P = 0.002$). Mean TSH level of patients with severe depression was higher significantly ($P = 0.007$). Beck depression scores of the female group was significantly higher ($P = 0.001$). Beck depression scores of the patients with TSH < 0.5 and TSH > 4 were higher than the group with TSH between 0.5-4 Mıu/l.
Conclusion
29.67% of the patients in study group had poor drug adherence. Drug adherence scores were not associated with hypothyroidism etiology, disease duration, levothyroxine dose or education background. Younger patients had lower drug adherence. TSH levels of the patients with severe depression was significantly higher. Follow-up of the patients and regular doctor visits is important for detection of drug adherence and keeping patients euthyroid.

Severe graves' disease presenting with supraventricular tachycardia (SVT) in a 54-year-old male smoker

Muhammad Haroon Riasat[1], Samraiz Nafees[1], Khaled Zamari[2], Shahzad Akbar[3], Ali Javeed[1], Adi Ahmed[1], Sarath Vayolipoyil[1], Khush Bakht[3], Muhammad Adnan Afzal[3], Arshad Jamil[4] & Ali Hassan[5]
[1]York and Scarborough Teaching Hospitals NHS Trust, Scarborough, United Kingdom; [2]Gloucestershire Hospitals NHS Foundation Trust, Gloucester, United Kingdom; [3]Hull University Teaching Hospitals NHS Trust, Hull, United Kingdom; [4]Sandwell and West Birmingham Hospitals NHS Trust, Birmingham, United Kingdom; [5]Manchester University NHS Foundation Trust, Manchester, United Kingdom

Background
Graves' disease is an autoimmune disorder characterized by hyperthyroidism, which can lead to various cardiovascular complications. This case report describes a 54-year-old Caucasian male smoker who presented with chest pain and subsequent collapse, leading to the diagnosis of severe Graves' disease complicated by supraventricular tachycardia (SVT).
Case Presentation
A 54-year-old Caucasian male, typically fit and an avid cyclist but a significant smoker, presented to the Emergency Department with a 6-week history of chest pain, followed by a collapse. Initial ECG revealed a heart rate of 200 bpm, diagnosed with SVT. The patient was resuscitated, stabilized with adenosine, and started on rate control medication. Physical examination revealed severe thyrotoxicosis, evidenced by tremors, sweating, and palpitations, without signs of orbitopathy. Blood investigations confirmed severe Graves' disease with fully suppressed TSH (< 0.01 mU/l), elevated T3 (39 pmol/l) and T4 (92 pmol/l), and TRAB levels of 15.9 U/l. Additional findings included mild anaemia, raised ALP, and hypercalcemia, likely secondary to thyrotoxicosis.
Management and Outcome
The patient was initiated on Carbimazole 40 mg once daily and counselled about potential side effects. Beta-blockers, previously started as prophylaxis for SVT, were continued with advised titration. Clinical improvement was observed on high-dose Carbimazole, with repeat thyroid function tests showing a reduction in free T4 to 30 pmol/l. The patient was informed about the high risk of relapse due to elevated TRAB antibodies, and future radioactive iodine (RAI) therapy was discussed.
Conclusion
This case highlights the importance of considering thyroid dysfunction in patients presenting with cardiac arrhythmias, especially in the presence of risk factors such as smoking. The rapid diagnosis and management of both the cardiac and thyroid components were crucial in stabilizing the patient. Regular follow-up and consideration of definitive treatment options, such as RAI, are essential in managing severe Graves' disease to prevent recurrence and complications. Smoking may exacerbate Graves' disease and increase cardiovascular risk. SVT can be an initial presentation of severe thyrotoxicosis. This case exemplifies the necessity for a multidisciplinary approach in managing complex endocrine-cardiac presentations and emphasizes the importance of thorough patient education and ongoing monitoring to achieve optimal outcomes.

Approaches for improving diagnostics precision, treatment anh monitoring relapse of graves' disease in national children's hospital

Thao Bui Phuong[1], Dung Vu Chi[1], Trang Ngo Thuy[1], Khanh Nguyen Ngoc[1], Ngoc Can Thi Bich[1] & Lan Nguyen Hoang[1]
[1]Vietnam National Children's Hospital, Center for Endocrinology, Metabolism, Genetics, and Molecular Therapy, Hanoi, Viet Nam

Research objective
Clarifying the relationship between TrAb antibody concentration and some clinical and paraclinical characteristics in pediatric Graves' disease and applying TrAb antibody testing in monitoring relapse of Graves' disease in children, requiring to use attacking dose of antithyroid drugs during maintenance phase.
Research subjects: 58 patients (from 24 months old to under 18 years old) treated at The Center of Endocrinology, Metabolism, Genetics and Molecular Therapy, Vietnam National Children's Hospital from Jan 2021 to Oct 2024.
Research method: Case series study.
Results
The mean age of patients in the study was 9.6 ± 3.1 years. The ratio of female/male patients was 2.4/1. The mean time for patients to see doctors since progression was 2.2 ± 1.8 months: this figures were 2.3 ± 1.1 months in boys and 2.2 ± 2.2 months in girls. The main reason for going to hospitals was thyrotoxicosis (71.2%). Common physical symptoms were hot and moist skin, hand tremors, tachycardia, bulging eyes and goiter, overeating. The other symptoms were weight loss (58.6%), insomnia (55.2%), and nervousness (46.6%). In our 58 patients, 9 patients(15.5%) developed relapse. The mean time to have relapse since starting treatment was 15.8 ± 4.8 months. The mean TrAb concentrations of patients at the time of diagnosis, the end of attacking dose time, and maintenance phase were 22.4 ± 11.3 U/l, 15.6 ± 11.4 U/l and 8.8 ± 8.1 U/l, respectively. The patients' mean TrAb concentrations at the time of diagnosis, the end of attacking dose

time, and maintenance phase were higher in relapse patients, compared to that of non-relapse patients, but the difference was not significant.
Conclusion
The disease has a long-term course of relapse, recurrence, requiring early treatment to avoid ophthalmological, cardiovascular, and neurological complications that affect children's physical development as well as their ability to work and study. Quantifying TrAb levels at diagnosis and during treatment helps to confirm the diagnosis of Graves' disease, but may not predict relapse.
Keywords
Graves' disease, hyperthyroidism, TrAb, children.

Paralyzed by potassium: the thyroid's sneaky trick
Priya Savani[1], Valeria De la Peña Dueñas[1], Akshay Kumar[1], Funda Korkmaz[1] & Vanessa Barboza[1]
[1]Jersey City Medical Center, Internal Medicine, Jersey City, United States

Introduction
Periodic Paralysis (PP) is a rare neuromuscular disorder characterized by painless episodes of muscle weakness. This disorder can manifest as either hereditary or acquired, with the former typically being autosomal dominant and the latter frequently associated with hyperthyroidism. Thyrotoxic Periodic Paralysis (TPP) represents a specific subtype of hypokalemic periodic paralysis, marked by sudden onset weakness in proximal muscles, most commonly affecting the lower extremities. TPP is reversible through prompt potassium replacement and normalization of thyroid hormones. However, without timely detection and management, TPP can progress to involve all limbs and respiratory muscles. This form of periodic paralysis is frequently observed in males of Asian origin between the ages of 20 and 40.
Case
A 31-year-old male with no significant medical history presented with sudden and severe lower extremity weakness. Physical examination revealed a thin anxious individual with bilateral flaccid paralysis of the lower extremities with a power of 1/5. Vital signs were remarkable for high blood pressure of 152/77 mmHg. Investigations were remarkable for potassium level of 2.1 meq/l, and creatine kinase (CK) of 1,842 U/l. MRI of Spine was unremarkable. Potassium repletion was initiated both intravenously and orally. After three hours of starting the potassium repletion, the patient regained normal strength in the lower extremities. Further investigations revealed very low thyroid-stimulating hormone (TSH) of <0.008 mIU/l with elevated T3 529 ng/dl and T4 5 ng/dl, thyroid peroxidase antibody >900 IU/ml, and thyroid-stimulating immunoglobulin (TSI) of 436 % confirming our diagnosis of TPP.
Discussion
Thyrotoxic periodic paralysis (TPP) is triggered by factors such as exercise or carbohydrate intake, leading to a shift of potassium into cells and resulting in low blood potassium levels. While our patient falls within the most commonly affected sex and age group, his African American racial background makes this case less typical, as TPP is less frequently observed in this population. This case highlights the importance of considering hypokalemic periodic paralysis (HPP) as a differential diagnosis in any patient presenting with hypokalemia and sudden-onset paralysis. Treatment involves potassium replacement, correction of thyroid hormone levels, and a strong emphasis on patient education to prevent triggering factors.

What is the role of Pro-inflammatory biomarkers in Hashimoto's thyroiditis?
Vidya Paboju[1], Ramesh Bangaraiahgari[2], Rajesh Bangaraiahgari[1], Laxmi Narayana Sripuram[1], Sushmitha Sree Mekala[2], Amith Anshuli Dubey[2], Kundana Sree K M[2], Varshitha Eadula[2], Sabaretnam Mayilvaganan[2] & Ramakanth Bhargav Panchangam[3]
[1]TRR Institute of Medical Sciences, Hyderabad, India; [2]SGPGIMS, Lucknow, India; [3]BGH, Vijayawada, India

Introduction
Hashimoto's thyroiditis (HT) is one of the most frequent organ specific autoimmune thyroid disease. Autoimmunity has been implicated as one of the main cause of HT. In this context, we set out study the role of Pro- inflammatory cytokines in HT.
Material and methods
This prospective case-control study was conducted on surgically managed HT patients. Institutional ethical committee approval was obtained. Diagnosis of HT was based on thyroid function tests, anti-TPO antibody titer, radionuclide scanning and histopathology. Exclusion criteria were subjects any systemic or chronic inflammatory disease or any medication which interferes with the normal function of the hypothalamic-pituitary-gonadal axis. Serum samples were collected from 20 HT subjects and 20 age matched healthy controls. Interleukin-6 (IL-6), Tumour necrosis factor-alpha (TNF-α) and high sensitive C reactive protein (hsCRP), Leptin levels were measured in all serum samples. Statistical analysis was performed by one way ANOVA with Dunnet's test and Pearson correlation tests.
Results
The mean hSCRP level in GD and controls were 14.5 ± 2.9 mg/ml and 6.4 ± 1.6 mg/ml respectively. The mean TNF-α level, IL-6 level and Leptin levels were 232 ± 25 pg/ml, 12.7 ± 4.4 pg/ml and 33 ± 4.7 ng/ml respectively. There was statistically significant difference of all the pro-inflammatory cytokines compared to controls (P value < 0.05).
Conclusions
This study shows raised titers of pro-inflammatory markers – IL-6, TNF-α and hsCRP, leptin correlated with HT suggesting a significant pathophysiological role. But, the exact immuno-modulatory role and pathogenetic mechanism needs more research.
(**Key words:** Hashimoto's thyroiditis; Tumour necrosis factor; Interleukin-6; Goiter; Auto-immunity; Leptin)

Predictive factors of relapse, TED, and thyroidectomy in graves' disease
Nuria Sánchez de la Blanca Carrero[1,2,3], Carmen Chozas[4], Pablo Sacristán-Gómez[1], Ana Serrano-Somavilla[5], Miguel Antonio Sampedro-Nuñez[4], Monica Marazuela[4] & Rebeca Martínez Hernández[1]
[1]IIS La Princesa, Hospital Universitario de La Princesa, Madrid, Spain; [2]Instituto de Investigación Princesa, Endocrinology Department, Madrid, Spain; [3]IIS La Princesa, Madrid, Spain; [4]Hospital de La Princesa, Madird, Spain; [5]Universidad Autónoma de Madrid, Madrid, Spain

Introduction
Graves' disease (GD) is one of the most common autoimmune thyroid disorders worldwide. Although GD is not life-threatening, complications significantly impact patients' quality of life: 52% of patients relapse, 50% develop thyroid eye disease (TED), and thyroidectomy remains the last resort in challenging clinical cases. In recent years, data engineering and multivariate statistical methods have been increasingly applied in the medical field. They provide a broader analytical perspective, accelerate statistical analysis and contribute to the development of predictive algorithms. This study aimed to identify clinical and biochemical variables collected at diagnosis that are associated with thyroidectomy, relapse, and future TED onset in GD patients using these methods.
Methodology
We analyzed data from GD patients diagnosed at *Hospital Universitario de La Princesa* between 2010 and 2018, with follow-up until 2022. Data engineering techniques were employed to clean the dataset by removing low-quality variables. The analytical process was conducted in two steps: 1) a univariate analysis was performed to identify significant associations with the outcomes of interest ($P < 0.1$), which were subsequently included in further models. 2) Next, supervised logistic regression (100-fold cross-validation-CV-) and time-to-event analysis (Cox models) were conducted.
Results
Multivariate analysis reported the following independent associations:
• **Relapse**: Significant associations were found with albumin ($\beta = -1.782$, $P = 0.064$) and CAS ($\beta = 1.238$, $P = 0.070$). However, time-to-event analysis did not show a clear impact of these variables on relapse.
• **TED**: Independent associations were observed with basophils ($\beta = -4.883$, $P = 0.016$) and GPT($\beta = 2.171$, $P = 0.084$). Both variables had a weak, but significant correlation($r = -0.212$, $P = 0.004$). Other correlations with thyroid hormones would suggest a link between them. Interestingly, basophils also showed significant independent associations in Cox models($\beta = -1.959$, $P = 0.076$), inferring a potential relationship between their levels at diagnosis and future TED onset.
• **Thyroidectomy**: Associations were found with immature granulocytes ($\beta = -22.272$, $P = 0.033$), anti-TG antibodies ($\beta = -23.643$, $P = 0.096$), leukocytes ($\beta = 3.310$, $P = 0.066$), eosinophils ($\beta = 2.969$, $P = 0.026$), potassium ($\beta =$-

3.801, $P = 0.093$) and goiter ($\beta = 2.308$, $P = 0.028$). However, the Cox model did not report any significant relationship between surgery timing and these variables.
The mean areas under the curve reflected poor quality models: **relapse**: 0.576 ± 0.076; **TED**: 0.663 ± 0.100 and **thyroidectomy**: 0.676 ± 0.107. A class imbalance in the dataset, a limited sample size and the lack of biomarkers may have contributed to the reduced model performance.
Conclusions
1. We obtained significant associations between relapse and albumin levels and CAS, already reported in the literature.
2. A novel relationship between TED onset and basophils.
3. Associations between thyroidectomy immune populations levels, goiter and potassium, which could contribute to its management.

From neurology to endocrinology: an atypical case of thyroid storm in a young adult

Ceren Karaçalık Ünver[1], Enes Ucgul[1], Oğulcan Boz[1], Hüseyin Demirci[1], Ilknur Ozturk Unsal[1], Mustafa Ozbek[1] & Erman Cakal[1]
[1]Ankara Etlik City Hospital, Ankara, Türkiye

Thyroid storm is a rare, life-threatening condition characterized by severe thyrotoxicosis. Common triggers include infection, trauma, surgery, iodine exposure, discontinuation of antithyroid medications. The Burch-Wartofsky criteria, assessing cardiovascular, gastrointestinal, CNS disorders and hyperpyrexia, is frequently used for diagnosis. An 18-year-old male was admitted to the Emergency Department with nausea, vomiting, four-limb paralysis and inability to speak, following ten-days of diarrhea. He was lethargic, febrile (38.5°C), tachycardic, and tachypneic. Neurology consultation was requested for paralysis and speech disturbance, and brain imaging ruled out other diagnoses. A lumbar puncture was performed to investigate CNS infection, but findings were negative. A psychiatric consultation excluded conversion disorder. Thyroid function tests revealed thyrotoxicosis (table 1). Burch-Wartofsky score of 65 confirmed thyroid storm. Treatment was initiated with propylthiouracil (PTU), hydrocortisone, Lugol's solution and propranolol. Ultrasound revealed thyroid inferno. Intensive antithyroid therapy led to significant increase in liver function tests, resulting in the discontinuation of PTU and the initiation of lithium treatment. After achieving euthyroidism, the patient underwent total thyroidectomy and started on thyroxine replacement therapy. The patient was clinically stable and discharged with plan for close follow-up. Central nervous system findings in thyroid storm may include neurological symptoms such as tremor, hyperreflexia, myopathy and seizures as well as psychiatric symptoms like anxiety, agitation, psychosis and delirium. Paralysis is a rare presentation. While hypokalemic periodic paralysis is one possibility, similar findings can occur in normokalemic patients. The sudden onset of the condition should be considered in differential diagnosis as it may lead to severe outcomes depending on the severity of muscle involvement. Early diagnosis and appropriate treatment can prevent complications and improve prognosis. Controlling thyroid function is crucial in managing this condition and preventing recurrence of paralysis.

Thyroid function test assay interference: biochemical and clinical challenges and its implications

Smriti Acharya[1], Sharon Daniel[1], Suyash Acharya[1], Chintavali Ajay Ramesh[1], Rajinder Gupta[1] & Daniel Kannappan[1]
[1]WWL, Wigan, United Kingdom

Introduction
Thyroid hormone tests are widely used globally and play a crucial role in guiding treatment decisions and further diagnostic evaluations. Any inconsistency between clinical symptoms and test results must be thoroughly investigated to prevent misdiagnosis and unnecessary treatment. Automated thyroid tests can be affected by interferences, which may alter results and influence treatment decisions. These interferences can lead to incorrect treatments and changes in therapy. This review aims to explore the impact of assay interference on clinical management and highlights the importance of early detection to avoid inappropriate care.
Case report
Case 1: A 73 Y/F with post thyroidectomy for multinodular goiter on Thyroxine replacement was referred to the endocrinology clinic due to unusual thyroid function test (TFT) results (Table 1). Her clinical condition wasn't corelating with TFT. Additional testing was performed at two separate laboratories using different methods, which confirmed interference. This helped avoid an unnecessary increase in her thyroxine dosage based on the initial abnormal results. Case 2: A 60 Y/F on thyroxine was referred for evaluation of persistent fatigue and tiredness. Her recent TFTs showed normal TSH but elevated FT4 levels, which did not match her clinical symptoms (Table 2). To clarify, repeat tests were done at two laboratories using different methods. The results confirmed a hypothyroid state, leading to an adjustment in her levothyroxine dose, which improved her symptoms.
Results
This table highlights the TFT variations across labs and reagents used.
Discussion
Laboratory interference is a significant cause of misdiagnosis, so it's important to always match test results with patient's symptoms. Patients often have vague symptoms and when test results don't match the clinical situation, interference should be suspected. A careful approach is needed, with collaboration between healthcare providers and lab experts to ensure accurate diagnosis and appropriate treatment.
Conclusion
According to the British Thyroid Association, TFT in the UK are requested around 10 million times annually, with an estimated cost of 30 million pounds. Collaboration between laboratory and clinical teams is essential for identifying potential interferences and ensuring that thyroid symptoms align with test results.

Risk of obstructive sleep apnea in patients with clinical hypothyroidism based on STOP-BANG score

Aakash Pandey[1], Priya Bansal[1] & Lekhraj Ghotekar[1]
[1]Lady Hardinge Medical College, New Delhi, India

Introduction
Hypothyroidism increases the risk of OSA. Obstructive sleep apnea (OSA) is a common sleep disorder with varied etiology and can affect a large population. OSA is associated with major adverse cardiovascular events. The presence of hypothyroidism has been linked to the development of obstructive sleep apnea. This cross-sectional study aimed to predict the risk of OSA in clinical hypothyroid subjects based on STOP-BANG score which is a reliable marker for OSA risk prediction and to study the independent effect of hypothyroidism on the risk of OSA by comparing the STOP-BANG score in age, sex, body mass index (BMI) matched non-hypothyroid subjects.
Methodology
Study group included consecutive clinical hypothyroid patients (cases) and age, sex, BMI-matched non-hypothyroid subjects (controls) presenting to the out-patient department and admitted in General Medicine wards of a tertiary care hospital of New Delhi, India. Sample size for the study was 150 which included 75 cases and 75 controls. Clinical hypothyroidism was diagnosed on the basis of thyroid function tests (both newly diagnosed and on treatment). All patients were evaluated for their STOP-BANG score and risk stratification for OSA done.
Results
Among hypothyroid participants, 48.0% were classified as having low risk of OSA, 45.3% as having moderate risk, and 6.7% as having high risk based on the STOP-BANG score. The risk of OSA increased with age and higher TSH levels. Importantly, the association of hypothyroidism and risk of OSA was statistically significant in patients with a higher BMI, presence of co-morbidities (diabetes and hypertension), and dyslipidemia (Total Cholesterol and Low-density Lipoprotein).
Conclusion
Uncontrolled hypothyroidism has the potential to increase the risk of OSA. Screening for OSA in hypothyroidism should be prioritized in individuals with a history suggestive of sleep apnea, higher BMI, dyslipidemia, and comorbidities.

Pancreatic mass during follow-up of a papillary thyroid microcarcinoma: lenvatinib's side effect, metastasis or primary tumor ?

Boussis Lemya[1,2], Amira Bouchenna[1], Mohamed M'hammedi Bouzina[1], Fayçal Bendjebbour[1], Abdelghani Tibouk[3], Brahim Ghennam[1] & Bensalah Meriem[1]
[1]Military Hospital, Medicine, Algiers, Algeria; [2]Military Hospital of Algiers, Algiers, Algeria; [3]Military Hospital of Oran, Oran, Algeria

Introduction
Papillary thyroid carcinoma is the most common type of thyroid cancer. Metastases are often pulmonary and osseous, other sites, such as the pancreas, are possible but remain exceptional. We report the case of a patient with refractory and progressive papillary carcinoma under lenvatinib who, during follow-up, presented with a pancreatic mass, raising a diagnostic dilemma: is it a metastasis, a side effect of lenvatinib, or a primary tumor?
Case Report
A 75-year-old patient with a history of hypertension was diagnosed in 2018 with papillary microcarcinoma with lymph node metastases, classified as PT1aN1bMx. He underwent four courses of radioiodine therapy, totaling 550 mCi, with the last post-therapeutic scan revealing a right mediastinal fixation, confirmed by thoracic CT, with three additional pulmonary nodules. He did not return for follow-up until 2024, when imaging revealed inoperable pulmonary and cerebral metastases, leading to the initiation of treatment with lenvatinib, which showed a good therapeutic response. Five months after starting treatment, he presented with jaundice, fever, abdominal pain, and leukocytosis. CT imaging identified a 5 cm pancreatic mass, and histopathological analysis confirmed a well-differentiated adenocarcinoma of the pancreatic head with positive CK7 and CK19 immunostaining but negative TTF1. The patient was presented in a multidisciplinary (RCP digestive), where chemotherapy was decided upon; unfortunately, he passed away before treatment could begin.
Discussion
The discovery of a pancreatic mass raises several diagnostic hypotheses: **Metastasis of thyroid cancer** The multimodal metastatic nature in our patient suggests the possibility of pancreatic metastasis. However, this diagnosis is rarely reported and requires histopathological and immunohistochemical confirmation. **Lenvatinib side effect** Although lenvatinib is known for its efficacy, reported side effects include acute or chronic pancreatitis. The occurrence of neoplasia under tyrosine kinase inhibitors has been exceptionally documented **Primary pancreatic neoplasia** This association has been previously reported in the literature. Histopathology revealed an exocrine adenocarcinoma, strongly suggesting a primary origin. The occurrence of this second cancer could be incidental or linked to underlying genetic mechanisms.
Conclusion
This case highlights the complexity of diagnosis in such a challenging clinical context and underscores the need for a multidisciplinary approach to guide diagnosis and treatment.

Papillary thyroid carcinoma treated with vandetanib

Wafiya Mokhtari[1], Bouchenna Amira[1], Ghenam Brahim[1], Tibouk Abdelghani[2], Hammoud Hassen[1] & Bensalah Meriem[1]
[1]Central Army Hospital, Algiers, Algeria; [2]Oran Military Hospital, Oran, Algeria

Patients with medullary thyroid carcinoma (MTC) usually present with extensive regional involvement or distant metastatic disease at diagnosis or during follow-up, preventing cure by initial thyroidectomy. Treatment options in advanced CMT include surgery, radiotherapy, and tyrosine kinase inhibitors (TKIs) such as vandetanib.
Materials and Methods
We aimed to evaluate four patients with metastatic CMT treated with vandetanib followed at our level between 2021 and 2024 with a minimum follow-up of 6 months.
Results
Four patients met the inclusion criteria, 3 men and one woman. The mean age was 40 years. All four patients underwent total thyroidectomy with lymph node dissection. Metastases were to the lung, bone, cerebellum and liver. The main indication for vandetanib was progression of lung metastases. Regarding response to treatment, one patient was stable, one patient showed a partial response and 2 patients escaped treatment after 6 to 12 months of stability. The average duration of treatment was 13 months [4-19 months]. Side effects were observed in 3 patients, including hypertension, QT prolongation, diarrhea, acne and hypocalcemia. In the end, two of the patients died.
Discussion
Vandetanib targets the RET oncogene, the vascular endothelial growth factor receptor and the epidermal growth factor receptor. The use of vendetanib can cause remarkable side effects, altering patients' quality of life, while response to treatment is not always satisfactory. Thus its prescription must take into account the benefit-risk balance and be discussed in a multidisciplinary meeting.
Conclusion
The use of vandetanib in the management of advanced CMT has led to stabilization of lesions and control of the disease for at least a certain period before escape.

Middle-aged women thyroid gland ultrasound assessment in the minsk-city

Elena Brutskaya-Stempkovskaya[1], Ihar Tarasik[2], Katsiaryna Dziachko[2], Yuliya Dydyshka[1], Alexandra Kuchar[1] & Efrosiniya Tsishkouskaya[1]
[1]Belarusian State medical University, Minsk, Belarus; [2]Minsk Clinical Consulting and Diagnostic Center, Minsk, Belarus

Background
Thyroid volume varies across populations depending on age and gender. Some studies show a correlation between thyroid volume and anthropometric parameters. The results of thyroid gland assessing of middle-aged women in Belarus population have not been published yet. The aim of the study is to

establish the normal thyroid volume and its correlation with anthropometric parameters in middle-aged women.
Materials and Methods
A retrospective cross-sectional study was conducted. We studied 131 women 45-59 years old without endocrine diseases who applied to the Minsk Clinical Consultative and Diagnostic Center in 2023-2024 years. The study included patients with normal echogenicity of the thyroid gland, without a severe echo structure disturbance and nodes (anechoic cyst-like formations 5 mm less were assessed as normal). Patients with thyroid hormone levels abnormalities were excluded from the study. Statistical processing of the results was carried out using the Statistica 10 program (StatSoft, USA). Examination: thyroid ultrasound, TSH, FT4, ATPO, height, weight, BMI. Results. Average age was 51.7 $\pm$ 3.44 years, height was 165 (161-170) sm, weight was 69 (61-76) kg, BMI was 26.3 (23.7-29.2) kg/cm^2. TSH level was detected 2.96 (1.93 - 3.58) mIU/ml, FT4 – 16.7 (14.9-19.8) pmol/l, ATPO -19.6 (12.3- 41.1) IU/ml. The right lobe average volume was 5.47 $\pm$ 2.11 cm^3, the left lobe of the thyroid gland was 5.43 $\pm$ 2.27 cm^3. The width of the isthmus was 2.5 (2.2-2.8) cm. Minimum registered total thyroid volume was 3,9 cm^3, maximum registered total thyroid volume was 22,1 cm^3. The total thyroid volume was recorded 10.1 (6.0-16.8) cm^3. Frequency range 5-95% was detected 5.9-17.4 cm^3. A strong direct correlation was found between BMI and total thyroid gland volume ($r = 0.7$).
Conclusion
The result of the study demonstrated the normal total thyroid volume was 5.9-17.4 cm^3 middle-aged women 45-59 years old without a history of endocrine diseases in the Minsk- city. A strong direct correlation was found between BMI and total thyroid gland volume ($r = 0.7$).

A rare case of thyrotropinoma inappropriately treated as Graves' disease

Sahar Alwakil[1], Ahmed Haroun[2], Dina Farouk[3], Christina Samir[4] & Randa Salam[1]
[1]Professor of Internal Medicine, Endocrinology and Diabetes Cairo University, Cairo, Egypt; [2]Assistant Professor of Internal Medicine, Endocrinology and Diabetes Cairo University, Cairo, Egypt; [3]Lecturer of Internal Medicine, Endocrinology and Diabetes Cairo University, Internal Medicine Department, Cairo, Egypt; [4]Assistant Lecturer of Internal Medicine, Endocrinology and Diabetes Cairo University, Cairo, Egypt

Introduction
Thyrotropinoma, TSHoma, TSH secreting pituitary tumor, is considered a very rare cause of hyperthyroidism. They account for less than 1 % of all pituitary adenomas. Almost all TSHomas express a variable number of somatostatin receptors.
Case report
A 44 year old male patient presented to Endocrinology unit for consultation about total thyroidectomy. The patient presented three years ago with goiter, palpitations, heat intolerance, irritability and tremors. Despite his initial thyroid profile showed elevated TSH, Free T3 and free T4, he was falsely considered Graves' disease kept on carbimazole 30 mg/day for 3 years. Patient's symptoms were not controlled, and he developed atrial flutter. Total thyroidectomy was considered so he was referred to surgery department who consulted us about the decision of total thyroidectomy.
Examination
BP: 120/70 mmHg, irregular pulse at rate of 90/mint Diffuse goiter, not tender, no palpable thrill, with no thyroid orbitopathy. Cardiac examination: accentuated heart sounds and mitral regurge. Complete blood picture, liver, kidney function, blood glucose, and lipid profile were normal. TSH **43** U/ml (0.5 - 4.8), Free T3: **12.7** pg/ml (2.3 - 4.2), Free T4: **3.5** ng/dl (0.8 – 1.7). ACTH 9 am: 42pg/ml (up to 65), serum Cortisol 9 am: 5.9 mg/dl (4- 22), serum prolactin: 5.5 ng/ml (2 -17.7), FSH: 4.36 mIU/ml (1.4 – 18), LH: 6.2 mIU/ml (1.5 -9.3). TSH receptor antibodies 0.9 IU/l (0-1.75) excluding coexisting primary thyrotoxicosis. Thyroid ultrasound showed enlarged heterogeneous thyroid gland, (4.2x3.5 cm) with increased vascularity. Dynamic MRI Sella with gadolinium showed a 7 mm right sided pituitary microadenoma. To confirm that the pituitary microadenoma is functioning, and as somatostatin scintigraphy was not available, a dynamic test using long-acting somatostatin analogue injection (somatostatin LAR) was done, thyroid profile was measured 28 days after with marked reduction of the thyroid hormones; TSH **27** U/ml (0.5 - 4.8), Free T3: **3.02** pg/ml (2.3 - 4.2), Free T4: **0.58** ng/dl (0.8 – 1.7), with improvement of the symptoms and reduction of the thyroid gland size. This step is considered a bridging therapy until transsphenoidal surgery is performed.
Conclusion
Thyrotropinoma is a very rare cause of secondary thyrotoxicosis and is frequently misdiagnosed as Graves' disease. Definite diagnosis depends on positive pituitary imaging and dynamic tests to differentiate TSHoma from other causes of central hyperthyroidism. Early diagnosis is important to prevent inappropriate management.

Levothiroxine malabsorbtion

Nino Lazrishvili[1] & Tamar Shervashidze[1]
[1]LTD David Metreveli Medical Center, TBILISI, Georgia

Background
Levothyroxine (L-thyroxine,) is a drug of choice for treating primary hypothyroidism, which in developing countries generally occurs due to Hashimoto thyroiditis, thyroidectomy, or iodine deficiency. L-T4 is absorbed in the small intestine, more precisely in jejunum and ileum, and to a small extent also in the stomach. Concomitant gastrointestinal diseases, such as celiac disease, *H. pylori* infection, lactose intolerance, inflammatory bowel disease, and even parasitic infestation (*G. lamblia*), etc. may cause L-T4 malabsorption
Case Presentation
The patient was treated for primary hypothyroidism in different endocrinological centers of Georgia for 10 years without significant changes and results. Referring to us, attention was paid to the clinical and laboratory signs characteristic of hypothyroidism, despite the fact that she was receiving 2800 mg of levothyroxine and up to 150 mg of T3 per day. Conducted diagnostic deductions with consultations, the total volume of the thyroid gland is 3.1 ml. Tsh-43.77 (N 0.4-4.0) miu/ml. Ft4 - 1.46 ng/dl (N 1.8-4.2). Antibodies within the norm. Due to the ineffectiveness of the standard scheme of treatment, a test was performed to rule out pseudo-malabsorption of levothyroxine, with a special protocol, thus confirming that the patient really had a syndrome of true malabsorption of levothyroxine oral preparations. An individual thyroxine treatment algorithm was developed. Alleviation of the patient's condition and compensation of hypothyroidism is possible only with parenteral replacement therapy. A parenteral injection of 500 mg of levothyroxine every third day was prescribed, as soon as hypothyroidism compensation was achieved.
Conclusions
Levothyroxine parenteral injection is an effective and safe way to achieve hypothyroidism compensation in case of levothyroxin malabsorbtion.

Lost and found: a thyroid tale of tissues gone rogue

Nada Ait Kassi[1], Hairchi Sara[1], Habbadi Zineb[1], Fatima Toulali[1], Ghizlane Sabbar[1], Kaoutar Rifai[1], Hinde Iraqi[1] & Mohamed El Hassan Gharbi[1]
[1]Ibn Sina Hospital Mohamed V University, Endocrinology, Rabat, Morocco

Background
Thyrotoxicosis following subtotal thyroidectomy is an uncommon occurrence. In rare cases, ectopic thyroid tissue may be the source of hyperthyroidism, particularly in the mediastinum. This report discusses an unusual presentation of hyperthyroidism many years post-surgery due to an ectopic thyroid tissue in the anterior mediastinum.
Case Presentation
We report the case of a 61-year-old female patient with a history of subtotal thyroidectomy in 2000, during which the upper left thyroid pole was preserved. The surgery was complicated by hypoparathyroidism. Years later, the patient developed both clinical and biochemical hyperthyroidism. Thyroid scintigraphy revealed an area of intense, heterogeneous uptake in the upper and middle

mediastinum, suggesting a plunging goiter component. A subsequent thoracic CT scan showed a lesion in the anterior mediastinum, with imaging characteristics consistent with ectopic thyroid tissue. The patient underwent surgical resection via sternotomy performed by the thoracic surgery team. Histopathological analysis confirmed the benign nature of the lesion.
Conclusions
This case emphasizes the need for clinicians to consider ectopic thyroid tissue as a potential source of hyperthyroidism, even in patients with previous thyroidectomy. Detection of ectopic thyroid tissue in the mediastinum underscores the importance of thorough imaging and surgical assessment when managing recurrent thyroid symptoms in post-thyroidectomy patients.

Dysphagia in old age, what if it's an ectopic thyroid?: a case report

Amal Riad[1], Kaoutar Rifai[1], Iraqi Hinde[1] & Mohamed Elhassan Gharbi[1]
[1]Ibn Sina Institution, Rabat, Morocco

Introduction
Thyroid ectopy is a rare condition whose pathogenesis remains poorly understood. It may be asymptomatic or manifest as clinical or biological hypothyroidism. We report a case of thyroid ectopy diagnosed at an advanced age.
Case Report
A 63-year-old patient with no previous history of any particular complaint presented with dysphagia and the sensation of an enlarging sublingual formation. Ultrasound showed an empty thyroid cavity with a lesional process at the base of the tongue. The thyroid work-up revealed mild hypothyroidism. The patient underwent a thyroid replacement and then an operation, and an APTH scan showed thyroid ectopy at the base of the tongue.
Discussion
Thyroid ectopy is defined as the presence of thyroid tissue outside its infrahyoid location. The association of thyroid ectopy and a thyroid in a cervical position is exceptional. Lingual thyroids are the largest group of thyroids and have been known for a very long time (VERNEUIL described them for the first time in 1853). Lingual thyroids are the result of a defect in the migration of the median thyroid outline, which normally leads the glandular cells from the floor of the mouth to the anterior surface of the trachea. Radiological investigation is based on cervical ultrasound as the first line of defence, CT with PDC injection or MRI. Tc99 scintigraphy confirms the diagnosis, demonstrating ectopic fixation.

JOINT2592

Cross-reactions between synthetic antithyroid drugs

Oussama Jaddi[1], Sana Rafi[1], Sara Ijdda[1], Ghizlane El Mghari[1] & Nawal El Ansari[1]
[1]Mohammed VI University Hospital of Marrakesh, Department of Endocrinology, Diabetes, Metabolic Diseases and Nutrition, Marrakesh, Morocco

Introduction
Synthetic antithyroid drugs, notably methimazole, carbimazole, and propylthiouracil (PTU), are commonly used medications for the treatment of hyperthyroidism. Although these drugs are generally effective, they can sometimes cause adverse effects and cross-reactions, meaning allergic or toxic reactions to different but chemically similar medications.
Observation
A 37-year-old female patient consulted for signs of hyperthyroidism: palpitations, significant unquantified weight loss deemed important. A thyroid panel was requested, revealing low TSH levels with a T4 level of 43.07 pmol/l. The cervical ultrasound suggested Graves' disease, with positive Anti-TSH receptor antibodies. The patient was initially placed on Methimazole 40 mg; after a few days, she developed skin lesions (urticaria), prompting a change in treatment to Carbimazole along with the initiation of antihistamine therapy, but without improvement in the allergic reactions. After achieving euthyroidism, the patient underwent total thyroidectomy without postoperative incidents.
Discussion
Cross-reactions between synthetic antithyroid drugs can be explained by the chemical similarity among these medications. Methimazole and carbimazole, for example, are closely related. Although rare, cross-reactions pose a significant clinical challenge. Patients who develop adverse reactions to one antithyroid drug are at an increased risk of reacting similarly to other drugs in the same class. Management of cross-reactions between synthetic antithyroid drugs requires a careful and personalized approach.
Conclusion
Cross-reactions between synthetic antithyroid drugs, although varied among different molecules, necessitate careful evaluation and appropriate management. In cases of intolerance or hypersensitivity, alternatives such as propylthiouracil, radioactive iodine, or surgery should be considered. Increased vigilance can help limit risks and optimize the treatment of patients with hyperthyroidism.

Rare coexistence of parathyroid adenoma and thyroid adenomas: a case report

Fatima Ezzahra Mennani[1], Sara Ijdda[1], Sana Rafi[1], Ghizlane El Mghari[1] & Nawal El Ansari[1]
[1]Department of Endocrinology, Diabetology, Metabolic Diseases and Nutrition Mohammed VI University Hospital, Marrakech, Morocco, Department of Endocrinology, Diabetology, Metabolic Diseases and Nutrition Mohammed VI University Hospital, Marrakech, Morocco

Introduction
Primary hyperparathyroidism (PHPT) and thyroid disease are two relatively common conditions that can coexist in the same patient. The etiology and risk factors remain unclear. We report here the case of a 55-year-old female patient presenting with a parathyroid adenoma, two normo vesicular thyroid adenomas discovered during an etiological work-up for kidney stones.
Case Report
55-year-old female patient with a history of recurrent kidney stones, right thyroid loboisthmectomy with anatomopathological examination: appearance of atypical reworked thyroid adenoma, referred to our training for further management of primary hyperparathyroidism. Cervical palpation revealed a 1 cm thyroid nodule lateralized to the left, biological workup showed hypercalcemia at 117 mg/l and PTH at 257 pg/ml. Cervical ultrasonography showed 2 left nodular formations classified as EuTirads 3, the largest measuring 13×10 mm. Parathyroid scintigraphy with Sesta-MIBI 99mTc showed a left sub lobar area preferentially fixing the MIBI-Tc 99m tracer, in favour of a parathyroid origin with no ectopic focus capturing the tracer. The patient underwent surgery involving removal of the left thyroid lobe and the left inferior parathyroid. Anatomopathological examination showed the coexistence of a normo vesicular thyroid adenoma and a parathyroid adenoma. Postoperative calcemia levels normalized.
Discussion
The coexistence of parathyroid and normovesicular thyroid adenomas is extremely rare. A combination of clinical, radiological and histological findings should lead to a diagnosis in the presence of an atypical presentation. Because of the risk of concomitant thyroid damage, thyroid imaging must be carried out prior to any surgical treatment of the parathyroid glands. Ultrasound provides a precise anatomical image, but cannot visualize certain parathyroid adenomas. Ultrasound symptomatology must be understood, as well as the pitfalls and difficulties involved. MIBI scintigraphy confirms the location of the parathyroid adenoma, while MIBI SPECT/CT offers greater sensitivity, accuracy and anatomical precision than ultrasound for preoperative parathyroid localization, even in the case of ectopic glands or coexisting thyroid pathology.
Conclusion
The association of a parathyroid adenoma with normo vesicular thyroid adenomas is extremely rare. Removal of the parathyroid adenoma should be completed by loboisthmectomy or total thyroidectomy, depending on the indication.

JOINT1207

Residual thyroid tissue post-thyroidectomy: a hidden driver of Graves' disease

Patricia Ferreira[1,2], Sílvia Santos Monteiro[1,2] & Joana Queirós[1]

[1]Serviço de Endocrinologia, Diabetes e Metabolismo, ULS São João, Porto, Portugal; [2]Faculdade de Medicina da Universidade do Porto, Porto, Portugal

Introduction

Graves' disease is an autoimmune thyroid disorder characterized by hyperthyroidism and elevated thyroid-stimulating antibodies (TRAbs). Management can be particularly challenging in patients with residual thyroid tissue post-thyroidectomy, especially when complicated by Graves' orbitopathy.

Case Report

A 48-year-old woman with a history of Graves' disease was referred to the endocrinology consultation for the recurrence of her condition. She had undergone total thyroidectomy in 2015 due to diagnosis of Graves' disease, followed by levothyroxine replacement therapy. In 2022, she developed tremors, anxiety, palpitations, and bilateral exophthalmos. Laboratory tests confirmed thyrotoxicosis with markedly elevated thyroid-stimulating hormone receptor antibodies (TRAbs) (>40 IU/l). Following this, she underwent a progressive reduction in levothyroxine dosage, ultimately stopping the medication. Despite being off levothyroxine for the six months prior to referral, she remained euthyroid on subsequent thyroid function tests. The patient had a significant history of smoking (20 UMAs) and presented with marked bilateral exophthalmos on examination. Ultrasounds showed a hypoechoic, heterogeneous nodule at the left and right surgical sites. Thyroid scintigraphy confirmed the presence of hyperfunctioning nodules in the surgical site and additional ectopic tissue in the thyroglossal duct/submental region. Given her euthyroid state, antithyroid drugs were not initiated, and radioactive iodine was avoided due to her significant Graves' orbitopathy. Recent laboratory tests, performed without any directed therapy, revealed thyroid-stimulating hormone (TSH) 1.05 µIU/ml, free thyroxine (FT4) 0.82 ng/dl (N: 0.70–1.48), free triiodothyronine (FT3) 3.15 pg/ml (N: 1.71–3.71), and TRAbs 47 IU/l. Surgical intervention was considered the best option to remove the residual thyroid tissue and prevent further progression of orbitopathy and thyroid autoimmunity. Smoking cessation was also strongly encouraged. The patient has surgery scheduled soon.

Conclusion

This case underscores the challenges in managing Graves' disease when residual thyroid tissue persists post-thyroidectomy, even in euthyroid patients. The persistence of elevated TRAbs and the risk of exacerbating orbitopathy highlight the need for a tailored treatment approach, involving careful monitoring and surgical intervention to prevent disease recurrence and minimize complications.

I. Parhon National Institute of Endocrinology, Pituitary and Neuroscience Department, Bucharest, Romania

Introduction

Although the most common cases of hyperthyroidism are due to Graves' disease, it is a rare circumstance when this condition occurs in patients with personal history of thyroid lobectomy. This is a case report of newly developed Graves' disease in a female patient with concomitant urinary system disorder, three years after partial thyroidectomy.

Case presentation

We present the case of a 57 years-old female with previous history of left hemithyroidectomy for large follicular thyroid adenoma, 3 years before. Thyroid function had been normal before surgery, with negative TPO antibodies and normal ultrasonographic appearance of the right thyroid lobe. Postoperatively, she received low dose of levothyroxine replacement therapy until her current presentation in our service. Her medical history included anterior pelvic exenteration for infiltrative carcinoma of the urinary bladder in 2019, post-operative radiotherapy and surgery for left aortic arterio-ureteral fistula, resulting in left nephrostomy, right ureterostomy and chronic kidney disease. Currently, she addresses to the endocrinology department complaining of weight loss, spontaneous retrobulbar pain, diplopia and hyperlacrimation. Thyroid function tests show TSH supression and increased FT4 (x 1.1 above ULN). Six weeks after discontinuation of levothyroxine therapy, thyroid function remains unchanged, TPO antibodies are slightly elevated (25 U/ml) and anti-TSH receptor antibodies present high levels (8.7 U/l- 5 times ULN). Ultrasonography revealed enlarged right thyroid lobe, with heterogeneous echotexture and hypervascularisation on color Doppler exam. Detailed ophtalmological evaluation is yet to be completed. Initiation of methimazole therapy is recommended and regular endocrine evaluation will be performed.

Conclusion

The physiopathological mechanism involved in the occurence of Graves' disease following hemithyroidectomy is still unclear. It may imply an overactive immune response, genetic factors or an environmental component. So far there are no predictive factors associated with development of this condition that are worth taken into account preoperatively. No cases showing association between bladder neoplasm and thyroid autoimmune disease or thyroid adenoma have been reported in the literature so far.

JOINT2475

Hypercalcemia secondary to postlaryngectomy thyroiditis: a case report

Paloma González Lázaro[1], Juan Antonio Mascuñana Calle[1], Pedro Jiménez Torrecilla[1], Cristina Contreras Pascual[2], Belvis Torres Arroyo[3] & Ines Gómez García[1]
[1]Hospital Universitario Mancha Centro, Alcazar de San Juan, Spain; [2]Hospital Santa Bárbara de Soria, Soria, Spain; [3]Hospital General Universitario Nuestra Señora del Prado, Talavera de la Reina, Spain

Introduction

Thyroid damage is a complication of total laryngectomy and may be caused by manipulation of the gland. There are isolated descriptions in the literature related to transient hyperthyroidism post-head and neck surgery. Hypercalcemia is an infrequent element in patients with hyperthyrodism. The appearance of a hypercalcemic crisis can trigger serious complications for the patient, being an exceptional event in patients with thyrotoxicosis

Case Report

We report the case of a 58-year-old man who underwent total laryngectomy and left thyroidectomy for a pyriform sinus tumor. Twenty days after the intervention, frank hyperthyroidism was detected (TSH 0.01, FT4 3.34, T3 4.82) with negative thyroid autoimmunity. Concomitantly, hypercalcemia was detected with calcium corrected for albumin of 11.2 and suppressed PTH with a good response to hydration and treatment with glucocorticoids. PTHrp was requested with results within normal limits. After 2 weeks, thyroid function and phosphocalcium metabolism normalized.

Conclusions

Post-laryngectomy thyroiditis has a prevalence of up to 54.6% in some series. Hypercalcemia is an uncommon element in patients with hyperthyroidism, the symptoms overlap with hyperthyroidism and its primary identification requires a high index of suspicion. The appearance of a hypercalcemic crisis can trigger serious complications in the patient, this being an exceptional event in patients with thyrotoxicosis. The hypercalcemia suppression test with steroids is of great clinical utility in its association with thyrotoxicosis to rule out concurrent hyperparathyroidism. We suggest measuring thyroid function and phosphocalic metabolism in the routine analysis of patients undergoing total laryngectomy.

Riedel's thyroiditis: a diagnosis not to be overlooked

Houas Jihene[1], Monia Ghammam[1], Jawaher Kechiche[1], Meriem Grassa[1], Malika El Omri[1], Abir Meherzi[1], Mouna Bellakhdher[1], Wassim Kermani[1] & Mohamed Abdelkefi[1]
[1]University of Sousse Faculty of Medicine of Sousse, Sousse, Tunisia

Introduction

Riedel's thyroiditis is a rare form of chronic thyroid inflammation characterized by extensive fibrosis extending beyond the thyroid gland, often mimicking thyroid malignancy. The objective of this study is to analyze the epidemiological,

clinical, and histopathological characteristics of this condition, along with its evolutionary patterns and therapeutic approaches.
Methods
We report three cases of Riedel's thyroiditis managed at the ENT and Cervicofacial Surgery Department of Farhat Hached Hospital in Sousse.
Results
Our series included two men and one woman, with a mean age of 41 years. The primary complaint in all cases was an anterior lower cervical swelling, without any compressive symptoms. Clinical examination revealed a well-defined, firm, painless, and mobile anterior cervical mass with intact overlying skin and no palpable cervical lymphadenopathy. Vocal cord mobility was preserved in all patients. Cervical ultrasound was performed in all cases, and one patient underwent thyroid scintigraphy. The initial surgical approach consisted of lobectomy with isthmectomy in all patients. In one case, the thyroid lobe was strongly adherent to the trachea, while in another case, it was adherent to the infrahyoid muscles. The diagnosis of Riedel's thyroiditis was confirmed histopathologically. Additionally, one patient was found to have an intrathyroidal micropapillary carcinoma of the follicular variant, necessitating completion thyroidectomy.
Conclusion
Riedel's thyroiditis remains an enigmatic entity with an unknown etiology. Its management involves a discussion between conservative surgery and medical treatment, including corticosteroids, tamoxifen, and mycophenolate mofetil, with treatment protocols potentially guided by additional paraclinical findings.

Thyroid surgery in children: Indications and outcomes

Mehdi Ferjaoui[1], Misbah Linda[1], Ghada Grassi[1], Nawres Bouaziz[1], Rachida Bouatay[1], Amel El Korbi[1], Nawres Kolsi[1], Khaled Harrathi[1] & Jamel Koubaa[1]
[1]Fattouma Bourguiba University Hospital, Monastir, Tunisia

Introduction
Thyroid nodules are rare in the pediatric population, with a predominance in females. Benign thyroid nodules and Graves' disease are the most common surgical indications. Surgical management can be challenging in children. This study explores indications, surgical techniques, and outcomes of thyroid surgery in children.
Matériel et méthodes:
This is a retrospective study conducted in the ENT department at Fattouma Bourguiba Hospital in Monastir over a four-year period, from January 2021 to December 2024., involving 16 cases that underwent thyroid surgery.
Résultats:
Our series includes 16 cases that underwent thyroid surgery. Among these patients, 15 cases were operated on for thyroid nodules, and one patient underwent surgery for Graves' disease resistant to medical treatment. The average age was 16.61 years, with extremes ranging from 13 to 17 years, and the sex ratio was 0.05 (1 male/17 females). Regarding medical history, one child was followed for Graves' disease, one for congenital hypothyroidism, and two cases had adrenal insufficiency. These children presented with anterior low cervical swellings without signs of compression. On examination, an anterior low cervical swelling, mobile on swallowing was found in all cases, measuring 3 to 5 cm, along with firm, mobile, painless cervical lymphadenopathies of 2 cm in one patient. Ultrasound findings showed an EUTIRADS 2 nodule in two cases (32–40 mm), EUTIRADS 3 in 11 cases (26–40 mm), EUTIRADS 4 in four cases (17–42 mm), EUTIRADS 5 in two cases (26 and 27 mm), and one case of a hypervascularized goiter suggestive of Graves' disease. Fine needle aspiration of a lymphadenopathy was performed in one patient, which was suggestive of metastasis from a papillary carcinoma. A lobectomy was performed in nine cases, total thyroidectomy in seven cases, mediastinal-recurrent lymph node dissection in two cases, and functional neck dissection in one patient. Postoperative outcomes were uneventful in all cases, with only one case of postoperative hypocalcemia, which was corrected with calcium supplementation. Histopathological examination revealed a benign nodule in 13 cases, a follicular carcinoma in one case, and a papillary carcinoma in two cases, which were referred to nuclear medicine for radioactive iodine treatment.
Conclusion
Pediatric thyroid pathologies requiring surgery are much rarer than in adults. Thyroid nodules in children should be evaluated with ultrasound and fine-needle aspiration cytology to assess the risk of malignancy. This approach will ensure appropriate surgical management.

Etiological insights into autoimmune hypothyroidism

Raida Ben Salah[1], Faten Hadj Kacem[1], Sameh Marzouk[1], Nabila Rekik[1] & Zouhir Bahloul[1]
[1]University of Sfax, Internal Medicine, Sfax, Tunisia

Introduction
Hypothyroidism is a common endocrine disorder characterized by a deficit in thyroid hormone production. This condition can arise from various underlying etiologies, predominantly autoimmune in nature. This study aimed to analyze the etiological spectrum of hypothyroidism in a cohort of patients followed in our center.
Materials and Methods
We conducted a retrospective study of patients diagnosed with hypothyroidism. The diagnosis was based on clinical presentation, hormonal assays, and the detection of thyroid-specific autoantibodies, including anti-thyroperoxidase (anti-TPO) and anti-thyroglobulin (anti-Tg) antibodies.
Results
Two main etiologies were identified in our cohort. Hashimoto's chronic lymphocytic thyroiditis was the most frequent cause of hypothyroidism, diagnosed in 69 patients. This group included 59 women and 10 men, with a mean age of 37.8 years. Anti-TPO antibodies were positive in 62 patients, while anti-Tg antibodies were positive in 41 cases, confirming the autoimmune nature of the disease. Chronic atrophic lymphocytic thyroiditis was less frequent, identified in 4 patients (3 women and 1 man) with a mean age of onset of 56 years. This diagnosis was based on a combination of late onset, thyroid atrophy observed on ultrasound, and positive autoantibody tests. Anti-TPO antibodies were positive in 3 cases, and anti-Tg antibodies were positive in 3 cases.
Conclusion
Hashimoto's thyroiditis is the leading cause of hypothyroidism in our cohort, predominantly affecting women in their late 30s. Chronic atrophic lymphocytic thyroiditis, while less common, presents at a later age and is characterized by thyroid atrophy and positive autoantibodies. These findings underscore the importance of detailed clinical evaluation and immunological testing in the diagnosis and management of hypothyroidism.

Prevalence and caracteristics of thyroid carcinoma in patients having Hashimoto's thyroiditis

Oumaima Benkhalifa[1], Jihen Marrakchi[1] & Raweh Bouzguenda[1]
[1]Hospital of Menzel Bourguiba Bizerte, Bizerte, Tunisia

Objective
The aim of our study was to determine the prevalence and caracteristics of thyroid carcinoma and Hashimoto's thyroiditis (HT) coexistence in histopathologic material of thyroidectomized patients.
Matherials and Methods
In a retrospective study, the clinicohistopathologic data of patients who underwent a thyroidectomy and had HT in the histopathological specimen, from the 1st of January 2018 to the 31st july 2023 were analyzed.
Results
Our serie includes 73 patients who have HT and are all female. 16 patients have a thyroid dysfunction. The only histological type present is papillary thyroid carcinoma(PTC). Thyroid carcinoma(TC) was detected in four cases and microcarcinoma(TMC) in three cases. The mean tumor diameter was 17 mm in the TC group and 6.5 mm in the TMC group. Oncocytic variant of PTC was detected in two cases in the TC group while vesicular variant of PTC was detected in the other two cases. Oncocytic variant of PTC was detected in two cases in the MTC group while tall cell variant was detected in one case. Bilaterality was detected in one case and multifocality was detected in two cases of TC group. There is no bilaterality or multifocality detected in the MTC group. Capsular effraction and vascular embol was detected in one case of TC group and no case of MTC. One patient underwent a recurrent lymph node dissection and no metastasis was detected.
Conclusion
We suggest that prevalence of PTC in patients having HT is low and have less agressive features

Association of papillary and medullary thyroid carcinoma: a report of 3 cases

Oumayma Zarrouk[1], Ezzine Abir[2], Rakia Ghanem[2], Hajer Boudriga[2], sihem mensi[2], Dardouri Teheni[2], Yosra Hasni[1] & Kaouther Chatti[2]
[1]University Hospital of Farhat Hached, Endocrinology Departement, Sousse, Tunisia; [2]University Hospital of Sahloul, Department of Nuclear Medicine, Sousse, Tunisia

Introduction
Papillary thyroid carcinoma (PTC), derived from follicular cells, is a common entity in endocrine oncology. In contrast, medullary thyroid carcinoma (MTC) is a less frequent pathology. The simultaneous occurrence of these two cancers is rare. We report three patients presenting with both PTC and MTC during the management of thyroid neoplasia, followed at the nuclear medicine department of CHU Sahloul.
Case Reports
Case 1: A 68-year-old female with a history of pulmonary and cutaneous sarcoidosis presented with a cervical swelling. The cervical ultrasound revealed signs of malignancy, which were confirmed by fine-needle aspiration cytology (FNAC), prompting a total thyroidectomy (TT) with bilateral mediastino-recurrent lymph node dissection (MRLD). Histopathological examination identified a micro-PTC measuring 0.2 cm and an MTC measuring 1.5 cm in the left lobe, with no lymph node involvement. The patient received ablative radioactive iodine (RAI) therapy (30 mCi) and showed favorable biochemical and morphological outcomes for PTC. **Case 2:** A 44-year-old female discovered a 1 cm cervical swelling during self-palpation. Cervical ultrasound revealed a poorly defined hypoechogenic nodule with microcalcifications, classified as EU-TIRADS V. She underwent TT with bilateral MRLD. Histopathological analysis revealed a mixed medullary and papillary carcinoma of the right thyroid lobe, with no lymph node metastasis. The PTC was classified as pT1aN0Mx, and the MTC as T3N1b. She received ablative RAI therapy (100 mCi) with a good biochemical and morphological response for PTC. **Case 3:** A 69-year-old male with diabetes presented with a suspicious lateral cervical swelling. Cervical ultrasound showed a 28 mm thyroid nodule classified as EU-TIRADS V, along with markedly elevated calcitonin levels (>5000 ng/ml). Preoperative staging was negative for distant metastasis, and the patient underwent TT with bilateral MRLD. Histopathology revealed a low-grade MTC in the right lobe measuring 4.4 cm (classified as pT3bN1bM0) and a millimetric PTC (classified as pT1aN1aM0). The patient received ablative RAI therapy (30 mCi) with favorable biochemical and morphological outcomes. Postoperatively, calcitonin levels decreased to 47 ng/ml. A follow-up by cervical ultrasound and serum calcitonin was indicated.
Conclusion
The synchronous association of MTC and PTC is rare, with only a few cases reported in the literature. This observation highlights the importance of preoperative calcitonin testing in patients with thyroid nodules. The prognosis primarily depends on the MTC, as PTC typically has a favorable prognosis and slow progression.

Navigating the thin line of risks and benefits: a case of nivolumab-induced hypothyroidism in a patient with metastatic melanoma

Carlo Casipit[1] & Bruce Casipit[1]
[1]Jefferson-Einstein Hospital, Philadelphia, United States

Background
Nivolumab is a monoclonal antibody directed against programmed cell death-1 (PD-1) and has become an effective treatment for metastatic melanoma. It enhances the cell-mediated killing of cancer cells however, it inadvertently increases the risk of autoimmune attack, which leads to various endocrinopathies, including hypothyroidism.
Case Presentation
A 48-year-old male with metastatic melanoma to the brain, who is currently undergoing monthly Nivolumab infusion, presented to the clinic with a 3-week history of fatigue, cold intolerance, and constipation. Vital signs were normal. Physical examination showed an intact sensorium, a symmetrically enlarged and nontender thyroid, and no skin changes. Laboratory tests were remarkable for a TSH of 27.1mIU/l (ref 0.3-4mIU/l), free T4 of 0.7 ng/dl (ref 0.9-1.7 ng/dl), negative thyroid receptor and thyroid peroxidase antibodies, and thyroid ultrasound showed a diffusely enlarged thyroid with low iodine uptake on the thyroid scan. No other hormonal abnormalities were detected. The endocrinology team was consulted, and the patient was started on Levothyroxine, which improved her symptoms, and the oncology team suggested temporarily discontinuing Nivolumab with frequent thyroid function monitoring and strict endocrinology and oncology follow-up.
Discussion
The incidence of Nivolumab-induced hypothyroidism is as high as 6.5%. It develops within 3-4 weeks of treatment. Smoking, hypertension, and other autoimmune diseases are risk factors. Thyroid autoantibodies are most often normal but can be elevated in some patients and a low TSH may indicate hypophysitis. Spontaneous thyroid recovery can occur. However, thyroid hormone replacement with serial measurements of thyroid function is often required. Because PD-1 inhibitors remain central in managing advanced melanoma, discontinuation may not be feasible, and continuation can be considered with close monitoring. Interestingly, according to Basak *et al*, the development of overt thyroid symptoms with higher antithyroid antibody levels during anti-PD-1 treatment of melanoma was associated with a significant improvement in overall and progression-free survival rates likely because of better malignancy response from treatment.
Conclusion
Immune checkpoint inhibitors such as Nivolumab remain central in managing different malignancies. However, all physicians should be aware of their potential endocrine adverse effects. In patients who develop Nivolumab-induced hypothyroidism, hormonal replacement with Levothyroxine is often needed. A multidisciplinary approach should be pursued for close monitoring and for patients to have a guided decision regarding possible Nivolumab continuation.

Challenges to implement thyroid cancer guidelines for thyroid surgeons of Bangladesh

Dewan Hasan[1]
[1]Bangladesh Specialized Hospital Ltd, Otolaryngology & Head-Neck Surgery, Dhaka, Bangladesh

Objective
Numerous published guidelines have described the optimal management of thyroid cancer. However, these rely on the clinical availability of diagnostic and therapeutic modalities. We hypothesized that the availability of medical resources and economic circumstances vary in Asia-Pacific countries, making it difficult to implement guideline recommendations into clinical practice.
Methods
We surveyed participants at the 2009 and 2013 Congresses of the Association of Southeast Asian Nations Federation of Endocrine Societies by distributing questionnaires to attendees at registration.
Results
Responses were obtained from 268 respondents in 2009 and 163 respondents in 2013. Similar to the high prevalence of low-risk thyroid cancer observed in the Surveillance, Epidemiology, and End Results database, across the Asia-Pacific countries surveyed in 2009 and 2013, 50 to 100% of the respondents from the Philippines, Malaysia, Singapore, China, Taiwan, Thailand, Hong Kong, Korea, and Sri Lanka reported that more than 50% of the patients had low-risk thyroid cancer on follow-up. Importantly, there was much variation with regards to the perceived availability of investigation and treatment modalities.
Conclusion
We found a wide variation in clinicians' perception of availability of diagnostic and therapeutic modalities in the face of a rise in thyroid cancer incidence and thyroid cancer management guidelines that emphasized their importance. The lack of availability of management tools and treatments will prove to be a major barrier to the implementation of thyroid cancer management guidelines in Southeast Asia, and likely in other parts of the world as well.

Thyroid tissue in a cervical lymph node is not always malignant: A case report

Mohamed Abdelraheim[1]
[1]Specialized Medical Hospital - Faculty of Medicine - Mansoura University, Endocrinology, Mansoura, Egypt

Thyroid tissue in cervical lymph nodes is an interesting and rare phenomenon that cannot be explained by embryology. It is often considered to be a metastasis of a primary thyroid malignancy. Since sixties, several cases of benign ectopic thyroid cervical lymph node tissue have been reported. Distinguishing between ectopic thyroid tissue, a metastasis or primary thyroid cancer in a cervical lymph node is very challenging. Our case is a 32- year - old mother assumed that she had had a hemothyroidectomy 10 years earlier. She was presented with a neck mass which was found to be two TIRADS 5 thyroid nodules over remnant of inflamed thyroid tissue from a previous surgery. FNAC revealed Bethesda III (atypia of undetermined significance) tissue. CT Neck was done and revealed extra-thyroidal extension of thyroid nodule with ipsilateral suspicious lymph node with very high thyroglobulin level. After total thyroidectomy with lymphadenectomy, frozen samples of the excised lymph node revealed just benign thyroid tissue. Samples were confirmed with IHC and conservative plan of management was done. Levothyroxine was given in a replacement dose. Before 2017 there were just 17 cases of benign thyroid tissue in cervical lymph nodes worldwide. Meanwhile, many studies supported the idea of conservative management of accidentally found thyroid tissue in a lymph node. Moreover, the origin and pathogenesis of ectopic thyroid tissue in cervical lymph nodes is still unclear and cannot be explained by current embryological theories. To date, this Phenomenon has only been reported in women. Here we showed that benign thyroid tissue in cervical lymph nodes can occur in the absence of a primary thyroid malignancy. Immunohistochemistry and molecular diagnostics in addition to conventional pathology can aid in making the distinction between benign and malignant thyroid tissue in cervical lymph nodes. We recommend a conservative approach if pathology shows benign thyroid tissue in cervical lymph nodes.

Pitfalls in the management of a palpable pediatric thyroid nodule: a case report

Kholoud Mohamed [1]
[1]Egyptian Health Insurance Institute, Pediatric Diabetes and Endocrine, Alexandria, Egypt

Background
Thyroid nodules in children are reported to be at 2-3-fold increased risk of being malignant when compared to thyroid nodules in adults. The risk for children of a thyroid nodule (> 1 cm) being malignant is 20–25% compared to in 5–10% for a thyroid nodule in adults, respectively. Pediatric differentiated thyroid carcinoma (DTC) is a rare disease; however, its worldwide incidence is rising. The most common presentation for DTC in children is that of a thyroid nodule.
Case report
A 13-year-old adolescent girl was referred to our health insurance endocrine clinic for a clinically concerning thyroid swelling. She presented with 2-year history of a neck swelling. She had no complaints, no local compressive symptoms or dysphagia. There was no history of head or neck irradiation and no family history of thyroid cancer. She had normal vital signs with a BP of 110/70, pulse of 67. Her exam was significant for a diffusely enlarged thyroid gland with an irregular contour and a firm nodule 2x1.5 cm on the RT lobe. The rest for her physical exam was completely normal. TSH was 1.47 mcIU/ml, Ft4 was 1.28 ng/dl and she had positive anti-thyroid peroxidase: > 600 and Anti-thyroglobulin antibodies: 395. Our patient had an abnormal thyroid exam for as long as two years prior to being seen in our health insurance clinic. Unfortunately, she was not examined or investigated properly. Parents were reassured as there was no aggressive symptoms, her thyroid function tests within normal and positive thyroid antibody tests. Based on the clinical examination, ultrasound thyroid was requested, and the report showed: multinodular goiter with hypoechogenicity and solid nodules, largest one in the RT lobe is wider than taller solid hypoechoic nodule with irregular margin and measures about 28.7x24.5 mm (TR4 nodule pattern, moderately suspicious nodule pattern for FNAC) with few bilateral cervical lymphnodes. A fine-needle aspiration biopsy of the RT thyroid nodule was performed. The cytology diagnosis was: "papillary thyroid carcinoma". Accordingly was referred for surgical removal.
Conclusion
As palpable thyroid abnormalities have a higher risk of malignancy in children and the risk of surgical complications can be significant, so they should be closely monitored with suspicion and worked up aggressively for possible malignancy even in the face of initially negative diagnostic testing.

Shear wave elastography (SWE) in the evaluation of thyroid tissue in children and adolescents with autoimmune thyroiditis

Hanna Borysewicz-Sanczyk[1], Filip Bossowski[1], Katarzyna Anikiej[1], Beata Sawicka[1], Justyna Michalak[1], Janusz Dzięcioł[2] & Artur Bossowski[1]
[1]Medical University of Bialystok, Department of Pediatrics, Endocrinology, Diabetology with a Cardiology Divisions, Bialystok, Poland; [2]Medical University of Bialystok, Department of Human Anatomy, Bialystok, Poland

Background
Hashimoto's thyroiditis and Graves' disease are autoimmune thyroid diseases (AITDs) mainly diagnosed on the basis of clinical symptoms, hormonal analysis, positive autoantibody titres and ultrasound (US). However, there is a group of patients who, despite developing autoimmunity in the thyroid, do not show typical ultrasound findings or an increase in antibody titres. It is well known that the autoimmune process alters the echogenicity, echostructure and vascularity of thyroid tissue and is associated with the presence of focal changes within the gland, which influences the mechanical properties of the affected tissue like tissue stiffness and elasticity. Shear wave elastography (SWE) is a non-invasive and painless to the patient ultrasound diagnostic method evaluating tissue's stiffness. Recent data suggest that elastography may improve the accuracy of differential diagnosis of thyroid diseases. The purpose of the study is to assess the thyroid elasticity in children and adolescents with autoimmune thyroid disease in comparison to heathy thyroid children.
Methods
74 pediatric patients with AITDs and 30 heathy thyroid children as a control are enrolled to the study and qualified to SWE which is followed by conventional US. SWE based on Young's modulus is expressed in kPa. In addition, patients have their thyroid hormone levels and antithyroid antibody titers evaluated.
Results
Our results indicate that thyroid tissue elasticity in patients with Hashimoto's thyroiditis and Graves's disease is reduced in comparison to those with normal thyroid parenchyma.
Conclusion
The results of our study suggest that SWE might be a viable diagnostic method for suspection of AITD in children, however it still seems to need further studies in a bigger group of pediatric patients.

Common but unexpected autoimmune endocrine disorders in pregnancy – case reports

Leonor Rodrigues[1], Hugo Marinho[1], Márcia Alves[1], Teresa Azevedo[1] & Joana Guimarães[1]
[1]ULS Região de Aveiro, Aveiro, Portugal

Autoimmune diseases are rarely diagnosed during pregnancy due to physiological immunosuppression. Clinical hyperthyroidism affects only 0.1–0.4% of pregnancies, with Graves' Disease (GD) responsible for 85% of cases. This report describes three cases of GD in healthy pregnant women with no prior thyroid dysfunction and one case of diabetic ketoacidosis (DKA) at delivery as the initial presentation of diabetes *mellitus*. 1. A 28-year-old woman, at 10 weeks of gestation: TSH <0.01mU/l(N 0.35–4.94), T4L 4.03ng/dl(N 0.7–1.48), T3L 16.8pg/ml(N 2.3–4.2), TSH receptor antibodies (TRAbs)11.0 (positive). Treatment was initiated with propylthiouracil (PTU) 50 mg 3id. At 15 weeks: TSH 0.03mU/l, T4L 0.50ng/dl, T3L 2.0pg/ml, leading to discontinuation of the antithyroid drug (ATD); at 29 weeks, TRAbs 2.6 (negative). At the first postpartum visit, she was euthyroid;14 weeks after delivery, GD recurred: TSH

0.01mU/l, T4L 2.51ng/dl, T3L 9.2pg/ml, TRAbs 5.4(positive). Methimazole 10 mg id was initiated. 2. A 32-year-old woman at 10 weeks of gestation: TSH 0.01mU/l, T4L 1.64ng/dl, T3L 4.9pg/ml, TRAbs 3.2(positive). PTU 50 mg id was started and discontinued at 20 weeks (TSH <0.01mU/l, T4L 0.79ng/dl, T3L 2.8pg/ml, TRAbs 2.9 (negative). She remained off therapy and, at six weeks postpartum, was euthyroid with TRAbs 2.4(negative). She is awaiting further evaluation. 3. A 34-year-old woman at 16 weeks of gestation: TSH <0.01mU/l, T4L 2.03ng/dl, T3L 7.8pg/ml, TRAbs 12.0(positive), initiating PTU 50 mg twice daily. At 19 weeks: TSH <0.01mU/l, T4L 0.84ng/dl, T3L 3.6pg/ml, leading to an adjustment to PTU 50 mg id. At 23 weeks, PTU was stopped due to TSH 0.02mU/l, T4L 0.86ng/dl, T3L 3.8pg/ml. She remained off ATD until delivery and is awaiting postpartum reassessment. 4. A 29-year-old woman, at 37 weeks of gestation was admitted to the Emergency Department with polydipsia, polyuria, weight loss, glycosuria (>1000 mg/dl) and hypertension. A cesarean section due to fetal distress was performed. Her fasting glucose in the first trimester was 81 mg/dl, and an oral glucose tolerance test(OGTT) at 26 weeks showed 84/149/119 mg/dl. During labor, sustained capillary glucose levels >500 mg/dl were observed, with pH 7.293, HCO3-9.5 mmol/l, lactate 2.3 mmol/l, ketonemia 4 mmol/l. Intravenous insulin infusion was initiated, with a favorable response. Good glycemic control was achieved after 19 hours. An intensive insulin therapy regimen was introduced. She was discharged after seven days of hospitalization. She is awaiting further evaluation and the results of autoantibody tests for T1DM. Despite the diagnosis of autoimmune disorders during pregnancy is rare, early detection and management of these conditions are essential to prevent maternal and fetal complications. Individualized follow-up is crucial for optimizing outcomes.

Outcomes of thyroid lobectomy in bethesda v and vi nodules: a clinical analysis

Miguel António Duarte[1], Catarina Isabel Lopes[1], Mariana de Griné Severino[1], Marta Vaz Lopes[1], José Vicente Rocha[1], Carolina Peixe[1], Mariana Lopes-Pinto[1], Sónia do Vale[1,2] & Ema Lacerda Nobre[1,2]
[1]Serviço de Endocrinologia, Diabetes e Metabolismo, Hospital de Santa Maria, Unidade Local de Saúde Santa Maria, Lisboa, Portugal; [2]Clínica Universitária de Endocrinologia, Faculdade de Medicina da Universidade de Lisboa, Lisboa, Portugal

Introduction
Thyroid nodules classified as Bethesda V (suspicious for malignancy) and Bethesda VI (malignant) present diagnostic and therapeutic challenges. Thyroid lobectomy is a possible surgical approach for these nodules, that may reduce morbidity, compared to total thyroidectomy, while ensuring oncologic safety. This study evaluates the efficacy and outcomes of lobectomy in patients with Bethesda V and VI cytopathology results, in order to optimize surgical decision-making and minimize complications.
Materials and Methods
We retrospectively revised and analysed the clinical data from seven patients with Bethesda V and VI nodules who underwent thyroid lobectomy in our hospital between 2022 and 2024, followed-up for ≥6 months.
Results
All seven patients were female, with a mean age at diagnosis of 59.6 years and a median follow-up time of 19 months. Only one patient had a personal history of cervical irradiation and there was no family history of thyroid malignancy. Four nodules were Bethesda VI and three were Bethesda V, all measuring less than 2 cm. Two patients presented with contralateral nodules (<1 cm). Papillary thyroid carcinoma was histologically confirmed in all cases, comprising six classic variants and one follicular variant. The mean tumor size was 9.3 mm and all tumors were unifocal, without evidence of angioinvasion, perineural invasion or lymph node metastasis. Microscopic extrathyroidal extension was noted in two patients. At six-month follow-up, five patients showed no evidence of disease, while two had an indeterminate response due to nonspecific imaging findings. These results remained consistent at the latest follow-up. No patients required completion thyroidectomy, and all are currently on levothyroxine to maintain target TSH levels (0.5-2 mU/l).
Conclusions
This study highlights the favourable outcomes of thyroid lobectomy in managing patients with Bethesda V and VI nodules, demonstrating its efficacy for small papillary thyroid carcinomas. With no cases requiring completion thyroidectomy and high remission rates, lobectomy proves to be a safe and effective approach in appropriately selected cases, minimizing patient morbidity.

JOINT949

Comprehensive summary of studies on goiterous hypothyroidism in infants and children: patient characteristics, treatment, and prognosis"

Ashraf Soliman[1], Nada Alaaraj[1], Abir Ali[1], Fawzia Alyafei[1], Shayma Ahmed[1] & Noor Hamed[1]
[1]Hamad Medical Corporation, Doha, Qatar

Background
Goitrous hypothyroidism in infants and children represents a critical endocrine disorder with significant implications for growth, neurodevelopment, and overall prognosis. This condition arises from diverse etiologies, including genetic mutations, iodine deficiency, and autoimmune thyroiditis. Recent advances in diagnosis and treatment underscore the importance of timely intervention to improve outcomes.
Objective
To provide a comprehensive review of studies on goiterous hypothyroidism in infants and children, focusing on patient characteristics, treatment approaches, outcomes, and prognosis.
Methods
A systematic review of relevant studies published between 1995 and 2023 was conducted. Data from primary research, case reports, and review articles were analyzed to compile patient characteristics, treatment modalities, and outcomes. Studies were arranged chronologically to reflect advancements in understanding and management.
Results
Ten studies were reviewed, encompassing 267 patients with goiterous hypothyroidism. Key findings include the following:
1. Patient Characteristics:
• Conditions ranged from congenital hypothyroidism (CH) due to thyroid dysgenesis or dyshormonogenesis to autoimmune thyroiditis and fetal hypothyroidism linked to maternal Graves' disease.
• Presenting symptoms varied, with neonatal respiratory distress and goiter being hallmark findings in severe cases.
• Risk factors included prematurity, family history of goiter, and maternal thyroid dysfunction.
2. Treatment Approaches:
• Levothyroxine remains the cornerstone of therapy, administered orally or intra-amniotically in fetal cases.
• Advances such as liquid levothyroxine formulations and prenatal thyroxine delivery via amniotic fluid were highlighted.
• Case reports emphasized the role of cordocentesis and ultrasonography in diagnosing and monitoring fetal thyroid function.
3. Outcomes and Prognosis:
• Early intervention consistently improved growth and neurodevelopmental outcomes.
• Intrauterine thyroxine resolved goiter in fetal cases, with normal postnatal thyroid function observed.
• Persistent hypothyroidism required long-term therapy in a subset of children with CH, while others experienced complete resolution.
Conclusion
This review underscores the critical role of timely diagnosis and tailored treatment in managing goiterous hypothyroidism in infants and children. Levothyroxine therapy, particularly in innovative forms, demonstrates robust efficacy in resolving goiter and normalizing thyroid function. Future research should focus on genetic etiologies and long-term outcomes to enhance individualized care. The chronological synthesis of data highlights the evolution of therapeutic strategies and their impact on prognosis.
Keywords
Goiterous hypothyroidism, infants, children, levothyroxine, treatment outcomes, prognosis, congenital hypothyroidism, intra-amniotic therapy.

Unraveling MEN syndrome: how genetic testing illuminates complex family histories and improves patient outcomes

Bratu Gratiela[1], Andrei Muresan[1], Elena Braha[1], Stanescu Laura-Semonia[1] & Corin Badiu[1,2]
[1]"C. I. Parhon" National Institute of Endocrinology, Endocrinology 4, Bucharest, Romania; [2]"C Davila" University of Medicine and Pharmacy, Endocrinology, Bucharest, Romania

RET mutations drive the development of multiple endocrine neoplasia (MEN) syndromes, including medullary thyroid carcinoma (MTC) and pheochromocytoma. We present three families with distinct RET mutations, revealing the complex clinical spectrum and hereditary patterns. The findings underscore the neccesity of early genetic screening and diagnosis. A male patient, aged 18 in 1977, was diagnosed with MTC. At that time, he underwent a subtotal thyroidectomy, as it was the standard procedure. In 2005, he required a total thyroidectomy due to disease recurrence, and again in 2014 for a further recurrence. Additionally, the patient was diagnosed with pheochromocytoma and primary hyperparathyroidism. Genetic testing in 4 out of 13 of his family revealed the presence of a RET mutation (c.1900 T>C, p. Cys634Arg, exon 11), in 3 members across 4 generations (one is asymptomatic), 1 being negative. The second family carries a germline RET mutation (c.1852T>C, p. Cys618Arg, exon 10) which was identified through testing a 43-year-old female patient, initially diagnosed with MTC. She underwent a total thyroidectomy, but with minimal residual disease and secondary lymphatic metastases. Genetic testing in 7 out of 21 family members across 3 generations revealed 5 positive for the same RET mutation (2 asymptomatic), including her two daughters (one of whom has MTC, and the other had MTC and pheochromocytoma), as well as in a nephew diagnosed with Hirschsprung disease, 2 being negative. The third family we are presenting carries a RET mutation (c.1902C>G, p. Cys634Trp, exon 11), identified in a 52-year-old male patient who initially presented with symptoms suggestive of pheochromocytoma, subsequently confirmed and surgically resected. The patient also has a diagnosis of MTC. Genetic testing in this family revealed the same RET mutation in his daughter (who has MTC) and his nephew (who has bilateral pheochromocytoma and MTC). In this family, across 2 generations, 8 out of 30 family members were tested: 6 were positive, 2 negative. From those postive, 2 were asymptomatic, while other 2 presented only MTC, and 2 MTC+Pheo. In conclusion, these families highlight the critical role of looking for RET mutations in the development of multiple endocrine neoplasia and related disorders. The diverse clinical manifestations observed—such as MTC, pheochromocytoma, and hyperparathyroidism—underscore the importance of genetic screening and family history evaluation for early diagnosis and proper management. Early detection, appropriate surveillance, and genetic counseling are key to improving outcomes and preventing further complications in affected families.

A rare case of palpation thyroiditis following parathyroidectomy

Randy Jing Hang Soh[1], Kevin Jun Hong Kwek[2], Sunder Balasubramaniam[3] & Ray Tian Rui Lai[1]

[1]Tan Tock Seng Hospital, Department of Endocrinology, Singapore, Singapore; [2]Khoo Teck Puat Hospital, Department of Endocrinology, Singapore, Singapore; [3]Tan Tock Seng Hospital, Department of General Surgery, Singapore, Singapore

Introduction

Sporadic thyrotoxicosis following manipulation of thyroid gland during neck surgeries, in particular parathyroid surgeries, has been infrequently described in medical literature and remains largely underrecognised today. We describe a rare case of palpation thyroiditis following parathyroidectomy.

Case Report

A 57-year-old Chinese female with background of end-stage renal disease (ESRD) complicated by tertiary hyperparathyroidism was electively admitted for total parathyroidectomy. She had no known thyroid disorders and was asymptomatic with no history of neck pain or irradiation. Intra-operatively, both thyroid lobes were mobilised and three parathyroid glands were excised except for the right superior gland which could not be definitively located. After parathyroidectomy, the patient remained asymptomatic but was found to have sinus tachycardia on post-operative day two. A thyroid function test done showed elevated free thyroxine (T4) at 53 pmol/l (8 - 16 pmol/l), elevated free triiodothyronine (T3) at 9.0 pmol/l (3.5 - 6.0 pmol/l) and suppressed thyroid-stimulating hormone (TSH) at 0.22 mIU/l (0.45 - 4.50 mIU/l). This was consistent with thyrotoxicosis, and differential diagnoses included palpation thyroiditis from recent parathyroidectomy and less likely undiagnosed Grave's disease. Further evaluation was then conducted with antithyroid antibody testing and radioiodine uptake thyroid scan. Decision was made to hold off thioamide initiation while awaiting the above investigations given that the patient was asymptomatic and if the diagnosis was truly thyroiditis, her thyrotoxicosis should improve further without treatment. Her thyroid function was closely monitored in the meantime, and she was started on a beta-adrenergic antagonist as needed for palpitations. Subsequently, her antithyroid antibodies including anti-thyroid peroxidase (anti-TPO), anti-thyroglobulin (anti-TG) and thyrotropin receptor antibodies (TRAb) returned negative. The Tc-99m pertechnetate thyroid scan showed generally reduced tracer uptake of the thyroid gland suggestive of thyroiditis, with no dominant 'hot' nodule detected. The patient was diagnosed with palpation thyroiditis from recent parathyroidectomy and managed conservatively. Two weeks later, her thyroid function test normalised with no recurrence of sinus tachycardia.

Discussion

It is important to recognise the entity of palpation thyroiditis post-parathyroidectomy – while majority of patients remain asymptomatic for which conservative management is appropriate, some may develop clinically significant thyrotoxicosis requiring further medical treatment.[1] Counselling patients undergoing bilateral neck exploration about this condition, along with prudent post-operative monitoring of thyroid function tests as clinically warranted, is essential for early detection and timely treatment.

Thyroid eye disease following total thyroidectomy in a complex case of graves' disease with reaction to antithyroid therapy

Zainab Alkheyr[1], Hassan Ibrahim[1], John Sommer[2], Brian Fish[3], Erika Damato[2] & Isra Ahmed Mohamed[1]

[1]Cambridge University Hospitals NHS Foundation, Diabetes and Endocrinology, Cambridge, United Kingdom; [2]Cambridge University Hospital NHS Foundation Trust, Department of Ophthalmology, Cambridge, United Kingdom; [3]Cambridge University Hospital NHS Foundation Trust, Department of Otolaryngology, Cambridge, United Kingdom

A 63-year-old non-smoker male was referred to the endocrinology clinic with symptoms of hyperthyroidism and abnormal thyroid function in November 2022. Initial tests confirmed Grave's disease: TSH <0.03 mU/l (0.35-5.5), FT4: 60.7 pmol/l (10.5-21.0), FT3: >30.8 pmol/l (3.5-6.5), Thyroid Stimulating Immunoglobulins (TSI) 12.8 IU/l (<0.56). Impaired Liver function test (LFT) was noted: (ALT 71 U/ L (10-49), ALP 145 U/l (30-130) and total bilirubin 8 umol/l (0-20). With a normal liver ultrasound, impairment was attributed to hyperthyroidism. The patient was commenced on carbimazole, but hepatic function deteriorated. A liver screen was negative, suggesting carbimazole-related hepatic impairment. Carbimazole was switched to propylthiouracil (PTU), but hepatic impairment persisted, leading to PTU cessation. Due to worsening thyroid function and reaction to antithyroid drugs, the patient was offered urgent total thyroidectomy, with preoperative preparation using Lugol's Iodine. The patient underwent a successful total thyroidectomy in March 2023. Histopathology confirmed diffuse thyroid hyperplasia/Graves' disease. 8 weeks postoperatively, symptoms of mild thyroid eye disease (TED) developed. TSI levels remained detectable at 2 and 3 months postoperatively (4.22 and 3.9 IU/l, respectively). An MRI at 4 months showed bilateral inferior rectus muscle enlargement, consistent with active thyroid ophthalmopathy. The patient was commenced on a 6-month course of selenium. At the 6-month ophthalmology follow-up, the patient had restricted upgaze and left lateral gaze, indicating ongoing TED. Visual function was intact. IV methylprednisolone (IVMP) was considered but not started. At the 10-month follow-up, ocular motility worsened. IVMP was initiated, with significant improvement after six infusions: reduced proptosis, resolution of lid retraction, and decreased upward gaze restriction. Some restrictions persisted, especially in the left upward gaze. Given the incomplete response to IVMP, he was considered for an additional IVMP course with orbital radiotherapy. Following combined therapy, TED became inactive, but diplopia and upward gaze restriction persisted. The strabismus team recommended a right superior oblique tuck or left inferior rectus recession. Monitoring continues whilst awaiting surgery. Graves' ophthalmopathy is known to occur with other endocrine features of thyrotoxicosis, typically occurring within 18 months of the disease. The new development of Graves ophthalmopathy following thyroid surgery is rare. This case highlights a rare example of Graves' ophthalmopathy developing following total thyroidectomy. Healthcare professionals must be aware of the possible late development of Graves' ophthalmopathy following total thyroidectomy and refer for appropriate assessment without delay.

Thyroid function replacement time after total and subtotal thyroidectomy

Matluba Rahmonberdieva[1], Shohista Karimjanova[1], Jonibek Bobokulov[1], Shakhnoza Akhmedova[1] & Zulaykho Shamansurova[2,3]
[1]Tashkent Pediatric Medical Institute, Tashkent, Uzbekistan; [2]Central Asian University, Endocrinology, School of Medicine, Tashkent, Uzbekistan; [3]Institute of Biophysics and Biochemistry at the National University of Uzbekistan, Metabolomics, Tashkent, Uzbekistan

Introduction
Thyroid surgery is usually performed when traditional drug therapy is ineffective, severe complications develop, or the risk of cancer is high. Recovery of body functions after surgery requires a certain period and specific treatments.
Aim
To study the recovery of thyroid function after total and subtotal thyroidectomy.
Materials and Methods
Between 2021 and 2023, 63 patients with thyrotoxicosis syndrome at RIIATEM were diagnosed with diffuse toxic goiter, nodular and multinodular toxic goiter, and underwent total and subtotal thyroidectomy. Of these patients, 11.1% were male, and 88.9% were female, with an average age of 43.48 ± 2.92. A subtotal thyroidectomy was performed on 38.1% of the patients, and a total thyroidectomy on 61.9%.
Results
Pre-surgery TSH levels in the examined patients ranged from 18.7-22.6 ± 1.0 mMe/ml; one month after surgery, these levels were 15.6 ± 0.7 mMe/ml in patients with subtotal thyroidectomy and 26.87 ± 1.08 mMe/ml in patients with total thyroidectomy, indicating clear signs of hypothyroidism. Three months post-surgery, the TSH levels were 10.4 ± 0.7 mMe/ml after subtotal thyroidectomy and 12.37 ± 0.78 mMe/ml after total thyroidectomy. Six months post-surgery, TSH levels decreased significantly to 6.3 ± 0.5 mMe/ml in subtotal thyroidectomy patients and 7.9 ± 0.86 mMe/ml in total thyroidectomy patients. One year post-surgery, the TSH levels were 1.9 ± 0.2 mMe/ml after subtotal thyroidectomy and 1.75 ± 0.17 mMe/ml after total thyroidectomy, nearing standard values.
Conclusions
Thus, the results after surgery indicate the effectiveness of the treatment, with a significant decrease in clinical manifestations of hypothyroidism in patients after thyroidectomy over the time. Immediate replacement therapy after total thyroidectomy thyroid function earlier reached normal ranges than in subtotal thyroidectomy.

Total thyroidectomy for Graves' disease in a patient with down syndrome and glycogen storage disease type ia

Elena Sani[1], Giuliana Da Prato[1], Silvia Rigon[1], Alice Dianin[2], Laura Rubert[2] & Maddalena Trombetta[1]
[1]Section of Endocrinology, Diabetes and Metabolism, Department of Medicine, University of Verona, Verona, Italy; [2]Inherited Metabolic Disease Unit, Pediatric Division C, Mother and Child Department, Azienda Ospedaliera Università Integrata Verona, Verona, Italy

Introduction
Autoimmune disorders are common in patients with Down syndrome (DS), particularly thyroid diseases. In DS patients, hyperthyroidism occurs less frequently than hypothyroidism, is mostly caused by Graves' disease, typically manifests between late childhood and early adulthood, shows no sex predominance, and often requires definitive treatment. There is a lack of consensus on the role of total thyroidectomy in the treatment of Graves' disease in DS patients due to potential anesthetic and surgical risks associated with craniofacial anomalies and short neck. However, surgery may be necessary when Iodine-131 therapy is contraindicated or refused by the family.
Case Presentation
We report the case of a 19-year-old female patient affected by DS and Graves' disease. Medical history included glycogen storage disease type Ia (GSD Ia), a rare autosomal recessive disorder of carbohydrate metabolism, characterized by fasting hypoglycemia, lactic acidosis, hepatomegaly, and risk of developing hepatocellular adenomas. Hyperthyroidism first manifested at the age of 11, with symptoms of fatigue and weight loss. TSH receptor antibody testing was positive (22 IU/l), while no goiter or exophthalmos were observed. She was started on methimazole therapy, up to 20 mg/day, which was discontinued after 3 years due to biochemical remission, without side effects. After 1 year of euthyroidism, Graves' disease relapsed and methimazole therapy was resumed. Given the recurrence of hyperthyroidism and the need for long-term methimazole therapy, particularly in the context of chronic liver disease, a definitive treatment was considered. Following discussion with the family, nuclear radiologist and endocrine surgeon, total thyroidectomy was preferred over Iodine-131 therapy. Because of GSD Ia-related risk of hypoglycemia and lactic acidosis, perioperative management included infusion of dextrose-containing solution and frequent monitoring of blood glucose and lactate. Total thyroidectomy was performed with a conventional surgical approach. No significant bleeding or recurrent laryngeal nerve paresis occurred, however, the patient developed transient hypocalcemia (down to 7.8 mg/dl), which resolved within 1 month. She was discharged on a liquid levothyroxine formulation due to fasting limitation, requiring frequent high-carbohydrate meals with uncooked corn-starch supplementation. Histological examination documented diffuse hyperplasia with interstitial lymphocytic infiltrates.
Conclusion
To our knowledge, there is limited evidence in the literature regarding the preferred definitive treatment for Graves' disease in individuals with Down syndrome. Our case suggests that total thyroidectomy may be a safe and effective treatment option for these patients. A multidisciplinary discussion—including endocrinologists, pediatricians, endocrine surgeons, nuclear radiologists, as well as the patient's and family's preference—is required.

Parapharyngeal cystic lymph node metastasis revealing differentiated thyroid microcarcinoma

Rachida Bouattay[1], Linda Misbah[1], May Ferjani[1], Khaled Harrathi[1] & Jamel Koubaa[1]
[1]ENT and Head and Neck Department, University Hospital of Fattouma Bourguiba, Monastir, Tunisia

Introduction
Later ocervical lymphadenopathies revealing a papillary microcarcinoma of the thyroid are rare (7 to 13% of cases). The parapharyngeal location of these metastatic lymphnodes is exceptional. We report a case of cystic lymph node metastasis of parapharyngeal location which revealed a papillary microcarcinoma of the thyroid.
Observation
A 40-year-old patient with no particular pathological history was admitted for management of an isolated right laterocervical swelling that had been developing for 4 months. The physical examination revealed two high and medium jugulocarotid swellings of 2 and 3 cm respectively, firm, mobile and painless. The rest of the lymph node areas as well as the thyroid lodge were free. On indirect laryngoscopy, the vocal cords were mobile. The cavum was free on nasal endoscopy. Cervical ultrasound showed two right jugulocarotid cystic adenopathies of 45 and 38 mm, the site of microcalcifications with a homogeneous thyroid gland. Cervical CT scan was suggestive of a cystic lymphangioma with the presence of a right parapharyngeal unilocular cystic formation. A complement by cervical MRI revealed right cervical cystic adenopathies, one of which is located in the right parapharyngeal space. A lymph node cytopuncture concluded with the diagnosis of lymph node metastasis of a papillary thyroid carcinoma. The repeated cervical ultrasound showed thyroid micronodules. The patient underwent functional right dissection with extemporaneous histological examination which confirmed the diagnosis of cystic metastasis of papillary thyroid carcinoma. A total thyroidectomy with bilateral recurrent mediastinal dissection was performed. An excision of the parapharyngeal component by the intraoral route after unilateral tonsillectomy was performed. The definitive histology concluded that there was a multifocal and bilateral papillary microcarcinoma of the thyroid (tumor foci between 1 and 5 mm) with central, lateral and parapharyngeal lymph node metastases. Iratherapy was indicated. The evolution was favorable after a 3-year follow-up.
Conclusion
Lymph node dissemination is often reported to the central compartment of the neck followed by the lateral region. Metastasis to the parapharyngeal space seem to be straight forward due to the close anatomical localisation, but a few cases of parapharyngeal involvement have appeared in the literature

Follicular adenoma with follicular epithelial dysplasia-a care report

Rajmonda Tare[1], Ema Lumi[2] & Adriana Lapardhaja[3]
[1]Regional Hospital Elbasan, Internal Unit, Elbasan, Albania; [2]Regional Hospital Korce, Internal departament, Korce, Albania; [3]Policlinic nr.4, endocrinology, Tirana, Albania

Introduction
Follicular epithelial dysplasia (FED) is suggested to be a pathogenic link between inflammation – related atypia and papillary thyroid carcinoma (PTC) and thus a premalignant percursor of papillary thyroid carcinoma, in Hashimoto – thyroiditis (HT) and in chronic lymphocytic thyroiditis (CLT).
Material and methods
A 66-year-old-woman presented with feeling suffocation, frequent heartbeats, sweating, insomnia, hand tremors. Anamnesis revelead that she was diagnosed with Hyperfunctioning Multinodular Goiter 15 years prior and is on antithyroid medication and antihypertensive medication with moderate success in achieving euthyroidism. On admission, the patient had FT4:0.29 ng/dl (ref 0.34 – 5.6), FT3: 4.44 pg/ml (ref 2.5 – 4.2) TSH:2.65 uUI/ml (0.25 – 5). Cervical ultrasound showed an enlarged thyroid with large nodules. Antithyroid medication was adjusted with Favistan 10 mg/day. At the next visit after 6 weeks the lab results: TSH: 0.344 uUI/ml, FT4: 11.3pg/ml, FT3: 5.82 pg/ml, Anti Tg 26, Anti TPO 6.49, TSH receptors 0.8. Total thyroidectomy was recommended to the patient. The post-surgery biopsy confirmed follicular adenoma with foci of epithelial dysplasia.
Conclusion
Our case demonstrate the presence of atypical microscopic lesions even in follicular adenoma

Keywords
follicular adenoma, follicular epithelial dysplasia, hyperfunxioning multinodular goiter.

Pazopanib in radioiodine refractory follicular thyroid carcinoma. a case report

S. Semrouni[1], A. Bouchenna[1], A. Tibouk[2], B. Ghennam[3], M. Medjaher[3] & M. Bensalah[1]
[1]Central Military Hospital (HCA), Endocrinology Department, Algiers, Algeria; [2]Central Military Hospital (HCA), Pathology Department, Algiers, Algeria; [3]Central Military Hospital (HCA), Nuclear Medicine Department, Algiers, Algeria

Introduction
Differentiated thyroid carcinoma (DTC), which includes papillary and follicular thyroid cancers, generally has an excellent prognosis. However, a minority of patients (10%) relapse with metastatic disease, and eventually develop radioactive iodine (RAI) refractory disease. Over the last fifteen years the emergence of tyrosine kinase inhibitors (TKIs) has provided important new avenues of treatment for these patients. Currently, Lenvatinib and Sorafenib, multitargeted TKIs, represent the standard first-line systemic treatment options for RAI-refractory thyroid carcinoma, while Cabozantinib is the standard second-line treatment option. There are many phase 2 studies evaluating different multitargeted TKIs with encouraging results, but these drugs do not have FDA or EMA approval.
Case presentation
A 46-year-old male with follicular thyroid carcinoma, diagnosed following pathological fracture of the right femoral neck due to metastatic lesion, for which he underwent total hip replacement, treated with surgery followed by adjuvant RAI (200 mCi) treatment and TSH suppression. The CT scan revealed lung and bone metastases that did not demonstrate any RAI uptake, justifying the initiation of systemic treatment with a 1st-line multitargeted TKI: Sorafenib 800 mg daily. Morphological evaluation at 6 months post-Sorafenib revealed progression of lesion status and appearance of a lytic lesion of the 4th thoracic vertebra with spinal cord compression, for which he underwent laminectomy. Given the progression of lesion status on Sorafenib, a switch to 2nd-line treatment with Pazopanib 400 mg daily was initiated. Response evaluation at 4 months post-Pazopanib showed a progressive disease according to RECIST criteria.
Discussion/Conclusion
Pazopanib is approved for the treatment of advanced renal cell carcinoma and soft tissue sarcoma. It shows unclear efficacy and clinical activity in patients with RAI-refractory DTC, with manageable toxicity profiles. The findings indicate that pazopanib demonstrates clinical activity in RAI-refractory DTC, with the partial response rates ranging from 35.6% to 49% and with a median PFS period of around 11 months. Further large-scale randomized trials are warranted to establish the optimal use of pazopanib in thyroid cancer treatment.

Pemphigus vulgaris and Graves' disease

Raida Ben Salah[1], Faten Hadj Kacem[1], Sameh Marzouk[1], Zouhir Bahloul[1] & Mohamed Abid[1]
[1]University of Sfax, Internal Medicine, Sfax, Tunisia

Introduction
Bullous dermatoses encompass a range of skin disorders, with pemphigus vulgaris being one of the most severe. Pemphigus is a chronic, recurrent and severe bullous skin disease with acantholysis in the epidermis. In some investigations, thyroid diseases have been found to be a comorbidity of several skin diseases, such as alopecia, vitiligo, chloasma and Sjogren's syndrome. A recent study showed that the relatives of pemphigus patients seemed more prone to thyroid diseases. And about 34% of pemphigus vulgaris patients had hypothyroidism, Graves' disease, toxic multinodular goiter or follicular carcinoma This report presents a case of pemphigus vulgaris associated with thyroid dysfunction, highlighting the potential interplay between autoimmune skin diseases and thyroid pathology.
Case Report
A 25-year-old female patient was admitted in dermatology hospital, where she was diagnosed with pemphigus vulgaris. She was treated with corticosteroids, and the disease course was marked by recurrent flare-ups. After 19 years of disease progression, the patient developed hyperthyroidism, accompanied by a firm goiter and bilateral exophthalmos. Laboratory tests revealed positive antibodies for antithyroid peroxidase (AAT) and anti-TSH receptor antibodies, leading to the diagnosis of Graves' disease. The patient was subsequently treated with a course of radioactive iodine (RAI), which resulted in hypothyroidism 10 months later. She has since been treated with L-thyroxine. HLA typing revealed the haplotype HLA_AB:A1, A white, B17, B40 (BW4, BW6).
Discussion
Some explanations regarding the coexistence of the two conditions are below. First, pemphigus and AITD may have a common susceptibility gene or allele, but show different phenotypes influenced by various genetic and environmental factors. Meanwhile, there may exist a common environment triggering the autoimmune pathogenesis of both. Second, HLA alleles related to the disease may express similar autoantigen epitopes in different tissues. The case underscores the importance of considering thyroid dysfunction in patients with autoimmune skin disorders. A thorough evaluation for thyroid disease is recommended in patients with chronic autoimmune conditions such as pemphigus vulgaris, especially when new symptoms suggest thyroid involvement.
Conclusion
This case illustrates the rare coexistence of pemphigus vulgaris and thyroid dysfunction, specifically Graves' disease. The presence of autoimmune thyroid markers in this patient highlights the potential for autoimmune diseases to be interrelated.

Uncommon presentation of thyroid-associated orbitopathy in hypothyroidism: a case report

Rihab Khochtali[1], Taieb Ach[1], Oumayma Zarrouk[1], Imen Halloul[1], Ghada Saad[1] & Yosra Hasni[1]
[1]University of Sousse, Faculty of Medicine of Sousse, Farhat Hached University Hospital, Endocrinology and Diabetology Department 4000, Sousse, Tunisia

Introduction
Thyroid-associated orbitopathy (TAO) is uncommon in patients with Hashimoto's thyroiditis (HT), with a prevalence of 10.36% in those with hypothyroidism. In rare cases, hypothyroidism, orbitopathy, and elevated TSH-receptor autoantibodies (TRAbs) can be associated.
Case Presentation
A 62-year-old male presented with sight-threatening TAO and recently diagnosed hypothyroidism. Three months earlier, he had been started on levothyroxine (75

μg/day) for symptoms of asthenia, myxedema, constipation, and mild exophthalmos without signs of activity. Initial thyroid function tests revealed significantly elevated TSH (34 mIU/l [0.25-4.5]) and low free thyroxine (fT4) (3 pmol/l [12-22]). Upon admission to the ophthalmology department, the patient exhibited severe active orbitopathy, characterized by bilateral visual acuity of 3/10, restricted upward and abduction eye movements, and eyelid swelling. Laboratory investigations showed normal thyroid function (TSH: 4 mIU/l, fT4:11.6 pmol/l) under regular levothyroxine therapy, significantly elevated TRAbs (32 IU/l, normal <2 IU/l), and markedly high anti-thyroid peroxidase antibodies (Anti-TPO) (500 IU/ml, normal <50 IU/ml). Orbital MRI revealed bilateral, symmetrical hypertrophy of the extraocular muscles compressing the optic nerves at the apices and grade 3 exophthalmos. Thyroid ultrasound showed a heterogeneous, pseudonodular gland suggestive of thyroiditis. Treatment involved high-dose intravenous methylprednisolone (1000 mg/day for three consecutive days), achieving partial improvement, followed by a cumulative corticosteroid dose of 4.5 g administered over 12 weekly injections. Selenium supplementation (200 μg/day) was initiated, associated with levothyroxine therapy. At the six-month follow-up, ophthalmological evaluation revealed resolution of oculomotor restriction, absence of disease activity, and improved bilateral visual acuity (5/10). However, persistent TSH suppression, despite adjustments in levothyroxine dosage, led to a six-month interruption of therapy. Subsequent follow-up tests revealed TSH of 0.01 mIU/l[0.25-4.5], fT4 of 16 pmol/l[12-22], undetectable TRAbs levels, and persistently elevated Anti-TPO.

Conclusion

The literature describes different types of TRAbs, including thyroid-stimulating and TSH-blocking autoantibodies, each linked to distinct clinical syndromes. In this case, the predominance of blocking-type TRAbs may explain the presence of hypothyroidism. A multidisciplinary approach is crucial for optimizing outcomes in TAO, particularly in complex cases. Long-term follow-up is essential to monitor both thyroid function and ocular health.

Primary thyroid lymphoma in hashimoto's thyroiditis: a case report and review of the association and diagnostic approach

Houas Jihene[1,2], Monia Ghammam[1], Jawaher Kechiche[1], Habiba Ben Sghaier[1], Malika El Omri[1], Abir Meherzi[1], Mouna Bellakhdher[1], Wassim Kermani[1] & Mohamed Abdelkefi[1]
[1]University of Sousse Faculty of Medicine of Sousse, Sousse, Tunisia; [2]Farhat Hached Hospital, Sousse

Introduction

Primary thyroid lymphoma (PTL) is a rare cancer, representing 1% to 5% of all thyroid malignancies and 1% to 7% of all extra nodal lymphomas. It predominantly affects females, with the highest incidence occurring in the seventh decade of life. The most common histotypes are diffuse large B-cell lymphoma, which accounts for 50% to 70% of cases. The most significant risk factor for PTL is Hashimoto's thyroiditis, which increases the risk of PTL by 40 to 80 times. However, it remains unclear whether Hashimoto's thyroiditis is a necessary condition for the development of PTL. The aim of this study was to describe a case report of a primary thyroid lymphoma associated with a lesion of Hashimoto's thyroiditis

Materials and Methods

This is a retrospective case report focusing on a patient diagnosed with primary thyroid lymphoma (PTL) associated with Hashimoto's thyroiditis. The study includes a detailed review of the patient's medical history, clinical presentation, imaging results, histopathological examination, and treatment course.

Results

An 84-year-old female patient was admitted for management of dysphagia. On examination, a hard, fixed mass was palpated in the anterior cervical region, adherent to the deep planes. Cervical ultrasound revealed a right-sided thyroid mass measuring 41x28x12 mm, causing mass effect on the trachea. A cervical-thoracic CT scan confirmed the presence of a mass in the right thyroid lobe. An esophagogastroduodenal transit showed deviation of the cervical esophagus to the right, consistent with extrinsic compression. The patient underwent an exploratory cervicotomy, revealing a firm, stone-like mass adherent to the right thyroid lobe, while the left lobe appeared normal. A multiple biopsy of the right mass confirmed a diagnosis of diffuse B-cell lymphoma of germinal center cells, while the left lobe showed lymphocytic thyroiditis. The patient was presented in a multidisciplinary case review (MCR) for chemotherapy consideration.

Conclusion

The strong association between Hashimoto's thyroiditis (HT) and primary thyroid lymphoma (PTL) highlights the significantly increased risk (40- to 80-fold) of developing PTL in patients with HT. PTL should be considered in the differential diagnosis of rapidly enlarging goiter or shortness of breath in patients with thyroiditis. Early recognition and prompt pathological diagnosis are crucial to initiate chemotherapy and improve patient outcomes.

Hypokalemic periodic paralysis in hyperthyroidism: a rare endocrine emergency

Alberto Arbex[1], Joyce Lucindo[2], Milena Meloni[2], Rafaela Medeiros[2], Paola Soares[2], Gustavo Arbex[1], Luiz Henrique Portari[2] & Renata Bussuan[2]
[1]Grossenwiehe Medical Clinic, Endocrinology, Flensburg, Germany; [2]AFYA Medical School, Endocrinology, Rio de Janeiro, Brazil

Case Presentation

A 20-year-old male patient, of south american and oriental descent, presented in January 2024 with sudden onset of muscle weakness and flaccid paralysis of the lower limbs, progressing rapidly to upper limb plegia, while respiratory movements remained preserved. Initial examination revealed hypertension (BP $>$ 140/90 mmHg), sinus tachyarrhythmia (ECG), and severe hypokalemia (K: 2.8 mEq/l). The patient was admitted to the Intensive Care Unit for potassium repletion, during which transient hyperkalemia occurred, but was resolved without serious consequences. After normalization of potassium (4.1 mEq/l), the patient was discharged. Approximately 30 days later, the patient experienced another episode of lower limb weakness and hypokalemia, prompting further investigation. Laboratory tests revealed hyperthyroidism (TSH: <0.008 μUI/ml, T4: 5.14 ng/dl, T3: 17.9 ng/dl) and elevated anti-thyroid antibodies. A diagnosis of hyperthyroidism was confirmed, and treatment with methimazole (30 mg/day) was initiated. After 90 days, follow-up tests showed improved thyroid function (TSH: 0.01 μUI/ml, T4: 1.12 ng/dl, TRAB: 1.51 U/l). Thyroid ultrasound showed a normal-sized gland with no solid or cystic lesions. The patient remains asymptomatic with no further episodes of tachycardia, hypokalemia, or paralysis.

Discussion

Hypokalemic periodic paralysis (HPP) is a rare complication of hyperthyroidism characterized by a triad of hypokalemia, thyroid dysfunction, and skeletal muscle paralysis. Episodes of HPP are often transient and can affect the lower limbs, occasionally progressing to the upper limbs. The condition is precipitated by high carbohydrate intake or intense physical activity and often occurs during the night or upon awakening. Thyroid symptoms can be subtle, with diagnosis confirmed through laboratory tests. In the electrocardiogram, signs of HPP include sinus tachycardia, ST-segment alterations, T-wave flattening, prolonged QT intervals, and in severe cases, ventricular fibrillation. Treatment involves controlling hyperthyroidism with antithyroid drugs, iodotherapy, or thyroidectomy. In acute episodes, careful potassium repletion and beta-blockers are essential to prevent recurrence.

Conclusion

Although rare, hypokalemic periodic paralysis (HPP) in the context of hyperthyroidism must be recognized promptly by clinicians. With increasing numbers of individuals of Asian descent in the world, understanding the pathophysiology and epidemiology of this condition is crucial for early diagnosis and treatment, which can prevent severe complications, including respiratory failure and death.

JOINT2577

Thyroid association ophthalmopathy in hashimoto's thyroiditis: a case report

Ons Maaoui[1], Nadia Khessairi[1], Elyes Kamoun[1], Fatma Chaker[1] & Malika Chihaoui[1]
[1]Rabta Hospital, Endocrinology Department, Tunis, Tunisia

Introduction

Ophtalmopathy is common in hyperthyroid patients due to Graves' disease. But in Hashimoto's thyroiditis, thyroid associated ophthalmopathy is rarely reported and only few cases have been reported in the literature. Here we report a case of thyroid associated ophthalmopathy in a patient with Hashimoto's thyroiditis.

Observation

A 40-year-old female patient was being followed for Hashimoto hypothyroidism with positive anti-thyroid peroxidase antibodies and thyroiditis on cervical

ultrasound. Two years after the diagnosis, she presented with blurred vision, bilateral exophthalmos and spontaneous ocular pain. On examination, she had bilateral palpebral edema and conjunctival and palpebral redness. clinical activity score (CAS) was 4. CT scan showed bilateral oculomotor muscle infiltration in connection with dysthyroidism and anti-TSH receptor antibodies were negative. The patient was put on corticosteroids: prednisone 1 mg/kg/day with improvement in the signs of ophthalmopathy activity: disappearance of conjunctival and palpebral redness and pain; she gradually tapered off the corticosteroids.

Conculsion

This case highlights the rare association between ophthalmopathy and Hashimoto's thyroiditis, emphasizing that thyroid-related orbitopathy is not exclusive to Graves' disease.

Surgical treatment of plunging goiters: challenges for ENT specialists

Mehdi Ferjaoui[1], Sabrine Farhani[1], Meriem Grassa[1], Nawres Bouaziz[1], Rachida Bouatay[1], Amel Elkorbi[1], Naourez Kolsi[1], Harrathi Khaled[1] & Jamel Koubaa[1]

[1]ENT Department Fattouma Bourguiba Hospital Monastir Tunisia, ENT Department Fattouma Bourguiba Hospital, Monastir, Tunisia

Introduction

A plunging goiter (PG) is any goiter whose lower limit is not palpable in the surgical position. Its diagnosis is first suspected clinically, then confirmed by imaging. It often requires surgical intervention due to associated life-threatening risks.

Objective

To study the epidemiological aspects of PG, the importance of preoperative imaging and to describe the modalities of surgical management.

Patients and Methods

Retrospective study of 15 cases of PG, operated on at the Department of Head and Neck Surgery and Otorhinolaryngology of the Fattouma Bourguiba University Hospital in Monastir over a period of 5 years from 2020 to 2024.

Results

In 5 years,15 cases of PG representing 1.5% of thyroidectomies performed. The average age was 60 years [33 to 79 years]. The sex ratio was 0.22 with a female predominance (86%). The plunging character was noted on clinical examination and confirmed by imaging. The consultation period was 3 years [4 months - 10 years]. The circumstances of discovery were dominated by the fortuitous discovery of an anterior baservical swelling in 100% of cases and the installation of compressive signs in 73% of cases. A family history of thyroid pathology was reported in 5patients (33%) and a personal history of dysthyroidism was noted in 3patients (20%). All our patients had a chest X-ray, a cervical ultrasound and an indirect laryngoscopy preoperatively. Among the 15 X-rays, an opacity Upper mediastinal goiter was objectified in 8 patients (54%), tracheal deviation in 7 patients (46%), and a normal appearance in 46% of cases. Ultrasound detected the plunging character in 6 patients (40% of cases) and the cervicothoracic CT scan confirmed it in 100% of cases. The goiter plunged to the right in 8 cases (54%), to the left in 6 cases (40%) and bilaterally in 1 case. It also revealed an anterosuperior mediastinal development of the goiter in 13 cases (86%), posterior in 2 cases (13%), and a displacement of the esophagotracheal axis in 9 cases (60%). A loboisthmectomy was performed in 4 cases (33%) and a total thyroidectomy in 11 cases (73%) by the exclusive cervical aaproach. The anatomopathological examination revealed11 benign lesions and 4 malignant ones. Postoperative complications included transient hypoparathyroidism in 2 cases, unilateral transient recurrent paresis in 1 case, and subcutaneous hematoma in another case.

Conclusion

Plunging goiters represent a distinct entity in thyroid pathology due to the complexity of their surgical management. The surgical indication, following a multidisciplinary approach, should be considered prior to the onset of compressive complications.

Atypical testicular germ cell cancer metastasis in the thyroid: a case report of a very rare clinical presentation

Diana Šimonienė[1] & Raminta Akelaitytė[2]

[1]Lithuanian University of Health Sciences (LUHS), Endocrinology, Kaunas, Lithuania; [2]Lithuanian University of Health Sciences (LUHS), Kaunas, Lithuania

Introduction

In contrast to primary thyroid cancer, which usually has a good prognosis, thyroid metastases from other primary tumors are associated with a poor prognosis, as they indicate far advanced primary disease [*Zivaljevic V, 2018*]. The most common metastatic sites of testicular cancer are retroperitoneal lymph nodes. In clinical practice, metastases in the thyroid are extremely rare (incidence ranging from 0.006 to 0.3%) [*Battistella E, 2020*].

Case description

A 22-year-old man was referred to the Emergency department due to a painless mass on the left side of his neck that appeared three weeks ago, a decrease in appetite and acute upper respiratory tract infection with negative dynamics that has lasted for three days. The neck ultrasound showed an enlarged left thyroid lobe, with a mixed-structure nodule occupying almost the entire lobe. Enlarged lymph nodes were present in the left supraclavicular and posterior cervical areas. Patient was admitted to the Endocrinology department. Blood tests showed normal thyroid hormone levels, ESR 101 mm/h, increased inflammatory markers. Treatment with NSAIDs was initiated, suspecting a subacute thyroiditis. A biopsy of the neck mass and lymph nodes was performed. The results indicated a mixed germ cell tumor with a high Ki67 proliferation marker. After the CT scan of the chest, abdomen, and pelvic organs, advanced testicular neoplastic process was suspected. After a whole-body PET/CT scan, a metabolically active mass in the right testicle was observed, with the most likely metastases in the liver and in the left supraclavicular, mediastinal, left inguinal region, lungs and neck lymph nodes. Neoadjuvant chemotherapy with BEP (Bleomycin, Etoposide, Cisplatin) was initiated before surgery.

Conclusions

We present an unusual clinical case of advanced testicular germ cell cancer that manifested with thyroid enlargement and metastasis in the neck. Testicular cancer with metastasis of the thyroid is an extremely rare occurrence, only 4 cases in the 40 years period were found in literature [*Mattavelli F, 2009 and Favero D, 2024*].

Autonomous resolution of a toxic thyroid nodule: a case report

Beatriz R Pereira[1], Joana Aço[2], Joana Vinhais[1], David Veríssimo[1], Catarina Ivo[1], Ana Cláudia Martins[1], Dolores Passos[1], Luís Lopes[1], Mafalda Marcelino[1], João Nunes e Silva[1], Lucília Salgado[2] & João Jácome de Castro[1]

[1]Endocrinology Department, Portuguese Armed Forces Hospital, Lisbon, Portugal; [2]Portuguese Institute of Oncology of Lisbon Francisco Gentil, Nuclear Medicine Department, Lisbon, Portugal

Introduction/Background

Management of toxic autonomous nodules usually involves antithyroid drugs for temporary control, while definitive treatment options include radioiodine therapy or surgery. However, the natural evolution of these nodules remains an area of interest with uncertain aspects to be explored.

Case Report

A 45-year-old female was sent to the endocrine clinic by her general practitioner with complains of neck discomfort. She was clinically euthyroid, presenting a painless thyroid nodule with about 3 cm on the left lobe. Laboratory tests revealed suppressed TSH levels (0.02 µUI/ml) with normal free T4 levels. Further results showed negative thyroid autoantibodies (antithyroid peroxidase, antithyroglobulin and thyrotropin receptor antibodies), negative C-reactive protein and erythrocyte sedimentation rate. Neck ultrasound revealed heterogeneous thyroid tissue, with a mixed solid and cystic nodule measuring 27 × 20 × 14 mm, in the upper part of the left lobe. Thyroid scintigraphy showed high uptake within the nodule with suppression of the surrounding parenchyma, consistent with an autonomous thyroid nodule. Since the patient was clinical euthyroid no medication was prescribed at the time. At re-evaluation, seven weeks after, TSH raised to 7.8 µUI/ml with free T4 at the lower limit of the reference range. After five weeks, TSH level become normal (2.57 µUI/ml). The patient remained clinically euthyroid and thyroid antibodies were persistently negative. An ultrasound was repeated showing a hypervascular, septated nodule with a cystic component measuring 23x16 mm. At that time scintigraphy also was repeated showing a diffuse increase in radionuclide uptake, with a partially hypoactive area corresponding to the previously detected toxic nodule.

Discussion/Conclusions

This case raises intriguing questions regarding the rare case of a spontaneous involution of the toxic autonomous nodule. Throughout this two-month period, the patient exhibited spontaneous thyroid function fluctuations—from

hyperthyroidism to hypothyroidism and finally to euthyroidism—always with negative thyroid autoantibodies. Possible mechanisms include functional exhaustion, fibrosis or necrosis. While toxic nodules are typically persistent and require treatment, this case highlights an unusual and spontaneous resolution with both biochemical and imaging correlation. The evolution of this patient's nodule from autonomous hyperfunction to apparent inactivation without intervention reenforces that, in selected cases, a conservative approach with close monitoring could justified. Further studies are needed to better understand the mechanisms underlying spontaneous resolution of toxic autonomous nodules and to define predictors of this phenomenon.

Levothyroxine absorption test: practical application. Importance of the clinical laboratory in the diagnosis of refractory hypothyroidism. A case report

Laura Cervera-Palou[1], Miguel-Angel Ruiz-Gines[1], Juan-Antonio Ruiz-Gines[2], Mercedes Agudo-Macazaga[1], Macarena Dubert-Perez[1], Maria-Carmen Lorenzo-Lozano[1], Belen-Maria Martinez-Mulero[3], Rocio Revuelta Sanchez-Vera[3], Ana Castro-Luna[3] & Julia Sastre-Marcos[3]
[1]Hospital Universitario de Toledo, Laboratory Medicine, Toledo, Spain; [2]Hospital Clínico Universitario Lozano-Blesa, Neurosurgery, Zaragoza, Spain; [3]Hospital Universitario de Toledo, Endocrinology, Toledo, Spain

Introduction
Hypothyroidism is a chronic disease with a high prevalence. The treatment of choice in most patients is synthetic levothyroxine (LT4) adjusted for body weight. The objective is to achieve normal levels of thyrotropin (TSH) (0.4-4 µU/ml). Refractory hypothyroidism is defined as persistent hyperthyrotropinemia despite high doses of LT4. Once the usual causes (pharmacological, dietary and/or pathological) that would justify LT4 malabsorption have been ruled out, as well as possible interferences in the measurement of TSH, a dynamic LT4 absorption test (DAT) can be performed. The test allows us to differentiate real malabsorption from pseudomalabsorption or lack of therapeutic adherence. Our purpose is to demonstrate the importance of using DAT in clinical practice.
Case Report
60-year-old woman, under study for difficult-to-control autoimmune primary hypothyroidism (APH), on treatment with Levothyroxine. TSH levels of 166 µU/ml (0.270-4.200) and FT4 of 0.34 ng/dl (0.930-1.700) with significant weight gain (>10 kg), BMI 32.95 (Obesity-Grade-I). Her Primary Care Physician (PCP) increased the dose of Levothyroxine. After a new analytical control, the following were observed: TSH 273.00 µU/ml, FT4 0.221 ng/dl, FT3 1.380 pg/ml (2.00-4.40) and IgG-antiperoxidase-TPO Ac. 187.00 IU/ml (9.00-34.00). The patient began with significant asthenia, hoarseness and dyspnea. Complementary tests were performed to assess intestinal and autoimmune causes, which were negative. There was no analytical interference (macro-TSH and heterophil antibodies). Subsequently, TSH levels were 243.00 µU/ml and FT4 0.308 ng/dl. DAT was performed, which consisted of the administration of 1000 µg of FT4 and monitoring of FT4 levels every 30 min for 4 hours. A baseline ECG and a blood test with TSH and FT4 must be performed beforehand. Absorption is considered normal when FT4 levels are >0.4 ng/dl with respect to the baseline value (absorption >60%). Results: DAT results: 0' TSH 207.00 and FT4 0.277; 30́ FT4 0.293; 60́ FT4: 0.550; 90́ FT4 0.862; 120́ FT4 1.63. 180́ FT4 1.950; 240́ TSH 70.90 and FT4 2.00, in µU/ml and nd/dl, respectively.
Discussion and conclusions
According to the results, everything indicates a pseudomalabsorption of FT4, that is, a lack of therapeutic compliance by the patient. Correct adherence to treatment is insisted upon. After 8 weeks, the thyroid profile is shown to be normalized (TSH 1.080 µU/ml, FT4 1.50 ng/dl, FT3 3.090 pg/ml). DAT is a safe and effective method that allows pseudomalabsorption to be demonstrated after ruling out interferences and underlying gastrointestinal pathology. pseudomalabsorción tras descartar interferencias y patología gastrointestinal subyacente.

Dual autoimmune thyroid disease: a case of simultaneous Graves' disease and hashimoto's thyroiditis

Nada Hassairi[1], Houcem Elomma Mrabet[1], Najoua Lassoued[1], Amine Bayoudh[1], Oumaima Dimassi[1], Boubaker Fadia[1], Zantour Baha[1], Alaya Wafa[1] & Sfar Mohamed Habib[1]
[1]Taher Sfar University Hospital, Endocrinology Department, Mahdia, Tunisia

Introduction
Autoimmune thyroid diseases (AITDs), including Hashimoto's thyroiditis (HT) and Graves' disease (GD), are distinct yet interrelated conditions. While HT typically causes hypothyroidism and GD results in hyperthyroidism, their coexistence in a single patient is rare. This case highlights the diagnostic and therapeutic complexities of overlapping HT and GD
Case Report
A 26-year-old woman with a positive family history of autoimmune thyroid disease and a personal history of chronic lymphocytic thyroiditis, diagnosed three years prior and managed with 50 µg of L-thyroxine daily, was referred to the endocrinology outpatient clinic for symptoms suggestive of hyperthyroidism. These symptoms persisted despite the progressive reduction and eventual discontinuation of treatment. On initial evaluation, the patient reported diarrhea, palpitations, and increased appetite. Physical examination revealed a non-enlarged thyroid and no exophthalmos. Thyroid function tests showed suppressed TSH levels (<0.001 mIU/l) and elevated free thyroxine (FT4) levels (48 pmol/l; normal range 10–28 pmol/l), persisting despite complete cessation of treatment. Both thyroperoxidase antibodies and TSH receptor antibodies were elevated at 115 IU/l (normal <8 IU/l) and 12.9 IU/l (normal <1.5 IU/l), respectively. Thyroid ultrasound revealed a slightly enlarged gland with irregular edges and increased vascular flow on Doppler, suggestive of thyroiditis. The patient was started on 10 mg of thiamazole and beta-blockers, resulting in significant improvement in clinical symptoms.
Discussion
The coexistence of GD and HT is rare but well-documented in several case reports (1–3). These autoimmune thyroid disorders share pathogenic mechanisms, including genetic and environmental factors, T-cell-mediated autoimmunity, and the presence of autoantibodies (1). Patients with simultaneous GD and HT may exhibit alternating phases of hyperthyroidism and hypothyroidism due to shifting antibody profiles (1). In this patient, hyperthyroidism was suspected when persistently suppressed TSH levels were observed despite reducing and eventually discontinuing L-thyroxine therapy. Diagnosing coexisting GD and HT can be challenging, requiring a thorough evaluation of clinical presentation, thyroid function tests, antibody assays, and imaging studies (3). Notably, our patient lacked classic clinical signs of GD, such as exophthalmos or a homogeneous goiter. Ultrasound findings were indicative of both HT (irregular gland edges, mild enlargement) and GD (increased vascular flow). Coexisting autoimmune thyroid diseases have been associated with other autoimmune conditions, including inflammatory bowel diseases, albeit rarely (4). Long-term monitoring of patients with autoimmune thyroid diseases is essential, even in the absence of clinical manifestations, due to the potential for disease progression (2).

Liquid biopsy in the molecular diagnosis of metastatic medullary thyroid cancer – case report

Estera Mikina[1], Agnieszka Walczyk[1,2], Katarzyna Żurek[2], Gabriela Steinhoff[2], Wiktor Zdeb[2], Dominik Szydełko[2] & Aldona Kowalska[1,2]
[1]Holy Cross Cancer Center, Jan Kochanowski University, Endocrinology Departament, Kielce, Poland; [2]Jan Kochanowski University, Collegium Medicum, Kielce, Poland

Introduction
The medullary thyroid carcinoma (MTC) is one of the most aggressive forms of thyroid malignancy, accounting for up to 10% of all types of this disease. The molecular profile of MTC is well-known. A germline activating mutation of the *RET* proto-oncogene occurs in nearly all patients with hereditary MTC, while a somatic *RET* mutation is found in about 50% of sporadic tumors. In this group of patients, selective tyrosine kinase inhibitors (IKT)are successfully used, particularly in cases of metastatic disease. Management of metastatic disease in patients without RET mutations presents a clinical challenge. The aim of this study is to present the case of a patient with MTC, who 18 years after thyroid surgery, developed liver metastases despite an excellent initial response to treatment. Molecular profile of the primary tumor was not conducted. At the time of liver metastases diagnosis, circulating tumor DNA analysis was performed, allowing determination the molecular profile of the cancer. The driver mutation for MTC was identified as a mutation in the *PIK3CA* gene, which encodes the catalytic subunit of the PI3K protein, playing a key role in the phosphatidyl-inositol-3 kinase /AKT pathways *(*PI3K/Akt) signaling pathway. This mutation is known from other cancers, such as colorectal, ovarian, breast, brain, liver, stomach and lung cancers. The *PIK3CA* mutation is very rare in MTC. Our patient did not have a dynamic progression of MTC (stable disease according to RECIST 1.1 after 12 months of observation). Currently, no decision has been made to

initiate systemic therapy, but knowledge of the molecular profile of the disease may help guide targeted molecular therapy in the future. The alpelisib an α-specific inhibitor of PI3K that targets p110α is currently available. The use of this drug, which has been shown to effectively inhibit tumor progression in patients with the PIK3CA mutation, including those with breast cancer, may be a promising therapeutic option for our patient.
Conclusions
Patients with MTC, even though an excellent response to treatment, require lifelong oncological follow up. Liquid biopsy is a new and valuable tool for molecular diagnostics of cancer, particularly in cases where tumor cells cannot be obtained for analysis.

Diffuse malignancies of the thyroid – clinical cases

Elena Chobankova[1,2], Antoaneta Argatska[1], Veselin Chonov[3], Rossen Dimov[4] & Boyan Nonchev[1,2]
[1]Medical University of Plovdiv, Endocrinology Department, Plovdiv, Bulgaria; [2]Kaspela University Hospital, Endocrinology Department, Plovdiv, Bulgaria; [3]Kaspela University Hospital, Pathology Department, Plovdiv, Bulgaria; [4]Kaspela University Hospital, Surgical Department, Plovdiv, Bulgaria

Introduction
Thyroid malignancies usually present as either single or multiple nodules with high-risk ultrasound features. Nevertheless, in some rare cases the thyroid gland can be diffusely and entirely affected by different types of thyroid cancer or a metastasis from another primary site. Clinical case 1: A 34-year-old male presented with a fast-growing lump in the left neck area. The thyroid gland was significantly enlarged, with indistinguishable high-risk zones on ultrasound. Suspicious neck lymphadenopathy was observed in the central and lateral neck compartments. Fine-needle aspiration (FNA) biopsy was performed with a malignant cytological result. The patient was referred for a thyroidectomy with lymph node dissection. The histological analysis of the removed tissue confirmed differentiated thyroid cancer. Clinical case 2: An 84-year-old woman with a history of autoimmune thyroiditis was referred for assessment in regards to a progressive swelling in the neck area. She was successfully treated in the past for non-Hodgkin's lymphoma. The ultrasound examination of the neck area revealed a high-grade diffuse retrosternal compressive goiter and enlarged regional lymph nodes in levels II, III and V on the right. FNA biopsy was performed with a benign cytological result. Due to the high clinical suspicion for malignancy, the patient was referred for a surgical biopsy, which confirmed B-cell lymphoma. Clinical case 3: A 55-year-old female with a progressive goiter presented with dyspnea and palpitations. She was diagnosed recently with advanced colon cancer and treated with polychemotherapy. Laboratory results revealed a hormonal constellation of destructive thyrotoxicosis and negative thyroid autoantibodies. The ultrasound examination revealed a massively enlarged goiter with altered structure and multiple pathological lymph nodes in the neck compartments bilaterally. FNA biopsy of several parts of the diffusely altered thyroid parenchyma was performed with a malignant cytological result. Glucocorticoid therapy was applied with regards to the thyrotoxicosis, with a beneficial effect. The patient was referred for a thyroidectomy, however, due to the abrupt worsening of her condition she was considered inoperable.
Conclusion
Diffuse thyroid gland involvement due to a malignant process is rarely seen. The combination of clinical and ultrasound data, medical history and cytological results from a FNA biopsy provide vital insights into the etiology of the pathological processes, affecting the thyroid in cases of both primary and secondary malignancies.

Non-graves orbitopathy in a patient with hypothyroidism, hashimoto's thyroiditis, and hiv on combined antiretroviral therapy

Naia Lataria[1] & Nino Rukhadze[2]
[1]Todua Clinic, Tbilisi, Georgia; [2]Tengiz Tsertsvadze Infectious Disease, AIDS and Clinical Immunology Center, Tbilisi, Georgia

Introduction
Hashimoto's thyroiditis, also called chronic autoimmune thyroiditis, is one of the most common autoimmune thyroid diseases. The clinical manifestations can include either hypothyroidism or, in rare cases, hyperthyroidism. Thyroid Eye Disease (TED) occurs when thyroid autoantibodies cause inflammation in the connective tissue of the extraocular muscles and orbital fat, leading to clinical symptoms such as periorbital edema, lid retraction, and proptosis, among others. There is a close relationship between TED and thyroid-stimulating hormone receptor antibodies (TRAb). TED can also occur in patients with chronic autoimmune thyroiditis. HIV infects CD4+ T cells, and approximately 10–40% of patients receiving antiretroviral therapy (ART) may develop immune reconstitution inflammatory syndrome (IRIS).
Case Report
A patient was referred to an endocrinologist by an infectious disease specialist. HIV was diagnosed eight years ago, and the patient has been on combination antiretroviral therapy (Tenofovir, Dolutegravir, and Lamivudine) since then. Approximately two years ago, the patient was diagnosed with autoimmune thyroiditis and primary hypothyroidism but refused consultation with an endocrinologist.
On November 11, 2024, laboratory tests showed:
- TSH: >100 mIU/ml
- Anti-TPO: >600 IU/ml

Levothyroxine 75 mg was prescribed.
On January 8, 2025, follow-up laboratory results showed:
- TSH: 38.81 mIU/ml (reference range: 0.27–4.2)
- FT4: 15.36 pmol/l (reference range: 12–22) Although there was a positive trend in thyroid function, the patient returned for consultation with signs of thyroid orbitopathy, more pronounced in the right eye, as well as spot baldness on the head and brow area—symptoms that were not present during the previous consultation two months prior. Before the endocrinology follow-up, the patient was evaluated by an ophthalmologist and was prescribed steroid eye drops. However, the patient did not notice any improvement in inflammation. On January 10, 2025, an MRI scan of the brain and orbits was performed, revealing:
- No acute focal organic pathology of the brain parenchyma
- Swelling of intraorbital fatty tissue in both eyes
- Exophthalmos in both eyes Levothyroxine dosage was increased to 100 mg, and Selenium 200 mg once daily was introduced for six months. Since Teprotumumab is not available in Georgia, intravenous methylprednisolone pulse therapy is being considered for further treatment.

Conclusion
This case highlights the importance of early ophthalmological evaluation in patients with autoimmune thyroiditis, including thyroid hormone assessment and thyroid autoantibody screening. It also underscores the need for early detection of eye complications, even in patients with autoimmune thyroiditis in the hypothyroid stage and without Graves' disease.

Introduction
Medullary thyroid carcinoma (MTC) accounts for 3–8% of thyroid cancers. In 20% of cases, it is diagnosed at a metastatic stage. Tyrosine kinase inhibitors (TKIs) have revolutionized the management of advanced and metastatic MTC. Among them, Vandetanib and Cabozantinib are the two approved treatments. However, access to these therapies may be limited in certain settings, justifying the exploration of alternatives such as Sorafenib.
Methods
A retrospective analysis of four metastatic MTC patients treated with Sorafenib was conducted. Clinical data, treatment response, and adverse effects were assessed.
Discussion
MTC requires systemic therapy in metastatic cases. Sorafenib, a multikinase inhibitor targeting RET and VEGFR, is used off-label when standard therapies are unavailable. While it stabilizes disease in some cases, efficacy remains modest. Adverse effects may impact adherence, requiring careful monitoring. Further research is needed to define Sorafenib's role and explore combination strategies.
Conclusion
Sorafenib may be an alternative for metastatic MTC when standard treatments are unavailable. Close monitoring is essential to manage adverse effects and optimize outcomes.

Discordance between clinic, biology and ultrasound in the diagnosis of Graves' disease: contribution of scintigraphy in a case report

Hanan Boualam[1], Sara Ijdda[1], Sana Rafi[1], Ghizlane Elmghari[1] & Nawal Elansari[1]
[1]Mohammed VI University Hospital of Marrakech, Department of Endocrinology, Diabetes, Metabolic Diseases and Nutrition, Marrakech, Morocco

Introduction
Graves' disease, the most common cause of hyperthyroidism, is linked to the presence of anti-TSH receptor antibodies. It is an autoimmune pathology, 5 to 10 times more frequent in women than in men, occurring at any age. Clinical symptoms include thyrotoxicosis and the specific signs of the disease (ophthalmopathy and pretibial myxedema). Biologically, a lowered TSHus concentration and elevated T4 and/or T3 confirm the diagnosis. Ultrasound and scintigraphy are sometimes useful in distinguishing Graves' disease from other causes of hyperthyroidism. When clinical and biological findings are incomplete and/or ultrasound is inconsistent, scintigraphy is of great help. We report on the contribution of scintigraphy to the diagnosis of Graves' disease with clinical, biological and ultrasound discordance.
Case report
A 54-year-old female patient with breast cancer, operated on 7 years ago and currently undergoing hormone therapy, consulted for thyroiditis discovered incidentally by cervical ultrasound, with a reduced thyroid gland, heterogeneous echostructure with hypoechoic areas, discreetly hypervascularized. Clinically, she showed no signs of dysthyroidism. A laboratory workup revealed subclinical hyperthyroidism with TSHus down to 0.05 µUI/ml (0.25-5), T4L and T3L normal. In the immunological work-up, anti-TPO antibodies were positive at 36 and TRAK was slightly elevated at 2.81 (>2.25). In view of this incomplete clinicobiological context and a discordant ultrasound, a Technicium 99m thyroid scintigraphy was requested as a complement, objectifying diffuse and homogeneous hyperfixation of the radiotracer compatible with Graves' disease. The patient was put on low-dose synthetic antithyroid drugs. Biological results were favourable (TSH, T4 and T3 normal at 1-month follow-up).
Discussion/Conclusion
The classic diagnosis of Graves' disease is clinicobiological and secondarily ultrasonographic. However, in the event of discrepancies between the two, and given the operator-dependent nature of ultrasound, scintigraphy can make a considerable contribution.

Ostéoporose radiale: une complication rare du traitement suppressif du carcinome papillaire de la thyroïde

Chayma Zouna[1], Hasna Ouirar[1], Ikram Qasdi[1], Zineb Habbadi[1], Fatima Toulali[1], Ghizlane Sabbar[1], Kaoutar Rifai[1], Hind Iraqi[1] & Mohamed Hassan Gharbi[1]
[1]CHU Rabat, Endocrinologie, Rabat, Morocco

Introduction
Hyperthyroidism reduces bone mass and increases fracture risk. These changes are clearly demonstrated in cases of frank thyrotoxicosis in postmenopausal women. Thyroid hormone treatment has a limited effect on bone. Clinical studies show contradictory results. Thyroid hormone treatment should be considered as an additional osteoporotic risk factor in postmenopausal women.
Observation
76-year-old postmenopausal patient, followed for papillary thyroid microcarcinoma operated and irradiated in 2014, initially put on braking treatment with TSH target <0.1 for the first year, given the good biological and morphological response, the TSH target was redefined between 0.5-2 with a dose of 62.5ug levothyroxine. An osteodensitometry was ordered as part of the work-up, and came back in favour of femoral and lumbar osteopenia with radial osteoporosis. The patient was referred to rheumatology for treatment and follow-up.
Discussion
A literature review analyzed 11 significant studies. All provided information on gender, menopause, bone density measured at different sites and a match to control subjects. All patients had received five or more years of hormone-reducing therapy. One limited cross-sectional study found a significant reduction in lumbar density of 2-6% per year since initiation of thyroxine therapy in postmenopausal women, while a single cross-sectional study found a reduction in femoral neck density, with no changes in lumbar or forearm density compared to control subjects. Of nine studies involving postmenopausal women only, six found no difference in bone density between thyroid cancer patients treated with hormone-braking therapy and controls. One study showed only a slight decrease in bone density at the distal end of the radius. In the work by Kung *et al*. thyroxine results in complete TSH suppression in all patients and a decrease in bone density at all sites evaluated in postmenopausal women. These contradictory results do not allow us to confirm or deny the deleterious effect of hormone replacement therapy on bone mass in postmenopausal women It is reasonable to consider hormone replacement therapy as an additional osteoporotic risk factor.

Unilateral ptosis in a patient with thyroid eye disease: A case report

Salsabil Haouach[1], Sara Ijdda[1], Sana Rafi[1], El Mghari Tabib Ghizlane[1] & Nawal Elansari[1]
[1]CHU Mohamed VI Marrakech, Marrakech, Morocco

Introduction
Thyroid associated orbitopathy (TAO) or graves disease is an autoimmune disorder associated with hyperthyroidism. Most common presentation is eyelid retraction followed by exophthalmos. Although it is associated with myasthenia gravis, it is a relatively uncommon cause of ptosis. We report a case of young adult woman who presented with unilateral ptosis in right eye revealing a graves disease.
Case Report
A 26-year-old female presented with a history of weight loss, panic attacks, palpitations and muscle weakness for 2 months. She had no history of thyroid affection. She complained of dropping of her right eyelid, which was insidious in onset and gradually progressive. Laboratory investigations revealed a hyperthyroidism; the free T3 level was 36.27 pmol/l (reference range: 3.10–6.80), free T4 level was 100 pmol/l (reference range: 12.0–22.0), TSH was 0.008 mIU/l (reference range: 0.27–4.20), and TSH receptor antibody (TRAb) was 6.49IU/l (reference range <1). She was diagnosed with Graves disease and started on intravenous methylprednisolone 120 mg followed by 3 days of 60 mg then 40 mg of Carbimazole.
Discussion
The relationship of muscle size to motility deficit using muscle diameter measurements on CT scans of patients with Thyroid Eye Disease(TED) was studied. There are several mechanisms of ptosis that have been reported in association with TED. Pathologic and radiographic studies revealed that although the inferior rectus is most commonly involved, every extraocular muscle, including the levator palpebrae, can be affected. The immunology of dysthyroid eye disease still complex. This case suggests that TED can significantly affect any muscle in the orbit, causing many unique symptoms and clinical presentations.

Adverse effects of hyperthyroidism therapies: insights from a clinical cohort

Raida Ben Salah[1], Faten Hadj Kacem[1], Nabila Rekik[1], Mohamed Abid[1] & Sameh Marzouk[1]
[1]University of Sfax, Internal Medicine, Sfax, Tunisia

Introduction
The treatment of hyperthyroidism often involves antithyroid drugs (ATDs), radioactive iodine therapy (RIT), and surgery. Although effective, these therapeutic approaches can lead to complications that impact patient outcomes. This study aims to describe and analyze the complications associated with hyperthyroidism treatment in our cohort.
Materials and Methods
We conducted a retrospective analysis of patients treated for hyperthyroidism in our center. Data on treatment-related complications, including their nature, onset, and outcomes, were collected and analyzed.
Results
31 patients were diagnosed with hyperthyroidism. Eleven patients had received treatment with synthetic antithyroid drugs alone. Seventeen patients were treated with radioactive iodine. Of these, 8 were initially treated with RIT and was used after failure of ATDs or intolerance to in 9 patients. A second course of RIT was indicated in 2 patients. Only one patient had a total thyroidectomy. Surgical treatment was indicated in view of resistance to TSA, poor socioeconomic conditions, association with T1DM and the patient's young age. Leukopenia secondary to ATDs was observed in one patient, requiring discontinuation of the therapy and initiation of RIT. Iatrogenic hypothyroidism occurred in 15 patients. Among these, 12 cases were attributed to RIT, with a mean time to onset of 3 years (extremes: 5 months to 6 years). Two cases followed ATD therapy, with a mean onset time of 2.5 years (extremes: 1.5 to 3.5 years). One case resulted from total thyroidectomy. ANCA-associated vasculitis was reported in two patients treated with benzylthiouracil (Basdene). One case resolved favorably, while the other resulted in a fatal outcome.
Conclusion
Treatment-related complications in hyperthyroidism range from manageable conditions, such as hypothyroidism, to severe and potentially fatal outcomes like ANCA-associated vasculitis. These findings underscore the need for careful patient monitoring and the selection of tailored therapeutic strategies to minimize risks and optimize outcomes.

Siblings sharing disorder; familial papillary thyroid carcinoma

Azri Sgery[1], Sardar Arif[1], Bayar Qasim[1] & Rezvan Abduljabbar[1]
[1]University of Duhok-College of Medicine, Duhok, Iraq

Introduction and Background
Papillary thyroid carcinoma (PTC), a form of well differentiated thyroid cancer, is a slow growing tumor and the commonest form of thyroid cancer in clinical practice, accounting for 80% of all thyroid cancers. Here we describe a case series of a one female sibling being diagnosed with Familial Papillary Thyroid Cancer after being symptomatic for a couple of months. After the surgery, other siblings did investigations and four others were diagnosed and treated for similar condition.
Case discussion
A 42 years old, married female was diagnosed as a case of FPTC. She is the oldest siblings to family of six siblings. The condition started with very delicate, pinpoint nodule in her neck that was associated with an irritating cough interfering with sleep and itching over the nodule. Later, as the mass was increasing in size, the patient started to complain of shortness of breath mainly at night the overall condition was associated with weight gain, heat intolerance, repeated miscarriage, generalized body swelling, palpitation, visual disturbance and double vision, and hair loss. Fine Needle Aspiration Cytology was not possible until 2 years has passed over symptoms. Later on, her siblings where diagnosed with FPTC following that by couple of years. The family has the history of Radiation exposure.

Immunotherapy-associated thyroid dysfunction during breast cancer treatment

Iulia Alexandra Pirga[1]
[1]University of Medicine and Pharmacy, Medicover, Craiova, Romania

Background
The discovery of immune checkpoint inhibitors (ICIs), such as anti-PD-1/PD-L1 and anti-CTLA-4 antibodies, has vastly improved survival outcomes among patients diagnosed with triple-negative breast cancer. However, immunotherapy is associated with immune-related adverse effects (irAEs), among which thyroid dysfunction is one of the most common. Understanding the clinical presentation and management of immunotherapy-associated thyroid dysfunction is of utmost importance.
Case Presentation
We report the case of a 50-year-old female with triple-negative breast cancer who developed thyroid dysfunction following treatment with pembrolizumab, an anti-PD-1 inhibitor. Paradoxically, the patient was asymptomatic, except for persistent fatigue which she believed was a frequent side effect of the treatment. Laboratory results revealed an elevated TSH of 195 μIU/ml and suppressed free T4 of 1.30 pmol/l, consistent with severe hypothyroidism, while thyroperoxidase antibodies (TPOAb) and thyroglobulin antibodies (TgAb) were negative. Thyroid ultrasonography showed diffuse heterogeneity and almost no vascular flow. She was started on levothyroxine therapy with gradual dose escalation. The oncologist decided to continue immunotherapy despite thyroid dysfunction and suggested close monitoring of thyroid function and symptom management.
Discussion
This case highlights the importance of thyroid function evaluation during immunotherapy treatment, even in the absence of clinical manifestations. A multidisciplinary approach is needed in order to optimize patient care and outcomes.
Conclusion
Immunotherapy-related thyroid dysfunction is a manageable irAE than can occur during breast cancer treatment. It is important to implement routine thyroid function monitoring as part of the clinical management of patients undergoing immunotherapy. With appropriate diagnosis and timely intervention, clinicians

can effectively reduce the impact of thyroid dysfunction on the patient's overall treatment protocol and quality of life.

An uncommon cause of hyperthyroidism - gestational trophoblastic neoplasia

Zhi Wen Loh[1]
[1]Tan Tock Seng Hospital, Singapore, Singapore

A middle-aged female (gravida 6, para 5) presented at 12 weeks amenorrhoea to the emergency department for persistent nausea and vomiting in pregnancy. Previous pregnancies had been uneventful. She described palpitations, which led to the discovery of hyperthyroidism in pregnancy. A trans-vaginal ultrasound revealed a bulky uterus with complex echogenic endometrial mass containing multiple small cystic areas. Hyperthyroidism was attributed to markedly elevated β-HCG from gestational trophoblastic disease. She underwent urgent dilatation and curettage after medical optimization and under close peri-operative monitoring. Thyroid function normalized within a few short weeks. β-HCG levels showed good early response with sharp decline over the first 2 weeks. However, the figure then plateaued above 10000 IU/l, leading to suspicion of persistent disease and gestational trophoblastic neoplasia. Imaging with computed tomography showed multiple pulmonary nodules and she was commenced on chemotherapy thereafter.

Evolutive aspects of SUBCLINICAL hypothyroidism

Wided Debbabi[1], Mouna Elfarouki[1], Hajer Marzouk[1], Samah Allous[1] & Issam Kharrat[1]
[1]Ibn Aljazzar University Hospital, Faculté de Médecine de Sousse, Endocrinology Departement, Kairouan, Tunisia

Subclinical hypothyroidism (SCH) is most often diagnosed incidentally, and raises the question of the treatment indication. The aim of this study was to describe the progressive profile of sch and to identify the factors associated with the absence of spontaneous normalization of the thyroid function.

Methods

Longitudinal study of a retrospective cohort of 69 patients with SCH defined by normal FT4 and TSH $>$ 4mUI/l. Patients were subdivided into two groups according to the spontaneous normalization or non-normalization of thyroid function during follow-up.

Results

The study population was composed of 57 women and 12 men, of mean age of 42.3 $\pm$ 15.8 years. After a mean follow-up time of 19,6 $\pm$ 15.1 months, thyroid function normalized spontaneously in 18 patients (26% of cases). the mean time to normalization of thyroid function was 9,8 $\pm$ 4,2 months. Absence of spontaneous normalization of thyroid function was inversely correlated with FT4 level $P = 0.04$). ATPO positivity was statistically different between groups ($P = 0.01$). ATPO levels were significantly higher in the absence of spontaneous normalization of thyroid function (589.7 $\pm$ 607.7 IU/l vs. 112.1 $\pm$ 54.8 IU/l, $P = 0.01$) and was associated with high prevalence of evolution to an overt hyperthyroidism. TSH level was non-statistically different ($P = 0.2$). Age, gender, presence of symptoms of hypothyroidism and presence of goiter on cervical ultrasonography were not associated with the progression of the SCH in our study

Discussion and Conclusion

Spontaneous normalization of thyroid function was observed in almost a quarter of patients with SCH. A lower FT4 rate, the positivity of ATPO were associated with absence of spontaneous normalization of thyroid function. A Higher rate of ATPO was associated with progression to overt hypothyroidism requiring close monitoring in these patients

Would you miss a thyroid storm in acute setting?

Furhana Hussein[1], Suzane Cadiz[1], Lina Eltayieb[1], Aylin Can[1] & Gideon mlawa[1]
[1]Barking, Havering, and Redbridge University Hospitals NHS Trust, Romford, United Kingdom, London, United Kingdom

Introduction

Thyrotoxicosis is one of the most common endocrine disorders and in its severe form can manifest as a thyroid storm in an acute setting leading to organ dysfunctions including heart failure.

Case Presentation

A 50-year-old man presented to the emergency department (ED) with a 3-week history of weight loss, palpitations, tremors, breathlessness, and leg swelling. He was initially discharged from the hospital with furosemide as a suspected diagnosis of heart failure. Chest-X-ray on admission demonstrated clear lungs fields. An echocardiogram after admission demonstrated normal left ventricular function (LVEF $>$ 55%), normal right ventricular function, mild MR and Pasp 22-27 mmHg. He was initially discharged with furosemide as a suspected diagnosis of heart failure. Patient remained feeling unwell and his GP performed further blood tests which showed a suppressed TSH and a free T4 $>$ 100, T3 35. ALT 53, Calcium 2.72. He was subsequently referred to the Acute Medicine Department at Queens Hospital. Upon review, there were clear symptoms of thyrotoxicosis. His lower limb swelling had improved with the furosemide prescribed previously. His Burch-Wartofsky Score was 30 suggestive of impending thyroid storm. The case was reviewed by an endocrinologist and the following medications were commenced:

- 4g once daily Cholestyramine 2weeks
- 30 mg Prednisolone 5days (following stat-dose hydrocortisone 100 mg IV in ED)
- 20 mg twice daily Carbimazole
- 20 mg three times a day Propranolol (following stat-dose 40 mg in ED)
- Furosemide 40 mg once daily

He was followed up in the Endocrine clinic and his symptoms had improved

Discussion

Thyrotoxicosis is a life-threatening complication of hyperthyroidism, clinically it is manifested as thyroid storm and triggered by a secondary external event such as infection, myocardial infarction, trauma or surgery. It is crucial to identify the underlying aetiology leading to the severe clinical manifestation of thyroid storm to start appropriate treatment. The consequence of delayed diagnosis and lack of correct treatment can lead to further complication such as delirium, thromboembolic disease, cardiovascular collapse and eventually death. Currently, the Burch Wartfosky point scale is used to diagnose thyroid storm. A score greater than or equal to 45 aligns with a clinical diagnosis of thyroid storm.

Conclusion

Thyroid storm is a medical and an endocrine emergency and appropriate and timely treatment will ensure better patient care and outcomes. In an emergency like acute thyrotoxicosis or thyroid storm, higher doses of antithyroid medications, beta-blockers as well as glucocorticoids can be used to return the patient to a euthyroid state.

Internet searches for thyroid disease and impact of the world thyroid day – a global overview and a local one for Greece

Christos Savvidis[1], Efthymia Kallistrou[1], Vassiliki Tsiama[1] & Ioannis Ilias[1]
[1]Hippokration General Hospital, Department of Endocrinology, Athens, Greece

Introduction

Thyroid diseases are a significant global health concern, affecting millions of people worldwide. Despite their prevalence, public awareness and understanding of these conditions are often limited. World Thyroid Day (WTD), observed annually on May 25th, is a significant event, conceived to raise awareness about thyroid health and the various diseases related to the thyroid gland. The importance of such an awareness day lies in its potential to educate the public, encourage prevention and early detection, and provide a platform for advocacy and support. The rise of the internet and search engines like Google has

transformed the way people seek health information. This study aims to explore the global and Greek Google search trends for thyroid disease, providing insights into public interest and awareness.
Aim
The primary aim of this study is to analyze the volume and patterns of Google searches related to thyroid disease globally and in Greece.
Method
The study used a retrospective observational design, using Google Trends data from 2008 to 2024. The search term "thyroid" (along with its Greek translation) was used for internet searches worldwide and also focused on Greece, as obtained from Google Trends. The results were broken into time periods, which were dictated by changes in Google's algorithms. Analyses of the relevant internet search interest for May (month of the WTD) vs all the other months per year, as well overall over time, were done with the Chi square and Pearson's test, respectively.
Results
Internet searches in months with WTDs were on a par with other months. Worldwide, a negative trend in internet searches (2008-2015) was followed by a positive one (2016-2019), whereas in Greece, trends were positive (2011-2015, for searches in English, 2016-2019, for searches in Greek and 2022-2024 for searches in both languages).
Discussion
An increase in searches related to thyroid health, symptoms, treatments, and related topics could suggest that the awareness campaign has successfully reached a significant number of people and prompted them to seek more information, regardless of the fact that searches were not numerous in months with WTDs. However, while changes in Google searches can provide valuable insights, they should be used in conjunction with other indicators. This is because not all people who become aware of thyroid health issues will turn to Google for more information. Furthermore, an increase in searches does not necessarily translate into changes in health behaviors or improvements in health outcomes.

Asymptomatic riedel's thyroiditis: a case report

Amal Riad[1], Kaoutar Rifai[1], Iraqi Hinde[1] & Mohamed Elhassan Gharbi[1]
[1]Ibn Sina Institution, Rabat, Morocco

Introduction
Riedel's thyroiditis is a rare form of chronic thyroiditis. It is characterised by extensive infiltrative fibrosis of the thyroid and adjacent organs. The aetiopathogenesis has not yet been elucidated. Diagnosis is anatomopathological.
Case Report
56-year-old female with known diabetis type 2 for 3 months on OAD. Consulted for an anterior basi-cervical swelling, hard, evolving for 1 year without signs of compression. Biologically, she presents with hypothyroidism. Morphologically, a cervical ultrasound showed a lesional process infiltrating the sternohyoid muscle. A thyroid biopsy confirmed the diagnosis of Riedel's thyroiditis. A CTAP scan ruled out other areas of fibrosis outside the thyroid. The patient was put on corticosteroids.
Discussion
Riedel thyroiditis (RT) represents the classic thyroid form of IgG4 disease. It involves the production of autoantibodies, the exact nature of which remains unclear, which activate B lymphocytes, leading to two distinct immunological responses. In the presence of IL-4 and IL-10 factors from a T helper lymphocyte, the B lymphocyte differentiates into an IgG4-secreting plasma cell. This IgG4, which can be measured in plasma circulation, does not appear to have any immunogenic potential and is only an indirect marker of the infiltrative process caused by the second type of immunogenic response mediated by CD4+ cytotoxic T lymphocytes, leading to the proliferative and/or fibrosing process of IgG4 disease, and therefore to the known clinical manifestations, including TR. In this case, impairment of thyroid and/or parathyroid function depends on the extent of infiltration and thyroid comorbidities (1).
Conclusion
As TR is not yet fully understood, the therapeutic approach remains empirical and imperfect. Corticosteroid therapy is effective in the constitutive phase of the disease, but its value beyond this is more controversial. Tamoxifen is a good alternative. Surgery may be indicated in cases of compression.

Feisty hyperplasia - a case of aggressive parathyroid hyperplasia

Dominic Oduro-donkor[1], Zehra Irshad[1], Puja Thadani[1], Manoj Dodiya[1], Narasimha Murthy[1], Timothy Robbins[1] & Ranganatha Rao[1]
[1]University Hospital Coventry and Warwickshire, WISDEM, Coventry, United Kingdom

Background
Parathyroid adenoma and hyperplasia are common causes of hyperparathyroidism, with solitary adenomas accounting for 85% to 90% of cases, while multiple gland hyperplasia constitutes approximately 10% to 15%. These typically result in moderately elevated PTH levels compared to carcinomas, which can reach significantly higher levels. Here, we present a case of aggressive parathyroid hyperplasia with severely elevated PTH.
Case Summary
An 86-year-old woman presented to the Emergency Department with drowsiness, weakness in her legs, polyuria, and abdominal pain. She had a history of longstanding constipation and unintentional weight loss, which the surgical team had already investigated; a CT scan of the thorax, abdomen, and pelvis ruled out malignancy. Initial investigations revealed severe hypercalcaemia (serum adjusted calcium 4.48 mmol/l, reference range 2.17 – 2.56 mmol/l) and hypokalaemia (serum potassium 2.4 mmol/l, reference range 3.5 – 5.3 mmol/l). The ECG was unremarkable. Work-up for hypercalcaemia indicated raised PTH-191.7 pmol/l (2.0-8.5), with normal inorganic phosphate at 1.02 mmol/l (0.8 – 1.5). Daily serum-adjusted calcium monitoring demonstrated a rising trend, reaching up to 5.11 mmol/l. She was treated with IV fluids, dexamethasone, zoledronic acid, and calcitonin. A CT scan and ultrasound of the neck revealed a 2.8 cm mass at the posterolateral aspect of the left thyroid nodule, with no lymphadenopathy, raising suspicion for parathyroid carcinoma as the primary differential. She was referred to the Parathyroid MDT and underwent an urgent parathyroidectomy. Surgery revealed left-sided superior and right inferior parathyroid lesions. Intraoperative PTH was 49.5 pmol/l and exploration for ectopic parathyroid tissue was undertaken, but none was found; immediate postoperative PTH was 25.3 pmol/l. Histopathology confirmed two glands of parathyroid hyperplasia with no evidence of malignancy. She was alert to time, place, and person post-surgery, achieving a GCS of 15/15. Her serum-adjusted calcium and PTH levels gradually normalised, leading to her discharge.
Conclusion
Such high PTH levels in parathyroid adenomas (PA) are rare and typically associated with parathyroid carcinoma. This case encourages consideration of suspected parathyroid carcinoma; however, it was ultimately determined to be (2-gland) parathyroid hyperplasia (PH). Genetic mutations, particularly MEN1 and cyclin D1, are noted in PH and PA; however, our patient did not have a known family history, so further genetic testing has been deferred.

JOINT1629

Nes-onset diabetes as a potential clue to the early diagnosis of pancreatic cancer

Natia Margvelashvili[1], Nino Zavrashvili[1] & Natia Shonia[1]
[1]Tbilisi Institute of Medicine, Tbilisi, Georgia

Introduction
Pancreatic cancer is the fourth leading cause of cancer death in the United States and the fifth leading cause of cancer death in Europe. It has a dismal five-year survival of 5%, primarily related to the fact that disease-specific symptoms occur late in the course of the disease; at the time of diagnosis, 50% have distant metastases, 29% have local and/or regional spread, and only 3% have tumors confined to the pancreas (19% remain unstaged/unknown). By the time of diagnosis $<15\%$ of patients have surgically resectable disease. The median survival of unresectable pancreatic cancer is 4–6 months. While the overall 5-year survival of resected pancreatic cancers (median size 32 mm) is 10–20%, it is 30–60% after resection of small pancreatic cancer (tumor size ≤ 20 mm) and it exceeds 75% when minute pancreatic cancers (≤ 10 mm in size) are resected. While future treatment advances may improve survival, the above noted statistics imply that, in order to substantially impact long-term survival, we will need to detect pancreatic cancer earlier.
Case report
We present a case of a 69-year-old women with strong family history of diabetes. Previous laboratory tests revealed negative anti-pancreatic antibodies and diagnosis of type 2 diabetes was considered. The patient was treated by metformin and gliclazide continued to loose weight. Considering high suspicion for type 1 diabetes patient was switched to basal-bolus insulin therapy. Patient had

unmanaged glucose values and insulin regimen was adjusted according to our recommendations. 2 years after initial diagnosis of diabetes patient was evaluated by internal medicine specialist due to new onset of jaundice. Locally advanced Pancreatic adenocarcinoma was diagnosed and corresponding treatment was initiated.

Conclusion

Patients with pancreatic cancer often have new-onset diabetes which resolves with cancer resection. New-onset diabetes not only defines a high-risk group for pancreatic cancer but is also a marker of early, asymptomatic cancer. Its occurrence in nearly half the patients with pancreatic cancer makes it an attractive screening target for early pancreatic cancer. This observation argues among several mechanisms explaining diabetes in subjects with pancreatic cancer, in favor of tumor-derived diabetogenic substance and suggests that diabetes mellitus could reveal pancreatic cancer even in the presence of conventional risk factors of type 2 diabetes.

A case of newly diagnosed thyroid hormone resistance syndrome in singapore

Mark Poh[1] & Abel Chen[1]
[1]Tan Tock Seng Hospital, Endocrinology, Singapore, Singapore

A 23 year-old Chinese lady was referred to the Endocrinology clinic by her primary care physician for hyperthyroidism in July 2024. She had reported 1 year history of worsening anterior swelling and palpitations. Her free thyroxine (fT4) was noted to be persistently elevated on different assay platform since 2017, with an inappropriately high-normal Thyroid Stimulating Hormone (TSH) level (see Table 1). Her primary care physician started her on carbimazole 2.5 mg OM in June 2024 prior to the Endocrinology review. On examination, her weight was 41.8kg (stable for the past few years) with a blood pressure of 89/75 mmHg, heart rate 75/min (regular). She had a moderate diffuse goiter, but no tremors and no proptosis. Her carbimazole was stopped and she underwent additional investigations. Of note, a fT4 by equilibirum dialysis was raised at 3.2 ng/dl (RR 0.8 - 2.0) and an alpha subunit /TSH molar ratio was 1.587. An MRI Pituitary showed no pituitary adenoma. A Thyrotropin Releasing Hormone stimulation test demonstrated a large rise in TSH from 2.92 (0 min) to 24.54 (60 min). Her parents (patient is an only child) had their thyroid function tested and were normal. Genetic testing later revealed a heterozygous mutation in the THRB gene (p. Pro453Thr alteration pointing to the diagnosis of Resistance to Thyroid Hormone Beta. The patient was subsequently managed with propranolol 10 mg TDS PRN for control of her palpitations and remains on follow-up with our clinic.

JOINT2024

Elevated calcitonin in the absence of medullary thyroid carcinoma: a diagnostic challenge

Aiste Stonyte[1], Emilija Tumenaite[1] & Laura Daugintyte-Petrusiene[1,2]
[1]Lithuanian University of Health Sciences, Kaunas, Lithuania; [2]Hospital of Lithuanian University of Health Sciences Kaunas Clinics, Endocrinology, Kaunas, Lithuania

Introduction

Calcitonin (CT) is essential for diagnosing medullary thyroid carcinoma (MTC), with levels >100 pg/ml being highly predictive, though elevated CT is not a pathognomonic factor of MTC. Hypercalcitoninemia has also been linked to conditions like hypercalcemia, hypergastrinemia, renal insufficiency, neuroendocrine tumors, other thyroid carcinomas, prolonged use of certain medications. Chronic autoimmune thyroiditis (AIT) may elevate CT, but its impact on hypercalcitoninemia is unclear. Investigating slightly elevated CT is important for determining treatment, whether monitoring thyroid-related disorders, addressing malignancies or benign conditions like AIT.

Case

A 22-year-old female (BMI 40.9) visited an endocrinologist due to hypercalcitoninemia found after detailed laboratory blood tests performed at the patient's initiative. Family history: thyroid disease, diabetes. In 2023, neck ultrasound showed normal-sized hypoechogenic thyroid with heterogeneous structure, connective tissue degeneration, normal blood flow. No pathological lymph nodes were observed. Both in 2023 and 2025 performed neck ultrasound suggested AIT. In 2025, the patient's thyroid fulfilled EU-TIRADS 2 criteria. Laboratory tests showed fluctuating CT levels from year 2023 to 2025 from 7.02 to 30.07 pg/ml (n. r.<5.89, Table 1). Following tests were within reference ranges: TSH, FT4, FT3, anti-TPO, anti-Tg, anti-TSRH, CEA. Due to low vitamin D (35.5 nmol/l, n. r.125-150), vitamin D3 was taken at 8000 IU/day for 3 months, then reduced to 4000 IU/day permanently. Since anti-TPO and anti-Tg antibodies were within normal limits, elevated CT cannot be linked to AIT. With no clinical signs of thyroid dysfunction, no treatment was prescribed. Blood calcium level, other electrolytes examined were within normal limits. No changes were observed on chest X-ray and abdominal ultrasound. Tests for adrenal conditions detected no pathology. Consequently, other endocrinological causes of hypercalcitoninemia were excluded. Currently, the patient is diagnosed with non-toxic multinodular goiter. Check-up is recommended after 6 months.

Table 1. CT levels

Date	03/2023	08/2023	03/2024	09/2024	01/2025
CT, pg/ml	20.51	7.02	15.00	30.07	20.16

Discussion

This case emphasizes the need to consider both common and rare causes and conduct a thorough evaluation when managing hypercalcitoninemia. Elevated CT levels should be assessed within the full clinical context. An aggressive approach may be unnecessary in patients with marginal increase in CT levels after excluding causes of hypercalcitoninemia demanding specific treatment. Adequate follow-up with serum CT measurement and thyroid ultrasound can prevent missing clinically significant MTC.

Corticosteroid therapy in dysthyroid orbitopathy: tolerance and therapeutic efficacy

Doaa El Bazi[1], Nassim Essabah Haraj[1], Siham El Aziz[1] & Chadli Asma[1]
[1]UHC Ibn Rochd, Department of Endocrinology, Metabolic Diseases and Nutrition, Casablanca, Morocco

Introduction

Corticosteroid therapy is a cornerstone in the treatment of active and moderate to severe forms of dysthyroid orbitopathy (DO) due to its powerful anti-inflammatory and immuno-suppressive effect

Materials and methods

This retrospective study included 79 patients managed in the endocrinology, diabetology, metabolic diseases and nutrition department of CHU Ibn Rochd in Casablanca, between 2012 and October 2024.

Results

The mean age of patients was 56.7 ± 14 years, with a male predominance (67%), with an F/H sex ratio of 0.49. Bilateral involvement was found in 80% of cases, with asymmetry in 20%. The average duration of OD was 8 ± 5 months. The onset

of DO coincided with Graves' disease in 42 patients, occurred after Graves' disease in 33, and preceded Graves' disease in 3 cases. Oral corticosteroid therapy was initiated in 6 patients with mild DO, at a dose of 20 to 30 mg/day for 3 months, with gradual tapering off. Intravenous corticosteroid therapy was administered in 69 of our patients (87%) with moderate to severe active forms, according to 3 protocols Protocol 1: a bolus of 500 mg/week for 6 weeks, followed by a bolus of 250 mg/week for 6 weeks, with a cumulative dose of 4.5g in 51 patients (74%). Protocol 2: a bolus of 750 mg/week for 6 weeks, followed by a bolus of 500 mg/week for 6 weeks, for a cumulative dose of 7.5g in 12 patients (17%). Protocol 3: a bolus of 1g/day for 3 consecutive days, at weekly intervals, followed by 500 mg/week for a cumulative dose of <8g in 6 patients (9%). With regard to the reasons for discontinuation of intravenous corticosteroid therapy, 7 patients developed keratitis, 2 conjunctivitis, 1 hepatic cytolysis, 4 infections (tuberculosis, syphilis, pulmonary infection), and 4 were lost to follow-up. Clinical improvement was objectified by improvement in functional signs with a reduction in the Mourits score from 4 before treatment to 2 after, with a significant improvement in patients' quality of life.

Conclusion

Corticosteroid therapy, particularly in its intravenous form, is an essential pillar in the management of active forms of DO, offering significant improvement in symptoms when used in an adapted and supervised manner.

When a hot nodule turns out to be an oncocytic carcinoma

Chaimae Taleb[1], Nada Ait kassi[1], Kaoutar El Moatamid[1], Zineb Habbadi[1], Ghizlane Sabbar[1], Fatima Toulali[1], Kaoutar Rifai[1], Hind Iraqi[1] & Mohamed El Hassan Gharbi[1]

[1]CHU Ibn Sina Endocrinology University of Mohammed V, Rabat, Morocco

Introduction

Oncocytic carcinoma is a rare form of thyroid cancer that develops from oncocytic cells, a specialized form of follicular thyroid cells. Representing only 4% of thyroid cancers, it is known for its more aggressive nature, with high potential for lymphatic and distant metastasis, requiring early treatment with regular monitoring to improve prognosis. Its detection as a hot nodule is exceptional, as it is most often considered a benign lesion.

Case report

We report the case of a 69 years old female patient with a medical history of type 2 diabetes treated with metformin, sulfonylurea, and basal insulin, hypertension treated with Ramipril, and dyslipidemia treated with simvastatin, followed for a multinodular goiter. The cervical ultrasound revealed an enlarged thyroid gland (58 ml) with several nodules, the most concerning being in the right upper pole, measuring 10x17 mm, classified as EUTIRADS IV. The biological assessment showed a low-normal TSH, and the additional thyroid scintigraphy with Tc99m revealed a large goiter predominantly on the left, with two hot nodules, one of which was a medium-sized apical nodule on the right. The patient underwent a total thyroidectomy, and the histopathological examination revealed the presence of an oncocytic carcinoma in the right lobe of the thyroid, with vascular emboli, classified as PT2NxMx. A follow-up high-dose radioactive iodine therapy was advised. The patient is currently receiving suppressive hormone therapy with levothyroxine.

Discussion and Conclusion

Thyroid cancers most often present as a cold nodule, and only 3% of cases present as a hot nodule. Fine needle aspiration of the latter is not recommended due to its low malignancy rate. However, it is crucial not to rule out the possibility of thyroid cancer and to inform the patient about the risk of its occurrence. The oncocytic form found in our patient remains even rarer, with few cases reported in the literature. Curative treatment involves total thyroidectomy which decreases the risk of recurrence and allows for postoperative monitoring of thyroglobulin levels, an essential marker for recurrence of oncocytic carcinoma. Additionally, if lymph nodes are clinically positive, a therapeutic neck dissection of the central and lateral compartments is indicated. In contrast to other types of thyroid cancer, oncocytic carcinoma has a reduced capacity for radioactive iodine uptake, making it less suitable for this treatment. However, newer therapies, including tyrosine kinase inhibitors, may be considered.

Growth challenges in congenital athyreosis: a case report and endocrine insights

Hajar Azagouagh[1], Karimi Meryem[1], Fatima Toulali[1,2], Rifai Kaoutar[2], Hinde Iraqi[1] & Mohamed El Hassan Gharbi[1]

[1]CHU Ibn Sina, Rabat, Morocco; [2]CHU Ibn Sina, Rabat, Morocco

Introduction

Congenital athyreosis is a major cause of neonatal hypothyroidism. Early treatment with L-thyroxine helps prevent severe complications. However, growth disorders may persist despite appropriate management.

Case Report

This is the case of an 11-year-old girl, the eldest of three siblings, born to non-consanguineous parents. The pregnancy was well-monitored and carried to term, with a birth weight of 4.5 kg. A prolonged neonatal jaundice was reported. Congenital hypothyroidism due to athyreosis was diagnosed at 4 months of age. The patient has been on L-thyroxine (62.5 µg/day). The clinical course was marked by growth stagnation over the past two years. Clinical examination revealed a weight of **24 kg (-2 to -3 SD)**, a height of **130.5 cm (-2 SD)**, and an estimated **target height of 161 cm** (1.5 growth channels below the expected range). Pubertal assessment showed **an infantile vulva, Tanner stage 1**. An endocrine and etiological workup was conducted, showing:

- **Karyotype**: Normal
- **8 AM cortisol levels**: Normal
- **Malabsorption screening**: Microcytic anemia, managed with iron supplementation
- **Anti-transglutaminase antibodies**: Negative
- **Liver and kidney function tests**: Normal
- **IGF-1 (Z-score)**: -0.39
- **TSH**: 6.04 mUI/l
- **Bone age**: 10 years and 3 months

Brain MRI revealed a **partial sellar arachnoidocele** with **reduced anterior pituitary volume**. A dynamic insulin-induced hypoglycemia test showed an adequate response, ruling out the need for growth hormone therapy. Under regular follow-up, an improvement in auxological parameters was observed.

Discussion

Congenital athyreosis results from a complete absence of the thyroid gland, confirmed by imaging (ultrasound and scintigraphy). It accounts for approximately **30% of congenital hypothyroidism cases**. Early diagnosis and prompt initiation of replacement therapy help prevent severe complications, particularly **irreversible intellectual disability and growth retardation**. In our case, the diagnosis was made at 4 months, which is late compared to **neonatal screening recommendations**, but still allowed the prevention of major sequelae.

Conclusion

This case highlights the importance of **regular monitoring** in patients with congenital athyreosis. Growth stagnation should prompt a **comprehensive endocrine evaluation** to differentiate between constitutional delay and an underlying pathology requiring specific management.

Brain metastasis in a patient with oncocytic thyroid carcinoma

Małgorzata Czetwertyńska[1], Olga Wajtryt[1], Andrzej Kowalczyk[1], Elwira Bakuła-Zalewska[2], Aleksandra Budrewicz[3], Tomasz Mandat[4] & Marek Dedecjus[1]

[1]Maria Sklodowska-Curie National Research Institute of Oncology, Department of Endocrine Oncology and Nuclear and Nuclear Medicine, Warsaw, Poland; [2]Maria Sklodowska-Curie National Research Institute of Oncology, Department of Pathology, Warsaw, Poland; [3]Maria Sklodowska-Curie National Research Institute of Oncology, Department of Radiology, Warszawa, Poland; [4]Maria Sklodowska-Curie National Research Institute of Oncology, Department of Neurosurgery, Warsaw, Poland

Introduction

Differentiated thyroid cancer has a good prognosis and survival rate. Oncocytic thyroid cancer (formerly known as Hürthle cell carcinoma) is generally considered to be less radioiodine-avid compared to other types of differentiated thyroid cancers. Clinically, oncocytic thyroid cancer is characterized by a higher incidence of locoregional recurrence than follicular thyroid cancer (FTC) and a higher incidence of distant metastases than in papillary thyroid cancer (PTC). Metastases of thyroid cancer to the brain are extremely rare and are usually associated with other typical metastatic locations (lung and bone).

Case Report
We present the case of a patient with a more than 50-year history of thyroid cancer. In 1969, the patient, then 17 years old, underwent a strumectomy for goiter. The documentation contained information about a Hürthle cell adenoma. Seven years later, in 1976, a total thyroidectomy was performed, and in the same year, chemotherapy was started in the Department of Haematology and Oncology. Between 1976 and 1977, the patient received chemotherapy based on 5-fluorouracil, cyclophosphamide, and doxorubicin for 16 months. In 1977, the patient underwent diagnostic scintigraphy with radioiodine I-131—no radioiodine uptake was visualized. Three years later, in 1981, a chest X-ray described multiple lung tumors that persisted for almost 20 years without treatment. In 2023, 54 years after the initial diagnosis, an MRI was performed after the onset of neurological symptoms and showed a lesion in the left occipital region measuring 60×42×52 mm. A craniotomy was performed and the tumor was removed; the course of the operation was complicated by a hematoma, and a reoperation was performed on day 2. A histopathological examination confirmed metastatic thyroid carcinoma from Hurthle cells. This was followed by radiotherapy to the locoregional area, with a total dose of 3000 cGy. Subsequently, treatment with radioiodine I-131 was carried out twice (total activity of 7,4 GBq). Posttherapeutic scintigraphy showed no uptake in the brain region and revealed pathological uptake in numerous diffuse foci in both lungs confirmed in CT scan of the chest. The patient remains in good condition, ECOG 1, without neurological symptoms.
Conclusions
The atypical course of the disease indicates a generally good prognosis in thyroid cancer, a slowly progressive course of lesions, and the possibility of metastasis many years after the initial diagnosis. CNS metastasis is rare, but should always be considered, especially if other lesions coexist.

A challenging etiological diagnosis of hypothyroidism following pazopanib treatment

Mohamed Khairi Arous[1], Bchir Najla[1], Roua Mankai[1], Anaam Ben Chehida[1], Chedia Zouaoui[1] & Haroun Ouertani[1]
[1]The Military Hospital of Tunis, Endocrinology, Tunis, Tunisia

Introduction
Hypothyroidism is a common endocrine disorder characterized by a wide range of etiologies, predominantly autoimmune causes in adults. While the etiological diagnosis is often straightforward, it can occasionally pose a challenge, particularly in cases of multiple or complex etiologies. We report the case of a patient presenting with peripheral hypothyroidism associated with pazopanib treatment.
Case Report
A 55-year-old woman, followed for 4 years for renal carcinoma with pulmonary metastases, treated with pazopanib (800 mg/day) for 13 months, presented with fatigue, hoarseness, and memory disturbances. Hormonal evaluation revealed a TSH level of 22 mIU/l and an FT4 level of 4 pmol/l, confirming peripheral hypothyroidism. Physical examination showed no goiter, and thyroid ultrasound revealed an atrophic thyroid gland. Anti-thyroperoxidase antibodies (anti-TPO) were strongly positive. The etiology was debated between atrophic Hashimoto's thyroiditis, a side effect of pazopanib, or a combination of both. Hormone replacement therapy led to clinical and biological improvement.
Discussion and conclusion
Pazopanib, a tyrosine kinase inhibitor targeting tumor growth and pathological angiogenesis, is associated with hypothyroidism in approximately 12% of cases. Proposed mechanisms include thyroid atrophy due to vascular inhibition, drug-induced thyroiditis, interference with iodine uptake, or anti-TPO activity. Paradoxically, cases of pazopanib-induced hyperthyroidism have also been reported, challenging these hypotheses. In this patient, thyroid atrophy and the presence of anti-TPO antibodies, rarely described with pazopanib, suggested Hashimoto's thyroiditis. For other tyrosine kinase inhibitors, such as sunitinib, hypothyroidism has been attributed to drug-induced anti-TPO activity. Regardless of the etiological diagnosis in our patient, the therapeutic approach remains unchanged, given the safety and efficacy of hormone replacement therapy.

Vitiligo and its association with thyroid dysfunction and other autoimmune diseases

Raida Ben Salah[1], Faten Hadj Kacem[1], Zouhir Bahloul[1], Mohamed Abid[1] & Nabila Rekik[1]
[1]University of Sfax, Internal Medicine, Sfax, Tunisia

Introduction
Vitiligo is a chronic autoimmune disorder characterized by the loss of skin pigmentation. It is frequently associated with other autoimmune diseases, including thyroid dysfunction. The objective of this study was to examine the clinical characteristics of vitiligo in relation to thyroid pathology and to investigate its association with other autoimmune diseases.
Methods
The study included 16 patients diagnosed with vitiligo, comprising 13 women and 3 men. The mean age of onset was 33.54 years, with a range from 15 to 68 years. We reviewed the clinical histories of the patients, specifically focusing on the chronological relationship between the onset of vitiligo and thyroid dysfunction. HLA typing was performed in one patient who had both hyperthyroidism and vitiligo.
Results
Vitiligo was associated with hypothyroidism in 10 cases, hyperthyroidism in 4 cases, and euthyroid-phase thyreopathy in 2 cases. In 10 patients, vitiligo preceded the onset of thyroid dysfunction, with a mean delay of 131.75 months (ranging from 12 to 480 months). In 4 patients, vitiligo followed thyroid dysfunction, with a mean delay of 111 months (ranging from 24 to 192 months). In only one patient, vitiligo and thyroid dysfunction were diagnosed concurrently, while the chronology of disease onset was unknown in one case. HLA typing in one patient with hyperthyroidism and vitiligo revealed the haplotype A2, A white, B17, B white (BW6). In addition to thyroid dysfunction, other autoimmune diseases were observed in these patients. These included type 1 diabetes in three cases, lichen planus in one case, Biermer's anemia in one case, alopecia universalis in one case, Sjögren's syndrome in one case, and rheumatoid arthritis in one case.
Discussion
This study highlights the frequent association between vitiligo and thyroid dysfunction. The results suggest a potential bidirectional relationship, with vitiligo either preceding or following thyroid pathology in most cases. The presence of other autoimmune diseases in these patients further supports the autoimmune nature of vitiligo. Additionally, the HLA typing results in one patient point to a possible genetic predisposition for both vitiligo and thyroid dysfunction.
Conclusion
The findings of this study reinforce the association between vitiligo, thyroid dysfunction, and other autoimmune diseases. Clinicians should consider conducting comprehensive evaluations for thyroid and other autoimmune disorders in patients with vitiligo. Further research is needed to explore the genetic, immunological, and environmental factors that contribute to these associations.

Exploring the link between universal alopecia and hashimoto's thyroiditis

Raida Ben Salah[1], Faten Hadj Kacem[1], Nabila Rekik[1], Sameh Marzouk[1] & Zouheir Bahloul[1]
[1]University of Sfax, Internal Medicine, Sfax, Tunisia

Introduction
Universal alopecia is a rare autoimmune disorder often associated with other autoimmune diseases. This study presents two cases of universal alopecia in patients with hypothyroidism, specifically Hashimoto's thyroiditis, highlighting the potential relationship between these autoimmune conditions. **Case 1** The first patient was a 48-year-old man admitted to the endocrinology department of Hedi Chaker University Hospital in Sfax for the management of profound hypothyroidism. The diagnosis of hypothyroidism had been made seven months prior, at the age of 47, following symptoms including psychomotor slowing, hoarseness, fatigue, and a heterogeneous goiter. During hospitalization, the diagnosis of Hashimoto's thyroiditis was confirmed, and the patient was started on levothyroxine therapy. The onset of hypothyroidism occurred 24 years after the development of universal alopecia. **Case 2** The second patient was a 54-year-old woman also hospitalized for the management of hypothyroidism, diagnosed

due to psychomotor slowing and fatigue. She was diagnosed with Hashimoto's thyroiditis and treated with L-thyroxine, showing good clinical and biological improvement. Her hypothyroidism was preceded by two other autoimmune diseases: universal alopecia and vitiligo. HLA typing was performed, revealing haplotype A2, A white, B50, B white (BW6).
Discussion
Both cases suggest a strong autoimmune association between universal alopecia and thyroid dysfunction, particularly Hashimoto's thyroiditis. The presence of other autoimmune diseases such as vitiligo in the second case further emphasizes the autoimmune nature of these conditions. The HLA typing results in the second case suggest a potential genetic predisposition.
Conclusion
This report underscores the need for clinicians to consider the association between universal alopecia, autoimmune thyroid disease, and other autoimmune disorders. Further investigation is needed to better understand the genetic and immunological factors involved in these co-occurring conditions.

Morphea and papillary thyroid carcinoma

Fourat Amor[1], Sarra Saad[1], Maha Lahouel[1], Oumaima Belhadj[1], Ghada Saad[2], Jacem Rouatbi[1], Mohamed Ben Rejeb[1], Nadia Ghariani[1], Marwen Ben Kahla[1], Sana Mokni[1], Amina Aounallah[1], Najet Ghariani[1] & Mohamed Denguezli[1]
[1]Farhat Hached University Hospital, Dermatology, Sousse, Tunisia; [2]Farhat Hached University Hospital, Endocrinology, Sousse, Tunisia

Introduction
Morphea is a rare chronic fibrosing skin disorder. While typically isolated, its occurrence as a paraneoplastic manifestation is uncommon. Here, we present a unique case of morphea associated with papillary thyroid carcinoma.
Clinical case
A 24-year-old woman, presented with facial skin stiffness, tightness, and discoloration persisting for one year. Examination revealed hypopigmented and indurated plaques with a brownish peripheral halo in the subpalpebral region, the cheek and the upper left lip (**Figure 1**). She denied dysphagia and Raynaud's phenomenon. Physical examination showed no sclerodactyly or abnormalities on nail fold capillaroscopy. A skin biopsy confirmed the diagnosis of morphea. Initial treatment with betamethasone 0.05% and tacrolimus 0.1% ointment showed no improvement after three months, prompting a switch to methotrexate (15 mg/week) and prednisone (30 mg/week), which led to slight improvement. Nine months later, she was diagnosed with papillary thyroid carcinoma. She underwent a total thyroidectomy with right recurrent lymph node dissection, followed by radioactive iodine and hormone therapy achieving curative outcomes. Three months later, morphea plaques softened, leaving residual hyperpigmentation (**Figure 2**).
Discussion
Morphea is a rare condition with a lifetime prevalence of 200 per 100,000 and a female predominance (3:1). It progresses through three stages: inflammatory, fibrotic, atrophic. Although primarily considered a skin-limited disorder, morphea can also affect the musculoskeletal and central nervous systems. Its pathogenesis remains unclear, but is thought to involve genetic susceptibility, vascular dysfunction, autoimmune dysregulation, and environmental factors such as viral infections, trauma, radiation, or medications. While systemic sclerosis is associated with an increased malignancy risk, attributed to shared risk factors, chronic inflammation, premature immunosenescence, impaired DNA repair, and therapy-related immunosuppression, data on morphea's risk remains limited. A recent 2024 cohort study identified non-melanoma skin cancer, cervical cancer, breast cancer, stomach cancer, and lung cancer as the most common malignancies following morphea. However, thyroid carcinoma is very rare, with only one case reported in the literature, specifically in a patient with atrophoderma of Pasini and Pierini. Tumor-derived substances such as hormones, cytokines, proteins, and their precursors may activate dermal fibroblasts causing sclerotic cutaneous lesions. In our patient, thyroid cancer diagnosed 9 months after sclerotic skin changes, without systemic involvement, suggested a probable paraneoplastic manifestation.
Conclusion
This case highlights the need for further research into the link between morphea and cancer. Early detection of malignancies allows timely intervention, prevents metastasis, and reduces the healthcare burden, underscoring the importance of close monitoring in patients with morphea.

A Case report: acute suppurative thyroiditis presenting with thyroid abscess

Aslınur Akıncı Altundal[1], Süreyya Hikmet Kozcu[2], Kenan Sakar[1], Neşat Çullu[3] & Gulhan Akbaba[1]
[1]Faculty of Medicine, Mugla Sitki Kocman University, Mugla, Türkiye; [2]Faculty of Medicine, Mugla Sitki Kocman University, Department of Otorhinolaryngology, Mugla, Türkiye; [3]Faculty of Medicine, Mugla Sitki Kocman University, Department of Radiology, Mugla, Türkiye

Introduction
Thyroid abscess is a rare condition that constitutes 0.1-0.7% of all thyroid diseases, usually occurring as a result of acute suppurative thyroiditis (AST), which is an infection of the thyroid gland. The rich blood supply of the thyroid gland, extensive lymphatic drainage, high iodine content, have a protective function against infections.
Case
An 18-year-old male patient presented to the emergency service with complaints of gradually increasing swelling, redness, and pain in the neck for approximately 2 weeks. He had no chronic disease and was not using any medication. Upon palpation of the patient's neck, a painful swelling was detected, and an USG was performed, which revealed a hypodense lesion compatible with an abscess, with lobulated contours of 57x50 mm in size in the midline of the neck. A neck CT was requested for additional pathology, which revealed an abscess within the thyroid parenchyma. Purulent fluid was obtained from the lesion in the emergency by fine needle aspiration, which was confirmed, and a sample was sent for culture and direct examination. Later, incision and abscess drainage were performed. Laboratory values were TSH: 10 (0.27-4.2 μIU/ml), CRP: 85 (0-5 mg/l), ALT: 455 (0-40 U/l), AST: 41 (10-41 U/l), WBC: 24.06×10^3/μL (%74 neutrophil), anti-TPO and anti-thyroglobulin antibodies negative, other values were normal. The patient was started on antibiotherapy (ampicillin sulbactam and metronidazole) with drainage. Viral hepatitis markers were negative. Immunoglobulin (IgG, IgA, IgM) values were normal. Gram positive and gram negative bacteria were seen in the abscess culture, but anaerobic bacteria were considered as the possible agent due to the absence of growth in the aerobic culture. The patient, whose symptoms and infection parameters regressed with treatment, was taken under follow-up.
Conclusion
Adult patients with AST usually have evidence of Hashimoto's thyroiditis or thyroid malignancy. Children with congenital anatomical anomalies such as branchial arch anomaly are at increased risk for AST. In our case, anomaly was investigated due to being in late adolescence, but no pathology was detected. Clinically, fever, neck swelling, sore throat, and difficulty swallowing are present as in our case. Rarely, thyrotoxicosis secondary to destruction can occur. In most cases, the predominant cause among bacterial etiology is Staphylococcus aureus. Treatment includes systemic antibiotic therapy with drainage. Recurrence of the abscess, worsening of symptoms, widespread necrosis may require lobectomy. As a result, although rare, AST and thyroid abscess are possible even in immunocompetent patients without congenital anomaly and thyroid disorder

JOINT155

Parotid metastasis as the first presentation of papillary thyroid carcinoma: a case report

Nouhaila Essafir[1], Siham Malki[1], Ghizlane Sabbar[1], Fatima Toulali[1], Kaoutar Rifai[1], Hind Iraqi[1] & Mohamed El Hassan Gharbi[1]
[1]Ibn Sina University Hospital, Endocrinology and Metabolic Diseases, Rabat, Morocco

Papillary thyroid carcinoma (PTC) is the most common histological type of thyroid cancer. Its spread is mainly lymphatic. Distant metastases are rare and most often affect the lungs, liver and bones. Despite the anatomical proximity of the parotid gland, metastases at its level are extremely rare. The revelation of a PTC by a metastasis of this region remains exceptional.
Observation
57-year-old patient, with no significant history, presenting with a latero-cervical swelling that had been developing for 3 years. Cervical CT scan revealed a right subparotid mass originating from the right sternocleidomastoid muscle, infiltrating the lower pole of the homolateral parotid. The patient underwent resection of the tumor mass and adenopathy of territory IIa, in addition to a right exofacial parotidectomy. The anatomical-pathological and immunohistochemical analysis was in favor of a parotid and lymph node localization of a CPT. The

patient was subsequently referred to our training for further management. The cervical examination was normal, without nodules or adenopathies. The cervical ultrasound revealed a small thyroid. Given the anatomopathological result of the initial surgery, a total thyroidectomy with bilateral recurrent and jugulo-carotid lymph node dissection was indicated and performed. The anatomo-pathological study showed two foci of invasive papillary carcinoma of 2 mm and 7 mm in long axis with the presence of 37N-/37N reactive lymph nodes. The CPT was classified as: pT1aN1bM1.

Discussion

Papillary thyroid carcinoma is the most common type of well-differentiated thyroid cancer. It is usually revealed by a thyroid nodule. Local and distant metastases of classic papillary thyroid carcinoma occur mainly in regional lymph nodes, lungs, and bones. Parotid involvement in PTC is unusual, and especially as the first presentation of the disease and rarely reported in the literature. Treatment is mainly based on surgery and radiation therapy, with recourse to chemo-radiotherapy in certain situations

Conclusions

The revelation of papillary thyroid carcinoma by a parotid metastasis constitutes the particularity of our case. Metastasis to parotid gland from thyroid origin, seems to be an indication of aggressive disease. Therapeutic management in this type of situation is based on surgery with the addition of adjuvant iratherapy and then hormone therapy at a restraining dose.

A vesicular carcinoma of the thyroid on Graves' disease: a rare association

Nouhaila Essafir[1], Dounia Talbi[1], Kenza Lazraq[1], Chaimae Taleb[1], Fatima Toulali[1], Ghizlane Sabbar[1], Kaouatar Rifai[1], Hind Iraqi[1] & Mohamed Gharbi[1]

[1]Ibn Sina University Hospital, Endocrinology and Metabolic Diseases, Rabat, Morocco

Thyroid carcinoma coexisting with hyperthyroidism is an uncommon occurrence, as low thyroid-stimulating hormone (TSH) levels can suppress the development and growth of differentiated thyroid carcinoma cells. The majority of nodules in patients with low TSH levels are considered to be benign; however, an increasing number of thyroid carcinoma cases are diagnosed in patients with Graves' disease, toxic goiter and functioning thyroid adenoma We report the case of a vesicular carcinoma discovered on anatomopathological study of a total thyroidectomy in a patient with **Grave's disease** The patient was 60 years old on hemodialysis for hypertensive renal failure. Consulted for a cervical swelling with thyrotoxicosis. The biological assessment showed suppressed TSH, elevated T4 and T3 levels, negative anti-TPO antibodies and elevated TSH receptor antibodies. Cervical ultrasonography revealed a multinodular goiter, the most significant nodule was left inferior polar measuring 31x19 mm classified eutirads3. Fine needle aspiration (FNA) of this nodule was non-contributory The patient received synthetic antithyroid drugs until euthyroidism was obtained, then she underwent a total thyroidectomy. Histology concluded to a vesicular micro carcinoma of the thyroid measuring 8 mm in diameter without vascular emboli. The patient did not receive iodine 131, simple monitoring with L-thyroxine inhibitor treatment were indicated. Hyperthyroidism does not exclude the possibility of associated thyroid cancer. The prevalence of this association varies according to recent series, from 0.2% to 8.3%. The association of Graves' disease and vesicular carcinoma remains rare.

Graves disease after radioactive iodine treated toxic adenoma

Joana Vinhais[1], Beatriz R Pereira[1], David Verissimo[1], Catarina Ivo[1], Ana Cláudia Martins[1], Mafalda Marcelino[1], Dolores Passos[1], Luís Lopes[1], João Jácome de Castro[1] & João Nunes e Silva[1]

[1]Portuguese Armed Forces Hospital, Endorinology Department, Lisbon, Portugal

Background

The most frequent causes of hyperthyroidism are Graves disease (GD) and toxic thyroid adenomas. The development of postradioiodine immunogenic hyperthyroidism/GD after radioiodine therapy (RAI) for toxic adenomas occurs in approximately 1.4% of the patients and seems to be more common in patients with increased anti-TPO levels pre-treatment. This effect occurs on average 4.6 months after RAI.

Case Report

A 49 years-old women was evaluated for thyroid nodular disease and hyperthyroidism on our endocrinology clinic in May 2021. She denied compressive symptoms, excessive sweating, loss of weight, or altered intestinal pattern, but confirmed occasional palpitations. No relevant personal or family history. Clinical exam was normal and exophthalmia not present. Cervical palpation unveiled bilateral goitre with palpable nodules bilaterally, 3 cm each, mobile on swallowing and absent cervical adenopathies. Biochemical evaluation reported TSH 0.02, FT4 1.07 (0.8-1.76), FT3 3.84 (1.88-3.18), ATG 499 (<4.11), ATPO 96.3 (<5.61), TRAb 1.2 (<1.8). Cervical ultrasonography (US) showed a multinodular goitre, EU-TIRADS 3 nodules, 33 mm and 13 mm on right lobe, 33 mm and 14 mm on left lobe, and 20 mm and 14 mm on isthmus. Thyroid scintigraphy revealed a hot nodule in the inferior right lobe. Patient initiated methimazole and performed fine needle aspiration biopsy of the cold nodules, revealing a benign cytology. The toxic nodule of the right lobe was treated with 10mCi of RAI I-131 achieving clinical and biochemical euthyroidism (TSH 1.54, FT4 1.05, FT3 3.02). One year later she presented with sinus tachycardia on clinical exam, but otherwise without hyperthyroidism signs or symptoms, and analysis reported TSH 0.09, FT4 1.27. Thyroid scintigraphy was repeated and revealed hypofixation of radiocontrast in the lower half of right lobe, and hyperfixation bilaterally in the remaining parenchyma. Laboratory workup reported TSH 0.011, FT4 1.44, FT3 5.37, TRAb 2.5. After discussion with the patient and in multidisciplinary reunion, total thyroidectomy was performed for definitive treatment of Graves disease.

Conclusion

This patient presented with GD 12 months after RAI therapy for toxic adenoma. This rare case highlights the importance of maintaining vigilance of patients after RAI, especially those with elevated anti-TPO.

Challenges in managing severe T3 thyrotoxicosis: a complex case of Graves' disease with multidisciplinary intervention and surgical resolution

Bratu Gratiela[1], Vlad Radulescu[1], Anastasia Patricia Stanescu-Smocot[1], Radu Mihai[2] & Corin Badiu[1,3]

[1]"C. I. Parhon" National Institute of Endocrinology, Endocrinology 4, Bucharest, Romania; [2]Churchill Hospital, Blenheim Head and Neck Centre, Oxford, United Kingdom; [3]"C Davila" University of Medicine and Pharmacy, Endocrinology, Bucharest, Romania

We present a case of severe T3 thyrotoxicosis in a 23-year-old female with Graves' disease. The patient presented in August 2023 with weight loss despite increased appetite, tachycardia (up to 130/min), and peripheral tremors. Laboratory tests confirmed thyrotoxicosis. Ultrasonographic examination revealed a homogenous goiter, with a volume exceeding 50 ml, with marked vascularization, consistent with the typical features of Graves' disease. The diagnosis was confirmed by high TRAB levels (36.94 UI/l) Initial treatment with Thiamazole (20 mg/day) triggered a mild allergic reaction (dermatitis) and was switched to propylthiouracil (PTU) 75 mg/day but this led to severe hepatotoxic reaction (liver enzymes elevated to 7xUNL). Despite switching to cholestyramine (20 mg/day), thyroid function remained poorly controlled, with persistently elevated T3 (on many occasions found to be over 600 ng/dl, reference range 35-193 ng/dl) and ongoing symptoms of thyrotoxicosis and Graves' ophthalmopathy. Intravenous methylprednisolone (MTP) was initiated, reaching a total dose of 1750 mg along 3 months, which led to a reduction in T3 levels and allowed to resume thiamazole treatment. Despite this, thyroid function remained unstable with suppressed TSH and high T3. Heart rate remained poorly controlled despite 120 mg daily propranolol. Given the severity of her thyrotoxicosis, surgical treatment was considered but it was declined by two surgeons due to the increased bleeding risk associated with uncontrolled disease, the cardiac risks of severe T3 thyrotoxicosis and the possibility of postoperative tracheotomy. The patient continued with 40 mg Thiamazole daily and 120 mg propranolol, but thyroid function remained inadequately controlled for T3 while fT4 reached target. In November 2024 she had an uneventful total thyroidectomy after preoperative treatment (10 days) with Lugol's iodine (15 drops/day), methylprednisolone (16 mg/day) and Thiamazole (40 mg /day). The gland was symmetrically enlarged

(max diameter 9 cm (right) and 10 cm (left)). Both recurrent laryngeal nerves showed normal parameters on intraoperative nerve monitoring and postoperative voice was unaffected. One month later, the patient achieved euthyroidism, with normal T3/TSH while on replacement therapy with Levothyroxine 100 µg/day. In conclusion, this case highlights the aggressive nature of T3 thyrotoxicosis, its resistance to conventional treatments, and the challenges posed by multiple medication allergies. It underscores the importance of a multidisciplinary approach in managing severe, refractory hyperthyroidism.

Hypoparathyroidism after total thyroidectomy: an epidemiological study

Nour Kraiem[1], Mehdi Ferjaoui[1], May Ferjani[1], Nawres Bouaziz[1], Amel El Korbi[1], Nawres Kolsi[1], Rachida Bouatay[1], Khaled Harrathi[1] & Jamel Koubaa[1]

[1]Fattouma Bourguiba University Hospital, ENT, Monastir, Tunisia

Introduction

Hypoparathyroidism is a recognized complication following total thyroidectomy

Aim

to investigate the epidemiological aspects of post-thyroidectomy hypoparathyroidism, including its incidence, risk factors, and duration.

Methods

Retrospective study for over a two-year period (2022-2023) including 100 patients who underwent total thyroidectomy. Data were collected from medical records, including patient demographics (age, sex), surgical indication, postoperative parathyroid hormone (PTH) and calcium levels (day 3 and 1 month post-operatively), hypocalcemia symptoms, and symptom duration.

Results

The study revealed a clear female predominance (female:male ratio of 16:1). The median age was 37 years (range 10-69). The incidence of hypoparathyroidism on postoperative day 3 was 17%, with a median PTH level of 6.2. Only 2 (11.8%) of the 17 patients with hypoparathyroidism exhibited symptomatic hypocalcemia, presenting with paresthesia and calcium levels < 1.8 mg/dl requiring parenteral calcium correction. The remaining 15 patients (88.2%) had mild hypocalcemia and remained asymptomatic. Hypoparathyroidism was most frequently observed in patients operated for papillary thyroid carcinoma (52.9%), followed by multinodular goiter (29.4%). Graves' disease, benign cysts, and lymphocytic thyroiditis each accounted for 5.9% of cases. At the one-month follow-up, all patients had normal PTH levels, with a median of 33.4. No patients exhibited signs of permanent hypoparathyroidism.

Conclusions

This study provides data on the incidence and risk factors of hypoparathyroidism after total thyroidectomy in our population. The high rate of transient hypoparathyroidism, particularly in patients with papillary thyroid carcinoma, highlights the importance of close postoperative monitoring and surveillance.

Recurrence of subacute thyroiditis 20 years after the first attack in two female patients

Irina A. Vaychulis[1]

[1]South-Ural State Medical University, Internal Medicine Department, Chelyabinsk, Russian Federation

Heterogenous clinical picture, variety of non-specific symptoms and atypical presentation may pose a diagnostic challenge in some patients with subacute thyroiditis (SAT). SAT occurs most often in young and middle-aged women. It is a self-limited inflammatory disease, but in many cases the resolution of symptoms can be achieved only by a medical treatment, and relapses are possible. The diagnosis of SAT in hyperthyroid phase was established in two 77 and 68-year-old female patients, due to self-referral to endocrinologist 10-20 days after the first symptoms had appeared. Both had a history of SAT 20,5 - 20 years ago, at the age of 56 and 48 years, respectively. Both received corticosteroids and stayed euthyroid after the end of treatment. Diagnostic delay in the first episode was more than 2 months. One patient was followed with a diagnosis of upper respiratory tract infection (treated with antibiotics) and mild anemia. In another woman clinical manifestations of SAT were initially regarded as symptoms of menopause. These cases demonstrate late recurrences of SAT two decades after complete recovery in two female patients of advanced age. Primary care physicians need to be better aware of SAT symptoms. At the same time, patients with medical history of SAT should be informed about potential repeated episodes at any age during lifetime. Prompt self-referral in case of resumption of suspicious manifestations, resembling those during the first attack, can reduce diagnostic delay, help to establish correct diagnosis, avoid unnecessary investigations and treatment.

The plunging goiter: a report of 18 cases

Ezzahoum Zaynab[1], Nassim Essabah Haraj[1], Siham El Aziz[1] & Asma Chadli[1]

[1]Ibn Rochd University Hospital, Faculty of Medicine and Pharmacy, Hassan II University, Department of Endocrinology, Diabetology, Metabolic Diseases, and Nutrition Ibn Rochd University Hospital, Casablanca. Laboratory of Clinical Neurosciences and Mental Health Faculty of Medicine and Pharmacy, Hassan II University, Casablanca, Morocco

Introduction

The plunging goiter is a rare and atypical form of goiter that extends into the chest, compressing the trachea and esophagus. This results in a variety of symptoms, including respiratory issues (dyspnea, cough) and digestive disturbances (dysphagia). Diagnosis is primarily based on imaging techniques, and treatment options range from medication to surgical intervention. This study aims to investigate the clinical features and therapeutic strategies for plunging goiter.

Objective

To evaluate the clinical presentation, diagnostic procedures, and treatment outcomes of plunging goiter, assessing the effectiveness of medical and surgical interventions in alleviating symptoms and reducing complications.

Patients and Methods

A descriptive study was conducted on 18 patients with plunging goiter admitted to the Endocrinology and Metabolic Diseases Department of Ibn Rochd University Hospital between 01/01/2022 and 20/01/2025.

Results

The study included 18 patients, with a predominance of females ($n = 12$) and an average age of 58.3 years. Eight patients were from endemic regions. The main presenting symptoms were dysphagia (4 patients), dyspnea (5 patients), dysphonia (1 patient), and signs of thyroid dysfunction (3 patients). Upon physical examination, 5 patients had grade 1 goiter, 6 had grade 2, and 7 had grade 3 goiter. Cervical ultrasound revealed multi-nodular goiters, and signs suggestive of malignancy were found in 4 patients. Chest CT scans performed on all patients confirmed the presence of plunging goiter. Management involved total thyroidectomy in 16 cases, with 2 patients undergoing ultrasound surveillance. Histopathological analysis showed papillary carcinoma in 3 patients and follicular carcinoma in 1. Immediate postoperative complications included cervical hematoma in 1 patient and dysphonia in 2 patients. Monitoring of calcium and phosphate levels post-surgery revealed hypocalcemia in 7 patients, requiring oral calcium supplementation. All patients were placed on thyroid hormone replacement therapy following surgery.

Conclusions

This study supports total thyroidectomy as the treatment of choice for plunging goiter. Continuous follow-up with thyroid hormone replacement therapy is essential for optimal long-term outcomes. Early diagnosis and timely surgical intervention are crucial for preventing complications and improving prognosis.

Out of service: late-onset hypoparathyroidism

Hairchi Sara[1], Ait Kassi Nada[1], Toulali Fatima[1] & Mohamed El-Hassan Gharbi[1]

[1]CHU Ibn Sina, Rabat, Morocco

Introduction
Post-thyroidectomy hypoparathyroidism is a well-documented complication, typically presenting within 48 hours of surgery. While most cases are transient, permanent hypoparathyroidism occurs in approximately 1.5% of patients. A rare and underrecognized form, delayed hypoparathyroidism, manifests years after surgery, likely due to progressive ischemia or atrophy of preserved parathyroid glands. This report discusses a case of severe hypocalcemia occurring 15 years after total thyroidectomy.
Case Presentation
A 50-year-old postmenopausal woman was admitted for the management of severe hypocalcemia (54 mg/l). Her medical history revealed a total thyroidectomy performed 15 years earlier for a retrosternal goiter with no immediate postoperative complications. Clinical examination showed a positive Chvostek sign, but the patient was hemodynamically and neurologically stable. Non-parathyroid causes of hypocalcemia were excluded, leading to a diagnosis of delayed post-surgical hypoparathyroidism.
Discussion
This case highlights potential mechanisms for delayed hypoparathyroidism, including progressive hypovascularization and scar tissue formation. Similar cases in the literature underline risk factors such as female gender, advanced age at surgery, and underlying thyroid pathology. Management included intravenous calcium correction followed by long-term oral supplementation with calcitriol and calcium, resulting in significant symptom improvement.
Conclusion
Although rare, delayed hypoparathyroidism should be considered in patients presenting with unexplained hypocalcemia and a history of thyroidectomy, regardless of the time elapsed since surgery. Prompt recognition and appropriate management can prevent severe complications and improve patient outcomes.

Endocrine follow-up during pregnancy for surgically treated medullary thyroid microcarcinoma

Zoran Gluvic[1], Milena Lackovic[1], Vladimir Samardzic[1], Bojan Joksimovic[1], Milos Marinkovic[1], Marija Sinik[1], Ilinka Popovic[1], Sonja Zafirovic[2] & Esma R. Isenovic[2]
[1]Zemun Clinical Hospital, Department of Endocrinology, Zemun, Belgrade, Serbia; [2]Institute of Nuclear science "Vinca", National Institute of REpublic of Serbia, Laboratory for radiobiology and molecular genetics, Belgrade, Serbia

Introduction
The impact of pregnancy on medullary thyroid microcarcinoma (MTmC) has not been extensively studied to date. Its management during pregnancy remains challenging. According to WHO grading criteria, the presence of at least one of the following criteria: mitotic index $\geq 5/mm^2$, Ki67 $\geq 5\%$, or tumor necrosis, qualifies MTmC as high grade, whereas MTmC lacking all three criteria is considered low-grade.
The case report
A pregnant woman, 31 years old, visits the outpatient Endocrine unit in the 6th week of pregnancy to check the quality of levothyroxine (LT4) substitution therapy. Her medical history revealed total thyroidectomy due to nodular thyroid disease and incidental histological finding of MTmC four months before pregnancy. Histological findings pointed out MTmC classical histological type, presented with low mitotic index, minimal amount of amyloid, and tumor-clear resection margins on the slide. Furthermore, lympho-vascular invasion and in-tumor necrosis were not detected. Biochemistry showed insufficient LT4 substitution in the first trimester of pregnancy (TSH 2.72), along with negative markers of MTmC recurrence or progression, and MEN syndrome presence (Calcitonin <0.5, CEA 0.8, PTH 17, Ca 2.45). The quality of LT4 substitution is improved during pregnancy and serial biochemistry follow-up on calcitonin levels were stationary (Calcitonin <0.5 at the 11th, 23rd, and 33th week of gestation). Genetic testing to rule out an inherited form of MTmC (RET gene, Thyroid carcinoma (HP:0002890, Neoplasm (HP:0002664 by *Exome 2.0 Illumina* panel) was negative.
Conclusion
Pregnancy did not increase the risk of a non-inherited MTmC recurrence in this 31-year-old patient with low-grade tumor characteristics. Based on the consistency of biochemical markers during pregnancy, there was no MTmC progression. The mainstay of thyroidectomized patients' surveillance for MTmC is a careful monitoring and individualized management throughout pregnancy.

Screening for dysthyroidism in pregnant women with diabetes

Ramla Mizouri[1], Rym Ben Othman[1], Rim Rachdi[1], Faten Mahjoub[2], Olfa Berriche[1], Nadia Ben Amor[2] & Jamoussi Henda[1]
[1]Institut National de Nutrition de Tunis, Service A, Tunis, Tunisia; [2]Institut National de Nutrition de Tunis, Tunis, Tunisia

Introduction
Pregnancy is accompanied by physiological changes that affect the functioning of the thyroid gland. These changes put pregnant women at increased risk of dysthyroidism. The objective of this study was to screen for dysthyroidism in pregnant diabetic women.
Methods
This is a descriptive study carried out on 50 diabetic pregnant women. The diagnosis of hypothyroidism is made at a TSH level greater than 2.5 µmol/l in the first trimester, and 3 µmol/l in the second and third trimesters.
Results
The average age of the patients was 33 years. Pregnancy was planned in 38% of cases, 84% of whom had controlled diabetes during hospitalization (average HBA1c of 6.33%). The average duration of progression of diabetes was 9 years. Forty-eight percent of pregnant women had type 1 diabetes. The average cholesterol level was 4.84 mmol/l. The mean FT4 level was 9.45 pmol/l and the mean TSH level was 2.1 µmol/l. The diagnosis of hypothyroidism was made in 22% of the population studied at an average term of 9 weeks of amenorrhea. All of these patients had type 1 diabetes. The patients were placed on a dose of 25 mg/day. Only two of them required an increase in the dose to 50 mg/day. No cases of hyperthyroidism were found.
Conclusion
Pregnancy planning in diabetic women is imperative. It is essential to systematically include a thyroid assessment in order to detect dysthyroidism and its fetal complications early.

New-onset diabetes associated with severe hyperthyroidism: a case report.

Rim Rachdi[1], Emna Mraihi[1], Rezgui Mohamed Amine[1], Ramla Mizouri[1], Rym Ben Othman[1], Faten Mahjoub[1], Berriche Olfa[1], Nadia Ben Amor[1] & Jamoussi Henda[1]
[1]National Institute of Nutrition, Department A, Tunis, Tunisia

Background
The association between diabetes mellitus and thyroid abnormalities is well established. However, a new-onset case of diabetes mellitus associated with severe hyperthyroidism poses a number of diagnostic and pathophysiological questions. We thus attempt to use this case to highlight the need to seek for an underlying autoimmune origin.
Case summary
A 52-year-old man, an active smoker with a family history of type 1 diabetes (T1DM) in both father and son, presented to the emergency department with a one month history of polyuria, polydipsia, polyphagia and significant weight loss. Physical examination revealed a fatigued patient with tachycardia at 120 beats/min, with no marked signs of thyrotoxicosis (exophthalmos, goitre). Finger glucose was 4.60 g/l. Urine examination showed two-cross glycosuria and one-cross ketonuria. Initial laboratory data revealed normal natraemia and kaliemia, alkaline reserves of 21 mmol/l, and creatinemia of 67 µmol/l. Glycated haemoglobin was 7.4%. New-onset diabetes with ketotic decompensation was diagnosed and the patient was admitted to emergency. An electrocardiogram confirmed the tachycardia. In parallel, thyroid function tests were performed. Decreased thyroid-stimulating hormone (0.005 µUI/l) and increased free thyroxine (84.4 pmol/l) confirmed the diagnosis of hyperthyroidism and anti–thyroid peroxidase autoantibodies were found to be markedly positive. In order to determine both the type of diabetes and the cause of the hyperthyroidism, we carried out an assay of antibodies (anti-glutamic acid

decarboxylase (anti-GAD65), anti-TSH receptor), and a cervical ultrasound scan, which showed signs of hyperthyroidism. The patient was treated with insulin, synthetic antithyroid drugs (Thyrozol 3 tablets/day) and a beta-blocker to control the tachycardia.
Discussion
The coexistence of new onset diabetes and severe hyperthyroidism suggests a common autoimmune cause. The diagnosis of Latent autoimmune diabetes in adults (LADA) associated with basedow's disease is the most likely in this family context of T1DM. Hyperthyroidism increases insulin resistance and exacerbates diabetes, requiring adjustment of insulin therapy. Early identification of anti-GAD and anti-TSH receptor antibodies is extremely important in order to adjust treatment and prevent complications.
Conclusion
This case highlights the importance of a rigorous assessment of associated endocrine disorders in a patient with newly diagnosed diabetes. Screening for associated autoimmune diseases allows more appropriate management and better prediction of complications.

Failure of a contraception in graves' disease woman, a case report

Redhouane Longo[1], Mourad Benrabah[1], Mounia Gharnouti[1] & Mohamed El Horri[2]
[1]Regional University Military Hospital, Oran, Algeria; [2]Military University Hospital Specialized in Orthopedic Surgery Rehabilitation and Orthoprosthetics, Algiers, Algeria

Introduction
Clinical hyperthyroidism in the first trimester of pregnancy secondary to Graves' disease can lead to maternal, obstetric and fetal complications requiring appropriate treatment to restore euthyroidism. Because of fetal malformations reported after treatment with carbimazole/methimazole during gestation, treatment of Graves' hyperthyroidism in pregnancy should be based on propylthio-uracil (PTU) during the first trimester, followed by carbimazole/-methimazole during the second and third trimesters of pregnancy.
Observation
A 40-year-old female patient with no previous medical history, consulted for management of clinically and biologically confirmed Graves' disease -already on treatment-, in the third month of pregnancy. Given that PTU was not available, and the hyperthyroidism was well tolerated, simple clinical and biological monitoring was decided for her. The pregnancy progressed correctly and the delivery was normal and uneventful. The child was male, in good general condition and without any malformations. After delivery, the patient was put back on antithyroid treatment and underwent total thyroidectomy.
Discussion
Subclinical or moderate thyrotoxicosis may improve during pregnancy (increase in TBG, decrease iodine pool, immune tolerance status) and does not require treatment in pregnant women. In this patient with Graves' disease treated with synthetic antithyroid drugs before pregnancy, euthyroidism was maintained without treatment during pregnancy, but a recurrence of the disease occurred after delivery, requiring radical treatment, illustrating the immune tolerance favoured by the pregnant state.

Anaplastic thyroid carcinoma with thoracic metastases: a case report

Nora Boutatss[1], Nassim Essabah Haraj[1], Siham El Aziz[1] & Asma Chadli[1]
[1]UHC Ibn Rochd, Department of Endocrinology and Metabolic Diseases Ibn Rochd University Hospital - Casablanca, Morocco Laboratory of Clinical Neurosciences and Mental Health Faculty of Medicine and Pharmacy - Hassan II University - Casablanca, Morocco, Casablanca, Morocco

Introduction
Anaplastic thyroid carcinoma (ATC) is among the rarest and most aggressive tumors, often diagnosed in late, advanced stages, showing local invasion and distant metastases. The most common site for metastases is the lungs, generally detected through imaging examinations of the thorax.
Case Presentation
We present the case of a 46-year-old male who has been diagnosed with anaplastic papillary thyroid carcinoma, managed with thyroidectomy. Three months later, the patient showed signs of progressive dyspnea along with discomfort in the chest. CT scan of the thorax revealed multiple bilateral pulmonary metastatic lesions associated with mediastinal lymphadenopathy and pleural effusion suggestive of advanced states of disease. Histopathological examination confirmed the presence of anaplastic thyroid carcinoma with capsular invasion and embolic dissemination. Aggressive treatment was rendered: total thyroidectomy with selective lymph node dissection and external beam radiation therapy. The patient's clinical condition rapidly deteriorated.
Discussion
This case demonstrates the rapidly progressing nature of anaplastic thyroid carcinoma, often diagnosed late with distant metastases, particularly in the thorax. Imaging studies such as CT scans of the thorax play a decisive role in assessment of the extent of possible metastatic spread and help inform treatment decisions. The clinical condition has a very grave prognosis, thus requiring early and multidisciplinary management of such cases for better patient outcomes.

Investigating the role of selenium and inositol supplementation in managing hashimoto's thyroiditis: a preliminary observational study

Hadi Tabesh[1], Hamidreza Bazrafshan[2,3] & Narges Kashanivahid[2]
[1]University of Tehran, Tehran, Iran; [2]Dr. Bazrafshan Clinic, Tehran, Iran; [3]University Hospital, Munich, Germany

Hashimoto's thyroiditis (HT) is an autoimmune disorder of the thyroid marked by increased levels of anti-thyroid antibodies and a gradual decline in thyroid function. This observational study investigates the effects of supplementing selenium and inositol three times a week on antibody levels in five patients diagnosed with HT. Throughout the treatment period, there was a notable decrease in the levels of anti-thyroid peroxidase (TPO) and anti-thyroglobulin (TG) antibodies. After two years of follow-up, four patients showed complete remission of HT, particularly those who maintained good mental health and engaged in regular exercise. These results indicate that selenium and inositol supplementation may have a positive impact on autoimmune activity in HT, potentially enhancing thyroid function and overall patient outcomes. However, further controlled studies are necessary to validate these initial findings and develop standardized treatment guidelines.

Discrepancy between cytological findings and histopathological results in thyroid nodules

Mariem Ayedi[1], Hamza Elfekih[1], Wiem Saafi[1], Imen Halloul[1], Younes Derbel[1], Ach Taieb[1], Ghada Saad[1] & Yosra Hasni[1]
[1]University of Sousse, Faculty of Medicine of Sousse, Farhat Hached University Hospital, Endocrinology Diabetology Department, Sousse, Tunisia

Introduction
Advancements in imaging techniques, particularly ultrasonography, have significantly improved the detection and characterization of thyroid nodules. The implementation of the EU-TIRADS classification system has standardized clinical practices, providing clear guidelines for fine-needle aspiration cytology (FNAC). Interpretation of FNAC using the Bethesda categories enables clinicians to decide between ultrasound surveillance and therapeutic intervention. However, discrepancies between imaging findings, cytological and histopathological results can pose diagnostic challenges, necessitating a multidisciplinary approach to ensure accurate diagnosis and appropriate management.
Case Presentations
Case 1: A 59-year-old female undergoing evaluation for chronic cough was found to have a heterogeneous macronodule in the left thyroid lobe on thoracic CT-scan, along with multiple nodules and micronodules present in both lung fields, osteolytic lesion affecting the body and right pedicle of the D3 vertebra with right paramedian and foraminal tumor-related epiduritis, likely of secondary origin.

Cervical ultrasound confirmed the 56×34×40 mm EU-TIRADS IV nodule where fine-needle aspiration (FNA) classified it as Bethesda II. Calcitonin level was normal. Despite normal calcitonin level, the clinical context and suspicious imaging findings prompted total thyroidectomy. Histopathology revealed a conventional subtype papillary carcinoma (pT3aN1M1). Case 2: A 20-year-old female presented with dysphagia and a cervical swelling. Ultrasound identified a 15×8×14 mm right loboisthmic nodule (EU-TIRADS III) and a 5×3 mm left mediolobar nodule (EU-TIRADS III). FNA of the right nodule indicated a benign lesion (Bethesda II). Due to compressive symptoms, a right lobectomy was performed, revealing a 20 mm encapsulated variant of papillary carcinoma (pT1bN0). Subsequent left lobectomy identified a 3 mm follicular variant of papillary carcinoma with capsular invasion (pT1bNxMx). Initial thyroglobulin level was 7 ng/ml.

Discussion

The diagnostic evaluation of thyroid nodules aims to accurately identify malignancy while avoiding unnecessary interventions. However, discordance between imaging and cytological findings should prompt clinicians to pursue further investigations and engage in specialized multidisciplinary discussions to reach an appropriate therapeutic decision, ensuring thyroid neoplasms are not overlooked. Our study highlights the limitations of FNA in certain clinical scenarios and the potential of multifocal disease despite benign cytology.

Rare recurrence of de quervain's thyroiditis

Lamys Abbes [1], Imen Halloul[1], Nassim Ben Hadj Slama[1], Ghachem Aycha[1], Ghada Saad[1] & Yosra Hasni[1]
[1]Faculty of Medecine of Sousse, University of Sousse, Sousse, Tunisia

Introduction

Subacute thyroiditis of Quervain is an acute inflammatory condition of the thyroid, most likely triggered by a viral infection. Its prevalence is estimated to be around 0.1% to 0.5% of the general population, making it relatively rare compared to other types of thyroiditis.

Case report

A 55-year-old female patient with no significant medical history who presented with a cervical swelling. Ultrasound examination revealed a thyroid nodule classified as EUTIRADS 4, with a Bethesda II on fine-needle aspiration cytology. In June 2024, the patient developed flu-like symptoms followed by the onset of a painful, vascular goiter in the context of a febrile illness. Laboratory investigations showed an inflammatory syndrome with a CRP of 179, and hyperthyroidism (TSH 0.02 mIU/l, FT4 36 pmol/l). The patient was treated with anti-inflammatory drugs for one month, resulting in significant improvement of the pain. Subsequent tests two months after the first episode revealed a hypothyroidism with a TSH of 87 mIU/l and FT4 of 3.6 pmol/l. Ultrasound imaging confirmed the presence of a goiter with features suggestive of acute thyroiditis. Levothyroxine therapy was initiated. Six months after this episode, the patient re-presented with the same plaints: bilateral neck pain and odynophagia. Examination revealed a tender goiter, with a CRP of 92 and an elevated erythrocyte sedimentation rate (ESR) of 91 mm/h and a TSH level at 13 mUI/l, confirming the recurrence of the Subacute thyroiditis.

Conclusion

The Quervain's thyroiditis typically follows a course of three phases: an initial hyperthyroid phase, followed by a hypothyroid phase, and eventual spontaneous recovery within two to three months, with recurrence being rare, occurring in only 1.4% to 10% of cases. These recurrences are mainly due to the inflammatory origin of this pathology, the underlying inflammation may persist or reactivate, potentially causing a recurrence of the disease. Additionally, factors such as genetics, the immune system, and recurrent viral infections could contribute to this reactivation.

De Quervain thyroiditis mimicking an aggressive thyroid malignancy

Shyam Seshadri[1] & Furrat Amen[1]
[1]Fitzwilliam Hospital, Milton Way South Bretton, ENT Department, Peterborough, United Kingdom

We report on a patient with likely de Quervain thyroiditis who presented with clinical features of an aggressive thyroid malignancy. A 46-year-old female was referred from the ENT department with a 4-week history of weight loss, feeling hot, and fullness of her neck which was becoming increasingly painful. There was no family history of thyroid disorders. The patient did not mention any clear predating symptoms of any viral catarrh or relevant history. Initial biochemistry through her doctor showed thyrotoxicosis with elevated T4, and T3 and suppressing TSH. Examination revealed a large irregular tender mass over the left lobe of the thyroid and multiple tender palpable lymph nodes in the neck. The patient was clinically thyrotoxic with tachycardia of 110 beats per minute and fine tremors over her outstretched hands but no clinical signs of any thyroid eye disease. An ultrasound of the thyroid revealed a poorly defined hypoechoic mass over the left lobe with a possible extension through the thyroid capsule and several level 3 and level 5 cervical lymph nodes. Thyroid antibodies were negative. She was initially commenced on carbimazole and propranolol for symptomatic control of her thyrotoxicosis while choosing simple analgesia over steroids for her neck soreness. An ultrasound-guided FNAC was carried out 2 weeks later. This revealed only scant follicular epithelial cells and hence labelled as Thy1. The patient made good progress with the carbimazole with good symptom control of her thyrotoxicosis and biochemical improvement. A repeat ultrasound-guided FNAC was carried out 2 weeks later which however showed very scant cells and hence relabelled as Thy1. The ultrasound at this stage however confirmed a sizeable reduction in the left lobe thyroid mass and now insignificant cervical lymphadenopathy. The patient was monitored for her thyroid biochemistry every 3 to 4 weeks with a titrating regime of carbimazole. The initial ENT opinion and a further review after 4 weeks concurred with the clinical diagnosis of likely thyroiditis. Further monitoring was deemed to be under endocrinology, and a further thyroid ultrasound in 3 to 6 months was agreed upon. The patient had come off her carbimazole after 6 weeks and remained euthyroid without any intervening hypothyroid phase. This case serves to highlight the need for clinical assessment and pertinent investigations to avoid overdiagnosis and potentially unhelpful surgical intervention. Hyperthyroidism can very rarely be a manifestation of metastatic follicular thyroid cancer which however was not the case in our patient.

JOINT3818

The impact of nighttime liothyronine and selenium supplementation on hypothyroid patient well-being and thyroid function

Narges Kashanivahid[1], Hamidreza Bazrafshan[1,2] & Hadi Tabesh[3]
[1]Dr. Bazrafshan Clinic, Tehran, Iran; [2]University Hospital, Munich, Germany; [3]University of Tehran, Tehran, Iran

Many patients with hypothyroidism who are taking levothyroxine (LT4) continue to experience ongoing symptoms and a general sense of unwellness, alongside issues like a slow metabolism and obesity. This observational study investigates the impact of adding low-dose liothyronine (LT3) taken at night, along with selenium supplements and foods rich in selenium, e. g. mushrooms, three times a week, for these patients. The study included seven participants of both genders, aged between 21 and 49 years, with TSH levels reaching as high as 6.4. By monitoring T3 levels and ensuring that both T3 and T4 remained within the upper normal range, adjustments were made to their TSH levels, targeting a range of 0.8-2 based on age. This treatment approach resulted in enhanced well-being, improved weight management through diet and exercise, and even a decrease in the size of thyroid nodules. Regular thyroid function tests every three months, including serum T3 assessments, along with thyroid ultrasounds every six months, proved crucial for these patients. These results emphasize the necessity for further research into the combined therapy of LT4, LT3, and selenium in a larger population.

Hypothyroidism is a common endocrine disorder characterized by the impaired function of the thyroid gland and reduced production of thyroid hormones. The clinical manifestations of hypothyroidism can vary significantly, ranging from asymptomatic presentations to those that are life-threatening. We present a unique case of acute renal failure attributed to rhabdomyolysis in conjunction with a severe form of hypothyroidism. Remarkably, the patient's condition improved completely following the administration of levothyroxine, resulting in the induction of a euthyroid state. This case underscores the importance of evaluating thyroid function in patients presenting with acute kidney failure, as it may play a critical role in clinical decision-making and management.

Unveiling the causes of hyperthyroidism: a retrospective analysis

Raida Ben Salah[1], Faten Hadj Kacem[1], Mohamed Abid[1], Nabila Rekik[1] & Zouhir Bahloul[1]
[1]University of Sfax, Internal Medicine, Sfax, Tunisia

Introduction
Hyperthyroidism is a frequent endocrine condition resulting from an over-production of thyroid hormones. The disorder is caused by diverse underlying etiologies, each with distinct clinical and immunological profiles. This study aimed to analyze the etiological distribution of hyperthyroidism in a cohort of patients followed in our center.
Materials and Methods
We conducted a retrospective analysis of patients diagnosed with hyperthyroidism in our institution. The diagnosis was based on clinical presentation, laboratory findings, and immunological markers. Specific antibodies, including anti-TSH receptor (anti-RTSH), anti-thyroperoxidase (anti-TPO), and anti-thyroglobulin (anti-Tg), were systematically assessed.
Results
31 patients were diagnosed with hyperthyroidism. Graves' disease was identified in 19 patients, including 10 men and 9 women, with a mean age of onset of 35.52 years. All patients presented with a goiter, and exophthalmos was observed in 11 cases. Anti-TSH receptor antibodies were positive in all patients, confirming the autoimmune nature of the disease. Hashitoxicosis was diagnosed in 12 patients, including 10 women and 2 men, with a mean age of onset of 36.83 years. Goiter was present in 9 cases. Immunological testing revealed positivity for anti-TPO and/or anti-Tg antibodies in all patients, while anti-TSH receptor antibodies were negative.
Discussion
Graves' disease emerged as the leading cause of hyperthyroidism in our cohort, consistent with global epidemiological data. Its hallmark clinical features, including diffuse goiter and the frequent occurrence of exophthalmos, underline the importance of clinical examination and antibody testing. Hashitoxicosis, often considered a transient phase of autoimmune thyroiditis, represented the second most common etiology. Its diagnosis relies on the presence of specific thyroid antibodies and the exclusion of anti-TSH receptor positivity.
Conclusion
This study emphasizes the predominance of Graves' disease and Hashitoxicosis as etiologies of hyperthyroidism. The distinct clinical and immunological profiles observed highlight the necessity for a comprehensive diagnostic approach to guide appropriate management strategies.

Echographic features of nodular hashimoto's thyroiditis

Oumaima Benkhalifa[1], Jihen Marrakchi[1] & Raweh Bouzguenda[1]
[1]Hospital of Menzel Bourguiba Bizerte, Bizerte, Tunisia

Objective
The aim of the study is to analyze the sonographic features of nodular Hashimoto thyroiditis (HT).
Methods and materials
In a retrospective study, the clinicohistopathologic and echographic (number, diameter, shape, margins, vascularity, halo) data of patients who underwent total or partial thyroidectomy and had a HT in the histopathological specimen, from the 1st of January 2018 to the 31st july 2023 were analyzed.
Results
Our serie includes 73 patients and 155 thyroid nodules. All the patients are female and the mean age is 47 years. 16 patients have a thyroid dysfunction. No patient have a personal history of neck irradiation. 12 patients have family history of thyroidectomy. The mean nodule diameter is 35,5 mm(4-68 mm). 59.3%of nodules are located in the right lobe while 40.6% are located in the left lobe. 43.2% are completely solid,10.3% are kystic and 46.4% have a mixed structure. 83.8% have an oval shape and 16.2% have a round shape. Nodules margins were sharp in 78.06% and indistinct in 21.9%. 16.12% are hyperechoic,54.19% are isoechoic,20.6% are moderately hypoechoic and 9.03% are very hypoechoic. 55.48% of nodules are surrounded by a thin halo and 44.5% does not. On color doppler,18..6% of nodules showed peripheral hypervascularity,32.9% were diffusely hypervascular and 49.03% were isovascular. 7.06% of nodules have microcalcification while 9.67% have macrocalcification.
Conclusion
The sonographic appearance is variable but the most common aspect is an isoechoiec, isovascular and oval shaped nodule with sharp margins.
