In essence, polycystic ovary syndrome (PCOS) is an endocrine-metabolic mode driven by ectopic fat [1]. It is unknown whether similar degrees of total, truncal, abdominal, visceral and hepatic adiposity associate to similar PCOS phenotypes in adolescent girls vs young women. The baseline data of an international PCOS intervention study [2] (www.spiomet4health.eu; Horizon 2020 grant 899671) offered an unanticipated opportunity to answer this question. Indeed, adolescent girls with PCOS ($n = 129$; mean $\pm$ SD; 16 $\pm$ 2 yr) and young women with PCOS ($n = 183$; 22 $\pm$ 1 yr) in this study happened to have similar measures of body adiposity: BMI 27 $\pm$ 5 vs 27 $\pm$ 5 kg/m^2; total fat (by DXA) 29 $\pm$ 11 vs 28 $\pm$ 11 kg; truncal fat (by DXA) 14 $\pm$ 6 vs 13 $\pm$ 6 kg; non-truncal fat (by DXA) 15 $\pm$ 5 vs 15 $\pm$ 6 kg; abdominal thickness of subcutaneous fat (by MRI) 6 $\pm$ 2 vs 6 $\pm$ 2 cm; abdominal area of subcutaneous fat (by MRI) 218 $\pm$ 77 vs 219 $\pm$ 84 cm^2; visceral fat (by MRI) 48 $\pm$ 29 vs 52 $\pm$ 34 cm^2; and hepatic fat (by MRI-PDFF) 7 $\pm$ 5 vs 7 $\pm$ 2 %. However, the PCOS phenotype was more severe (all $P < 0.001$) in adolescent girls than in young women: hirsutism score (modified Ferriman-Gallwey) 13 $\pm$ 6 vs 10 $\pm$ 6; SHBG 32 $\pm$ 18 vs 41 $\pm$ 20 nmol/l; free androgen index 6.8 $\pm$ 4.6 vs 4.9 $\pm$ 3.0; HOMA-IR 3.3 $\pm$ 3.2 vs 2.3 $\pm$ 2.5; mean serum insulin during oGTT 437 $\pm$ 456 vs 253 $\pm$ 218 pmol/l; HDL-cholesterol 1.3 $\pm$ 0.3 vs 1.6 $\pm$ 0.4 mmol/l. In conclusion, the baseline data of an intervention study disclosed unexpectedly that a similar fat distribution associates with a more severe PCOS phenotype in adolescent girls than in young women. A differential secretion of growth hormone may be among the mechanisms underpinning the difference in PCOS phenotype [3,4]. In order to reverse PCOS, measures to reduce adiposity and/or to redistribute fat may thus be even more relevant for adolescent girls than for young women.

Health behaviours in women conceiving by medically assisted reproduction vs natural conception: a cross-sectional study of 23,334 nulliparous women

Ann Hansen[1,2], Lærke Priskorn[1,2], Niels Joergensen[1,2], Nina Nathan[3], Anja Pinborg[3,4], Anders Juul[1,2,4] & Hanne Heggard[3,4]
[1]Department of Growth and Reproduction, Copenhagen University Hospital- Rigshospitalet, Copenhagen, Denmark; [2]International Center for Research and Research Training in Endocrine Disruption of Male Reproduction and Child health (EDMaRC), Copenhagen University Hospital - Rigshospitalet, Copenhagen, Denmark; [3]Department of Gynecology, Fertility and Obstetrics, Copenhagen University Hospital – Rigshospitalet, Copenhagen, Denmark; [4]Department of Clinical Medicine, University of Copenhagen, Copenhagen, Denmark

Introduction

Women conceiving by fertility treatment have a planned pregnancy, easing adherence to preconception recommendations, which they are expected to be highly motivated to comply with. However, little is known about the actual adherence among these women. Thus, we investigate to what extent women conceiving by fertility treatment adhere to recommendations from the Danish Health Authority regarding preconception health behaviour and whether the adherence differs from that observed in women conceiving naturally. Secondly,

we elucidate differences in health behaviour in early pregnancy by mode of conception.
Material and methods
A cross-sectional study using clinical patient-reported questionnaire data from 23 443 nulliparous women collected in connection with their first-trimester nuchal translucency scan from 2012 to 2022 at Copenhagen University Hospital in Denmark. The women answered an online clinical questionnaire including information on whether they conceived by fertility treatment, which type of treatment, and their health behaviours before and in early pregnancy. This included alcohol consumption, smoking, exercise, and intake of dietary supplements. Differences in health behaviours by mode of conception were analysed using multiple logistic regression with adjustments of age and educational level.
Results
Overall, 91% of women responded to the questionnaire. Women who conceived by MAR (15%) had healthier preconception behaviours with significantly higher odds of taking folic acid supplements (aOR 11.04), smoking cessation due to planning of pregnancy (aOR 1.72), and avoiding smoking (aOR 4.67), passive smoking (aOR 2.02), and alcohol consumption (aOR 2.40) compared to women conceiving naturally. Despite these healthier behaviours, adherence among women conceiving by MAR was only 30.6% for alcohol avoidance and 42.7% for meeting the recommended hours of exercise per week. In early pregnancy, both groups generally exhibited healthy behaviours; however, women conceiving by MAR still had significantly healthier behaviours overall, except for exercise.
Conclusion
Women conceiving by MAR generally exhibited healthier preconception behaviours than women conceiving naturally, though they showed poor adherence to recommendations on avoiding alcohol and engaging in exercise. In early pregnancy, women conceiving by MAR also overall demonstrated healthier behaviours. Health professionals at fertility clinics may consider motivating women to engage in exercise and avoid alcohol.

Combining machine learning and metabolomics to identify the metabolic signatures of polycystic ovary syndrome patients according to body mass index

Tatiana Lecot-Connan[1,2,3], Morrigan Rives[1], Guillaume Bachelot[2,3], coumba sow[2,3], Salma Fourati[4], Isabelle Tejedor[1], Thibaud Godon[5], Antonin Lamaziere[2,3] & Anne Bachelot[1]
[1]Pitié Salpêtrière Hospital, Sorbonne university, AP-HP, Department of Endocrinology and Reproductive Medicine, Centre de Référence des Maladies Endocriniennes Rares de la Croissance et du Développement, CRMERC, Endo-ERN, Paris, France; [2]Sorbonne Université, Inserm, Centre de Recherche Saint-Antoine, CRSA, Paris, France; [3]Saint Antoine Hospital, AP-HP, Sorbonne University, Department of Clinical Metabolomic, Paris, France; [4]Pitié Salpêtrière Hospital, Sorbonne university, AP-HP, Department of Endocrine and Oncology Biochemistry, Paris, France; [5]Laval University, Department of Computer Science and Software, Montréal, Canada

Introduction
Polycystic ovary syndrome (PCOS) is frequently associated with metabolic disorders such as obesity and/or insulin resistance. A metabolic assessment is recommended by 2023 ESHRE PCOS guidelines in all patients, regardless of body mass index (BMI). However, in the literature, normal-weight PCOS patients are less explored and the increased risk of diabetes in this population is still in debates. The aim of this study was to identify the associated metabolic profile of normal-weight patients with PCOS.
Material and Methods
A retrospective study in the Pitié-Salpêtrière endocrinology department was conducted between January 2019 and December 2023. Clinical and biological data were collected during day hospital check-up. PCOS patients were classified into 3 BMI categories: 152 patients with a normal BMI (< 25 kg/m^2), 96 overweight patients (25-30 kg/m^2) and 149 obese patients (BMI ≥ 30 kg/m^2). All 76 control patients had a normal BMI. To identify metabolomic profile according to BMI, we used a combined mass spectrometry and machine learning approach. In addition to bioclinical parameters, we have also integrated blood steroidome (including 20 molecular species quantify thanks to mass spectrometry).
Results
HOMA-IR, to assess insulin resistance, was higher in the obese group than in the overweight and normal BMI groups ($P < 0.0001$) and HOMA-IR$>$ 2.5 was more frequent in obese PCOS patients. Lean PCOS patients presented a better metabolic profile with high HDLc, low LDLc and triglycerides, and normal liver function. In terms of hormonal assessment, due to a higher SHBG, lean patients have a lower bioavailable testosterone than obese PCOS patients ($P < 0.0001$). The LC-MS/MS circulating steroid profiles showed increase in delta5 steroids in normal-weight PCOS patients compared to obese PCOS women but there was no difference with control cohort. To identify a characteristic metabolomic signature, we used a combined approach including mass spectrometry data and machine learning modeling. We used this approach to characterize PCOS patients compared to control patients and to characterize PCOS patients according to their BMI. The resulting model showed a continuum between hormonal variables on the one hand and metabolic variables on the other hand. Interestingly, some obese patients were metabolically healthy and positioned on the hormonal side. In contrast, some lean patients had a more metabolic profile.
Conclusion
Metabolic profile of normal-weight PCOS patients is characterized by lower HOMA-IR, higher HDLc and bioavailable testosterone, and normal lipid and liver functions.

Detection of piRNA-associated proteins as a diagnostic tool for spermatogenic arrest

Gülizar Saritas[1,2,3], Sofia Boeg Winge[2,3], Nina Mørup[2,3] & Kristian Almstrup[1,2,3]
[1]University of Copenhagen, Department of Cellular and Molecular Medicine, Copenhagen, Denmark; [2]Copenhagen University Hospital - Rigshospitalet, International Center for Research and Research Training in Endocrine Disruption of Male Reproduction and Child Health (EDMaRC), Copenhagen, Denmark; [3]Copenhagen University Hospital - Rigshospitalet, Department of Growth and Reproduction, Copenhagen, Denmark

Introduction
Emerging evidence suggests that pathogenic variants in genes (like *MYBL*, *PIWIL1*, *TDRDs*) that are involved in the processing of PIWI-interacting RNAs (piRNAs) are a major genetic contributor to spermatogenic arrest. Studies suggest that the entire piRNA processing pathway is affected if one component of the piRNA biogenesis is missing.
Hypothesis
We hypothesize that the lack of single piRNA components may be indicative of a faulty piRNA biogenesis and cause spermatogenic impairment.
Methods
Testicular expression of piRNA-associated proteins were analyzed in 117 biopsies from 115 patients with impaired ($n = 87$) or complete ($n = 30$) spermatogenesis. Immunohistochemical (IHC) and *in situ* hybridization (ISH) stainings identified MYBL and PIWIL1 protein and transcript. Image segmentation was used for quantitative analysis. Statistical significance was determined using Mann-Whitney U and Fisher's exact tests.
Results
Biopsies from patients with complete spermatogenesis consistently expressed MYBL and PIWIL1 proteins in spermatocytes and round spermatids while 32% (37/117) of biopsies with impaired spermatogenesis showed absence of one or both of these proteins. Quantitative image analysis of a subset of the samples revealed a significantly reduced expression of MYBL and PIWIL1 proteins ($P<0.001$ and $P<0.001$, respectively) and transcripts ($P=0.002$ and $P<0.001$, respectively) in the biopsies with impaired spermatogenesis.
Conclusion
The observed lack of MYBL and PIWIL1 expression in 32% of biopsies with impaired spermatogenesis substantiates the critical role of piRNA-associated proteins for spermatogenesis. Whether the observed lack of PIWIL1 has an effect on the expression of piRNAs during spermatogenesis remains to be established.

Sexual health in women with type 1 diabetes – a qualitative study from the ReproDia study

Sandra Steintorsdottir[1,2,3], Cecilie Varsi[4], Jesini Anurathan[1], Astrid Stalheim[3] & Elisabeth Qvigstad[6,7]
[1]Oslo University Hospital, Dept of Endocrinology, Oslo, Norway; [2]University of Bergen, Dept of Endocrinology, Bergen, Norway; [3]Haukeland University Hospital, Dept of Endocrinology, Bergen, Norway; [4]University of South-Eastern Norway, Faculty of Health and Social

Sciences, Drammen, Norway; [5]Oslo University Hospital, Division for Obstetrics and Gynaecology, Oslo, Norway; [6]Oslo University Hospital, Department of Endocrinology, Oslo, Norway; [7]University of Oslo, Dept of Endocrinology, Oslo, Norway

Background
Sexual health is a state of physical, emotional, mental, and social well-being related to sexuality, and it can be affected in women with type 1 diabetes (T1D). There is limited knowledge about how sexual health is perceived and experienced among women with T1D.
Objective
To explore thoughts and experiences related to sexual health among women with T1D.
Methods
Semi-structured individual interviews were conducted with women with T1D at a diabetes outpatient clinic in Norway. Data were analysed using thematic analysis.
Results
From June to November 2022, 24 women with T1D, aged 18–45 years, were contacted and invited to participate in the study, of which 17 accepted. Four main themes were identified: (1) Inadequate communication and information about sexual health; prompting reflections on the information healthcare providers should offer depending on the life stage. (2) The impact on women's relationships and intimacy; where decreased sexual desire, vaginal dryness, pain, as well as glycaemic variations and the intrusions from diabetes equipment were highlighted as significant factors. (3) The relationship between menstrual cycle and diabetes management; where varied experiences were reported regarding the regularity of menstruation and its impact on glycaemic variations, ranging from no influence on daily life to a marked impact. (4) Genitourinary infections; where different experiences and concerns were expressed. Hyperglycaemia was perceived as a risk factor, and the emotional burden of such infections was emphasized.
Conclusion
Women with T1D experience numerous challenges related to sexual health, indicating a need for improved follow-up from healthcare services. There was significant individual variation in experiences, underscoring the importance of empathetic communication and tailored information at relevant times throughout a woman's life stages.

A novel variant in the NDNF gene in a 17-year old boy with hypogonadotropic hypogonadism and anosmia

An Jacobs[1,2], Miel Theunis[3], Paul Van Crombrugge[4], Tommaso Todisco[5,6], Nelly Pitteloud[5,6], Jeroen Breckpot[3] & Leen Antonio[7,8]
[1]University Hospitals Leuven, Department of Paediatric Endocrinology and Diabetes, Leuven, Belgium; [2]KU Leuven, Department of Cellular and Molecular Medicine, Leuven, Belgium; [3]University Hospitals Leuven, Department of Human Genetics, Centre for Human Genetics, Leuven, Belgium; [4]AZORG, Aalst, Belgium; [5]University of Lausanne, Lausanne, Switzerland; [6]Lausanne University Hospital, Service of Endocrinology, Diabetology and Metabolism, Lausanne, Switzerland; [7]University Hospitals Leuven, Department of Endocrinology, Leuven, Belgium; [8]KU Leuven, Clinical and Experimental Endocrinology, Department of Chronic Diseases and Metabolism, Leuven, Belgium

Introduction
Congenital hypogonadotropic hypogonadism (CHH), whether or not associated with anosmia (Kallmann syndrome), is a rare genetic disorder characterized by the absence of pubertal development and infertility, caused by GnRH deficiency. Recently, neuron-derived neurotrophic factor (NDNF) has been identified as a novel factor involved in GnRH neuron ontogeny. NDNF enhances the GnRH neuron migratory route during embryological development and plays a role in GnRH release in the median eminence, suggesting a possible role in GnRH neuron biology beyond embryonic development.
Clinical case
A 16-year-old boy was referred to endocrinology because of the absence of pubertal development and anosmia. Medical history revealed bilateral cryptorchidism, treated with orchidopexy at 12 years of age. Testicular volume was 1 ml bilaterally, with Tanner stage 3 for pubic hair. Morning serum testosterone, FSH and LH were undetectably low, whereas the other pituitary hormones were normal. Testicular ultrasound confirmed prepubertal volumes of 14x10x5 mm and 11x3x4 mm. MRI of the brain showed an absent olfactory bulb, and normal anatomy of the pituitary gland and stalk. Bone age was more than 2 years delayed. Family history revealed cryptorchidism and late puberty in his father, without fertility problems. The clinical diagnosis of Kallmann syndrome was made and pubertal induction with gonadotropins was started. Gene panel testing for hypogonadotropic hypogonadism revealed a heterozygous variant in the *NDNF* gene, NM_02457.4:c.509_513dup p.(Pro172Ilefs*13). This variant is predicted to cause a frameshift in the last exon, presumably escaping nonsense-mediated decay leading to a truncated protein missing both C-terminal fibronectin type III domains, crucial for its migratory function. No other relevant variants in known CHH genes were detected.
Discussion/Conclusion
We describe a novel variant in the *NDNF* gene in an adolescent with Kallmann syndrome, contributing to the evidence of Ndnf as a novel factor involved in GnRH neuron ontogeny. A previously published gene-based burden test in a cohort of 240 CHH patients revealed 4 other *NDNF* rare likely pathogenic variants in 4 patients with hypogonadotropic hypogonadism with anosmia (OMIM # 618841), with *in vitro* analysis showing a loss of function of these variants. Three of these probands' family members also carried the *NDNF* mutation and had partial and milder phenotypes, suggesting an autosomal-dominant inheritance with variable expression. Further research on the molecular role of *NDNF* on GnRH neuron migratory route and GnRH functioning is needed.

Testicular parenchyma inhomogeneity is a potential new marker for testicular dysfunction and subfertility in men born with hypospadias

Maaike Kroon[1], Anne-Françoise Spinoit[1], Piet Hoebeke[1], Alexander Springer[2], Ursula Tonnhofer[2], Stefan Riedl[3], Manuela Hiess[4], Ahmed Mahmoud[5], Erik Van Laecke[1], Martine Cools[6] & Lloyd Tack[6]
[1]Ghent University Hospital, Department of Urology, Ghent, Belgium; [2]Medical University of Vienna, Department of Pediatric Surgery, Vienna, Austria; [3]Medical University of Vienna, Department of Pediatrics and Adolescent Medicine, Vienna, Austria; [4]Ordensklinikum Linz, Department of Pediatric Urology, Linz, Austria; [5]Ghent University Hospital, Department of Endocrinology/Andrology, Ghent, Belgium; [6]Ghent University Hospital, Department of Internal Medicine and Pediatrics, Ghent, Belgium

Introduction
Hypospadias is a common congenital urological condition associated with testicular dysfunction, such as reduced semen quality and subclinical hypogonadism. The severity of dysfunction varies, and is influenced by the degree of undervirilization and prenatal factors (e.g. being born small for gestational age). Despite these associations, testicular morphology—specifically parenchymal inhomogeneity and microcalcifications—remains understudied in men born with hypospadias. This study investigates testicular morphology in boys and men with hypospadias compared to controls using ultrasound. Specifically, we examine changes across puberty and their associations with clinical, prenatal, and lifestyle factors.
Methods
Cross-sectional case-control study: evaluation of testicular ultrasound studies of 244 boys/men born with hypospadias (Tanner 1: $n = 17$; Tanner 2-4: $n = 27$; Tanner 5: $n = 200$) and 51 controls (all Tanner 5) by three physicians (junior doctor, senior urologist and pediatric endocrinologist). Homogeneity and microcalcifications were scored on a 4-point and 3-point Likert scale, respectively. Associations were sought with clinical data (e.g. hormone assays, semen characteristics and physical exam) and maternal, dietary and substance factors (through a questionnaire).
Results
Substantial interobserver agreement was seen for microcalcifications ($\kappa = 0.735$, $P < 0.001$) and inhomogeneity ($\kappa = 0.647$, $P < 0.001$). Testicular inhomogeneity was more common in men born with hypospadias compared to controls ($P = 0.004$), also when divided in subgroups mild ($P = 0.006$), severe ($P < 0.001$), and complex hypospadias ($P < 0.001$). Descriptive analysis showed increasing abnormalities with puberty progression. Furthermore, associations were found between inhomogeneous testicular parenchyma and reduced semen quality, number of penile surgeries, shorter adult stretched penile length, being born small for gestational age and unhealthy lifestyle (i.e. smoking, drug use, high alcohol consumption and/or fast food intake). No difference in the prevalence of testicular microcalcifications was found between men born with hypospadias and controls ($P = 0.599$).
Discussion
More frequent testicular parenchymal inhomogeneity was found in men born with hypospadias and multiple associations were seen between testicular inhomogeneity and testicular and prenatal factors. We therefore hypothesize testicular inhomogeneity could serve as a relevant, non-invasive marker hinting towards possible impaired testicular function in men born with hypospadias. Screening may be recommended starting from late puberty as the first morphological changes are typically observed at this stage and could help determine which men need to be referred for endocrine or fertility work-up. Future research should explore long-term implications, particularly the link to sub- and infertility and potential risk to develop testicular germ cell malignancies.

The impact of organ specific autoimmunity on menopause onset in females with Graves' disease

Sofia Chatzi[1], Vasiliki Georgakopoulou[1], Andreas Goules[1], George Mastorakos[2] & Georgios Boutzios[1]
[1]Department of Pathophysiology, National and Kapodistrian University of Athens, Laiko General Hospital, Athens, Greece; [2]Unit of Endocrinology, Diabetes mellitus, and Metabolism, Aretaieion Hospital, School of Medicine, National and Kapodistrian University of Athens, Athens, Greece

Introduction
Menopause is the permanent cessation of menstruation, as a result of inclining levels of ovarian hormones. Few studies demonstrate diminished ovarian reverse, fertility defects and menopause onset at a younger age, in female patients with autoimmune and inflammatory disorders. Aim of the study is to evaluate the potential effect of Graves' disease (GD) induced, organ-specific thyroid autoimmunity, on menopause onset.
Material and Methods
We recruited 140 menopausal women with GD, admitted in Autoimmune Endocrinopathies outpatient clinic, Department of Pathophysiology, Laikon General Hospital, between 2020-2023. The analyzed data were respectively collected from patients' medical record by a single investigator. We recorded demographic characteristics, comprehensive medical history, family medical history and smoking status. Medical history was focused on GD features. Moreover, we included past medical history related to reproductive and overall gynecologic health including age of menarche, mensuration irregularities, number of pregnancies, number of pregnancy loss and age of menopause onset. Patients underwent laboratory evaluation for autoantibodies (TPO-Abs, Tg-Abs, TSI, ANA, APCA) and biochemistry. The group of patients was compared to healthy control group of menopausal females (2:1).
Results
Mean patients age at the time of the study was 64.36 ± 8.56 years and mean BMI 27.13 ± 5.46 kg/m^2 . Age at menopause onset did not show statistically significant differences between the two groups, despite the fact that patients with GD had menopause onset at a slightly older age (49.42 ± 3.63 vs 48.88 ± 4.66 years, $P = 0.391$). Regarding menstrual irregularities during reproductive years, higher percentage of patients reported such disturbances compared to controls, without reaching statistical significance. Infertility issues were more commonly presented in patients with GD (32.1% vs 12,9%, $P = 0.006$). Pregnancy loss did not ascertain in 79.3% of patients with GD and in 82.9% of healthy controls ($P = 0.983$). Median menarche age was 12 years ($P = 0.20$) and it was the same for both groups.
Conclusion
From our study, a statistically significant impact of GD on menopause onset is not demonstrated, whereas we found significant difference in infertility issues between the two groups. Further prospective studies with higher number of participants should be conducted to establish potential correlation.

Luteinizing hormone/choriogonadotropin receptor (LHCGR)/G protein-coupled estrogen receptor (GPER) heteromers do not modulate reproductive signals in male and female gonadal cells

Clara Lazzaretti[1], Ginevra Pelagatti[1], Carmela Perri[1,2], Claudia Fusco[1], Samantha Sperduti[1,3], Manuela Simoni[1,3,4] & Livio Casarini[1,3]
[1]Unit of Endocrinology, University of Modena and Reggio Emilia, Department of Biomedical, Metabolic and Neural Sciences, Modena, Italy; [2]International PhD School in Clinical and Experimental Medicine (CEM), University of Modena and Reggio Emilia, Modena, Italy; [3]Center for Genomic Research, University of Modena and Reggio Emilia, Modena, Italy; [4]Department of Medical Specialties, Azienda Ospedaliero-Universitaria di Modena, Baggiovara, Modena, Italy

The G protein-coupled estrogen receptor (GPER) forms heteromeric complexes with the gonadotropin receptors, reprogramming proliferative and anti-apoptotic signals. In the transfected HEK293 cell line, co-expression of GPER and luteinizing hormone (LH)/choriogonadotropin (hCG) receptor (LHCGR) specifically prevents LH- and hCG-dependent activation of Gq-mediated pathway and inhibits cell proliferation. In this study, we evaluated whether LHCGR/GPER heteromers modulate gonadotropin-dependent signals in gonadal cells endogenously expressing the two receptors. Expression level of genes coding G proteins (*GNAS, GNAQ*), and receptor (*LHCGR* and *GPER*) were quantified by digital droplet PCR, in native and GPER/Gper-coding cDNA transfected murine Leydig tumor cell line 1 (mLTC-1) and primary human granulosa cells (hGLCs). Receptor-receptor interactions were evaluated by proximity ligation assay (PLA). Cells were treated with LH/hCG, and signaling analysis was performed to evaluate intracellular calcium ion (Ca^{2+}), cAMP, inositol monophosphate (IP1) increase, and steroid production by bioimaging methods, and homogeneous time-resolved fluorescence (HTRF). Data was analyzed by Kruskal-Wallis test and Dunn's post-hoc test ($P < 0.05$; $n = 4$ to 6), as appropriate. Gene expression analysis confirmed that both cell lines have *LHCGR* and *GPER* transcripts, whose levels increased in transfected cells. PLA revealed the presence of LHCGR/GPER heteromers on mLTC-1 and hGLC cell surface. Receptor co-expression did not impair LH/hCG-dependent Gq-mediated pathway, as gonadotropins failed to activate it. In mLTC-1 and hGLC cells, Gs expression levels are higher than those of Gq, with LHCGR:G protein 10:1 e 0.5:1 ratio respectively, suggestive of preferential receptor occupancy by Gs, and only marginal Gq coupling. Therefore, LH/hCG-treatment activates intracellular cAMP response and steroid production but fails to trigger Ca^{2+}/IP1 activation in both gonadal cell types. IP1 response is restored in tranfected cells overexpressing Gq protein. In conclusion, endogenous GPER naturally interacts with LHCGR in Leydig and granulosa cells. However, GPER has no effect on Gq pathway, which is switched off by preferential LHCGR coupling to Gs.

JOINT3386

A case of syndromic sexual dysgenesis caused by DAX1 gene duplication

Ping Li[1], Zhiruo Zhao[1] & Jie Xing[1]
[1]the Second Hospital of Jilin University, Department of Developmental Pediatrics, Changchun, China

Background
The DAX1 (NR0B1) gene, located at Xp21.2, encodes a nuclear receptor critical for adrenal and reproductive system development. Its dosage sensitivity is documented, with duplications causing 46,XY disorder of sexual development (DSD) through testicular dysgenesis. This case report expands the phenotypic spectrum of Xp21 duplication syndrome and reinforces DAX1's role in sex determination pathways.
Clinical Case
A pediatric patient presented with syndromic features including hypertelorism, epicanthic folds, low-set ears, broad nasal bridge, and global developmental delay. Genital examination revealed ambiguous external genitalia (Prader stage II). Chromosomal microarray analysis identified two pathogenic copy number variations: a 37.2 Mb duplication at Xp22p21 (chrX:168,546-37,348,545) encompassing DAX1, and a 3.5 Mb duplication at Yp11.2 (chrY:24,985,261-28,458,663). Karyotype confirmation demonstrated 46,XY, dup(X)(p22p21). Endocrine evaluation showed elevated gonadotropins (FSH 18.7 IU/l, LH 12.3 IU/l) with low anti-Müllerian hormone (1.2 ng/mL), consistent with testicular insufficiency.
Conclusion
This case provides definitive evidence that DAX1 duplication alone suffices to cause 46,XY DSD, independent of Y chromosome anomalies. The identified Xp22p21 duplication (containing 63 OMIM genes including IL1RAPL1 and ARX) may explain the neurodevelopmental comorbidities. We propose that DAX1 copy number analysis should be integrated into first-tier genetic testing for 46,XY DSD, particularly in syndromic cases. These findings underscore the necessity of comprehensive genomic characterization to unravel complex genotype-phenotype correlations in sexual differentiation disorders.

Follow-up of the pearl cycle app–evaluation: an integrated ovulation prediction kit (OPK) with urine test strips. fertility characteristics, number and course of pregnancies observed

Melissa Niti Suwarno[1], Vanadin Seifert-Klauss[1], Katharina Hancke[2] & Juan Leonardo Martinez[3]

[1]Technische Universität München, School of Medicine and Health, Klinik und Poliklinik für Frauenheilkunde am Universitätsklinikum Klinikum rechts der Isar, Munich, Germany; [2]Universität Ulm, Department of Gynaecology, UniFee, Fertility and gyn. Endocrinology, Ulm, Germany; [3]Colorimetrix GmbH, München, Germany

Fertility depends on the complex interaction of various factors. The most common causes include hormonal dysregulation or sperm abnormalities. The follow-up of the Pearl Cycle App study aimed to characterize fertility influencing factors (FIF), and the number and course of pregnancies observed. Women aged between 21 and 45, trying to conceive for up to 24 months and without hormone intake, were recruited in the gynaecological outpatient clinics of the Technical University Munich and the University of Ulm. After informed consent participants downloaded the app "Pearl Fertility" and received OPKs with lateral flow immunoassay test strips (LFIA) for LH, FSH, PdG and hCG for at home measurements. The LFIA colour change was analysed via camera detection and three algorithms calculated the ovulation date. Folliculometry was performed sonographically before and after the predicted day of ovulation. Participants were observed for up to three cycles and followed-up after one year. Three questionnaires assessed baseline characteristics, user experience, and later pregnancy outcomes and FIF. Out of 89 recruited women, 22,5% (20) and 11,2% (10) of their partners, had at least one FIF which became known before, during, or after participation. In 29,2% (26) of the couples at least one FIF was identified. In participants with hormonal dysregulation and/or irregular cycles, ovulation prediction was correct in 61,5% (16) of 26 cycles analysed. 15,7% (14) became pregnant after 1,3 (SD ± 0,5) cycles. Of these, 21,4% (3) had at least one FIF. 71,4% (10) of these pregnancies resulted in live births. 48/89 (53,9%) women responded to the follow-up. 50% (24) had become pregnant 11,1 (SD ± 8,3) months after participation. 14 (48,3%) of a total of 29 pregnancies post participation resulted in live births. 33,3% (8/24) were currently pregnant at the time of the follow-up. 37,5% (9/24) had used assisted reproduction technology and 8,33% (2/24) ovulation induction. The information on pregnancies and FIF is based on the patient surveys. Therefore, the true numbers might be even higher. The high proportion of couples with FIF and/or ART use after the study combined with the short participation period may explain why a pregnancy did not occur during participation or did not result in a birth. This could also reflect a selection bias as the app was likely used by women who had struggled to conceive. This information can also provide additional insights into the effectiveness of the ovulation prediction and highlights the need for medical evaluation of personalised approaches to fertility treatment.

Late bedtime was associated with increased androgen and reduced lean mass in women with polycystic ovary syndrome: a cross-sectional study

Yuqin Zhang[1], Min Zhang[1], Meili Cai[1], Xiaowen Shao[2], Diliqingna Dilimulati[1], Jiayi Lu[3], Cuiling Zhu[1], Haibing Chen[1], Changbin Li[4], Shen Qu[1] & Manna Zhang[1,4]
[1]Department of Endocrinology and Metabolism, Shanghai Tenth People's Hospital, School of Medicine, Tongji University, Shanghai, China; [2]Department of Obstetrics and Gynecology, Shanghai Tenth People's Hospital, School of Medicine, Tongji University, Shanghai, China; [3]Department of Clinical Laboratory, Shanghai Tenth People's Hospital, School of Medicine, Tongji University, Shanghai, China; [4]Department of General Practice, Shanghai Tenth People's Hospital, School of Medicine, Tongji University, Shanghai, China

Background
Despite limited evidence regarding the effect of bedtime on androgen and lean muscle mass, it is widely recognized as being associated with various metabolic diseases. The present study aimed to investigated the relationship between bedtime, androgen-associated traits, and dual-energy x-ray absorptiometry (DEXA)-based lean mass (LM) in polycystic ovary syndrome (PCOS).
Methods
This cross-sectional study recruited 899 reproductive-aged women with PCOS in the PCOS subspecialty clinic at Shanghai Tenth People's Hospital, and finally 636 women entered the study. Anthropometric, metabolic, sex and reproductive hormonal characteristics, and body fat and lean composition measured by DEXA were collected. The information on bedtime was adapted from the Pittsburgh Sleep Quality Index and bedtime was categorized into three aspects: early bedtime ($\leq$23:00), intermediate bedtime ($>$23:00 to 24:00), and late bedtime ($>$ 24:00) according to the time of falling asleep.
Results
There was 24.4% of participants fell asleep before 23:00, and 75.6% fell asleep after 23:00. After adjusting for age in covariance analysis, participants in both intermediate and late bedtime groups had fewer menstrual cycles and higher levels of anti-mullerian hormone (AMH) than those in the early bedtime group. Compared with early and intermediate bedtime, those with late bedtime had higher levels of total testosterone (TT) and androstenedione (AD). After controlling possible confounders, multiple liner regression analysis found that compared with early bedtime, late bedtime was independently associated with higher levels of TT and AD, meanwhile intermediate bedtime was independently associated with higher levels of AMH. Furthermore, late bedtime was independently correlated to reduced levels of muscle mass index LM/height^2 and appendicular muscle mass index appLM/height^2 compared with early bedtime.
Conclusion
This study provides novel insight that late bedtime (after 24:00) was independently related to elevated androgenic hormones and reduced LM in individuals with PCOS.

Keywords
polycystic ovary syndrome, sleep, bedtime, lean mass, androgen.

Impaired sperm quality in previous illicit users of anabolic androgenic steroids

Yeliz Bulut[1,2], Niels Brandt-Jacobsen[1], Niels Jørgensen[3], Anders Juul[2,3], Jon Jarløv Rasmussen[1] & Caroline Kistorp[1,2]
[1]Copenhagen University Hospital - Rigshospitalet, Department of Nephrology and Endocrinology, Copenhagen, Denmark; [2]Faculty of Health and Medical Sciences, University of Denmark, Department of Clinical Medicine, Copenhagen, Denmark; [3]Copenhagen University Hospital - Rigshospitalet, Department of Growth and Reproduction, Copenhagen, Denmark

Background and Aims
Former use of anabolic androgenic steroids (AAS) may result in irreversible damage on testicular Leydig cell function. Impaired semen quality was reported in current AAS users but, the impact of long-term AAS usage is unclear. The primary aim of the current study was to assess semen quality in current and former AAS users compared with nonusers who had never used AAS.
Methods
Cross-sectional study including men involved in recreational training, grouped according to their AAS history. Medical records and AAS history were obtained during personal interviews. Each participant provided a semen sample to assess classical semen parameters. Impaired semen quality was defined as total sperm count below 39 million sperm, and oligospermia by a cutoff below 15 million sperm per milliliter semen, according to the World Health Organization 2021 guidelines.
Results
We included 46 former, 59 current AAS users, and 46 nonusers as controls. The mean (SD) age of all participants was 34.7 (8.5) years. The accumulated duration of AAS use, among current users was 153 weeks (114;207) (geometric mean (95% CI)), and among former users, 106 (77;145) weeks, $P = 0.092$. The elapsed duration since AAS cessation, was 1.3 (0.9;1.9) (geometric mean (95% CI) years in former users. A total sperm count $<$ 39 million was more prevalent among current and former users than in nonusers, 45 (76%) vs 13 (28%) vs 2 (4%), $P <$ 0.001. Furthermore, sperm concentration $<$15 million/ml was observed in 48 (81%) current vs 16 (35%) former users vs 5 (11%) nonusers, $P < 0.001$. Azoospermia was only present in current and former users (25 (42%) vs 2 (4%) vs 0 (0%), $P < 0.001$. The frequency of sperm immotility was increased among current 43 (23%) and former users 36 (20%) compared with nonusers, 26 (14%) (respectively $P < 0.001$, and $P = 0.005$) In a multivariable logistic regression model using men with previous use of AAS every doubling of duration since AAS cessation (log2) was associated with almost 50% reduction in the risk of total semen count below $<$ 39 million (odds ratio, 0.55, 95% CI, (0.33; 0.92), $P =$ 0.022) when adjusting for age and accumulated duration of AAS.
Conclusions
Anabolic androgenic steroids use is associated with impaired sperm count and motility among younger men with previous use more than one year after cessation. A potential improvement of sperm count over time following cessation was observed.

JOINT3582

Establishing mouse ovarian ex vivo tissue culture

Chimène van Ham [1], Lív Bech Árting[1], Anne Jørgensen[1] & Martin Blomberg Jensen[1]
[1]Copenhagen University Hospital - Herlev and Gentofte, Department of Endocrinology and internal medicine, Copenhagen, Denmark

Introduction
Infertility is an issue of increasing concern with an estimated 1 in 6 adults affected during their lifespan. This highlights the need for more comprehensive insight about the biological events that can affect the female fertility potential during a lifetime, and the importance of a more detailed understanding of ovarian physiology. Thus, this project aims to establish a foetal and a prepubertal mouse ovarian *ex vivo* culture model. These tissue culture models will be an essential tool to study the effects of selected manipulations on ovarian development, and early folliculogenesis.
Methods
Three *ex vivo* culture approaches were tested using ovaries from foetal and prepubertal mice including culture; on agarose gel fragments, in hanging drops, and on porous membranes. Ovaries were cultured for 48 hours, and 7 days. After the culture period, the three methods were evaluated, and overall tissue preservation was compared. Tissue morphology was evaluated using Periodic Acid-Schiff staining, while proliferation and apoptosis was investigated using BrdU incorporation and cleaved PARP staining, respectively. Subsequently, the established ovarian cultures will used to study effects of selected treatment given through the culture media. Analysis will include quantification of germ cells (Oct4-positive cells) and follicles (from PAS sections) and immunohistochemical stainings for cell lineage markers such as, granulosa cells (AMH, CYP19A1), and theca cells (CYP11A1, CYP17A1). +.
Results
The analysis of the three culture methods and culture lengths are currently ongoing. The optimal culture method will be determined based on preservation of morphology, minimal apoptosis, and sustained cell proliferation.
Conclusion
Preliminary findings suggest that *ex vivo* culture of foetal and prepubertal mouse ovarian tissue is feasible with the tested culture approaches. Ongoing analysis will identify the most appropriate culture approach for future studies examining the effects of manipulating various signaling pathways involved in the regulation of ovarian development and function.

The impact of estrogens on gut microbiome in post-menopause and premature ovarian insufficiency - a meta-analysis and systematic review

Kristina Saravinovska[1,2], Daniele Santi[3], Francesco Costantino[3], Antoan Stefan Sojat[1], Giorgia Spaggiari[4], Miomira Ivovic[1,2], Irene Lambrinoudaki[5], Elena Armeni[5,6], Svetlana Vujovic[1,2] & Ljiljana Marina[1,2]
[1]Clinic of Endocrinology, Diabetes and Metabolic Diseases, University Clinical Centre of Serbia, National Centre for Infertility and Endocrinology of Gender, Belgrade, Serbia; [2]Faculty of Medicine, University of Belgrade, Belgrade, Serbia; [3]Unit of Endocrinology, Department of Biomedical, Metabolic and Neural Sciences, University of Modena and Reggio Emilia, Modena, Italy; [4]Unit of Endocrinology, Department of Medical Specialties, Azienda Ospedaliero-Universitaria of Modena, Modena, Italy; [5]2nd Department of Obstetrics and Gynaecology, University of Athens, Aretaieio Hospital, Athens, Greece; [6]Royal Free Hospital NHS Trust, London, United Kingdom

Objectives
There has been a rising interest in the relationship between gut microbiome (GM) changes and women's reproductive health, with estrobolome taking a central role in the interplay. This meta-analysis aimed to systematically review and combine existing data to assess GM alterations in postmenopausal and women with premature ovarian insufficiency (POI) - hypoestrogenic women when compared to premenopausal (euestrogenic) women.
Design and methods
Medline, EMBASE and Cochrane Library were searched for relevant articles and selected according to the strict inclusion criteria. Studies comparing euestrogenic (premenopausal) to hypoestrogenic (POI or postmenopausal) women were considered. The inclusion criteria were: no use of hormonal replacement therapy (HRT) or hormonal contraceptives, no active infections, no active intestinal diseases and no actual history of cancer of any origin. Seven of 15 papers assessed for eligibility were included in the analysis, incorporating data from 1730 participants. The risk of bias was assessed using the Newcastle-Ottawa scale. This study was registered on the International Prospective Register of Systematic Reviews (PROSPERO), CRD42024497630.
Results
No statistically significant differences were observed in α–diversity ($P = 0.990$), Bacteroidetes (B) ($P = 0.440$), or Firmicutes (F) abundance ($P = 0.110$) between hypoestrogenic and euestrogenic groups. Similarly, the B/F ratio ($P = 0.400$) showed no significant difference between the groups. However, the results were highly heterogeneous in the current literature, with I^2 scores ranging from 68% to 99%.
Conclusion
This meta-analysis showed no differences in GM composition between postmenopausal and premenopausal women, nor between women with POI and premenopausal women. These findings should be interpreted with caution due to the high heterogeneity of the populations studied. Future research prioritizing the exclusion of already known GM disruptors is critical for women with POI and postmenopausal women. This meta-analysis challenges the assumed link between estrogen levels and GM alterations while stressing the need for rigorous, high-quality research to elucidate GM characteristics in estrogen-dependent states.

Health implications of self-reported PCOS in a developing country: the brazilian longitudinal study of adult health

Flavia Tinano[1], Iza Machado[1], Isabela Bensenor[2], Paulo Lotufo[2], Ana Claudia Latronico[1] & Larissa Gomes[1]
[1]School of Medicine, University of Sao Paulo, Discipline of Endocrinology and Metabolism, Department of Internal Medicine, São Paulo, Brazil; [2]School of Medicine, University of Sao Paulo, Department of Internal Medicine, São Paulo, Brazil

Context
The diagnosis of polycystic ovary syndrome (PCOS) remains challenging due to its heterogeneous clinical presentation and the absence of a single diagnostic marker. While clinical diagnosis integrates clinical, laboratory, and imaging assessments, population studies often depend on self-reported PCOS (srPCOS), leading to inconsistent findings regarding associated health risks. This study evaluates the prevalence of key clinical symptoms of PCOS, specifically oligomenorrhea (OA) and hirsutism, among women with self-reported PCOS (srPCOS) in a developing country and investigates their reproductive and cardiometabolic outcomes.
Methods
The ELSA-Brazil study integrates cross-sectional and prospective cohort analyses of 15,105 civil servants across Brazil. Participants underwent four longitudinal evaluations, including interviews, anthropometric assessments, and biochemical tests. This analysis included 7,623 women aged 35–74 years who participated in the first two evaluations (2008–2014). srPCOS was defined as a self-reported medical diagnosis based on clinical criteria, ultrasound findings, or unspecified parameters. Clinical symptoms assessed included OA (cycles >35 days) and hirsutism (self-administered questionnaire based on Ferriman–Gallwey score ≥ 5). Metabolic outcomes included obesity, central obesity, type 2 diabetes mellitus (T2DM), dyslipidemia, hypertension, metabolic syndrome, and hepatic steatosis on ultrasound. Reproductive outcomes included pre-eclampsia, gestational diabetes, and infertility/subfertility, while cardiovascular outcomes encompassed self-reported myocardial infarction, angina, myocardial revascularization, stroke, and heart failure. Statistical analyses were adjusted for age, race, education, smoking, alcohol intake, and physical activity, with significance set at $P < 0.05$.
Results
The prevalence of srPCOS was 11.7% ($n = 888$), with 12.3% reporting clinical diagnosis, 78% ultrasound-based diagnosis, 4.1% both, and 5.5% unspecified. Among women with srPCOS, 3.5% reported OA, and 21.9% reported hirsutism. The proportion of women with both OA and hirsutism was very low ($\leq 1\%$), while 22.5% reported either OA or hirsutism. srPCOS was associated with higher odds of obesity (OR 1.2), T2DM (OR 1.4), metabolic syndrome (OR 1.2), infertility/subfertility (OR 2.1), angina (OR 1.6), and heart failure (OR 2.3) (all $P < 0.05$).
Conclusions
In this large Brazilian cohort, most women with srPCOS reported an ultrasound-based diagnosis alone, and the prevalence of both hirsutism and OA was low—findings that differ from previous studies. srPCOS was linked to certain cardiometabolic and reproductive outcomes but not to others traditionally

associated with PCOS. This discrepancy likely reflects diagnostic heterogeneity in self-reported cases, emphasizing the need for improved classification methods in epidemiological studies.

Objective

Congenital hypogonadotropic hypogonadism (CHH) is a rare endocrine disorder characterized by absent or incomplete puberty due to deficient gonadotropin-releasing hormone (GnRH) function. A subset of affected individuals present with additional developmental anomalies, including cleft lip and palate (CLP). This study explores the clinical and genetic overlap between CHH and CLP.

Methods

A total of 336 CHH probands were evaluated for CLP. High-throughput sequencing was performed, and variant analysis focused on known CHH and CLP genes.

Results

Twenty-one patients (6%) had CLP. Genetic analysis identified pathogenic (P) or likely pathogenic (LP) variants in genes associated with both conditions (e.g. *FGFR1*, *CHD7*). Additionally, 17% of CHH probands without CLP carried deleterious variants in CLP genes (e.g. *DVL3*, *PLCB4, NIPBL* and *EDNRA*). Further, digenic inheritance involving genes from both conditions was observed in 4 cases. *FGFR1* was found in digenicity with 3 other genes in 3 patients (e.g. TP63, TGFBR2 and INTS1) and one case involved *PNPLA6* and *PIEZO2*.

Conclusion

These findings support a phenotypic continuum between CHH and CLP with genetic overlap, reinforcing the role of shared developmental pathways. Research into overlapping syndromes may improve diagnostic accuracy and personalized care for affected individuals.

Opposite degrees of virilisation in two individuals with 46,XY DSD and variants in NR5A1/SF1

Jimena C. Lopez Dacal[1], Lourdes Correa Brito[1,2], Angela Figueroa Sobrero[3], Miguel Jr. Podestá[4], Martín Medin[5], María Gabriela Ropelato[1,2], Andrea Arcari[1], Romina P. Grinspon[1] & Rodolfo A. Rey[1,2]

[1]Centro de Investigaciones Endocrinológicas "Dr César Bergadá" (CEDIE), CONICET-FEI-División de Endocrinología, Hospital de Niños Ricardo Gutiérrez, Buenos Aires, Argentina; [2]Hospital de Niños Ricardo Gutiérrez, Unidad de Medicina Traslacional, Buenos Aires, Argentina; [3]Hospital San Roque, Paraná, Argentina; [4]Hospital de Niños Ricardo Gutiérrez, Unidad de Urología, Buenos Aires, Argentina; [5]Hospital de Niños Ricardo Gutiérrez, Servicio de Anatomía patológica, Buenos Aires, Argentina

In 46,XY DSD with *NR5A1*/SF1 variants, genotype-phenotype correlations have failed to be found. SF1 is a nuclear receptor regulates early testis differentiation and the expression of steroidogenic enzymes, the androgen receptor (AR) and AMH. Variants affecting SF1 would be expected to result in gonadal dysgenesis and/or specific defects in androgen synthesis or action and/or in AMH expression, leading to various degrees of undervirilisation. This report describes two cases with 46,XY DSD and variants in *NR5A1* and opposite phenotypes, with hormonal and anatomic features that challenge the hypotheses on the potential pathogenic mechanisms. Case 1, assigned male at birth, was referred at 2 years of age, the phallus was 2.5-cm long, with penoscrotal hypospadias, partial labioscrotal fusion and labioscrotal gonads (External Genital Score-EGS: 7/12). Serum hormone levels were: FSH 5 mIU/mL (ref: 0.3-1.7), AMH 338 pmol/l (300-1800), LH 0.8 mIU/mL (0.1-0.3). At 6 years, testosterone post-hCG was 150 ng/dl. Altogether, these results indicated a mild primary hypogonadism. Müllerian remnants were absent in imaging studies. Gonadal histology, showing abnormally branching seminiferous tubules with typical Sertoli and premeiotic germ cells and a normal albuginea, was interpreted as mild testicular dysgenesis. Genetic analysis by NGS identified a heterozygous, missense, likely pathogenic variant NM_004959.5:c.259C>T, NP_004950.2:p.(Arg87Cys) in exon 4, corresponding to the DNA-binding domain (DBD), of *NR5A1*. Case 2, assigned female, was referred at 11 years of age for clitoromegaly. The phallus length was 3.5 cm, completely separated labia majora, a single urogenital opening and nonpalpable gonads (EGS 3/12). Hormone levels were: FSH 23 mIU/mL (ref for 46,XY: 1.3-6.5), AMH 10 pmol/l (40-400), LH 10 mIU/mL (0.7-5.2), testosterone 272 ng/dl (40-550), indicating mild primary hypogonadism. Surgical exploration showed the existence of abdominal gonads and absence of Müllerian remnants. Gonadal histology, showing normal albuginea, seminiferous tubules with typical Sertoli cells, absence of germ cells and thickened basement membrane, and interstitial tissue with typical Leydig cells, was interpreted as typical testicular tissue with changes associated with cryptorchid position. NGS identified a heterozygous, missense, likely pathogenic variant NM_004959.5:c.1210T>A, NP_004950.2:p.(Tyr404Asn) in exon 7 corresponding to the ligand-binding domain (LBD) of *NR5A1*. In conclusion, these two cases with very mildly affected testicular function showed normal Müllerian duct regression, as expected, but completely opposite androgen activity. These observations advocate against an effect of the *NR5A1* variants on testis differentiation and AMH expression, with potentially different effects on testosterone production and/or AR activity, and highlight the need for further functional explorations.

JOINT1226

Reevaluating reference intervals for androstenedione in reproductive-aged woman

Adriana Bokulic[1], Domagoj Marijančević[1], Ivana Zec[1] & Sanja Goreta[1]

[1]Sestre Milosrdnice University Hospital Center, Department of Clinical Chemistry, Zagreb, Croatia

Introduction

Reference intervals (RIs) for androstenedione should be specific to the population and immunoassay method. Generally, laboratories are responsible for verifying RIs established by an external source (e.g. a manufacturer) or determining their own. Initially, the laboratory adopted a manufacturer-defined RI for reproductive-aged women calculated by the direct method. As we noted many results above the upper reference limit, we needed to implement more suitable RIs for our population. We opted for an indirect approach using routine laboratory data stored in the laboratory information system. This study aims to compare (i) manufacturer-defined and calculated indirect RI and (ii) calculated indirect RIs from one and five years of data.

Methods

Manufacturer-defined 90%RI for reproductive-aged women was 1.71-4.58 nmol/l measured by Roche electrochemiluminescent immunoassay. All unique visits from women aged 20 to 45, with androstenedione, testosterone, sex hormone binding globulin (SHBG), and follicle-stimulating hormone (FSH) results, were extracted from the database. All patients with testosterone, SHBG and FSH outside the RI (0.29-1,67 nmol/l, 32-128 nmol/l, < 25.8 IU/l, respectively) were excluded. After the data-clearing step: (i) the initial data set included 520 subjects from one year of data, which is considered a small sample size for an indirect approach, and (ii) the subsequent data set included 2664 subjects from 5 years of data. Outliers were tested for each group separately and subsequently eliminated. RIs were calculated for the total age group (20 – 45 years) and subgroups (20-30 and 30-45 years) with the parametric method after Box-Cox transformation.

Results

For the first data set, the 95%RI in the total age group (20-45 years) was 2.48-8.89 nmol/l with a median of 5.13 nmol/l. The age-stratified 95%RIs were 3.02-9.43 nmol/l (20-30 years) and 2.23-7.75 nmol/l (30-45 years). The number of subjects was 518, 267, and 250, respectively. For the second data set, the 95%RI for the total age group (20-45 years) was 2,13-8,74 nmol/l with a median of 4.73 nmol/l.

The age-stratified 95%RIs were 2.81-9.25 nmol/l (20-30 years) and 1.88-7.96 nmol/l (30-45 years). The number of subjects was 2640, 1524, and 1391, respectively.
Conclusion
A larger dataset drawn from a broader data range showed RIs comparable to those calculated initially from a smaller sample size. This study confirms significant differences between calculated and manufacturer-reported RIs. Both calculated medians exceeded the manufacturer-declared upper reference limit, indicating that more than half of our subjects would have shown elevated androstenedione concentrations had the manufacturer-defined RI been applied.

[1]UMIB - Unit for Multidisciplinary Research in Biomedicine, ICBAS - School of Medicine and Biomedical Sciences, University of Porto, 4050-313 Porto, Portugal, Porto, Portugal; [2]ITR - Laboratory for Integrative and Translational Research in Population Health, 4050-600 Porto, Portugal, Porto, Portugal; [3]Centre for Medically Assisted Procreation/Public Gamete Bank, Gynecology Department, Centro Materno-Infantil do Norte Dr. Albino Aroso (CMIN), Centro Hospitalar Universitário de Santo António (CHUdSA), Unidade Local de Saúde de Santo António (ULSSA), 4099-001 Porto, Portugal, Porto, Portugal; [4]CEIE – Centro de Estudos de Infertilidade e Esterilidade, 4050-345 Porto, Portugal, Porto, Portugal

Polycystic ovary syndrome (PCOS) is an endocrine disorder characterized by oligo-ovulation, clinical or biochemical hyperandrogenemia and polycystic ovaries, which affect reproductive function. Besides anovulation, there are several other hormone and metabolic factors that can have a negative impact in fertility outcomes of women with PCOS. Conception requires ovulation of a mature oocyte and the presence of mature spermatozoa. During ovulation, the oocyte is released into the oviduct along with follicular fluid (FF) that modulates its fluid composition, while within the oviduct spermatozoa undergo capacitation that is required for fertilization. The FF hormone and metabolic profile of women with PCOS is known to depict distinctive molecular fingerprints. However, whether the FF profile associated with PCOS affects spermatozoa capacitation is unknown, which this study aimed to disclose. For this purpose, spermatozoa were isolated from seminal fluid of men with normozoospermia ($n = 12$) and incubated with FF collected from women undergoing *in vitro* fertilization (IVF) treatments. FF was harvested from age-matched women with PCOS and normal weight (BMI $< 25 kg/m^2$; PCOS; $n = 6$), women with PCOS and obesity (BMI > 30 kg/m^2; PCOS + Ob; $n = 6$) and normo-ovulatory women with normal weight (BMI $<$ $25 kg/m^2$, CTRL; $n = 6$) submitted to IVF treatments due to tubal and/or male infertility factors. FF of each group was pooled before incubation with spermatozoa. Spermatozoa isolated from seminal fluid were incubated in capacitating medium (BWW) at 37ºC. After the first 2h of incubation, spermatozoa were treated with 20% pooled FF from each group (CTRL, PCOS, PCOS + Ob) for an additional 1h. Vitality and motility (total and progressive) were assessed hourly. While the FF did not affect vitality at all tested conditions, the progressive motility was significantly increased after incubation with FF from CTRL as compared to the pre-treatment conditions ($48.76 \pm 12.74\%$ vs $38.69 \pm 17.33\%$, $P = 0.0251$), which was not observed after incubation with FF from PCOS ($36.57 \pm 16.81\%$, $P = 0.8895$) nor PCOS + Ob ($35.69 \pm 16.17\%$, $P = 0.6560$). Moreover, progressive motility was higher after treatment with FF from the CTRL group as compared to the PCOS ($P = 0.0029$) and PCOS + Ob group ($P = 0.0009$). Overall, our results suggest that the FF from women with PCOS negatively impacts spermatozoa capacitation. While further studies are required to identify the molecular mechanisms, our study identified a potentially novel mechanism through which PCOS negatively impacts on fertility.

Perfluorooctanoic acid (PFOA) and male reproductive health: redox status imbalance in Wistar rat testes

Đurica Marić[1], Jovana Živanović[1], Katarina Baralić[1], Evica Antonijević Miljaković[1], Danijela Đukić-Ćosić[1], Zorica Bulat[1], Biljana Antonijević[1] & Aleksandra Buha Djordjevic[1]
[1]Faculty of Pharmacy, University of Belgrade, Department of Toxicology "Akademik Danilo Soldatović", Belgrade, Serbia

Per- and polyfluoroalkyl substances (PFAS) include several thousand compounds with a carbon chain and charged functional groups such as sulfonate or carboxylate. They are present in the environment mainly due to their widespread use and applicability in a large number of industrial sectors and consumer products. Due to their harmful effects on human health, the production and use of many compounds from this group have been banned, but due to their high persistence in the environment, these compounds are still present and represent a global problem. Previous studies have shown the harmful effects of these chemicals on the immune, metabolic, endocrine and reproductive systems. Among the long-chain PFAS, perfluorooctanoic acid (PFOA) is certainly one of the most important representatives of this group of compounds beingn abundant in the serum of the human population. The aim of this work was to examine the influence of PFOA on the parameters of oxidative stress and antioxidant protection in testicular tissue of Wistar rats. Groups M1 and m^2 were treated with doses that correspond to the lower (0.015 mg/kg b.w./day) and higher levels of exposure (0.15 mg/kg b.w./day) of the general population, respectively. Group M3 was treated with a dose that can be considered safe according to the literature (0.625 mg/kg b.w./day). PFOA solutions were prepared in a 0.5% solution of Tween-20 in deionized water. The experiment also included a control group that received a 0.5% solution of Tween-20 in deionized water. There were 6 animals in each group. After 28 days of exposure, the animals were sacrificed, testes tissue samples were collected, and IMA, MDA, SH groups, GSH, and SOD were determined by the spectrophotometric method. A statistically significant increase in MDA was observed in the m^2 group. Of the examined parameters of antioxidant protection, statistically significant decrease in the level of GSH compared to the control group was observed only in m^2 group. Probably, the decrease in GSH contributed to the increase in MDA in the m^2 group, as weakened antioxidant defense allows for greater lipid damage in cell membranes. The levels of SH groups and SOD were not significantly changed compared to the control. It has been shown that exposure to PFOA at doses that may reflect exposure in the general population can cause disturbances in the oxidative status of the testes, which can disrupt key hormonal pathways, leading to reproductive dysfunction and broader endocrine imbalances.

What matters most? gender diverse individuals' perspective in gender-affirming hormone therapy – the TRANSFORM study

Hüseyin Cihan[1,2], Johannes Kliebhan[1], Lena Morgenthaler[3], Marc Inderbinen[4], Lars Hemkens[2], David Garcia Nuñez[5] & Bettina Winzeler[2,6]
[1]University Hospital Basel, Endocrinology, Diabetology and Metabolism, Department of Internal Medicine, Basel, Switzerland; [2]University of Basel, Department of Clinical Research, Basel, Switzerland; [3]Peer community representative, Basel, Switzerland; [4]University of Basel, Department of Clinical Psychology and Psychology, Faculty of Psychology, Basel, Switzerland; [5]University Hospital Basel, Innovation Center for Gender Variance, Basel, Switzerland; [6]University Hospital Zürich, Endocrinology, Diabetology and Metabolism, Zürich, Switzerland

Background
Gender-affirming hormone therapy (GAHT) is guided by personalized patient objectives/goals, lab-based clinical monitoring, and safety considerations. Guidelines incorporate laboratory-based monitoring and safety data but encounter challenges when integrating patient goals into research, as patient goals are non-standardized and subjective. Key patient goals should be identified, integrated into clinical trials, and should be prioritized in endpoints of research; this could increase the relevance of research findings for clinical practice. This study aims to address this gap by exploring the personal goals and needs of transgender and gender diverse individuals regarding gender affirming hormone therapy, emphasizing the inclusion of gender diverse individuals' perspectives, which remain largely understudied.
Method
Following comprehensive literature research, we developed an anonymous, cross-sectional web-based online survey in collaboration with professionals and community representatives. Our target population was transgender and gender diverse individuals above age 16 who were currently undergoing, planned to start, or stopped GAHT. In addition to sociodemographic questions, participants rated predefined goals (physical changes, quality of life, sexuality, reduced gender dysphoria, safety) on a scale from 1 to 10 and then ranked them by priority (most

important, 2nd most important, etc.). If these goals didn't apply, they could specify a personal goal.
Result
Between May and September 2024, 738 individuals participated in the survey (407 transmasculine, 304 transfeminine, and 27 other gender identities). The median age was 25 [21-31] for transmasculine and 29 [25-39] for transfeminine participants. A total of 229 (56.3%) transmasculine and 106 (34.9%) transfeminine individuals identified as non-binary. Regarding hormone therapy, 75.4% of transmasculine and 86.8% of transfeminine individuals were currently receiving treatment. The most frequently reported primary goal of gender-affirming hormone therapy (GAHT) varied by gender identity. While **physical changes** were prioritized by binary transgender and gender diverse participants, non-binary transgender and gender diverse participants had more diverse goals, including **quality of life and reducing gender dysphoria**. Prioritization of treatment outcomes also reflected this variation, with sexuality and safety ranked lower across all groups.
Conclusion
Our findings help caretakers by guiding conversation with transgender and gender diverse individuals in terms of GAHT and informing future research priorities. Further, therapy goals differ significantly between binary and non-binary transgender and gender diverse individuals. Considering these diverse needs, especially those of non-binary individuals, can enhance gender-affirming care.

Hair mercury levels in children with central precocious puberty and healthy individuals from two distinct geographic regions of Brazil

Aline Almeida Bastos[1], Andréa Novaes[2], Larissa Baracho Macena[1], Ana Pinheiro Machado Canton[1], Iracina Maura de Jesus[3], Ludmila Fernandes Pedrosa[1], Vinicius Nahime de Brito[1], Berenice Mendonca[1] & Ana Claudia Latronico[1]
[1]Sao Paulo University, Endocrinology, Sao Paulo, Brazil; [2]Universidade Estadual do Pará, Endocrinology, Santarém, Brazil; [3]Carlos Chagas Foundation, Environment, Santarém, Brazil

Background
The relationship between central precocious puberty (CPP) and endocrine disrupting chemical (EDCs) has been rarely demonstrated in children from different parts of the world. Longitudinal studies showed that mercury, a heavy metal considered an EDC, may increase the risk of CPP in American girls (Boston region). In Brazil, there are regions with high mercury environmental exposure, such as North region (Amazonian region) and a which may increase the risk of CPP.
Aim
To compare the hair mercury levels in children with CPP and control groups from two distinct geographic regions of Brazil (North and Southeast) with distinct levels of mercury environmental exposure.
Patients and Methods
This is a cross-sectional cohort study in which 127 children were evaluated: 71 from the North region (47 cases with CPP and 24 controls) and 56 from the Southeast region (34 cases with CPP and 22 controls). Sample collection followed a pre-established protocol with a small fraction of hair strands (about 20 strands) taken from the occipital region (1 to 2 cm away from the scalp). Hair mercury levels were analyzed using cold vapor atomic absorption spectrometry (CV-AASa) at the Carlos Chagas Foundation. The quantification limit of the method was 0.006 mg/g, and the reference values were 2-6 mg/g of hair mercury. Data were presented as the median (interquartile range), group comparisons were performed using the Mann-Whitney test in Stata program, and statistical significance was set at $p < 0.05$.
Results
In North CPP and control groups, the median hair mercury levels were 0.39 mg/g (0.06-1.72 mg/g) and 0.42 mg/g (0.08-1.6 mg/g), respectively. There was no statistically significant difference between these two groups. In Southeast CPP and control groups, the median hair mercury levels were 0.07 mg/g (0.01-0.77 mg/g) and 0.25 mg/g (0.17-0.45 mg/g), respectively. The comparison between these two groups showed a statistically significant difference ($P < 0.05$). Of note, the North CPP and control groups had higher median hair mercury levels compared to the South CPP and control groups ($p < 0.05$).
Conclusion
The higher hair mercury levels observed in both CPP and control groups from the North region confirmed an increased environmental mercury exposure in this part of Brazil. However, we could not identify an association between mercury exposure and CPP in this cohort.

JOINT3366

Establishment of a foetal and prepubertal testis ex vivo mouse model

Tessa van Hoof[1], Nadia Krarup Knudsen[1], Anne Jørgensen[1] & Martin Blomberg Jensen[1]
[1]Copenhagen University Hospital - Herlev and Gentofte, Department of Endocrinology and Internal Medicine, Herlev, Denmark

Introduction
Previous research has demonstrated that inhibition of RANKL signalling with the monoclonal antibody denosumab results in increased sperm count and testis weight in a humanized mouse model. Additionally, when culturing adult testis from the humanized RANKL mouse, inhibition of RANKL resulted in an increase in germ cell proliferation. Based on these effects we hypothesized that RANKL signalling may also play a role in prepubertal and foetal testis. Therefore, this project aims to establish an *ex vivo* culture model for prepubertal and foetal mouse testis tissue to examine the involvement of RANKL signalling in testicular development and in the onset of spermatogenesis.
Materials and Methods
Three different *ex vivo* culture approaches were tested using prepubertal and foetal mouse testis tissue, namely hanging drop, porous membranes and agarose gel fragments. The prepubertal testis tissue was cultured for 48 hours, 4 days and 1 week. Foetal testis tissue was cultured for 48 hours or 1 week. After the culture period, the tissue was fixed, and paraffin embedded. Hematoxylin and eosin (H&E) staining was performed to evaluate tissue morphology, and immunohistochemical stainings and analyses was subsequently conducted to assess cell proliferation (BrdU incorporation) and apoptosis (cleaved PARP).
Results
Analysis of the three culture methods and culture lengths are currently ongoing. The optimal culture method will be determined based on preservation of tissue morphology, sustained cell proliferation, and minimal apoptosis.
Discussion
Preliminary results show that *ex vivo* culture of both prepubertal and foetal mouse testis tissue is feasible with the tested approaches. Ongoing analysis will identify the most effective culture method. The establishment of *ex vivo* models for both developmental stages will provide a crucial framework to investigate the role of RANKL signalling in testicular development.

Neurocognitive function in males with 46,XX testicular disorder of sex development

Etki Albayrak Rasborg Hartogsohn[1,2], Mirkka Hiort[3], Julia Rohayem[4,5], Jens Fedder[6,7], Sandra Laurentino[3], Jörg Gromoll[5], Lukas Ridder[1,2], Anne Skakkebæk[8,9], Cecilie Buskbjerg[10], Agnethe Berglund[2,8] & Claus H. Gravholt[1,2,9]
[1]Department of Endocrinology, Aarhus University Hospital, Aarhus, Denmark; [2]Department of Molecular Medicine, Aarhus University Hospital, Aarhus, Denmark; [3]Centre of Reproductive Medicine and Andrology, University of Münster, Münster, Germany, Münster, Germany; [4]Children's Hospital of Eastern Switzerland, St. Gallen, Switzerland; [5]Centre of Reproductive Medicine and Andrology, University of Münster, Münster, Germany; [6]Centre of Andrology & Fertility Clinic, Odense University Hospital, Odense, Denmark; [7]Research Unit of Gynaecology and Obstetrics, University of Southern Denmark, Odense, Denmark; [8]Department of Clinical Genetics, Aarhus University Hospital, Aarhus, Denmark; [9]Department of Clinical Medicine, Aarhus University, Aarhus, Denmark; [10]Psychology and Behavioral Sciences - Unit for Psychooncology and Health Psychology, Aarhus University, Aarhus, Denmark

Background
46,XX testicular disorder of sex development (46,XX T-DSD) is a rare condition, in which individuals with a typical female chromosome pattern (46,XX) present with a male phenotype. Although previously considered to have minimal influence on neurocognitive function, recent research indicates an association with neurocognitive challenges, including lower educational attainment.
Objective
The aim of this study was to assess neurocognitive function in males with 46,XX T-DSD compared to 46,XY male controls, utilizing the Wechsler Adult Intelligence Scale, Fourth Edition (WAIS-IV). Cases and controls were matched on educational level.
Methods
A total of 47 participants were included in the study, comprising 25 males with 46,XX T-DSD and 22 46,XY male controls. All participants completed the

WAIS-IV. Based on subtest scores, we calculated Full-Scale IQ and the four index scores: Verbal Comprehension Index, Perceptual Reasoning Index, Working Memory Index, and Processing Speed Index. T-tests or Wilcoxon rank-sum tests were used to compare Full-Scale IQ, index scores, and subtest scores, depending on data normality.
Results
Males with 46,XX T-DSD demonstrated significantly lower performance on the Working Memory Index (93.3 $\pm$ 15.7 vs. 104.3 $\pm$ 14.6, $P = 0.017$) compared to controls, with significantly lower scores on two out of three subtests. A trend towards lower performance was also observed in the Verbal Comprehension Index (91.6 $\pm$ 16.7 vs. 98.9 $\pm$ 11.4, $P = 0.092$), with significantly lower scores on two out of three subtests. Similarly, a trend towards lower Full-Scale IQ was observed (93.8 $\pm$15.6 vs. 100.7 $\pm$ 10.3, $P = 0.086$). Among males with 46,XX T-DSD, 56% scored in the low average range or below on the Full-Scale IQ, compared to only 13.6% in the control group. Additionally, two males in the 46,XX T-DSD group fell within the extremely low range, whereas none in the control group did.
Conclusion
These results indicate that males with 46,XX T-DSD exhibit certain neurocognitive challenges compared to 46,XY males. Significantly lower scores were found in the Working Memory Index and on two of three subtests in the Verbal Comprehension Index. In addition, a trend towards lower Full-Scale IQ suggests potential global cognitive weaknesses, warranting further investigation. These results emphasize the importance of early identification of neurocognitive challenges and the development of tailored interventions to support both educational and functional outcomes in this population. Future studies should focus on identifying strategies to minimize diagnostic delay, enabling timely intervention.

Polycystic ovary syndrome in adolescent females with type 1 diabetes: a gonadotropins, leptin, insulin interplay

Mona El Samahy[1], Rana Mahmoud[1], Asmaa Mohamed[1] & Nouran Salah[1]
[1]Ain Shams University, Pediatrics, Cairo, Egypt

Background
Menstrual irregularities and polycystic ovary syndrome (PCOs) are recognized morbidities among women with type 1 diabetes mellitus (T1DM) representing significant physical and psychological burden. Identifying the risk determinants of these morbidities and providing therapeutic interventions for them is of utmost importance.
Objectives
assess the frequency of PCOs among adolescent females with T1DM and correlate it with serum leptin, abdominal adiposity, insulin resistance, glycemic and lipid metrics.
Methods
Hundred-seventy five adolescent females with T1DM were assessed for diabetes duration, insulin therapy, menstrual regularity, manifestations of insulin resistance, hirsutism, anthropometric measures, systolic and diastolic blood pressure percentiles. Serum leptin, glycated-hemoglobin (HbA1c), fasting blood glucose and lipids, basal and stimulated follicle stimulating hormone (FSH) and luteinizing hormone (LH) were measured with calculation of the LH/FSH ratio and estimated glucose disposal rate (eGDR). Trans-abdominal pelvic ultrasound was done with measurement of the right and left ovarian size and endometrial thickness. Rotterdam criteria were adopted to diagnose PCOs.
Results
Sixty four adolescent females with T1DM had PCOs (36.6%). Adolescent females with T1DM having PCOs had significantly higher diabetes duration, total daily insulin dose, abdominal adiposity (waist/hip ratio z score), insulin resistance, serum leptin, LH/ FSH ratio and low density lipoproteins (LDL) than those without ($P < 0.05$). Multivariate-logistic regression analysis showed that diabetes duration (p-value = 0.030), waist/hip ratio (p-value = 0.030), LDL (p-value = 0.034), eGDR ($P = 0.008$), serum leptin (p-value = 0.009), and right ovarian volume ($P = 0.008$) were the most significant independent factors associated with PCOs among this vulnerable cohort.
Conclusion
PCOs is a prevalent morbidity among adolescent females with T1DM being associated with abdominal adiposity, insulin resistance, and hyperleptinemia.
Keywords
Adolescent females; Type 1 diabetes; Polycystic ovary; Leptin, Glycemic control.

Introduction
Recent research recognises Polycystic Ovary Syndrome (PCOS) as a multisystem condition that impacts several systems, including reproductive, dermatologic, metabolic, cardiovascular, and psychological health. Given the complexity of PCOS, a structured Model of Care (MOC) is crucial to reduce care variability. An evidence-based MOC should integrate clear referral pathways to tertiary care and align with international guidelines. The 2018 and 2023 international PCOS guidelines emphasise structured care models, yet a recent review indicated a lack of comprehensive data on implementing such models. This study aims to evaluate the characteristics of existing MOCs for PCOS care across multiple countries, assess their alignment with international guidelines, and analyse the outcomes of treatments.
>Materials and Methods
This multi-country study, conducted from May 2023 to March 2024, involved seven clinics from the United Kingdom, Turkey, Greece, India and Georgia. Clinics were invited to share their MOCs and first consultation management protocols for PCOS. Data were collected from patients seen between January 1, 2020, and December 31, 2023. The data included demographic information, clinical assessments (e.g., hirsutism, acne, metabolic screening), and biochemical tests (e.g., glucose, cholesterol, hormonal profiles). Adherence to the 2023 PCOS guidelines, including lifestyle advice and long-term risk education, was also evaluated. An online questionnaire was used to collect detailed MOC information. Data were analysed using the SPSS software version 29.0.1.1. Continuous data were assessed for normality using the Shapiro-Wilk test combined with graphical methods. Non-normally distributed data were presented as medians with interquartile ranges (IQR), while categorical data were expressed as absolute frequencies and percentages. All tests were performed at a 0.05 significance level.
Results
The study included 1,321 patients with a median age of 27 years (IQR 24-32). The most common clinical features at presentation were hirsutism (71.6%) and acne (28.7%). Screening for dermatology (86.9%), cardiometabolic health (80.9%), and reproductive health (75%) was commonly performed, but emotional well-being (37.1%) and long-term risk education (34.2%) were less frequently addressed. Biochemical testing varied widely, with hormonal (e.g., testosterone, FSH, LH) and metabolic parameters (e.g., glucose, HbA1c, lipid profile) being assessed in most cases. Significant differences were observed across countries in the types of parameters assessed and the proportion of patients diagnosed according to guidelines (overall $P < 0.001$).
Conclusion
This study highlights substantial variation in implementing PCOS care models across different countries, particularly in emotional well-being and long-term risk education. To improve patient outcomes globally, care practices must be standardised to align with international guidelines.

Association of insulin resistance surrogate indices and erectile dysfunction: a systematic review and meta-analysis

Alireza Azarboo[1], Sayeh Jalali[1], Negar Zareshahi[1], Amir Hossein Behnoush[1], Amirhossein Shirinezhad[1], Seyyed Yasin Hoseini[1], Amin Javidan[1] & Amirhossein Ghaseminejad-Raeini[1]
[1]School of Medicine, Tehran University of Medical Sciences, Tehran, Iran

Background
Erectile dysfunction (ED), a condition impacting quality of life, is increasingly linked to insulin resistance (IR). This study aims to evaluate the relationship between IR indices and the incidence and severity of ED, providing insights into their diagnostic and predictive utility in practice.
Methods
A comprehensive search across PubMed, Embase, Web of Science, and Scopus was carried out. Required data were extracted and meta-analyzed. The Newcastle-Ottawa Scale (NOS) was employed to evaluate the studies' risk of bias. Sensitivity analyses and meta-regressions were conducted to explore heterogeneity and the impact of confounding variables.
Results
Seventeen studies with a total of 3810 patients with ED and 8252 without ED were included. Meta-analysis revealed that males with ED had significantly higher levels of Homeostasis Model Assessment of Insulin Resistance (HOMA-IR) (SMD = 0.59, 95% CI [0.15, 1.03], I2 = 82%, P < 0.01), Triglyceride-Glucose Index (TyG) (SMD = 0.53, 95% CI [0.31, 0.75], I2 = 69%, P < 0.01), and Visceral Adiposity Index (VAI) (SMD = 0.45, 95% CI [0.25, 0.64], I2 = 76%, P < 0.01) compared to those without ED. However, there was no significant correlation between a one-unit increase in HOMA-IR (OR = 0.63, 95% CI [0.03, 13.69], I2 = 91%, P = 0.77) or TyG (OR = 0.53, 95% CI [0.02, 11.53], I2 = 88%, P = 0.68) and the odds of ED. Additionally, a one-unit increase in VAI was associated with more severe ED (SMD = 0.34, 95% CI [0.03, 0.64], I2 = 16%, P = 0.03). The diagnostic accuracy of these indices varied.
Conclusions
The results indicate a significant connection between insulin resistance and erectile dysfunction, as shown by HOMA-IR, TyG, and VAI. These indices highlight the potential role of metabolic dysfunction in the pathophysiology of ED, suggesting that IR may contribute to endothelial dysfunction and vascular impairment. Clinically, it is important to assess IR in men with ED, particularly in those with comorbid cardiometabolic conditions. Given the observed association between VAI and ED severity, targeting visceral adiposity through lifestyle modifications, weight management, and pharmacological treatments aimed at improving insulin sensitivity may concurrently alleviate ED progression. Future research should focus on standardizing IR assessment methods and exploring integrated diagnostic models that combine IR indices with other biomarkers to enhance predictive accuracy and clinical applicability. This approach could pave the way for personalized treatment strategies, ultimately improving both metabolic and sexual health outcomes in affected individuals.

JOINT622

Identification of two novel likely pathogenic NR5A1 variants associated with DSD and infertility in two Kuwaiti families

Wafaa Laimon[1], Doaa Ibrahim[2] & Iman Al-Basari[1]
[1]Mubarak Al Kabeer Hospital, Ministry of Health, Department of Pediatrics- Pediatric Endocrinology and Diabetes unit, Kuwait, Kuwait; [2]Kuwait Medical Genetic Center, Kuwait, Kuwait

Background
Nuclear receptor subfamily 5 group A member 1 gene (*NR5A1*) plays a crucial role in adrenal and gonadal development. *NR5A1* mutations are associated with a wide phenotypic spectrum of differences of sex development (DSD). While, heterozygous inheritance is the prevalent pattern, *NR5A1* dosage significantly influences its biological function.
Case description
We report the first two Kuwaiti families with identifiable *NR5A1* mutations. **Case1:** A 13-years-10-month-old individual, raised as a female, and presented with delayed puberty. Clinical examination revealed Tanner stage 1 breast development, Tanner stage 4 pubic hair, posterior labioscrotal fusion, a 4.5 cm phallus and bilateral palpable inguinal testes (External genital Score was 6.5). Laboratory tests indicated hypergonadotropic hypogonadism, low anti-Mullerian hormone (AMH) and high testosterone levels. MRI pelvis confirmed bilateral small testes at external inguinal rings with no mullerian structures. Karyotype was 46, XY (SRY+). Whole exome sequencing (WES) and Sanger sequencing revealed a novel heterozygote in-frame deletion (c.1070_1075del; p.Gln357_Leu358del). The father, carrying the same mutation, had severe oligospermia and required assisted reproductive techniques (ART) for conception. **Case 2:** A 1-month-old 46, XY infant presented with penoscrotal hypospadias and bilateral undescended testes. Post-human chorionic gonadotropin (hCG) testing indicated an adequate testosterone response. WES and Sanger sequencing revealed a novel heterozygous missense (c.1105G > T; p.Val369Phe) variant in the NR5A1 gene. Although, parents were not genetically tested, the father also had severe oligospermia and required ART. Both cases have normal adrenal functions by ACTH stimulation test and a normal spleen on ultrasound.
Conclusion
Trio sequencing (patient and parents) is crucial to establish inheritance patterns. The broad phenotypic spectrum of *NR5A1* gene mutations within and across families may be related to the epigenetic modifiers or coinheritance of pathogenic variants in different testis/ovarian-determining genes. These findings expand the mutational spectrum of *NR5A1* and highlight the importance of genetic screening in DSD and infertility cases.

Disorders of sex development due to 17ß-hydroxysteroid dehydrogenase type 3 deficiency: searching for a phenotype-genotype correlation

Hamdi Frikha[1], Nesrine Dhieb[1], Dhoha Ben Salah[1], Yesmine Elloumi[1], Khouloud Boujelben[1], Mouna Mnif[1], Mouna Elleuch[1] & Nabila Rekik Majdoub[1]
[1]Hedi Chaker University Hospital, Endocrinology, Sfax, Tunisia

Introduction
Disorders of sexual steroid biosynthesis are the leading cause of disorders of sex development (DSDs) in non-Western societies. Molecular studies on cohorts have shown that testicular enzyme deficiency-related DSDs due to 17β-hydroxysteroid dehydrogenase type 3 (17HSD3) deficiency are more frequent than previously reported, particularly in the Middle Eastern and North African regions, and are underestimated due to very mild forms. This study aims to characterize, both phenotypically and genotypically, a Tunisian population with 17HSD3 deficiency.
Methods
This is a descriptive study including patients followed for 46,XY DSD secondary to 17HSD3 deficiency at the Department of Endocrinology, University Hospital of Sfax, Tunisia. Phenotypic evaluation was based on Tanner's sexual maturation staging and Prader's virilization grading of the genitalia. We measured a panel of sex steroids before and after stimulation with human chorionic gonadotropin (hCG). The molecular study was conducted at the Department of Genetics using next-generation sequencing (NGS).
Results
We identified seven patients, all assigned female at birth. The main reasons for consultation were pubertal virilization (4/7) and genital anomalies (2/7). None of the pubertal-aged patients exhibited signs of sexual maturation (Tanner stage S1). The mean genital differentiation score was 3 ± 1. The hormonal profile showed a low Testosterone/Δ4-Androstenedione ratio after hCG stimulation of < 0.8 in all patients. Genetically, we identified the nonsense mutation c.618C > A in the HSD17B3 gene, which was common to all seven patients, confirming its founder effect in our region. The phenotypic expression was variable, even among patients with the same genotype, indicating a weak phenotype-genotype correlation.
Conclusion
DSDs due to defects in the final step of steroidogenesis are common in North African populations, with an increasingly well-defined phylogeny. Phenotypic expression is highly variable and appears to be minimally influenced by genotype. This variability may be attributed to the presence of yet unidentified polymorphisms in the HSD17B3 gene, modifying genes, extragenic polymorphisms, alternative steroidogenesis pathways, environmental factors affecting 17βHSD3 protein activity, and the presence of other 17βHSD isoenzymes.

A case of 46, XY complete gonadal dysgenesis presenting with precocious peripheral puberty

Gökçe Velioğlu Haşlak[1], Elvan Bayramoglu[1], Funda Feryal Tas[2], Aslı Bestas[2], Mert Ucar[1], Ilayda Altun[1], Hasan Karakas[1],

Abdurrahman Guney[1], Zeyneb Demirkol[1], Ismet Mehmet Etyemez[1], Ayse Kalyoncu Ucar[3], Hande Turan[1] & Olcay Evliyaoglu[1]
[1]Istanbul University-Cerrahpasa, Cerrahpasa Medical Faculty, Pediatric Endocrinology, Istanbul, Türkiye; [2]Gazi Yasargil Education and Research Hospital, Pediatric Endocrinology, Diyarbakir, Türkiye; [3]Istanbul University-Cerrahpasa, Cerrahpasa Medical Faculty, Pediatric Radiology, Istanbul, Türkiye

Introduction
46, XY complete gonadal dysgenesis, also known as Swyer syndrome, is a rare disorder of sex development characterized by a normal female phenotype at birth. Patients usually present in adolescence with complaints of menstrual failure or lack of breast development. This case presents a rare clinical presentation.
Case: A six-year and two-month-old female presented with breast enlargement observed three months prior. Her older sister had been examined for primary amenorrhea at 17 years, karyotyped as 46 XY, and underwent gonadectomy. The patient's height was 116.7 cm (-0.1 SDS) and weight 19.2 kg (-0.72 SDS). External examination showed no axillary hair, pubarche at stage 1, and thelarche at stage 3. Laboratory tests yielded: LH: 0.1 mIU/ml, FSH: <0.3 mIU/ml, estradiol: 13 pg/ml, total testosterone: 16 ng/dl, AFP: <0.9 IU/ml, and β-HCG: 88.8 mIU/ml. Gonadotropins were suppressed in GnRH stimulation test. Bone age was consistent with 6 years and 10 months. Ultrasonography revealed a uterus measuring 45x25x10 mm, with thin endometrium, and both gonads approximately 0.4 ml in volume. The patient was diagnosed with precocious peripheral puberty (PPP). Screening tests were performed considering elevated β-HCG as a cause. Cranial and sella MRI examinations were normal. PET-CT demonstrated calcific foci without fluorodeoxyglucose uptake in both adnexal areas. Contrast-enhanced pelvic MRI exhibited hypointense areas in both gonads, suggestive of dysgerminoma on the background of gonadoblastoma. The patient's karyotype was 46 XY. Bilateral gonadectomy was performed, with histopathological examination pending. Postoperative monitoring indicated regression of β-HCG and estradiol levels.
Conclusion
This case report presents a rare clinical finding in a patient with 46 XY complete gonadal dysgenesis. Patients typically show absence of pubertal signs in adolescence due to dysfunctional gonads. However, rare cases presenting with PPP have been documented, as observed in our patient. This presentation is thought to be due to high aromatase activity and tumoral hormone production in dysgenetic gonads. Since dysgenetic gonads can undergo neoplastic changes, they should be removed upon diagnosis regardless of patient age. This case report highlights atypical findings that may complicate diagnosis and delay urgent gonadectomy.

Testicular growth and sperm detection rates following combined hcg and rfsh therapy in adolescents with congenital and acquired hypogonadotropic hypogonadism

Hasan Karakas[1], gürkan Tarçın[1], Hande Turan[1], Abdurrahman Güney[1], Gökçe Velioğlu Haşlak[1], Mert Uçar[1], Ilayda Altun[1], Aydilek Dagdeviren Cakir[1], Elvan Bayramoğlu[1] & Olcay Evliyaoglu[1]
[1]Istanbul University-Cerrahpasa Cerrahpaşa Faculty of Medicine, Department of Pediatric Endocrinology, Istanbul, Türkiye

Introduction
While testosterone monotherapy has traditionally been used in adolescents with hypogonadotropic hypogonadism (HH), there has been growing experience with hCG and rFSH therapies. Unlike testosterone monotherapy, these treatments offer a more physiological approach and enhance fertility potential. This study aims to present our treatment protocol and outcomes.
Method
This retrospective study included adolescent males who received combined rFSH and hCG therapy between 2018-2025. In all cases, 2-month rFSH regimen at 75 IU/day (Dwyer protocol) was followed by low-dose rFSH and hCG, gradually increased every 3–6 months up to 150 IU rFSH and 3000 IU hCG twice weekly (Sato *et al.*, 2015). After the Dwyer protocol, testosterone therapy was also initiated at 25 mg monthly and increased to 125 mg every 6 months. Testicular volumes were recorded quarterly, and semen analysis was performed after the third year.

Table 1. Increase in testicular volume during treatment.

	ΔTesticular volume (mL) from baseline		
	6th month	12th month	18th month
Complete congenital ($n = 11$)	1±0.6	1.8±0.6	3.1±1.3
Acquired ($n = 6$)	1.6±0.9	3.6±2	5.8±2.4
p	0.216	**0.027**	**0.036**
Partial congenital ($n = 2$)	1.2±0.7	3.5±3	9±5

Results
Twenty-one patients (15 congenital, 6 acquired) were included. Two genetically confirmed congenital cases with LH >5 IU/l but no pubertal progression were classified as partial HH. The mean age at treatment initiation was 16.6±2.1 years (13.1–19.8), and the median treatment duration was 32.8 months (12–82). Congenital cases included 3 with Kallmann syndrome and 12 with non-Kallmann HH, while acquired cases comprised 5 with craniopharyngioma and 1 with prior radiotherapy for nasopharyngeal carcinoma. Table 1 shows the increase in testicular volume from baseline in cases with an 18-month follow-up. In partial HH cases, a dramatic increase was notable at 18 months. In acquired HH cases, the increase became more pronounced compared to complete congenital cases from the 12th month. In the third-year semen analysis, sperm was detected in both partial congenital HH cases. The sperm detection rates in complete congenital and acquired cases were comparable (2/4 vs. 2/3, $P = 0.658$).
Conclusion
Combined therapy effectively increases testicular volume and, based on semen analysis, improves fertility potential in both congenital and acquired HH cases. Given the lack of evidence for adverse effects of testosterone at priming doses on testicular development, low-dose testosterone alongside conventional therapy may enhance bone mineral density and secondary sexual characteristics earlier, making treatment responses more visible and improving adherence. Further clinical experience will contribute to establishing an optimal protocol.

Multilingual menopause comics: combating misinformation and enhancing global health literacy through peer-reviewed educational videos

Vardhan Venkatesh[1], Maria Mathiopoulou[2], Khushi Kumar[1], Shams Ali Baig[1], Bogdan Milenkovic[3], Maiar Elhariry[4], Eleni Armeni[5], DEVI Collaboration[1] & Punith Kempegowda[6,7]
[1]Birmingham Medical School, College of Medicine and Health, University of Birmingham, Department of Applied Health Sciences, Birmingham, United Kingdom; [2]Hospital of Uster, Zurich, Switzerland; [3]University Clinical Center of Serbia, Clinic for Endocrinology, Diabetes, and Metabolic Diseases, Belgrade, Serbia; [4]Sandwell and West Birmingham NHS Foundation Trust, Birmingham, United Kingdom; [5]Royal Free Hospital, Royal Free London NHS Foundation trust, London, United Kingdom; [6]University of Birmingham, Department of Applied Health Sciences, School of Health Sciences, College of Medicine and Health, Birmingham, United Kingdom; [7]Queen Elizabeth Hospital Birmingham, University Hospitals NHS Foundation Trust, Birmingham, United Kingdom

Introduction
Women navigating menopause often face significant barriers to accessing reliable and accurate educational resources, which are exacerbated by the prevalence of misinformation online. Traditional, text-heavy resources frequently fail to engage modern audiences. The CoMICs (Concise Medical Information Cines) initiative produces short, engaging, evidence-based educational videos to address this limitation. However, these CoMICs are usually in English. Similar resources needed to be created in non-English languages to address health literacy and language barriers.
Objectives
• Develop peer-reviewed, evidence-based educational videos on menopause in multiple languages.
• Assess these educational videos' digital dissemination and engagement across social media.
Methods
This study was conducted in the UK between July and December 2024. A multidisciplinary team—including medical students, healthcare professionals,

and women with lived menopause experiences—collaborated to produce visually engaging, peer-reviewed videos. Using the five-phase CoMICs framework, the project involved script creation, video production, publication, evaluation, and impact analysis. The Menopause CoMICs in English were translated into 10 languages. Clinical experts and experts by experience rigorously reviewed the materials to ensure scientific and linguistic accuracy. The translated CoMICs were disseminated on social media between October 1 and 18, 2024. Full-length videos were uploaded to YouTube every other day, while shorter snippets tailored to platform-specific algorithms were shared on TikTok, Instagram, Facebook, and X (formerly Twitter). The engagement of these CoMICs across social media was tracked for three months. Views, likes, and shares were monitored to assess each video's reach and engagement.
Results
The initiative garnered 18,059 views, 112 likes, and 44 shares across all platforms. TikTok achieved the highest engagement with 5,891 views, followed by Instagram with 5,323 views and X with 6,845 views. A single video's highest view count was 1,600 on X, 1,500 on Instagram, and 1,092 on TikTok. Instagram led in likes, generating 52, followed by X with 46 and TikTok with 14. Stratified by language, the most viewed CoMIC videos were in Polish, followed by Serbian, Spanish, and Turkish, with the English video ranking sixth.
Conclusion
Menopause CoMICs successfully developed peer-reviewed audiovisual resources that overcame linguistic barriers. The preference for non-English videos highlights the importance of multilingual approaches in health education. By leveraging digital platforms, the initiative effectively promoted evidence-based education and combated misinformation about menopause. Future efforts will aim to expand content into additional languages and address a broader range of medical conditions, ensuring more inclusive and far-reaching health education.

Role of anti-TPO antibodies on ovarian reserve and early embryo development in assisted reproductive technology

Durdona Samatova[1] & Zulaykho Shamansurova[2,3]
[1]Republican Specialised Scientific Practical Medical Centre of Endocrinology, Tashkent, Uzbekistan; [2]Central Asian University, Endocrinology, School of Medicine, Tashkent, Uzbekistan; [3]Institute of Biophysics and Biochemistry at the National University of Uzbekistan, Metabolomics, Tashkent, Uzbekistan

Introduction
Autoimmune thyroid disease (AITD) is among the most common endocrine disorders and occurs more frequently in women. Circulating antithyroid antibodies associated with AITD are known to affect various tissues, including the ovaries. As a result, this prevalent condition may influence female fertility, which is the focus of the present research. The aim of this study is to explore the role of anti-TPO antibodies in ovarian reserve and early embryo development in assisted reproductive technology (ART) based on the existing literature.
Material and Methods
Data regarding AITD and female reproduction, ovarian reserve and embryo development in ART were searched in MedLine, PubMed, WebofScience, Scopus, Google Scholar data base. Data were combined and presented as main conclusion.
Results
Infertility is a major global health concern, yet in-vitro fertilization (IVF) success rates remain low (8.6-46.2%). The molecular mechanisms linking reduced fertility to the presence of thyroid antibodies remain unclear. One important area of investigation is the role of immunological markers, specifically circulating autoantibodies, that impact female fertility. There are potential ways that anti-TPO antibodies could negatively affect the reproductive system, particularly ovarian tissue, can pass into the ovaries and have been found in the fluid surrounding eggs, targeting the zona pellucida in women with ovarian inflammation also reacted and suggests that ATPO might bind to the zona pellucida, potentially disrupting fertilization, embryo development, and implantation. Recent findings indicate a strong correlation between thyroid hormone levels in serum and follicular fluid. Additionally, the ratio of T4 to T3 in follicular fluid, along with serum TSH levels, showed a positive association with the number of retrieved oocytes, including mature ones, as well as the number of embryos. Relationship between ovarian reserve and the presence of anti-thyroid autoantibodies is limited. It is reasonable to suggest that fibrotic changes may develop in the ovary as part of the typical inflammatory response, potentially impacting ovarian reserve. Indeed, some studies have reported a decline in key markers of functional ovarian reserve in patients with AITD.
Conclusion
Although the impact of thyroid autoimmunity on natural conception and ART success rates is still a subject of debate, the current study suggests that the presence of antithyroid autoantibodies, including ovarian function, the composition of follicular fluid (which serves as the environment for oocyte maturation), as well as folliculogenesis and embryogenesis. Therefore, presence anti-TPO antibodies in the blood can reflect its follicular fluid level and can impact IVF outcomes.

Body composition and bone mineral density in adolescents with gender incongruence

Paola Lorello[1], Raffaella Di Mase[2], Sara Vasaturo[1], Fabiana Santamaria[2], Francesca Rotondo[1], Donatella Capalbo[1] & Mariacarolina Salerno[1]
[1]Unit of Paediatric Endocrinology - University of Naples "Federico II", Transaltional Medical Science Department, Naples, Italy; [2]Pediatric Endocrinology Unit, Department of Mother and Child, University of Naples "Federico II", Naples, Italy

The number of adolescents with gender incongruence seeking for gender-affirming hormone treatments (GAHT) is increasing. There are a few studies about changes in BMI, body composition and bone mineral density (BMD) following treatment, often limited by small sample sizes and heterogeneous therapeutic protocols.
Objective
The aim of our study was to describe BMI, body composition and BMD of transgender adolescents before and after one year of GAHT.
Methods
We conducted a prospective study on 81 transgender adolescents, 34 assigned female at birth (AFAB) and 47 assigned male at birth (AMAB), aged 17 years (14.66-18.2), followed from 2019 to 2024. Anthropometric parameters, body composition, BMD were evaluated before and after one year of GAHT. Body composition was evaluated using Bioelectrical Impedance Analysis (BIA) to determine lean mass (FFM) and fat mass (FM). BMD was assessed using Dual Energy X-ray Absorptiometry (DEXA).
Results
At study entry mean BMI was within normal range in both AFAB (23.77 $\pm$ 5.95) and AMAB (22.79 $\pm$ 4.99). However, the rate of obesity was higher than in the region general population matched for age (19.7% vs 4.2%) as well as underweight (11% vs 1.4%). AFAB were more frequently obese (26.5%) than AMAB (14.8%) whereas AMAB were more frequently underweight (14.9%) than AFAB (5.9%). After one year of treatment, no significant changes in BMI were observed (AFAB 25.64 $\pm$6.53; AMAB 22.77 $\pm$4.96). Body composition showed significant changes after 1 year of treatment. FFM (%) was significantly reduced (72.77 $\pm$ 6.99) vs baseline (79.26 $\pm$ 10.14; $P = 0.026$) and FM (%) increased (27.23 $\pm$ 6.99) vs baseline (20,70 $\pm$10.14; $P = 0.022$) in the AFAB group. In the AFAB group, no significant changes in FFM (%) (68.09 $\pm$ 8.20 vs 67.32 $\pm$ 8.56) or FM (%) (31.91$\pm$8.20 vs 32.68$\pm$8.56) were observed. BMD z-score was within normal range in transgender adolescents. AMAB had significantly lower lumbar BMD-z score (-0.82 $\pm$0.85) compared to AFAB (1.17 $\pm$ 0.09; $P = 0.033$). After one year of treatment, no significant changes in BMD-z score were observed in both AMAB (-1. $\pm$0.76) and AFAB (-0.47 $\pm$0.73).
Conclusion
Transgender adolescents have a higher frequency of weight abnormalities before treatment, with a higher frequency of obesity among AMAB, and of underweight among AFAB. After one year GAHT, changes in body composition were observed aligning with the desired gender. No significant changes in BMI or BMD were detected.

Familial papillary thyroid carcinoma: identification of 12 families and novel putative gene defects in the finnish population

Camilla Schalin-Jantti[1], Pekka Kejo[2], Iiro Kostiainen[1], Minna Poyhonen[3] & Taina T Nieminen[4]

[1]Endocrinology, Abdominal Center, Helsinki University Hospital and University of Helsinki, ENDO-ERN (European Reference Network on Rare Endocrine Conditions), Helsinki, Finland; [2]Department of Gastroenterological Surgery, Abdominal Center, Helsinki University Hospital and University of Helsinki, Helsinki, Finland; [3]Department of Medical and Clinical Genetics, University of Helsinki and Helsinki University Hospital, GENTURIS-ERN (European Reference Network on Genetic Tumour Risk Syndromes), Helsinki, Finland; [4]Department of Medical and Clinical Genetics, Medicum, University of Helsinki, Helsinki, Finland

Background

Papillary thyroid carcinoma (PTC), the most common endocrine cancer, is usually sporadic and little is known about possible genetic determinants. However, we recently identified a truncating pyruvate dehydrogenase phosphatase (PDH) regulatory subunit gene variant segregating with familial PTC in the USA. Our aim was to identify PTC families and search for possible predisposing germline variants in the genetically homogenous Finnish population, an ideal population for the discovery of rare genetic defects of monogenic disorders.

Methods

We identified patients with familial papillary thyroid carcinomas from our University Hospitals and used whole-genome sequencing (WGS) to identify putative pathogenic variants. All patients were clinically characterized, including thyroid antibody measurements and careful histopathological examinations. Only gene variants shared by all PTC patients within the families were considered. Variants were confirmed by Sanger sequencing. Population frequencies were assessed with the gnomAD v.4.1.0 browser. *In-silico* protein prediction tools and databases were used for further analyses.

Results

We identified 12 families with PTC, 5/12 families have so far undergone WGS. A novel *DLD* c.100A>G (p.Thr34Ala) variant was found in family 1, and a novel *SIRT4* c.755A>C (p.Glu252Ala) variant in family 5. The corresponding allele frequencies in a global control population were 0.00086 and 0.00012, respectively. The *DLD* c.100 site is predicted to contain GATA4 and SMARCA4 transcription factor binding sites. In family 7, a protein truncating variant c.422-423 del (p.Leu141ProfsTer23), which leads to a premature stop codon in exon 2 in the *ZNF197* gene was found. The *ZNF197* c.422-423 site contains CTCF, CBX3 and SP1 transcription binding sites.

Conclusion

We have identified 12 Finnish families with PTC and three novel putative underlying gene defects. Two of them, *DLD* and *SIRT4*, regulate the pyruvate dehydrogenase complex (PDH) and one, *ZNF197*, is a VHL-associated KRAB-A domain containing protein, which is overexpressed in some thyroid cancer samples. We hypothesize that the mutations might destroy transcription factor binding sites and impair *DLD* and *ZNF197* gene expression. Further studies are needed to better understand the molecular mechanisms predisposing to PTC in these families.

THRIVE-2 phase 3 trial of Veligrotug (VRDN-001) in chronic thyroid eye disease (TED): efficacy and safety at 15 weeks

Patrice Rodien[1], Michael Schittkowski[2], Onur Konuk[3], Anja Eckstein[4], Adrienne Csutak[5], Edwina Eade[6], Jimmy Uddin[7], Vickie Lee[8], Marco Sales Sanz[9], Will Conroy[10], Abhijit Narvekar[10], Thomas Ciulla[10] & Antonio Manuel Garrido Hermosilla[11]

[1]Centre Hospitalier Universitaire d'Angers – Hématologie, Angers, France; [2]Universitätsmedizin Göttingen, Göttingen, Germany; [3]Gazi University Medical School, Department of Ophthalmology, Ankara, Türkiye; [4]Universitätsmedizin Essen, School of Vision, Essen, Germany; [5]Optimum Vision Center, Budapest, Hungary; [6]North Shore Private Hospital, New South Wales, Australia; [7]Moorsfields Eye Hospital, London, UK; [8]Imperial College Healthcare NHS Trust – Western eye Hospital, London, UK; [9]Hospital Universitario Ramón y Cajal, Madrid, Spain; [10]Viridian Therapeutics, Inc., Waltham, USA; [11]Hospital Universitario Virgen Macarena, Universidad de Sevilla, Seville, Spain

Purpose

TED remains a condition with significant unmet needs, particularly in the chronic phase, where treatment options are limited. IGF-1R antagonism has emerged as a key therapeutic approach, addressing inflammation and proptosis. Veligrotug (veli), a full antagonist humanized monoclonal antibody targeting IGF-1R, previously demonstrated positive results in the ongoing phase 3 THRIVE trial for active TED. Here, we present efficacy and safety data from the ongoing phase 3 THRIVE-2 trial (NCT06021054) of veli in chronic TED at the primary timepoint of 15 weeks.

Methods

Adults with moderate-to-severe chronic TED (onset >15 months, proptosis ≧3 mm, with any clinical activity score [CAS]) were randomized (2:1) to 5 IV infusions 3 weeks apart of either 10 mg/kg veli or placebo. The following were assessed through 15 weeks: proptosis responder rate (PRR), defined as ≧2-mm reduction vs baseline by Hertel exophthalmometry; overall responder rate (ORR; PRR and no worsening in CAS); PRR by MRI/CT; mean change from baseline in proptosis; improvement and complete resolution on the Gorman subjective diplopia scale; and treatment-emergent adverse events (TEAEs).

Results

188 patients were randomized to veli ($n=125$) or placebo ($n=63$) and included in the intent-to-treat population. Baseline values for veli vs placebo were balanced including mean proptosis, 24.3 mm vs 23.8 mm; presence of diplopia, 52% vs 59%; and CAS ≧3, 57% vs 52%. 15-week results for veli vs placebo were as follows: Hertel PRR, 56% vs 8% ($P<0.0001$), with a mean reduction of 2.34 mm vs 0.46 mm ($P<0.0001$); MRI/CT PRR, 48% vs 3% ($P<0.0001$); ORR, 56% vs 7% ($P<0.0001$). In patients reporting diplopia on the Gorman subjective diplopia scale at baseline, 56% vs 25% ($P=0.0006$) reported improvement and 32% vs 14% ($P=0.0152$) reported complete resolution. Achievement of CAS 0/1 in patients with CAS ≧3 at baseline was nominally significant (54% vs 24%, $P=0.0060$). Most TEAEs were mild, with most common being muscle spasms (36% vs 6%) and menstrual disorders (33% vs 10% for menstruating women). Hearing impairment was 13% vs 3%. Serious TEAEs were 2% vs 3% (1 related to treatment in each group).

Conclusions

THRIVE-2, which assessed 5 IV infusions of veli vs placebo, is the first RCT in chronic TED to show statistically significant improvement not only in proptosis, but also in diplopia, with a generally well-tolerated safety profile. Results suggest the promising potential of veli in chronic TED. Follow-up through 52 weeks is ongoing.

JOINT1965

Atypia of undetermined significance (AUS) in pediatric thyroid nodules: Surgery after first fine needle aspiration (FNA) or follow-up?

Yaprak Ece Yola Atalah[1], Dogu Vuralli Bakkaloglu[2], Yasemin Ozluk[2], Yalin Iscan[3], Ismail Cem Sormaz[3], Nihat Aksakal[3], Yasemin Giles Senyurek[3], Asli Derya Kardelen Al[1], Melek Yildiz[1], Firdevs Bas[1] & Sukran Poyrazoglu[1]

[1]Istanbul University, Istanbul Faculty of Medicine, Department of Pediatric Endocrinology, Istanbul, Türkiye; [2]Istanbul University, Istanbul Faculty of Medicine, Department of Pathology, Istanbul, Türkiye; [3]Istanbul University, Istanbul Faculty of Medicine, Department of Endocrine Surgery, Istanbul, Türkiye

Introduction

The subsequent management of AUS in pediatric FNAs remains a controversial issue. While the 2015 American Thyroid Association (ATA) guideline recommends surgery after the initial AUS diagnosis, the 2022 European Thyroid Association (ETA) guideline advocates for performing a second FNA after 6 months. In the literature, the malignancy rates of pediatric patients diagnosed with AUS in FNAs present contradictory results. We aimed to investigate the follow-up and postoperative data of patients with AUS in FNA.

Methods

The medical records of 54 patients (F/M:36/19) with FNAs classified as AUS were reviewed retrospectively. Potential risk factors for malignancy predisposition in patients diagnosed with AUS and their follow-up were retrospectively examined (age, family history, previous diseases, nodule characteristics on ultrasonography).

Results

The mean age of patients was 14.1± 3.2 (5.7–21). Of the 54 patients, 49 underwent definitive surgery. Twenty-nine patients underwent surgery following the initial FNA, while 20 patients have surgery after subsequent FNA. The malignancy rate was 48.3% (14/29) after single AUS and 75% (15/20) after repeated FNA. Risk factors for thyroid cancer were similar in both groups. No

specific ultrasound findings indicative of malignancy was identified in the patients with AUS having malignancy. Patients with malignancy after single FNA of AUS were operated within 0.18 ± 0.08 years. However, patients with the second FNA diagnosis were operated within 1.2 ± 1.3 years, ($P < 0.05$).

Conclusion

Our study revealed that the rate of malignancy is high in pediatric patients with AUS. However, performing surgery after first AUS leads to unnecessary surgery in 51.7% of patients. To avoid unnecessary surgery or delayed diagnosis, molecular analysis and cytopathologic atypia subclassification should be performed in management of AUS in pediatric patients.

JOINT3443

Diving into the shared genetics between hypothyroidism and its co-morbidities: Multi-trait meta-analyses and gene prioritization provide novel insights into the common genetic and biological factors

Hermina Jakupović[1], Chloé Pittman[1], Sofie Bliddal[2,3], Ulla Feldt-Rasmussen[2,4] & Tugce Karaderi[1]

[1]Center for Health Data Science, Section for Health Data Science and Artificial Intelligence, Department of Public Health, Faculty of Health and Medical Sciences, University of Copenhagen, Copenhagen, Denmark; [2]Department of Nephrology and Endocrinology, Rigshospitalet, Copenhagen, Denmark; [3]Department of Gynaecology and Obstetrics, Hvidovre Hospital, Copenhagen, Denmark; [4]Institute of Clinical Medicine, Faculty of Health and Medical Science, University of Copenhagen, Copenhagen, Denmark

Background

Hypothyroidism is a common endocrine condition affecting up to 10% of the general population. Patients experience a high degree of heterogeneity in symptoms, co-morbidities, and treatment effect. We aimed to investigate the shared genetic architecture of hypothyroidism and its co-morbidities for a better understanding of the disease mechanisms.

Methods

We leveraged publicly available genome-wide association study (GWAS) summary statistics to perform seven multi-trait GWAS meta-analyses (MTAG) based on four co-morbidity categories (Category 1 – Cardiometabolic; Category 2 – Psychiatric; Category 3 – Reproductive; Category 4 – Immune-mediated polyautoimmunity syndromes). MTAG boosts statistical power by JOINT analysis of multiple traits, enabling detection of new genetic associations. Thus, we aimed (1) to identify new genetic associations for hypothyroidism, and (2) to explore the genetic overlap across 26 genetically correlated conditions. Furthermore, we carried out gene prioritization, based on the new associations identified, to detect and characterize the potentially functional genes using two parallel combined SNP-to-Gene methods; (1) Otargen, a GraphQL-based R-package for tidy data accessing and processing from Open Targets Genetics, including nearest gene, variant-to-gene and locus-to-gene strategies, and (2) combined S2G-Framework (cS2G).

Results

MTAG analyses identified 114 new variants in 92 loci for hypothyroidism ($P < 5x10^{-8}$) compared to the input GWAS summary statistic data. Based on these new associations, a total of 1,134 genes were prioritized (1,114 genes by Otargen and 94 genes by cS2G). Out of 1,134 genes, 26 genes were prioritized as 'top-scoring' across the two methods, including 16 nearest protein-coding genes (*GLIS3, NFE2L3, NRG1, AFF3, TAGAP, S1PR1, CHN2, FOXK2, SWAP70, FCRL3, UBASH3B, SLC25A37, ABO, CD2, KCTD5, IL12RB2*). *GLIS3, NRG1, KCTD5*, and *SLC25A37* had significant expression or regulation patterns in the thyroid. Among the genes of interest, for instance, *GLIS3*, expressed in early embryogenesis with a role in multiple organ development, was highlighted as its variants have previously been associated with multiple co-morbidities of hypothyroidism including rheumatoid arthritis, type 1 diabetes, depression, as well as thyroid-related traits blood cholesterol and sex hormone levels. *GLIS3* loss-of-function mutations lead to hyperglycemia, hypoinsulinemia, and congenital hypothyroidism. Supporting our finding, it has also been briefly mentioned in a recent larger GWAS investigating the overlap between thyroid traits and the reproductive system.

Conclusion

Multi-trait analyses and gene prioritization approaches revealed new genetic associations and potential functional genes for hypothyroidism based on publicly available data, providing further fundamental insights into its genetic architecture and expanding the understanding of the common genetics and biological processes between hypothyroidism and its co-morbidities.

Epithelial and tumor microenvironment changes driven by BRAF/RAS mutations in thyroid cancer progression

Young Shin Song[1], Eun Hye Joo[2], Han Sai Lee[3], Jae Kyung Won[4], Woong Yang Park[5] & Young Joo Park[2]

[1]Department of Internal Medicine, Seoul Metropolitan Government Seoul National University Boramae Medical Center, Seoul, South Korea; [2]Department of Internal Medicine and Genomic Medicine Institute Medical Research Center, Seoul National University College of Medicine, Seoul, South Korea; [3]Department of Molecular Medicine and Biopharmaceutical Sciences, Graduate School of Convergence Science and Technology, Seoul National University, Seoul, South Korea; [4]Department of Pathology, Seoul National University College of Medicine, Seoul, South Korea; [5]Samsung Genome Institute, Samsung Medical Center, Geninus Inc., Seoul, South Korea

Background

Thyroid cancer (TC) progression involves distinct mutation-specific pathways, primarily driven by BRAF and RAS mutations. These mutations influence epithelial cell states and tumor microenvironment (TME) dynamics, but their differential effects remain largely unexplored.

Methods

We conducted a multimodal genomic and transcriptomic analysis, integrating single-cell RNA sequencing, spatial transcriptomics, and bulk RNA sequencing across BRAF-driven (PTC-B, ATC-B) and RAS-driven (FTC-R, ATC-R) TCs. Additional validation was performed using public datasets.

Results

In ATCs, the proportion of epithelial cells decreased, while TME components expanded, as confirmed by multimodal transcriptomic analysis. Pseudotime analysis revealed distinct dedifferentiation pathways, with BRAF-driven TCs undergoing gradual dedifferentiation and RAS-driven TCs showing abrupt epithelial transitions, suggesting mutation-specific pathogenesis. Intracellular pathway activation also varied, with ATC-B exhibiting antigen processing/presentation and B-cell receptor signaling activation, while ATC-R displayed upregulation of EMT, hypoxia, and ECM-related pathways. TME-epithelial interactions, particularly those involving fibroblasts, were significantly increased in ATC-R, aligning with pseudotime trajectory shifts. Furthermore, receptor-ligand interactions differed between DTCs and ATCs, with those localized in stroma or ATC regions strongly correlating with poorer survival outcomes, emphasizing the role of mutation-driven TME remodeling.

Conclusions

Epithelial distribution, dedifferentiation trajectories, and TME interactions differ significantly between BRAF- and RAS-driven TCs, suggesting mutation-specific pathogenesis. These findings highlight the importance of considering epithelial states and mutation profiles when selecting TME-targeted therapeutic strategies, emphasizing the potential for personalized diagnosis and treatment.

Thyroid eye disease: online medical education unveils knowledge gaps and barriers regarding targeted immunotherapy

Siggi Trier[1], Kate Carpenter[1], Maya Khalaf[1], Tiphaine Barras[1] & Vickie Lee[2]

[1]Medscape, Education Global, Newark, United States; [2]Imperial College & London North West University Healthcare NHS Trusts, Consultant Ophthalmic & Oculoplastic Surgeon, Thyroid Eye Services Ophthalmology Lead, London, United Kingdom

Thyroid eye disease (TED) has profound impact on quality of life. Several novel immunotherapies are in late-stage development. We aimed to identify learning needs on disease facts, diagnosis and management and attitudes towards novel treatment options. Physicians completed an online accredited 25-item clinical practice assessment of 20 knowledge and 5 attitudinal questions with evidence-based feedback on correct answers. Learning objectives were to increase knowledge regarding TED facts, treatment guidelines and self-assess learning needs on management. Launch Sep 6, 2024; data through Oct 22, 2024. Assessment completers: 139 ophthalmologists, 92 endocrinologists. Physicians showed a lack of knowledge using clinical activity score questionnaires for initial and follow-up assessments and had knowledge gaps on atypical TED presentations. Knowledge on immunotherapy targets for rituximab and teprotumumab was insufficient, most physicians were unaware of efficacy data showing proptosis reduction with teprotumumab. The role of selenium

supplementation for mild active TED was not known widely, instead steroids were seen as most appropriate for the majority of patients. The place of orbital decompression surgery in sight-threatening TED not sufficiently responsive to iv corticosteroids also required education. The majority of physicians stated that up to 50% of their patients are not adequately controlled on local therapy or corticosteroids, however less than half would be willing to prescribe a specific immunotherapy if available, due to cost concerns and lack of knowledge on safety and efficacy. Less than half of physicians felt confident (very or quite) about TED diagnosis and management. Physicians had a high interest for education on emerging therapies, in particular safety aspects. Online medical education is an effective method to identify TED learning needs to help the adoption of novel targeted immunotherapies for patients who can benefit from them.

Mental health, anxiety, depression, and the risk of incident thyroid dysfunction

Fabrice Bonnet[1], Juanjuan Zhang[2], Yuerong He[2], Ruiqi An[2], Jie Bai[2], Jianping Gong[3], Yafei Zhou[4] & Yang Xia[5]
[1]CHU Rennes, Rennes, France; [2]Hebei University, School of Public Health, Baoding, China; [3]Affiliated Hospital of Hebei University, Baoding, China; [4]School of Nursing, Hebei University, Baoding, China; [5]Department of Clinical Epidemiology, Shengjing Hospital of China Medical University, Shenyang, China

Background and Aim
Psychological stress has been implicated in the development of various autoimmune diseases. The relation between depression, anxiety and thyroid dysfunction (TD) remains poorly understood. The aim of the study was to investigate the longitudinal association between mental health, anxiety, depression, and the risk of TD. We also determined whether the relation between mental distress and the onset of TD was influenced by genetic predisposition.
Methods
A total of 418,622 TD-free participants from the UK Biobank were enrolled in the study. The mental health score was measured at baseline using the Patient Health Questionnaire-4 (PHQ-4), which has been shown to be a reliable and valid screening tool to assess psychological distress and in particular anxiety and depression in the general population. The diagnosis of TD, which included hyperthyroidism and hypothyroidism, was made using medical records. Polygenic risk score for hyperthyroidism and hypothyroidism was created. Survival curves with the Kaplan-Meier method was used to compare the differences in the cumulative incidence of TD according to mental health states. Cox proportional hazards models were used in multivariate models.
Results
During a median follow-up of 12.3 years, 2,242, and 9,419 new cases of hyperthyroidism and hypothyroidism were documented respectively. There was a graded association between mental health score at baseline and the risk of incident TD over the follow-up. The adjusted hazard ratio (HR) per SD increase was 1.13 (95% confidence interval [CI]: 1.08, 1.18) $P<0.001$ for hyperthyroidism and 1.11 (95% CI: 1.09, 1.13) $P<0.001$ for hypothyroidism. Individuals with severe mental health score had an increased risk of developing either hyperthyroidism (adjusted HR: 1.70, 95% CI: 1.09-2.65) or hypothyroidism (adjusted HR: 1.70, 95% CI: 1.36-2.12) compared with those with a low mental health score. Anxiety and depression as considered separately was each significantly associated with the risk of TD. Results were unchanged when considering clinical diagnosis of depression or anxiety instead of the PHQ-4 questionnaire. There was no significant interaction between the mental health and genetic risk score for the association with the incidence of TD.
Conclusion
Mental health, anxiety and depression were strongly and independently associated with the onset of both hyperthyroidism and hypothyroidism in general population. These findings suggest considering the potential risk of TD in individuals who experienced psychological distress, anxiety or depression.

Bufalini Cesena, Cesena, Italy

Background
Subjects affected by RASopathies have an increased susceptibility to autoimmune diseases.
Aims
The aim of our study was to define the prevalence of antithyroid antibodies (ATAs) and ultrasound (US) abnormalities of the thyroid gland in a population of children and young adults with RASopathies.
Methods
Eleven Italian Pediatric Endocrinology Centers participated to this cross-sectional observational study. Inclusion criteria were molecular diagnosis of Rasopathies and availability of data on thyroid function (TSH, fT3, fT4), thyroid immune profile (anti-thyroglobulin, anti-thyroperoxydase, anti-TSH receptor antibodies) and thyroid doppler ultrasound.
Results
In this study data from 136 subjects with Rasopathies, 70 males (51.5%) and 66 females (48.5%), with an average age of 12.1 years, were collected. Among them, 127 patients (93.4%) were affected by Noonan Syndrome (NS) and 9 patients (6.6%) by other Rasopathies (3 Mazzanti Syndrome (MS), 2 Neurofibromatosis I (NF I), 2 Cardiofaciocutaneous Syndrome (CFCS), 2 Noonan Syndrome with multiple lentigines (NSML). The most prevalent genetic mutation was PTPN11, which was detected in 93 patients (68.4%). Further mutations were found in the following genes: SOS1/2, RAF1, NRAS, KRAS, LZTR1, SHOC2, BRAF, ERF, NF1, RIT 1, MEK1, MAP2K1, PPP1CB, PRMT6, NTNG1. ATAs positivity was detected in 23 out of 136 patients with an overall prevalence of 17.1% (7.7% of whom with double positivity), without a significant difference in gender or pubertal stage. Among patients with ATA positivity, 20 were affected by NS (17 PTPN11, 1 LZTR, 1 BRAF, 1 SOS1) and 3 were affected by MS (SHOC2). Four patients with NS (2 PTPN11, 1 LZTR, 1 SOS1) and positive ATAs presented a condition of hypothyroidism while 19 patients (16 NS and 3 MS) were in euthyroidism. Among patients with ATAs positivity, 69.2% presented with US abnormalities (thyroid nodules, increase or decrease in thyroid volume, abnormal echotexture) and 5.6% showed an US pattern of thyroiditis. Patients with positivity for at least one ATAs had a significantly higher prevalence of US abnormalities. No association was found between PTPN11 gene mutation and the biochemical profile of thyroid function, the ultrasound pattern of autoimmune thyroiditis, abnormalities of thyroid volume and echotexture or thyroid nodules.
Conclusions
Subjects with Rasopathies have a higher prevalence of autoimmune and nodular thyroid disease compared to the general population. Further studies are needed to define the genotype-phenotype correlation and to identify early risk factors for the development of autoimmune thyroid disease and thyroid nodules in these patients in order to prevent long-term complications.

Fatal carotid blowout syndrome induced by lenvatinib and nivolumab combination therapy in anaplastic thyroid cancer: a case report

Ho-Cheol Kang[1], Ji Young Park[1], A Ram Hong[1], Jee Hee Yoon[1] & Hee Kyung Kim[1]

[1]Chonnam National University Medical School, Internal Medicine, Gwangju, South Korea

Anaplastic thyroid carcinoma (ATC) is an aggressive malignancy with a dismal prognosis despite multimodal treatment approaches. Tyrosine kinase inhibitors (TKIs), such as lenvatinib, and immune checkpoint inhibitors (ICIs), including nivolumab, have emerged as promising therapeutic options for ATC. Carotid blowout syndrome (CBS) is a rare but life-threatening vascular complication in patients with head and neck cancer, typically associated with prior surgical intervention and radiotherapy. Here, we report a fatal case of CBS following combination therapy with lenvatinib and nivolumab in an ATC patient who initially demonstrated a dramatic response to treatment. A 69-year-old male presented with a rapidly enlarging 6 cm right thyroid lobe mass and hoarseness. Total thyroidectomy and imaging studies confirmed ATC with tracheal and right recurrent laryngeal nerve invasion, along with synchronous lung and brain metastases (T4bN0M1, Stage IVc). Genomic profiling revealed NRAS (c.182A > G), TP53 (c.430C > T), TERT promoter (c.-146C > T) mutations with a high tumor mutational burden (23.4 mutations/Mb) and wild-type BRAF. The patient underwent external beam radiotherapy (EBRT; 6600 cGy in 30 fractions) followed by systemic therapy with lenvatinib (20 mg/day) and nivolumab (200 mg every 3 weeks). Two months after initiating systemic therapy, follow-up imaging demonstrated a significant partial response in pulmonary metastases and complete resolution of brain metastases, correlating with clinical improvement and weight gain. However, three months into therapy, the patient developed sudden-onset odynophagia. Neck computed tomography (CT) revealed a right tracheal wall defect with an exposed and unsupported right common carotid artery, indicative of impending CBS. Despite immediate cessation of systemic therapy and a recommendation for surgical intervention, rapid progression of tracheal necrosis led to acute carotid blowout, resulting in a fatal outcome. This case highlights the potential for severe vascular complications, such as CBS, in ATC patients receiving TKI and ICI combination therapy, even in the presence of an initial robust therapeutic response. Tracheal invasion and prior EBRT likely contributed to the pathogenesis of CBS, emphasizing the complex interplay between tumor biology, treatment modalities, and vascular integrity. These findings suggest that the administration of EBRT should be carefully considered or potentially omitted in ATC patients undergoing TKI and ICI combination therapy. Alternative treatment strategies should be explored to mitigate the risk of catastrophic vascular events.

Timing of levothyroxine ingestion in the INFINITY-study: a randomized controlled trial comparing dose-adjusted, non-fasting and fasting levothyroxine ingestion

Jeresa Willems[1], Daan van Twist[1], Floris Helmich[1], Marco Medici[2], Robin Peeters[2] & Roderick Tummers - de Lind van Wijngaarden[1]
[1]Zuyderland Medical Center, Internal Medicine, Heerlen/Sittard-Geleen, Netherlands; [2]Erasmus Medical Center, Internal Medicine, Rotterdam, Netherlands

Background
Levothyroxine (LT4) co-ingestion with food may lead to reduced absorption and increased thyroid-stimulating hormone (TSH) levels. Therefore, fasting ingestion is recommended. Yet, in a recent study we found that the majority of patients are burdened by fasting ingestion. Therefore, we aimed to investigate whether dose-adjusted, non-fasting LT4 ingestion could achieve stability of TSH levels comparable to fasting ingestion.
Methods
Patients were randomized to a fasting group, taking LT4 as usually recommended, or a non-fasting group, ingesting LT4 with breakfast after increasing the baseline LT4 dose by 15% to compensate for reduced absorption due to non-fasting ingestion. TSH, free T4 (FT4) and total T3 (TT3) levels were measured every six weeks until study completion. Patients were followed for 12 weeks in case two consecutive TSH levels fell within reference range. If TSH was out of range, follow-up was extended to 18 or 24 weeks. TSH stability was defined as a mean difference in TSH from baseline to study end ranging between -1 and +1mIU/l.
Results
Eighty-eight patients (80.7% female, median age 62y [IQR:49-69]) were randomized: 43 to the fasting and 45 to the non-fasting group. No significant differences were observed between the fasting and non-fasting group in mean difference of TSH (+0.22±1.00mIU/l vs. +0.22±0.92, p=NS), FT4 (-0.48±2.41 vs. -0.96±2.75pmol/l, p=NS) and TT3 (0.07±0.18 vs. 0.08±0.22nmol/l, p=NS), respectively. TSH stability was achieved in 71.8% of the fasting group and 73.2% of the non-fasting group (p=NS). By study end, 93.3% of the non-fasting group preferred to continue taking LT4 with breakfast.
Conclusion
Dose-adjusted, non-fasting LT4 ingestion achieved TSH stability comparable to conventional fasting LT4 ingestion. Therefore, this could be considered as an alternative to fasting LT4 ingestion.

Natural course of subclinical hyperthyroidism in primary care in the netherlands

Stan Ursem[1], Wendy den Elzen[2], Jesse van den Berg[3], Anita Boelen[1], Petra Elders[4], Raymond Noordam[5] & Annemieke C Heijboer[1]
[1]Amsterdam UMC, Endocrine Laboratory, Laboratory Medicine, Amsterdam, Netherlands; [2]Amsterdam UMC, Laboratory of Specialized Diagnostics & Research, Laboratory Medicine, Amsterdam, Netherlands; [3]Pharmo Institute, Utrecht, Netherlands; [4]Amsterdam UMC, General Practice, Amsterdam, Netherlands; [5]Leiden University Medical Center, Internal Medicine, Section Gerontology and Geriatrics, Leiden, Netherlands

Background
Subclinical hyperthyroidism (SHT) is characterized by a suppressed thyroid-stimulating hormone (TSH) concentration with normal free thyroxine (FT4) levels. While SHT has potential health implications, the epidemiology and contributing factors for its natural course and guideline adherence in primary care remain unclear.
Objectives
To investigate the incidence and natural course of SHT in primary care and assess guideline adherence to follow-up recommendations within Dutch primary care.
Methods
Using a retrospective cohort design, we analyzed data from the PHARMO General Practitioner database in the Netherlands (2012 to 2021). Patients with biochemically confirmed SHT were followed to assess progression to hyperthyroidism, recovery, or persistence. Adherence to the Dutch primary care guideline on SHT management was evaluated.
Results
The annual incidence of SHT was approximately 200 cases per 100,000 person-years, with a temporary increase in 2016-2017 coinciding with a national thyroid medication shortage. Among the 11,163 patients with SHT, 47% recovered, 11% persisted, and 8% progressed to overt hyperthyroidism over a median follow-up of five years. Female sex and baseline TSH <0.1 mU/l were associated with higher progression rates (1,69 (CI 1,32 - 2,17) and 2,36 (CI 1,97 - 2,83), respectively). Guideline adherence evaluation showed 33% received follow-up TSH measurement within six months, and 4% underwent TSH receptor antibody testing.
Conclusion
This study highlights that a small subset of SHT patients progresses to overt hyperthyroidism. Significant contributing factors of progression included lower TSH at baseline and female sex. In addition, our findings indicate a need for improved guideline adherence in follow-up and diagnostic testing.

Trends in thyroid cancer in the balearic islands, insights from 2000 – 2020 to 2021 – 2023

Alicia Sanmartín Sánchez[1], Santiago Tofé Povedano[1], Guillermo Serra Soler[1], Mercedes Noval Font[1], Guadalupe Pérez Bec[2], Irene Rodríguez Rodríguez[2], Andreu Campos Peris[1], Ramón Zafra Jiménez[1], Alejandro De la Cruz Bonilla[1] & Iñaki Argüelles Jiménez[1]
[1]Son Espases University Hospital, Endocrinology and Nutrition, Palma de Mallorca, Spain; [2]Son Llàtzer University Hospital, Endocrinology and Nutrition, Palma de Mallorca, Spain

Summary
Thyroid cancer (TC) incidence has been rising globally, including in the Balearic Islands. From 2010 to 2020, the spread use of neck ultrasound (US) by clinicians led to the detection of many subclinical cancers, causing overdiagnosis. Our aim is to assess the ongoing trends in TC during the 2021-2023 period.

Table 1. Trends in TC parameters in the Balearic Islands.

	Before US (2000-2009)	After US (2010-2020)	LU (2021-2023)
Disease crude incidence (x105 habitants)	3.35	8.39	7.46
Estimated annual percent change in incidence, %	3.05	11.37	-9.77
Incidence of MPTC, %	14.20	20.50	21.40
Incidence of aggressive histology, %	6.48	7.15	18.01
Anaplastic carcinoma, % (n)	0.93 (3)	0.66 (7)	2.48 (8)
Median tumor size (cm ±SD)	2.78 ±0.45	2.04 ±1.56	1.88 ±3.88
Lymph node at diagnosis, %	7.97	11.28	17.24
Distant metastases at diagnosis, %	1.38	1.91	4.19
Initial Lobectomy, %	1.93	5.13	33.55
Initial I-131 ablation therapy, %	87.21	74.61	54.04
Initial thermal ablation therapy, % (n)	0	0.56 (6)	2.61 (8)

Methods
We reviewed 322 new TC cases diagnosed between 2021 and 2023 (last update – LU) in the Balearic Islands. Data on histological subtypes, tumor size, initial presence of lymph node and distant metastasis, disease management and disease progression were compared with earlier periods: 2000-2009 (before US), and 2010-2020 (after US), respectively.
Results
TC incidence has tapered down since 2020, but several important trends observed in previous periods are maintained in regards of disease incidence, management and cancer aggressiveness (Table 1).
Conclusions
During 2021 to 2023, global incidence of TC decreased slightly as compared to our previous series, but overdiagnosis is still present as evidenced by increased incidence of MPTC and smaller tumor size. Nevertheless, there is a persistent trend towards an increased incidence of more aggressive types of tumors both in histological subtypes (including a sharp increase in anaplastic carcinoma) and disease presentation with neck lymph involvement and distant metastases. In line with current recommendations, TC management has improved towards less aggressive procedures (lobectomy and thermal ablation) in selected patients.

Levothyroxine use in Belgium in 2003-2020: a longitudinal population-level registry-based cohort analysis

Kevin Van Compernolle[1], Annick VAN DEN BRUEL[2], Annouschka Laenen[3], Koen Cornelis[4], Rose-Marie Ntahonganyira[4], Christiaan Vanhaecht[4], Jocelijn Stokx[4], Karel David[1] & Brigitte Decallonne[1]
[1]University Hospitals Leuven, Department of Endocrinology, Leuven, Belgium; [2]General Hospital Sint-Jan, Department of Endocrinology, Bruges, Belgium; [3]KU Leuven, Center of Biostatistics and Statistical Bioinformatics, Leuven, Belgium; [4]Christelijke Mutualiteit-Mutualité Chrétienne, Department of Health Policy & Studies, Brussels, Belgium

Background and Objective
Levothyroxine (LT4) is among the most frequently used medications in the Western world. In Belgium, where health insurance is mandatory, 5.85% of the population was prescribed LT4 in 2023, raising concerns regarding overdiagnosis and overtreatment. We investigated prevalence and incidence of LT4 use in relation to TSH screening intensity, treatment threshold, and risks of over-treatment.
Method
Retrospective registry-based cohort analysis in 2003-2020 based on aggregated data from the largest Belgian health insurance provider representing 42% of the Belgian population (±4.5 million individuals).
Findings
Prevalence of LT4 use steadily increased from 2.59% in 2003 to 5.29% in 2020 (slope over time +0.153;$P < 0.0001$) whereas incidence of LT4 use was stable around 0.40%/year (slope +0.003;$P = 0.0628$) (adjusted for age category, sex, region, socioeconomic status). In the 80+ age category, prevalence rose from 5.36% in 2003 to 11.63% in 2020 (slope +0.418;$P < 0.0001$), but incidence decreased from 0.70%/year to 0.53%/year (slope -0.005;$P = 0.046$). Among non-LT4 users, the proportion with high TSH testing rate ($\geq$1 TSH test/year) steadily rose from 26.05% to 38.53% over time. Prescription (first and following) of exclusively the lowest dose (25µg) rose from 8.33% to 19.83%. Incidence of thyroid surgery was stable at around 0.05%/year. First-time LT4 use was associated with high TSH testing rate in the preceding year (Rho 0.86;$P < 0.0001$), prescription of exclusively the lowest dose (Rho 0.736;$P = 0.0007$), and incidence of thyroid surgery (Rho 0.552;$P = 0.0252$). Among LT4 starters, a low subsequent TSH testing rate ($\leq$1 TSH test within two years after start) was present in 16.52% in 2003 and 14.19% in 2018. The proportion of low TSH testing rate was negatively associated with calendar year (Rho -0.915;$P < 0.0001$). Compared to non-LT4 users, those using LT4 for $\geq$2 years had a higher risk of subsequent initiation of antiarrhythmic (RR 1.113;$P = 0.0284$) and antiresorptive drugs (RR 1.129;$P = 0.0305$), but lower mortality risk (RR 0.885;$P = 0.0082$). Additionally, we found a higher risk of statin use (RR 1.483;$P < 0.0001$), flu vaccination (RR 1.273;$P < 0.0001$), and $\geq$2 GP visits/year (RR 1.165;$P < 0.0001$).
Discussion
These findings suggest that increased LT4 use may partially be attributed to increased detection (TSH testing rate) of subclinical hypothyroidism (prescription of only the lowest LT4 dose), and highlight the need for better TSH monitoring after starting LT4. Whether the higher use of antiarrhythmic and antiresorptive medications in LT4 users is causally related or explained by other factors such as more intensive medical follow-up needs to be further explored on a subject-level base.

Paediatric thyroid cancer management in france: a TUTHYREF network

Magalie Haissaguerre[1], Cécile Vérité[2], Malanie Roy[3], Françoise Borson-Chazot[3], Camila Nascimento[4], Arnaud Jannin[5], Frédéric Illouz[6] & Livia Lamartina[7]
[1]Universitary Hospital of Bordeaux, Haut Leveque Hospital, Endocrinology and Endocrine Oncology Department, PESSAC, France; [2]Universitary Hospital of Bordeaux, Bordeaux, France; [3]Universitary Hospital of Lyon, Lyon, France; [4]Universitary Cancer Institute of Toulouse, Toulouse, France; [5]Universitary Hospital of Lille, Lille, France; [6]Universitary Hospital of Angers, Angers, France; [7]Gustave Roussy Institute, Villejuif, France

Differentiated thyroid cancer (DTC) is rare in children requiring expert multidisciplinary management. The aim of this multicenter retrospective study by the national TUTHYREF network was to describe care pathway and outcome of these patients aged under 18. 93 patients, median age 15 years, managed for CPT between 2010 and 2022 were included. Surgery was performed by a pediatric surgeon in 14% of cases, in a university hospital in 53% of cases, with validation of surgical extension by a multidisciplinary team in 32% of cases. All patients underwent total thyroidectomy followed by radiotherapy (RAI). Central and lateral lymph node dissection was performed in 79 and 45% of cases respectively, with 19% R1 resection. Definitive hypoparathyroidism occurred in 5% of patients. Most patients had papillary DTC (84%), tumor size greater than 20 mm (45% pT2, 16% pT3), lymph node involvement (LNI) (21% N1a, 38% N1b), vascular invasion (42%), extra-thyroid invasion (37%). All patients had at least one iodine treatment (median activity 80 mCi), with a median Tg of 3.4 ng/mL and positive Tg Ac in 21% of cases. After a course of iodine, 69% of patients had an excellent response to RAI. After RAI, persistent and metastatic disease were observed in 22% and 12% of patients respectively. Of the 15 patients with morphological locoregional persistence or recurrence, 60% underwent re-operation. Among the 11 metastatic patients, metastases were synchronous in 73% of cases, with a median number of iodine treatments of 3 (1-6) and a Tg at diagnosis of 123 ng/mL. At the end of a median follow-up of 8 years in these patients, 64% were in remission and 36% in biological or morphological persistence, and none were refractory to iodine. Children under 15 had more aggressive disease (higher Tg at 16 ng/mL vs. 1.4 and 23% metastases vs. 2%), but the remission rate remained comparable to patients over 18. After a median follow-up of 4 years (1-13), 92% of patients were cured, 4% had an indeterminate response and 4% stable metastatic disease. Our study confirms that LNI and metastatic disease are more frequent in children, with a prognosis and sensitivity to RAI that remain excellent. The care pathway seems very heterogeneous, sometimes lacking the pediatric or social psychological and genetic intervention that is usually recommended and raises the question of pediatric surgical expertise, always complicated to assess to avoid excessive LND or incomplete surgery.

Is postoperative radioactive iodine (RAI) ablation necessary for low- and low-to-intermediate-risk papillary thyroid carcinomas? a web survey among Greek endocrinologists

Marina Michalaki[1], Eleni Sazakli[1], Olga Karapanou[2], Grigoris Effraimidis[3] & Katerina Saltiki[1]
[1]Faculty of Medicine, School of Health Science, University of Patras, Patras, Greece; [2]Endocrine Department, NIMTS Veteran's Hospital, Athens, Greece; [3]Faculty of Medicine, School of Health Sciences, University of Thessaly, Department of Endocrinology and Metabolic Diseases, University General Hospital of Larissa, Larissa, Greece

Objectives
The majority of patients with a low-risk DTC has a favorable outcome. Consensus statements and recent prospective studies do not recommend RAI-ablation for low-risk microcarcinomas ($\leq$10 mm). However, RAI-ablation strategy for other low-risk PTC cases remains controversial and the therapeutic policy varies significantly among endocrinologists.
Aim
To evaluate treatment strategies of Greek endocrinologists for low- and low-to-intermediate-risk PTC in terms of RAI-ablation.
Methods
Between November 2023 and April 2024, a web-based survey was conducted among members of the Hellenic Endocrine Society (HES). Four clinical scenarios involving a 60-year-old patient with a low-risk PTC were analysed. The scenarios varied according to primary tumor size ($\leq$ or $>$1 cm) and the presence or not of either postoperative cervical lymph node (LN) involvement or minimal extrathyroidal extension (ETE). The scenarios addressed questions regarding the extent of surgery, the decision for postoperative RAI-ablation and the appropriate RAI dose if indicated.
Results
A total of 201 endocrinologists (25% of HES members) participated in the survey. For low-risk PTC patients, responses varied by tumor size: for 7 mm tumors, the majority (95.0%) did not recommend RAI ablation, whereas for 18 mm tumors, 51.8% recommended it. Among those who opted for RAI ablation, the recommended doses were 30 mCi (36.5%), 50 mCi (35.6%), 70 mCi (3.5%), and 100 mCi (14.4%). For low- to intermediate-risk PTC cases with either three microscopic LN metastases (1–2 mm) or minimal ETE, but no other high-risk features, most endocrinologists (92.5%) favoured RAI ablation/adjuvant therapy. Their preferred doses were 30 mCi (13%), 50 mCi (26.6%), 70 mCi (31.2%), and 100 mCi (29.2%).
Conclusions
Greek endocrinologists continued to favour postoperative RAI therapy for low-risk and low-to-intermediate-risk T1b PTC, often at high doses—a concerning trend. These findings highlight the need for more randomized controlled trials, clearer guidelines and educational programs to ensure consistent and evidence-based care.

Background
Hypothyroidism is a common endocrinological disorder affecting approximately 10% of the general population, with a 10-fold higher prevalence in women. Despite levothyroxine being one of the most prescribed treatments worldwide, 30–50% of patients are over- or under-treated, with many reporting dissatisfaction with their treatment and quality of life. Hypothyroidism patients present with significant heterogeneity in symptoms, co-morbidities, and treatment requirements, yet large and comprehensive studies addressing this complexity remain lacking. Our study aims to identify clustering patterns and varying trajectories of hypothyroidism patients by leveraging longitudinal health and demographic data. We seek to characterise patient clustering patterns by defining respective co-morbidities and risk/protective factors, while also exploring the overlapping disease mechanisms involved in these co-morbidities.
Methods
We identified 21,790 (17,028 women and 4,761 men) hypothyroidism patients from the Copenhagen Hospital Biobank based on hypothyroidism diagnosis in hospital records and levothyroxine prescription data, ensuring a comprehensive dataset reflecting diverse patient profiles. We constructed longitudinal health sequences capturing each patient's history of hospital diagnoses, prescriptions, procedures, and laboratory Results To address the complexity and high dimensionality of the data, we applied a machine learning approach: the Deep Generative Decoder (DGD), which learns low-dimensional representations even for small datasets, based on a transformer architecture to identify long-term dependencies and intricate patterns in sequential health data. The DGD integrates a Gaussian Mixture Model to capture latent space distributions and uncover data substructures. Patient representations generated through this pipeline were clustered, enabling the identification of unique patterns. These clusters were further characterized to highlight key patterns.
Results
Preliminary findings indicate that hypothyroidism patients are clustered with distinct and varying longitudinal patterns, notably differentiating between reproductive co-morbidities such as infertility and miscarriage (observed exclusively in women) and cardiovascular co-morbidities such as essential hypertension and atrial fibrillation (present in both sexes). Ongoing model refinement with additional data will improve these findings. Further detailed analyses of these clustering patterns and their associated health outcomes will be discussed, providing insights into the underlying disease mechanisms and potential ways for providing more personalised prevention, diagnosis and treatment options.
Conclusion
This study highlights the importance of understanding the heterogeneous nature of hypothyroidism patients in a sex-specific manner. By identifying patient clustering patterns, we aim to enhance clinical management and therapeutic approaches, ultimately improving patient outcomes in this diverse population. Further results and detailed characterisations will be presented at the conference.

[1]Vall d'Hebron University Hospital, Barcelona, Spain; [2]Hospital de Palamós, Palamós, Spain; [3]Hospital Universitaria Arnau de Vilanova, Lleida, Spain; [4]Hospital del Mar, Barcelona, Spain; [5]5Hospital Universitari Joan XXIII, Tarragona, Spain; [6]Hospital Mútua de Terrassa, Terrassa, Spain; [7]Hospital Universitari Germans Trias i Pujol, Badalona, Spain; [8]Hospital Sant Joan de Deu, Esplugues de Llobregat, Spain; [9]Hospital Universitari Sant Joan de Reus, Reus, Spain; [10]Hospital Universitari de Girona Doctor Josep Trueta, Girona, Spain; [11]University Hospital Vall d'Hebron, Barcelona, Spain

Introduction
Non-autoimmune subclinical hypothyroidism (NASHT) is characterized by elevated TSH levels with normal concentrations of thyroid hormones. Genetic defects, which can determine disorders in the biosynthesis process of thyroid hormones, such as in the TSH receptor (*TSHR*) or in the dual oxidase 2 (*DUOX2*) genes, have been described. It is suspected that other genes that regulate or participate in the biosynthesis of thyroid hormones could be involved in NASHT, suggesting a more complex pathogenesis although few studies have explored its genetic basis.
Objective
To perform a molecular characterization and genotype-phenotype correlation in NASHT patients.

Patients and methods
Multicenter study in 11 Spanish centers. Patients with NASHT were included with TSH > 7 μUI/mL in two measurements. Patients exposed to medical treatments or radiotherapy capable of affecting thyroid function were excluded. The data collection were: clinical, familial, analytical, thyroid ultrasound, and levothyroxine treatment. Molecular analysis was performed using a high-throughput sequencing panel (Cell3 Target Custom Panel tier 2, NONACUS) covering 18 genes, the most relevant: *TG, TPO, DUOX2, DUOXA2, PAX8, TSHR, SLC5A5, and SLC26A4*. Statistical analysis: IBM®SPSS®Statistics v25.
Results
Ninety patients were studied (mean age at diagnosis 5.6 ± 3.4 years; 58% male). Fifty patients (56%) received levothyroxine treatment. Mean TSH at diagnosis: 9.7 ± 3.7 μUI/mL; maximum TSH: 11.7 ± 4.4 μUI/mL. Thyroid ultrasound showed thyroid hypoplasia in 13 patients and hyperplasia in 2. A total of 55 patients (61%) had candidate variants in the studied genes, of which 44 (80%) were heterozygous, 9 (16%) digenic, and two were compound heterozygous; one for *DUOX2* and another for *TPO*. In total, 64 candidate variants were identified, with their distribution in *Table1*. Among heterozygous patients, 21 (48%) had a variant described as pathogenic (PAT) or likely pathogenic (LPAT), and 23 (52%) had variants of uncertain significance (VUS). Family segregation studies are ongoing to determine the possible inheritance of candidate variants and their potential cosegregation with NASHT clinical features.
Conclusion
A significant proportion (61%) of NASHT patients have variants in thyroid dyshormonogenesis-related genes, some previously undescribed. The possible oligogenic origin of NASHT is highlighted, as 9 patients showed variants in two genes. These genetic findings may help to better characterize patients and define their prognosis and need for treatment. Additionally, given the high percentage of VUS identified, our results support the need for functional studies to determine the clinical relevance of these findings.

Evaluation of the diagnostic accuracy of European and ACR-TIRADS classification systems for thyroid nodules exceeding 20 mm in diameter

Nicholas Angelopoulos[1,2], Dimitrios Goulis[3], Sarantis Livadas[1], Rodis Paparodis[1,4], Anastasios Boniakos[1], Ioannis Androulakis[1] & Ioannis Iakovou[2]
[1]Hellenic Endocrine Network, Athens, Greece; [2]AHEPA University Hospital, Faculty of Medicine, School of Health Sciences, Thessaloniki, Greece, 2nd Academic Department of Nuclear Medicine, Thessaloniki, Greece; [3]Unit of Reproductive Endocrinology, Faculty of Medicine, School of Health Sciences, Aristotle University of Thessaloniki, Greece, 1st Department of Obstetrics and Gynecology, Thessaloniki, Greece; [4]Loyola University Medical Center Maywood, IL and Edward Hines, Jr. VA Hospital, Hines, IL, USA, Endocrinology, Chicago, United States

Background
Determining which thyroid nodules require fine-needle aspiration (FNA) cytology remains a critical challenge in clinical practice. To address this, the Thyroid Imaging Reporting and Data System (TIRADS) was developed, with the two most commonly used formats being the European (EU-TIRADS) and American (ACR-TIRADS) versions. Despite their widespread application, clinical observations indicate that TIRADS 3 nodules measuring ≥20 mm present difficulties in accurate risk stratification. This study aimed to evaluate the efficacy of EU-TIRADS and ACR-TIRADS in differentiating between benign and malignant nodules in this subgroup of nodules.
Material and Methods
Between May 2023 and March 2024, 1,094 patients with thyroid nodules underwent thyroid ultrasound (US) at a University Hospital. Comprehensive data, including clinical parameters, US characteristics, and cytological or histopathological findings, were collected. Nodules measuring ≥20 mm were categorized using EU-TIRADS and ACR-TIRADS, and their predictive performance for malignancy was assessed. Malignancy was confirmed via histopathological examination post-thyroidectomy or through US-guided FNA cytology categorized by the Bethesda classification system.
Results
The study analyzed data from 267 patients (mean age 60.3 ± 14.3 years; 46 men and 221 women) with 308 thyroid nodules. These were classified using EU-TIRADS into categories 3, 4, and 5, with all nodules undergoing FNA. Of the total, 22 nodules were malignant, and 286 were benign. When the EU-TIRADS 3 FNA criteria were adjusted to include thresholds of 25 mm or 30 mm, the rates of avoided FNA procedures were 24% and 41%, respectively. Using the ACR-TIRADS system, 26.6% of FNAs could be avoided ($P > 0.05$). Two malignancies were missed across these adjusted criteria.
Conclusion
The performance of EU-TIRADS and ACR-TIRADS is comparable when the FNA referral diameter threshold for seemingly benign nodules is standardized to 25 mm. Adjusting the EU-TIRADS 3 threshold to 25 mm or 30 mm could significantly reduce unnecessary FNA procedures and healthcare costs. However, the potential trade-off includes an increased risk of missing malignant cases, which underscores the need for careful risk assessment and individualized patient management. Future studies should explore ways to enhance the sensitivity of these grading systems while maintaining efficiency to optimize patient care.

Radiofrequency ablation (RFA) for locoregional structural incomplete response (SIR) in differentiated thyroid cancer (DTC)

George Simeakis[1], Aikaterini Kapama[2], Rodis Paparodis[3], Pyrros Gkousis[4], Panayiotis Koursaros[4], Christos Kokkinis[4], Maria Zozolou[5] & Myrsini Gkeli[4]
[1]Thyroid Cancer Outpatient Clinic - Endocrine Department 401 General Military Hospital of Athens, Athens, Greece; [2]Department of Endocrinology, Diabetes and Metabolism, European and National Expertise Center for Rare Endocrine Disorders, Evangelismos General Hospital, Athens, Greece; [3]Division of Endocrinology, Diabetes and Metabolism, Loyola University Medical Center, Maywood, IL and Edward Hines Jr. VA Hospital, Illinois, United States; [4]Saint Savvas, Anticancer Oncology Hospital of Athens, Department of Radiology, Athens, Greece; [5]Athens Vision Eye Institute, Athens, Greece

Objectives
Structural incomplete response (SIR) to treatment, characterized by persistent or recurrent disease, is observed in 2 - 6% of low-risk differentiated thyroid cancer (DTC) cases and in 67 - 75% of high-risk cases. For locoregional recurrence, surgery remains the optimal treatment when the smallest dimension of the targeted lesion is at least 8 mm in the central compartment or 10 mm in the lateral compartment. However, in cases with smaller lymph nodes, contraindications to surgery, or when the patient declines reoperation, alternative approaches such as active surveillance (AS) or minimally invasive treatments (MITs), like radiofrequency ablation (RFA) may be considered. The aim of this study is to evaluate the safety and efficacy of RFA in DTC patients with SIR.
Methods
It is a retrospective study of eight DTC patients with SIR confirmed by ultrasound (U/S)-guided fine-needle aspiration cytology (FNAC) and measurement of Thyroglobulin (Tg) in the washout fluid. Fourteen malignant lesions were ablated by radiofrequency (RF). We assessed the volume of each lesion, serum Tg and Anti-Tg antibodies and calculated the volume reduction ratio (VRR) prior RFA and then at one month, three months and subsequently every three months.
Results
Patients were followed for a mean period of 14.75 months (range: 4–24) after RFA was performed. The targeted lesions reduced significantly from a median volume of 0.24 mL (range: 0.09 - 0.9) to 0.01 mL (range: 0 - 0.03) ($P < 0.05$), with a median volume reduction rate (VRR) of 96.5% (range: 87 - 100%). Out of the 14 lesions that were ablated, 4 (28.6 %) were no longer visible on the U/S. Volume reduction was accompanied by a significant biochemical response, with a decrease in serum thyroglobulin (Tg) levels from a median of 1.05 ng/mL to 0.13 ng/mL ($P < 0.05$). In one patient with an aggressive radioiodine (RAI)-refractory histological variant, re-recurrence was documented, which was successfully treated with repeat RFA. Two patients developed Horner syndrome as a complication of RFA, but in both cases it was fully resolved within six months.
Conclusions
RFA may be considered as an effective and safe MIT in selective DTC patients with SIR, especially in cases of smaller lesions. Additional prospective studies, including aggressive DTC histological variants are needed towards tailored-made therapy.

Clinical characteristics and outcomes of graves' disease in patients with prior hypothyroidism

Afif Nakhleh[1,2,3], Eyal Robenshtok[4,5], Limor Adler[5,6], Shirley Shapiro Ben David[5,6], Daniella Rahamim-Cohen[6], Ori Liran[5,6] & Sagit Zolotov[1,2]

[1]Maccabi Healthcare Services, Diabetes and Endocrinology Clinic, Haifa, Israel; [2]Rambam Health Care Campus, Institute of Endocrinology, Diabetes and Metabolism, Haifa, Israel; [3]Bar-Ilan University, Azrieli Faculty of Medicine, Safed, Israel; [4]Beilinson Hospital, Rabin Medical Center, Endocrinology and Metabolism Institute, Petah Tikva, Israel; [5]Tel Aviv University, Faculty of Medicine, Tel Aviv, Israel; [6]Maccabi Healthcare Services, Health Division, Tel Aviv, Israel

Background and Aims
Graves' disease (GD) and Hashimoto's thyroiditis are autoimmune disorders that can transition from one to the other. The shift from hypothyroidism to GD is rare. This study compared clinical characteristics, treatments, and outcomes in patients with new-onset GD following hypothyroidism vs those with new-onset GD without prior thyroid disease.
Methods
This retrospective cohort study used the electronic medical database of Maccabi Healthcare Services, an Israeli health maintenance organization. We included adults with new-onset GD between 1.2010–12.2022 who had thyroid-stimulating immunoglobulin (TSI) titers >140% within a year of thyrotoxicosis diagnosis. Subjects with prior amiodarone use were excluded. Data included demographics, clinical history, treatments, and laboratory Results The end of follow-up was 31.10.2024. Data were analyzed using chi-square or Fisher's exact tests for categorical variables, t-tests or Mann-Whitney U tests for continuous variables, and Cox regression models adjusted for age and sex.
Results
We included 2402 patients with new-onset GD. Of these, 2146 had no prior thyroid disease (GD-controls) and 256 had prior hypothyroidism (post-hypo-GD patients). Compared to GD-controls, post-hypo-GD patients were older (51.4 ± 14.3 vs. 47.4 ± 13.6 years; $P < 0.001$), predominantly female (88.1% vs. 76.9%; $P < 0.001$), and had a higher prevalence of autoimmune disease (19.5% vs. 12.9%; $P = 0.003$). At diagnosis, post-hypo-GD patients had lower median free thyroxine (fT4) levels (21.7 [interquartile range (IQR), 17.5-28.5] vs. 26.8 [IQR,19.8-38.6] pmol/l; $P < 0.001$) and free triiodothyronine (fT3) levels (8.5 [IQR,5.9-11.5] vs. 10.4 [IQR,7.2-15.8] pmol/l; $P < 0.001$). Over a median follow-up of 7.2 [IQR,4.6–10.9] years, antithyroid medications were used less frequently in post-hypo-GD patients (65.6% vs. 81.0%; hazard ratio [HR] 0.64; $P < 0.001$). Radioactive iodine ablation (HR 0.68; $P = 0.26$) and total thyroidectomy (HR 1.29; $P = 0.33$) were utilized at comparable rates. Post-hypo-GD patients had a higher incidence of hypothyroidism requiring levothyroxine (41.8% vs. 21.0%; HR 2.58; $P < 0.001$).
Conclusions
Patients with post-hypo-GD present with milder thyrotoxicosis and more often revert to hypothyroidism.

Biological activity and therapeutic potential of SAFA-based long-acting rhTSH

Daham Kim[1], Min Jeong Kang[1], So Jeong Lee[1], Yoon Hee Cho[2], Gunuk Zi[3], Jeongsuk An[3], Jinjoo Park[3], Jaekyu Han[3], Susan Chi[3], Sang-hoon Cha[3] & Eun Jig Lee[1]
[1]Yonsei University College of Medicine, Department of Internal Medicine, Institute of Endocrine Research, Seoul, South Korea; [2]Yonsei University College of Medicine, Department of Tropical Medicine, Seoul, South Korea; [3]Kangwon National University, Aprilbio Co., Ltd., Rm 602, Biomedical Science Building, Chuncheon, South Korea

Thyrogen, a recombinant human thyroid-stimulating hormone (rhTSH), has a short half-life in the bloodstream, which necessitates multiple doses during treatment. Therefore, we developed a new long-acting rhTSH using anti-serum albumin Fab-associated (SAFA) technology to validate its biological activity through *in vitro* assays, pharmacokinetic (PK) studies in healthy mice, and pharmacodynamics (PD) studies in a TSH-suppressed mouse model. SAFA-TSH was produced using a Chinese hamster ovary expression system. To verify its biological activity, we generated Nthy-ori 3-1 cells stably overexpressing TSHR and measured the production of cyclic adenosine monophosphate (cAMP). In a rat study, slow-release triiodothyronine (T3) pellets were implanted 3 days before administering Thyrogen or SAFA-TSH, to measure the amount of thyroxine (T4) release alone resulting from exogenous administration. SAFA-TSH increased cAMP production dose-dependently, but less effectively than Thyrogen at similar concentrations. SAFA-TSH required six times the dose of Thyrogen to achieve similar cAMP levels, likely due to differences in molecular weight and relative bioactivity. In a rat study, SAFA-TSH produced elevated thyroid hormone levels well after the decline in the response to Thyrogen. SAFA-TSH had significantly higher cumulative effects on T4 and free T4 levels compared with Thyrogen, as observed by a more than two-fold higher average area under the effect curve of 262.56 vs 118.89 μg×h/dl and 127.47 vs 60.75 μg×h/dl, respectively. SAFA technology created successful long-acting TSH that demonstrated bioactivity. These findings endorse the continued development of SAFA-TSH for clinical use, highlighting its potential as a significant advancement treating thyroid cancer patients.

Washout CYFRA 21-1 as a biomarker for thyroid cancer diagnosis in thyroid nodules

Jeogmin Lee[1], Jeongun Kwak[1], Seulki Kim[2], Hye Lim Park[3], Jung-Min Lee[1], Sang-Ah Chang[1] & Dong-Jun Lim[4]
[1]Eunpyeong St. Mary's Hospital, College of Medicine, The Catholic University of Korea, Division of Endocrinology and Metabolism, Department of Internal Medicine, Seoul, South Korea; [2]Eunpyeong St. Mary's Hospital, College of Medicine, The Catholic University of Korea, Pediatrics, Seoul, South Korea; [3]Eunpyeong St. Mary's Hospital, College of Medicine, The Catholic University of Korea, Division of Nuclear Medicine, Department of Radiology, Seoul, South Korea; [4]Seoul St. Mary's Hospital, College of Medicine, The Catholic University of Korea, Division of Endocrinology and Metabolism, Department of Internal Medicine, Seoul, South Korea

Background
Thyroid nodules with non-diagnostic or atypia of undetermined significance (AUS) cytology results often require repeat testing, leading to diagnostic delays and uncertainty. CYFRA 21-1, a fragment of cytokeratin-19, has been suggested as a complementary biomarker to improve diagnostic accuracy and predict malignancy in such ambiguous cases. This study aims to evaluate the diagnostic and predictive utility of washout CYFRA 21-1 in thyroid nodules.
Methods
This retrospective study analyzed data from 153 patients with thyroid nodules who underwent fine-needle aspiration cytology (FNAC). Washout CYFRA 21-1 levels were measured from FNAC washout fluid. Diagnostic performance was assessed using receiver operating characteristic (ROC) curve analysis to identify the optimal washout CYFRA 21-1 cutoff value by maximizing the Youden index. Multivariate logistic regression analysis was performed to evaluate the association between washout CYFRA 21-1 levels and thyroid cancer.
Results
The mean washout CYFRA 21-1 level was 53.25 ± 146.14 ng/mL. Of the nodules, 13.73% were thyroid cancer, while 81.70% were benign. Non-diagnostic and follicular neoplasm cases accounted for 1.96% and 2.61%, respectively. Most nodules were classified as K-TIRADS 4 (49.02%) or 5 (21.57%). Washout CYFRA 21-1 levels demonstrated a significant association with malignancy, with levels markedly higher in PTC compared to benign or indeterminate outcomes ($P < 0.0001$). The optimal cutoff value for washout CYFRA 21-1 was 60.39 ng/mL, achieving a sensitivity of 88.0%, specificity of 94.5%, positive predictive value of 82.8 %, negative predictive value of 93.8%, and accuracy of 90.2% (AUC = 0.833). Multivariate analysis showed that high CYFRA 21-1 levels (≥ 60.39 ng/mL) were strongly associated with malignancy (adjusted OR: 9.257, 95% CI: 13.452–180.356, $P < 0.0001$).

JOINT2684

Combining TERT promoter mutations with american thyroid association risk stratification system to predict short-term prognosis in papillary thyroid carcinoma

Ji Hyun yoo[1], So Hyun Cho[1], Da Eun Leem[1], Bo Ram Kim[1], Jae Hoon Chung[1], Sun Wook Kim[1] & Tae Hyuk Kim[1]
[1]Division of Endocrinology and Metabolism, Department of Medicine, Thyroid Center, Samsung Medical Center, Sungkyunkwan University School of Medicine, Seoul, South Korea

Background
TERT promoter mutations are associated with poor long-term outcomes in papillary thyroid carcinoma (PTC), but their influence on short-term prognosis

remains unclear. Understanding this association could enhance early risk stratification and support clinical decision-making. While the 2015 American Thyroid Association (ATA) guidelines acknowledge the potential prognostic value of TERT promoter mutations, they do not provide specific recommendations on their use or indicate when testing should be performed. This study evaluates the impact of TERT mutations on short-term clinical outcomes and proposes an enhanced risk stratification model integrating TERT mutation status.
Methods
This retrospective cohort study analyzed 3,078 patients who underwent thyroidectomy for PTC at Samsung Medical Center (2019–2021). Among them, 57 patients had TERT promoter mutations. Using propensity score matching (4:1) by age and sex, a matched cohort of 57 patients with TERT promoter mutations and 227 patients with wild-type TERT. Short-term outcomes were classified as no evidence of disease (NED), biochemical incomplete response, or structural incomplete response. Kaplan-Meier survival analysis and hazard ratios were used to assess recurrence risk. To improve risk prediction, we developed an alternative classification (RSS-T) that integrates TERT mutation status into the ATA risk stratification system.
Results
Patients with TERT promoter mutations had larger tumor, wider disease extent, and received more aggressive treatment. Short-term outcomes differed significantly ($P < 0.001$): NED was achieved in 95.6% of wild-type patients but only 64.9% of mutation carriers, with mutation carriers exhibiting higher rates of structural incomplete response (29.8% vs. 2.2%). When stratified by the ATA risk system, all low-risk patients achieved NED regardless of TERT status. However, in the intermediate- and high-risk groups, TERT mutations were associated with significantly poorer outcomes ($P < 0.001$ and $P = 0.004$, respectively). The RSS-T system categorized patients as RSS-T1 (low-risk, regardless of TERT status), RSS-T2 (intermediate/high-risk with wild-type TERT), and RSS-T3 (intermediate/high-risk with TERT mutation). RSS-T demonstrated superior predictive accuracy for structural persistence/recurrence compared to the ATA system (C-index 0.890 vs. 0.794, $P = 0.03$) and explained a greater proportion of variance (86% vs. 70%).
Conclusion
TERT promoter mutations are associated with worse short-term outcomes in PTC, particularly among intermediate- and high-risk patients. Integrating TERT status into the ATA risk stratification system (RSS-T) improves predictive performance and provides valuable guidance for clinical decision-making. Selective TERT testing in intermediate- and high-risk patients could refine risk assessment and enable more personalized, aggressive management strategies, ultimately improving patient outcomes.

Circulating tumor DNA as a diagnostic marker for molecular alterations in anaplastic thyroid cancer using next generation sequencing

Emilia Niedziela[1,2], Sebastian Zięba[3], Danuta Gąsior-Perczak[1,2], Iwona Pałyga[1,2], Agnieszka Walczyk[1,2], Janusz Kopczyński[4], Artur Kowalik[3,5] & Aldona Kowalska[1,2]
[1]Holy Cross Cancer Center, Department of Endocrinology, Kielce, Poland; [2]Jan Kochanowski University, Collegium Medicum, Kielce, Poland; [3]Holy Cross Cancer Center, Department of Molecular Diagnostics, Kielce, Poland; [4]Holy Cross Cancer Center, Department of Tumor Markers, Kielce, Poland; [5]Jan Kochanowski University, Division of Medical Biology, Institute of Biology, Kielce, Poland

Introduction
Anaplastic thyroid cancer (ATC) is rare, but the most aggressive type of thyroid cancer (TC), with disease-specific mortality approaching 100%. A new therapeutic option that improves overall survival is molecularly targeted therapy. To date, the tumor tissue analysis using next generation sequencing (NGS) is a gold standard for mutational profiling. The circulating tumor DNA (ctDNA) is a component of liquid biopsy, with a potential to expedite the diagnosis in a minimally invasive way. This study aims to evaluate the feasibility of NGS ctDNA analysis for the identification of molecular alterations in ATC.
Methods
A prospective, single-center study was conducted from 2023 to 2024. Treatment-naïve patients with a diagnosis of ATC were included in the study. 10 ml blood samples for ctDNA analysis were collected from patients after histological diagnosis. Tissue and ctDNA samples were analyzed using NGS with the Oncomine Precision Assay, which detects molecular alterations in 50 genes. The minimum concentration of free DNA required for the assays was 0.33 ng/μL. The results were correlated with clinical data.
Results
Ten patients (mean age: 71, 6 females) with stage IVB ($n = 4$) and IVC ($n = 6$) ATC were enrolled in the study. In 5 patients, mutations were detected both in tissue and ctDNA. The mutation-based concordance between tissue and ctDNA was 71%, with 100% concordance of negative Results The most common mutations detected in ctDNA were *BRAF*^{V600E} (20%) and *TP53* (20%), followed by *PIK3CA* (10%) and *PTEN* (10%) mutations. One patient with *BRAF*^{V600E}mutation in tumor tissue, had a unique *TP53* mutation in ctDNA with no evidence of other malignancy, suggesting heterogeneity of the tumor. Based on the results, dabrafenib plus trametinib treatment was introduced in three patients. Mean turnaround time was 17.75 days (range 2-33), depending on the urgency of the referral for a blood test.
Conclusion
The high concordance of detected alterations highlights the potential of liquid biopsy as an effective initial screening tool for molecular alterations in ATC. Our study shows that the detection of any alterations in ctDNA should lead to further diagnostic evaluation by tissue analysis, due to complete concordance in patients with negative Results Using ctDNA may improve and expedite the diagnostic process, contributing to more precise cancer treatment, especially in cases of inoperable tumors or lesions that are difficult to biopsy. Due to the rarity of ATC, larger multicenter studies are necessary to validate and further explore the utility of ctDNA in clinical practice.

Differentiated thyroid carcinomas and its pre-operative characterization: a single centre study

Joana Vinhais[1], Beatriz R Pereira[1], David Verissimo[1], Catarina Ivo[1], Ana Cláudia Martins[1], Mafalda Marcelino[1], Dolores Passos[1], Luís Lopes[1], João Jácome de Castro[1] & João Nunes e Silva[1]
[1]Portuguese Armed Forces Hospital, Endorinology Department, Lisbon, Portugal

Background
EU-TIRADS classification and nodule's size on ultrasonography (US) guide fine needle aspiration biopsy (FNAB) recommendation. Bethesda classification is the report system used to describe cytopathological findings of FNAB. These classification systems help estimate the risk of malignancy and select the appropriate treatment.
Aims
Assess the pre-operative EU-TIRADS and Bethesda classification of nodules diagnosed with differentiated thyroid carcinoma (DTC).
Methods
Retrospective observational study, including patients with anatomopathological diagnosis of DTC submitted to surgery between January/2017 and July/2024.
Results
We included 36 patients with 38 biopsied nodules. Patients diagnosed with DTC corresponded to nodules classified as EU-TIRADS 3, 4 and 5 (16%, 53% and 32%, respectively) on imaging and Bethesda I, II, III, IV or V (3%, 29%, 24%, 29% and 16%, respectively) on FNAB. Nodules classified as EU-TIRADS 5 on US, corresponded to Bethesda IV on FNAB (42%), followed by Bethesda V (33%). Eleven nodules were classified with benign cytology, Bethesda II: Six corresponded to EU-TIRADS 4 on US; 4 to EU-TIRADS 3; 1 to EU TIRADS 5. These patients were submitted to surgery due to dimensional criteria or symptomatic disease. Most patients ($n = 7$) had carcinomas ≤ 1 cm.
Discussion
In this sample, 85% of the patients with DTC had nodules classified as EU-TIRADS 4 or 5 on US, pointing to a strong correlation between US imaging and DTC. Nodules classified as Bethesda II on FNAB have a ROM of 0-3%, however they are among one of the most common FNAB results in this sample. This could be explained by the presence of small foci of DTC or multifocal carcinoma within large thyroid nodules, that can be missed in FNAB.
Conclusion
The presence of high suspicion features in US positively correlates with Bethesda IV and V in FNAB in 75% of the cases. Thyroid carcinoma can be present in nodules with Bethesda II on FNAB, pointing to the presence of false negatives in this category, especially in big nodules. This highlights the importance of combination of EU-TIRADS and Bethesda classifications, as well as of careful selection of biopsy sites and the need to collect several samples from the same nodule, especially in nodules >4 cm.

Clinical outcomes of non-invasive follicular thyroid neoplasm with papillary-like nuclear features: a single-center experience

Miguel António Duarte[1], Leonor Branquinho Ruivo[2], Catarina Isabel Lopes[1], Mariana de Griné Severino[1], Marta Vaz Lopes[1], Carolina Peixe[1], José Vicente Rocha[1], Mariana Lopes-Pinto[1], Dolores López-Presa[2], Sónia do Vale[1,3] & Ema Lacerda Nobre[1,3]

[1]Serviço de Endocrinologia, Diabetes e Metabolismo, Hospital de Santa Maria, Unidade Local de Saúde Santa Maria, Lisboa, Portugal; [2]Serviço de Anatomia Patológica, Hospital de Santa Maria, Unidade Local de Saúde Santa Maria, Lisboa, Portugal; [3]Clínica Universitária de Endocrinologia, Faculdade de Medicina da Universidade de Lisboa, Lisboa, Portugal

Introduction

Non-invasive follicular thyroid neoplasm with papillary-like nuclear features (NIFTP) is a thyroid tumor characterized by its indolent behaviour. Although similarities are found with papillary thyroid carcinoma, NIFTP is thought to be a pre-malignant lesion with hallmark features such as being non-invasive and contained within the tumor capsule. This study aims to analyse the clinicopathologic characteristics and outcomes of NIFTP in order to optimize treatment and reduce overtreatment.

Materials and Methods

We reviewed our hospital's pathology database for NIFTP cases between 2014 and 2024, excluding those with separate *foci* of carcinoma. Clinical data from 50 patients meeting these criteria was retrospectively analysed, with a minimum follow-up of 6 months.

Results

Of the 50 patients diagnosed with NIFTP, 74% ($n = 37$) were female and the mean age at diagnosis was 54.5 years. The median follow-up period was 20.3 months. Total thyroidectomy was performed in 82% ($n = 41$) of cases, while 9 patients underwent lobectomy. Tumor size ranged from 2 to 78 mm, with a median size of 22 mm. All tumors were fully excised, with clear margins in 92% ($n = 46$) and close margins in 4 cases. No lymph node metastases were observed at diagnosis, and in the patients with available nodal tissue ($n = 12$), there were no positive findings. None of the patients received postoperative radioactive iodine therapy. One patient required reoperation to remove remnant thyroid tissue due to compressive symptoms, which was confirmed as benign. At the latest follow-up, none of the patients had experienced recurrence.

Conclusion

This study reaffirms the very low recurrence risk associated with NIFTP, indicating an excellent prognosis even with less extensive surgical approaches, such as lobectomy. Our findings support the possibility of managing patients with NIFTP similarly to those with follicular adenomas, in the absence of separate *foci* of carcinoma or suspicious features like contralateral nodules in patients who underwent lobectomy.

Hemithyroidectomy vs. total thyroidectomy for low-risk differentiated thyroid carcinoma: a retrospective cohort study from romania

Andreea Bojoga[1,2], Dumitru Ioachim[3], Romana Teodora Netea-Maier[2,4] & Corin Badiu[1,5]

[1]"Carol Davila" University of Medicine and Pharmacy, Bucharest, Romania; [2]Radboud University Medical Center, Nijmegen, The Netherlands, Department of Internal Medicine, Division of Endocrinology, Nijmegen, Netherlands; [3]"C. I. Parhon" National Institute of Endocrinology, Bucharest, Romania; [4]"Iuliu Hatieganu" University of Medicine and Pharmacy, Cluj-Napoca, Romania

Introduction

In the past decade, differentiated thyroid cancer (DTC) management has shifted towards de-escalation to reduce overtreatment and improve quality of life. Guidelines now favor less aggressive surgery, with lobectomy preferred for low-risk tumors. This study aimed to determine the proportion of patients in Romania eligible for initial hemithyroidectomy (HT) according to ATA guidelines and the frequency of recommended completion of total thyroidectomy (TT).

Methods

This retrospective cohort study included patients diagnosed with DTC who were treated or followed up in our department between 2015 and 2021. Exclusion criteria were ectopic tumors, missing data or follow-up <12 months, and age under 18 years at surgery. Eligibility for initial HT was defined by the following criteria: DTC ≤ 4 cm, no suspicious lymph nodes and no extrathyroidal extension on preoperative imaging, and no distant metastases. Patients classified postoperatively as intermediate or high risk according to the 2015 ATA guidelines were considered to require a completion TT.

Results

Records of 169 patients were review. 62 patients were excluded for insufficient data (no preoperative evaluation available) or follow-up less than 12 months. Of the 107 patients included, 51 (45,9%) would have been eligible for initial HT. Among them, 14 (27,4%) would have required a completion TT after postoperative initial risk classification, of whom 7 patients would have excellent response to therapy. In the HT-eligible group, 49 had papillary thyroid cancer (PTC), including 15 cases (29.4%) of microcarcinoma, along with 1 case of follicular carcinoma (FTC) and 1 case of Hürthle cell carcinoma. In the TT-eligible group, there were 49 cases of PTC (including 3 tall cell variants), 2 FTC, 3 Hürthle cell carcinomas, and 2 poorly differentiated thyroid carcinomas. The mean age was similar between the HT-eligible and TT-eligible groups (49 ± 14.52 vs. 48.8 ± 13.75 years), as well as presence of multifocality, in 17 cases (32.6%) in the HT-eligible group and 18 cases (31.5%) in the TT-eligible group. Patients eligible for HT had significantly higher remission rates and lower rates of persistent and recurrent disease compared to those who required upfront total thyroidectomy (71.1% vs. 33.9%, $P < 0.0001$).

Conclusions

A less extensive surgical approach with appropriate follow-up can be a valid alternative to total thyroidectomy in selected cases, given the potential benefits of a stepwise strategy and the favourable prognosis of low-risk DTC. This highlights the importance of shared decision-making in managing patients with DTC ≤ 4 cm.

Evaluation of the role of systemic immune-inflammatory markers in predicting malignancy in patients with thyroid nodules

Gökhan Rıza Baykal[1], Müge Keskin[2], Kübra Katipoğlu[3], Ersin Gürkan Dumlu[4], Didem Özdemir[5], Oya Topaloglu[5], Reyhan Ersoy[5] & Bekir Cakir[5]

[1]Ankara Bilkent City Hospital, Department of Endocrinology and Metabolism, Ankara, Türkiye; [2]Ankara Bilkent City Hospital, University of Health Sciences, Department of Endocrinology and Metabolism, Ankara, Türkiye; [3]Ankara Bilkent City Hospital, Department of Pathology, Ankara, Türkiye; [4]Ankara Yıldırım Beyazıt University, Faculty of Medicine, Ankara Bilkent City Hospital, Department of General Surgery, Ankara, Türkiye; [5]Ankara Yıldırım Beyazıt University Faculty of Medicine, Ankara Bilkent City Hospital, Department of Endocrinology and Metabolism, Ankara, Türkiye

Background

Inflammation significantly contributes to the pathogenesis of thyroid cancers, as well as various cancer types. Studies indicate that many inflammatory biomarkers are reliable indicators of prognosis and progression in malignant tumors. These include the neutrophil/lymphocyte ratio (NLR), the platelet/lymphocyte ratio (PLR), the lymphocyte/monocyte ratio (LMR), the systemic immune-inflammation index (SII), the systemic inflammatory response index (SIRI), and the systemic inflammation aggregate index (SIAI). These markers have been shown to be linked to multifocality, tumor growth, and metastasis in differentiated thyroid cancers. They can also help predict central lymph node metastasis and the prognosis. The aim of this study was to evaluate the role of systemic immune-inflammatory markers in predicting malignancy in patients who underwent surgery for thyroid nodules.

Methods

A total of 400 patients who underwent surgery for thyroid nodules were included in this study, and the patients were divided according to the cytological results defined by Bethesda classification. We recorded demographic characteristics, Bethesda findings, NLR, PLR, LMR, SII, SIRI, SIAI values, and postoperative histopathological Results.

Results

Preoperative cytology results were benign in 62 (15.5%), nondiagnostic (ND) in 36 (9%), atypia of undetermined significance (AUS) in 115 (28.75%), follicular neoplasm (FN) in 30 (7.5%), suspicious for malignancy in 70 (17.5%), and malignant in 87 (21.75%) patients. The postoperative malignancy rate in patients with AUS was 49.56%. There was a significant difference between NLR, PLR, LMR, SII, SIRI, and SIAI between the patients with AUS who had benign and malignant histopathology ($P < 0.001$). In patients with FN, NLR was significantly different ($P = 0.035$). For those with ND cytology, there was no significant difference in any marker. Area Under the Curve (AUC), sensitivity, and specificity values for markers were found, respectively, as 0.753, 0.702, 0.31 for NLR, 0.692, 0.632, 0.36 for PLR, 0.697, 0.649, 0.362 for LMR, 0.751, 0.702, 0.293 for SII, 0.729, 0.632, 0.345 for SIRI, and 0.733, 0.684, 0.31 for SIAI. The cut-off values for markers were 1.935 for NLR, 123.675 for PLR, 5.965 for LMR, 493.56 for SII, 0.68 for SIRI, and 161.525 for SIAI.

Conclusion

The NLR, PLR, SII, SIRI, and SIAI values were all significantly higher while the LMR value was significantly lower in AUS patients who had malignant

histopathology compared to those with benign histopathology. All these markers might be helpful to predict malignancy in patients with preoperative AUS cytology.

Discordant thyroid function tests – a case report of ewly identified rare mutation of transthyretin related euthyroid hyperthyroxinaemia

Stamatios Tzanninis[1], Hina Aslam[1] & Georgina Page[1]
[1]Royal Bournemouth Hospital, Endocrinology and Diabetes, Bournemouth, United Kingdom

We present a 24-year-old male who was referred to endocrinology team for evaluation of discordant thyroid function tests (TFTs). TFTs were first sent when he presented to Primary Care with intermittent palpitations. He was otherwise fit and healthy, with no comorbidities. Results showed elevated free T4 of 31pmol/l (Reference range 10-22 pmol/l) with a normal TSH of 0.91 miu/l (reference range 0.3 – 5.5 miu/l). On review in the endocrine clinic, his detailed history and systemic examination were unremarkable. He was not on any prescribed or over-the-counter medications. TSH-receptor antibodies were negative, and assay interference was ruled out by counter-checking TFTs on Roche & Beckman testing separately. There was no known family history of thyroid dysfunction. Given the patient's young age and symptoms, we undertook genetic testing to look for possible *de novo* thyroid hormone resistance. The genetics laboratory undertook analysis of all the coding regions and exon/intron boundaries of the hyperthyroidism gene panel (ALB, SECISBP2, SLC16A2, THRA, THRB, TSHR and TTR). The initial report showed that a genetic cause for the hyperthyroidism had not been identified. After several months, we received further correspondence from the genetics team re-reporting his results as they had identified a rare cause of discordant TFTs consistent with a genetic diagnosis of TTR-related dystransthyretinaemic hyperthyroxinaemia. At the time of initial report, this gene mutation was labelled as "likely benign" with no correlation with isolated hyperthyroxinaemia. However, in the following months, similar variants were identified in more cases with similar findings and therefore labelled as "likely pathogenic" in context of isolated hyperthyroxinaemia. This functional genetic polymorphism is counter checked by Exeter and Cambridge genomic laboratories. In these cases, offspring would be at 50% risk of inheriting this variant and being predisposed to hyperthyroxinaemia. Hence, testing is recommended for family members affected with hyperthyroxinaemia. Variants in THRB are found in ~86% patients with Resistance to Thyroid Hormone beta. GWAS studies have shown a statistically significant positive association between this variant and FT4 levels.

Conclusion

Isolated hyperthyroxinaemia with normal TSH could be related to underlying genetic mutation involving transthyrenin receptors and therefore should be looked for. This does not require any treatment but testing for symptomatic family members is recommended. We feel this case highlights the importance of investigating discordant thyroid function tests to help the identification of previously unknown genetic variants.

Endocrine specialist nurse-led post-radioiodine care pathway improves patient outcomes

Neomal De Silva[1,2], Annette Lee[2], Kim Johnston[2], Louise Duffy[2], Simon Pearce[2,3] & Earn Gan[2]
[1]District General hospital Matale, Matale, Sri Lanka; [2]The Newcastle upon Tyne hospitals NHS foundation trust, Newcastle upon Tyne, United Kingdom; [3]Translational and Clinical Research Institute, Newcastle University, Newcastle upon Tyne, United Kingdom

Background

Radioactive iodine (RAI) therapy is an effective treatment for thyrotoxicosis and is recommended by the National institute for Health and Care Excellence (NICE) in the UK as the first line treatment. Hypothyroidism is one of the most common adverse effects of RAI and occur in up to 80% of patients receiving this treatment. The NICE guideline recommends thyroid function monitoring every 6 weeks for 6 months following RAI for early detection and treatment of hypothyroidism. A previous audit revealed that our centre fell short of the standard recommended by national guideline. A specialist nurse-led post-RAI care pathway was subsequently implemented in 2022. This study evaluates the impact of a nurse-led care pathway on patient outcomes and adherence to national guideline.

Methods

We conducted a retrospective study of adult patients who received RAI between May 2022 to July 2023 in a single tertiary hospital. The post-RAI care pathway involved thyroid function monitoring every 6 weeks, until serum thyrotropin was within the normal reference range. We included patients with a minimum of 12 months follow-up. Clinical data were retrieved from the hospital electronic medical records.

Results

A total of 54 patients (mean age: 56.9 $\pm$ 14.3 years, 79.6% female) were included. The majority (70%) had Graves' disease (GD), followed by toxic multinodular goitre (19%), solitary toxic nodule (9%), and euthyroid goitre (2%). After implementing the ESN-led post RAI care pathway, the mean time to the first thyroid function check decreased from 51 to 39.6 days after RAI. The proportion of patients having their first thyroid function checked prior to 7 weeks after radioiodine therapy increased from 63.2% to 94.4%. The incidence of hypothyroidism at first follow-up review decreased from 9% to 4%. Among patients with Graves' disease who had not restarted block and replace regime after RAI, the proportion who became hypothyroid by the time levothyroxine was initiated decreased from 61% to 44.4%. No patients developed severe hypothyroidism or TSH $>$ 30 mIU/l when levothyroxine was initiated, as compared to 25% of patients, prior to the implementation of this new care model.

Conclusions

The implementation of an ESN-led post-RAI care pathway has significantly improved adherence to the national guidelines. The better monitoring of thyroid function has led to larger proportion of patients receiving thyroid hormone replacement in a timely manner and prevent severe hypothyroidism after RAI. This approach provides a care model that improve patient outcomes and increase consultant clinic capacity.

New de novo variants in THRA gene in adolescent patients: two clinical cases

Gabriella Pozzobon[1], Giulia Tarantola[1], Carmen Bucolo[1], Gaia Vincenzi[1], Silvia Meroni[1], Marco Abbate[1], Ilenia Teresa Petralia[1], Luisa Del Giacco[1] & Maria Cristina Vigone[1]
[1]IRCCS Ospedale San Raffaele, Department of Pediatrics, Milano, Italy

Resistance to thyroid hormones due to mutations in THRA (RTHα) is a very rare disease, of which only 40 cases have been described so far in the literature (27 in children and 13 in adults). However, its incidence could be much higher than currently estimated: in fact, many affected relatives with a mild phenotype were only diagnosed by genetic screening after initial diagnosis of the index cases. Twenty-five variants in THRA gene have been identified so far, but likely there are many more we have not discovered yet. Both our patients first came to our attention due to short stature when they were starting pubertal development; however, failure to growth was associated to other clinical features of which some could possibly be associated with untreated hypothyroidism (e.g. neurodevelopmental delay, delayed tooth eruption, constipation) while others were not directly related with hypothyroidism but anyway suggestive for a syndromic disease (e.g. dysmorphic features of the face and trunk, several nevi, ligaments' hyperlaxity, redundant skin, clinodactyly). Thyroid function tests in both patients were typical for RTHα, but they were not recognised as such: the first showed fT4 levels at the lower limits of normal associated with normal TSH values, but fT3 was never measured; the second patient had two other central hormonal deficits (GH and ACTH), therefore low fT4 levels were attributed to a form of central hypothyroidism, which can be tricky to distinguish from RTHα. Definitive diagnosis was made with exome sequencing, which revealed de novo heterozygous variants in both patient: in the first a variant of unknown significance (c.G802C, protein p.Asp268His), while in the second the variant c.1204_1215del causes deletion of four amino acids in the protein p.(Leu402_Phe405del). After the diagnosis, we repeated thyroid function tests and we calculated fT3/fT4 ratio, which was above mean reference values in both patients. After the start of therapy with L-T4, both our patients had immediate amelioration of symptoms such as constipation. To conclude, it is

crucial to keep in mind RTHα in the differential diagnosis for children with growth failure, dysmorphic features, and delayed psychomotor development. fT3/fT4 ratio is of fundamental importance in not-straightforward cases. Early diagnosis would allow children to start treatment with L-T4 and thus possibly avoid severe neurodevelopmental outcomes, together with the amelioration of constipation leading to better quality of life for the patient and the family.

Parathyroid cyst in an adolescent girl – a rare pathology in pediatric population

Nikolinka Yordanova[1], Iva Ivanova[2], Mira Siderova[2], Rositsa Stoycheva[3] & Violeta Iotova[1]
[1]Medical university of Varna, Pediatrics, Varna, Bulgaria; [2]Medical university of Varna, Endocrinology, Varna, Bulgaria; [3]Medical university of Varna, Hygiene and Nutrition, Varna, Bulgaria

Introduction
Parathyroid cysts are rare (0.8–3.41% of all parathyroid lesions) usually asymptomatic formations in the anterior neck region that account for 1 to 5% of neck masses in adults. Depending on the presence of hyperparathyroidism, they can be subdivided into two groups - functioning and non-functioning (approximately 90% of parathyroid cysts). However, there is a limited number of published studies focusing on pediatric cases.
Case Report
We present the case of a 16-year-old girl with a palpable, non-tender mass in the lower left quadrant of the neck. The mass was visible, asymptomatic and appearing to be located in the right thyroid lobe. The patient was referred to the clinic by a pediatric endocrinologist with a suspicion of a thyroid nodule. The patient was a healthy adolescent, with no significant history of any diseases. Her maternal grandmother had a history of goiter. Biochemical parameters, including parathyroid hormone (PTH), thyroid hormones and thyroglobulin were all within normal ranges. Ultrasound examination revealed a cystic lesion nearly completely occupying the right lobe of the thyroid gland with dimensions in the longitudinal section: 35.8/16.2 mm. A fine-needle aspiration (FNA) biopsy was performed by a more experienced adult endocrinologist, yielding 5 ml of water-clear, rapidly aspirated fluid. Following evacuation, a residual formation was observed with dimensions in the longitudinal section: 29.3/10.5 mm. Cytological analysis of the fluid showed no cellular content. However, the aspirated fluid had a markedly elevated PTH level (>2500 pg/mL, reference range: 11–87 pg/mL), confirming the parathyroid origin of the cyst. Based on expert consultation, puncture, aspiration, and sclerotherapy with ethanol were recommended one month later.
Conclusion
Non-functioning parathyroid cysts although rare present a diagnostic challenge, frequently being mistaken for thyroid pathology due to overlapping clinical and imaging characteristics. More frequent and prolonged follow-up is required due to the risk of recurrence and the potential need for surgical removal. Using additional imaging modalities such as computed tomography could be helpful, especially when surgery is chosen for a definitive treatment option. Given the rarity of this condition and the lack of clear guidelines for its diagnosis and management in pediatric patients, consultation with experienced specialists is crucial.
Key Words
parathyroid cysts, fine-needle aspiration, sclerotherapy.

Preoperative detection of pathogenic variants in children and adolescents

Olivia Cillikova[1], Vlasta Kuklikova[1], Jitka Carkova[1], Katerina Vyhnalova[1], Eliska Vaclavikova[1], Barbora Bulanova[1], Karolina Mastnikova[1], Zdenek Novak[2], Jan Jiskra[3], Josef Vcelak[1] & Bela Bendlova[1]
[1]Institute of Endocrinology, Department of Molecular Endocrinology, Prague, Czech Republic; [2]Institute of Endocrinology, Department of Clinical Endocrinology, Prague, Czech Republic; [3]General University Hospital in Prague and First Faculty of Medicine, Third Department of Internal Medicine – Department of Endocrinology and Metabolism, Prague, Czech Republic

Introduction
In recent years, the incidence of thyroid tumors in children and adolescents has been increasing. Compared to adult patients, these tumors exhibit a more aggressive course, higher invasiveness, and a greater tendency to metastases. Molecular genetic analysis of fine-needle aspiration biopsy (FNAB) is an effective tool for the more precise diagnosis of thyroid nodules. The aim of this study was to detect pathogenic variants in a cohort of children and adolescents.
Materials and Methods
A total of 145 FNAB samples from patients aged 6–20 years were analyzed. Initially, the V600E variant in the *BRAF* gene was tested using real-time PCR. Subsequently, additional gene analyses were performed using massively parallel sequencing, fusion gene analysis by real-time PCR, or capillary sequencing.
Results
Pathogenic variants were detected in 35 patients: 9 in the *BRAF* gene, 7 in *RAS* genes (1 *HRAS*, 1 *KRAS*, and 5 *NRAS*), 11 in fusion genes (1 *TPM3/NTRK1*, 3 *ETV6/NTRK3*, 3 *RET/PTC3*, 3 *RET/PTC1*, 1 *EML4/ALK*), 1 in the *TSHR* gene, and 7 in the *DICER1* gene. Postoperative histological examination data were available for 25% of patients (36/145).
Conclusion
Preoperative molecular genetic analysis is important not only in adults but also in pediatric patients. While *BRAF* V600E mutations and fusion genes are associated with an almost 100% risk of malignancy, recommending total thyroidectomy, *RAS* gene mutations carry a lower malignancy risk and are more often associated with lobectomy recommendations. Germline mutations in the *DICER1* gene are linked to *DICER1* syndrome, which predisposes individuals to various tumor types from early childhood. *Supported by AZV NU21-01-00448 and Ministry of Health of the Czech Republic RVO 00023761.* .

Efficacy and safety of the FCRN inhibitor, batoclimab, in graves' thyroidal and extrathyroidal disease: a proof-of-concept study

George Kahaly[1], Jan Wolf[1], Anna-Lena Ganz[1], Maximillian Luffy[1], Katherine Albert[2], Maria Alba[2], E Lin[2] & William Macias[2]
[1]Johannes Gutenberg University Medical Center, Mainz, Germany; [2]Immunovant, Inc., New York, NY, United States

Introduction
Thyrotropin receptor autoantibodies (TRAb) cause Graves' hyperthyroidism (GH) and its extrathyroidal manifestations. Batoclimab, a neonatal fragment crystallizable receptor (FcRn) inhibitor, reduces IgG levels, including TRAb.
Objective
To describe serological and clinical outcomes from a phase 2a, proof-of-concept, open-label, single-center study evaluating batoclimab in patients with GH.
Methods
Eligible patients had serologically confirmed GH and elevated TRAb and were hyperthyroid despite ongoing therapy with moderate-to-high dose anti-thyroid drugs (ATD) for $\geq$12 weeks. Batoclimab was administered via subcutaneous injection at a dose of 680 mg weekly for 12 weeks, followed by 340 mg weekly for 12 weeks. Key endpoints included the proportion of patients who achieved FT3 and FT4 normalization (serum levels $\leq$upper limit of normal [ULN] and $\geq$lower limit of normal [LLN]) or FT3 and/or FT4 $<$LLN without increase in ATD dose; proportion of patients with FT3 and FT4 normalization or FT3 and/or FT4$<$LLN and ATD dose $\leq$50% of baseline; and reductions in TRAb.
Results
As of the data cutoff, 25 patients either completed Week 24 ($n = 23$) or discontinued prematurely due to non-treatment-related reasons ($n = 2$). Eighty percent (20/25) had pre-existing Graves' orbitopathy. By Week 2, 15/25 (60%) patients achieved FT3 and FT4 $\leq$ULN, without an increase in ATD. After 12 weeks of high-dose (680 mg) batoclimab, 19/25 (76%) patients had FT3 and FT4 $\leq$ULN without an increase in ATD, including 14/25 (56%) who were off ATD and 5/25 (20%) who achieved normal thyroid-stimulating hormone levels. At Week 24, after 12 weeks of lower-dose (340 mg) batoclimab, 17/25 (68%) patients had FT3 and FT4 $\leq$ULN without an increase in ATD, including 9/25 (36%) who were off ATD. Mean TRAb decreased from baseline by 74% and 70% at Weeks 12 and 24, respectively, and 5/25 (20%) and 3/25 (12%) patients achieved seroconversion (TRAb-negative), respectively. Improvement from baseline in ophthalmic parameters (eg, proptosis, lid aperture, clinical activity score) and reduction in ultrasound-assessed thyroid volume were also observed. Batoclimab was well-tolerated, with all adverse events being mild-to-moderate in severity; no new safety signals were observed.
Conclusion
Subcutaneous batoclimab very rapidly normalized FT3 and FT4 in most patients. By Week 12, more than half of patients had both T3 and T4 $\leq$ULN and were off

ATD. Batoclimab also improved extrathyroidal signs. These data are the first clinical evidence that FcRn inhibition may be effective for treating Graves' hyperthyroidism.

Introduction

Highly immunogenic tumors can spontaneously prime protective immunity, thus preventing tumor growth, a phenomenon known as tumor immunity. Autoimmunity, is a distinct form of autoreactive immunity that targets one's own cells, but in the presence of cancer, it could prove tumoricidal. Thyroid peroxidase antibodies (TPO-Abs) are the hallmark of thyroid autoimmunity. Thyroglobulin antibodies (Tg-Abs), do not appear as effective in their cytotoxic capacity as TPO-Abs, and their role in thyroid cancer development/progression remains unclear. We designed the present study to evaluate their role.

Methods

We reviewed retrospectively thyroidectomy (Tx) cases operated in 13 centers in Greece and 2 centers in the US over 10 years. We recorded their age, gender, BMI, TSH and Tg-Abs preoperative and histology report. Thyroid cancer (TC) incidence and tumor aggressiveness descriptors were compared between patients with elevated vs. low Tg-Abs titers (Tg-Abs+ $\geq$30 vs. Tg-Abs- $\leq$30IU/l).

Results

After collecting $n = 9643$ Tx, we enrolled $n = 2870$ patients, mean BMI of $27.3 \pm 5.5 Kg/m^2$, age 47.0 ± 14.5 years; $n = 2127$ (74.1%) were females. Their average TSH was 2.11 ± 5.09IU/l, and Tg-Abs 96.0 ± 614.6IU/l. Tg-Abs- were found in $n = 2232$ (77.8%) patients. TC was present in $n = 1587$ (57.1%) cases, of the following histology: papillary (PTC) $n = 1487$, follicular (FTC) $n = 35$ Hürthle cell (HCC) $n = 23$, medullary $n = 30$, anaplastic (ATC) $n = 1$, poorly differentiated thyroid cancer (PDTC) $n = 7$, other $n = 3$, lymphoma $n = 1$. The larger tumor dimension was 1.5 ± 2.0 cm, and the average number of tumor foci was 1.8 ± 1.8, $n = 26$ (1.6%) had gross and $n = 249$ (15.7%) had microscopic extrathyroidal extension (ETE), $n = 212$ (13.4%) had capsular invasion (CI), $n = 391$ (24.6%) had lymph nodes (LNs) metastasis, while $n = 24$ (1.5%) had distant metastases. The incidence of thyroid cancer was not different between the two subgroups (elevated vs. low Tg-Abs titers), as did distant metastases (OR 0.98, $P > 0.05$). Patients with Tg-Abs+ had larger tumors (1.8 vs. 1.4 cm), more LNs infiltrated by TC (OR 2.2), more ETE (OR 1.25) and capsular invasion (OR 1.20). Non-PTC histology was less common in Tg-Abs+ patients (OR 0.49) ($P < 0.05$).

Conclusion

Tg-Abs behave differently compared to TPO-Abs as they seem unable to protect from TC. Their rise tends to be a marker of the immune response to the expanding PTC, when this extends beyond the thyroid capsule, and when thyroglobulin might become exposed to the immune system. It remains to be proven if Tg-Abs result from TC immunoediting. However, Tg-Abs titers should be evaluated preoperatively as they might provide prognostic value to the evaluation of patients with thyroid nodules.

Afirma genomic classifier in clalit health services: preserving thyroids and promoting equality

Hadar Duskin-Bitan[1,2,3], Doron Netzer[1,4], Ilan Shimon[2,3] & Eyal Robenshtok[2,3]

[1]Clalit Health Services, Tel Aviv, Division of Community Medical Services, Tel-Aviv, Israel; [2]Rabin Medical Center – Beilinson Hospital, Institute of Endocrinology, Petach Tikva, Israel; [3]Tel Aviv University, Faculty of Medical and Health Sciencest, Tel-Aviv, Israel; [4]Ariel University, Adelson School of Medicine, Ariel, Israel

Background

Thyroid nodules evaluated through fine-needle aspiration (FNA) cytology yield indeterminate results (Bethesda III or IV) in approximately 15% of cases, with a malignancy risk ranging from 15% to 50%. These uncertainties often result in unnecessary surgical interventions. To address this issue, advanced molecular tests, including the Afirma genomic classifier, were developed. In 2023, Clalit Health Services integrated Afirma testing into its insured services, providing it at no cost to patients to reduce unnecessary surgeries. This study assesses the utilization and impact of Afirma testing within this healthcare framework.

Methods

Data on demographics, laboratory findings, imaging results, and Afirma test outcomes were retrieved from Clalit Health Services records. Ethical approval for the study was obtained from the organizational ethics committee.

Results

Between January 1, 2023 and September 30, 2024, 298 Afirma tests were performed. The mean age was 56.2 ± 16.6 years, and the mean TSH level prior to testing was 2.1 ± 1.5. During this period, patients underwent an average of 4 ± 3.5 neck ultrasounds and 2.9 ± 1.6 FNAs. Among the cohort, 26 patients (8.7%) were Arabs, 16 (5.4%) were Orthodox Jews, and 96 (33%) had a low socioeconomic score. Fifty-two percent of the tests (156 patients) yielded benign Results Among the suspicious findings, NRAS mutations were identified in 13 cases (10%), BRAF V600E in 8 cases (6%), and HRAS in 6 cases (5%). Within the study period, 38 patients underwent thyroidectomy following Afirma testing.

Conclusion

Afirma testing prevented surgery in 52% of patients. The inclusion of Afirma testing in Clalit Health Services facilitated access to advanced diagnostics for patients with lower socioeconomic status, who represented 33% of the cohort, thus reducing healthcare disparities in Israel.

The increased coexistence of autoimmune thyroid disease (AITD) in children and adolescents with differentiated thyroid carcinoma (DTC) in years 2015–2024 compared to 1996-2000; one center experience

Marek Niedziela[1], Jerzy Harasymczuk[2] & Pawel Kurzawa[3]

[1]Poznań University of Medical Sciences, Karol Jonscher's Clinical Hospital, Department of Paediatric Endocrinology and Rheumatology, Poznan, Poland; [2]Poznań University of Medical Sciences, Karol Jonscher's Clinical Hospital, Department of Paediatric Surgery, Poznan, Poland; [3]Poznań University of Medical Sciences, Karol Jonscher's Clinical Hospital, Department of Clinical Pathology and Immunology; Department of Oncological Pathology, Poznan, Poland

Introduction

37 thyroid carcinomas were diagnosed in our region in years 1996–2000, 30 in girls (81.1%) and 7 in boys (19.9%). The predominance of papillary thyroid

carcinoma (PTC - 26/37 - 70.3%) compared to follicular thyroid carcinoma (FTC - 10/37 - 27.0%) and medullary thyroid carcinoma (MTC -1 - 2.7%) was observed. AITD (autoimmune thyroiditis – AIT and Graves' disease - GD) coexisted in 1 PTC/GD among all DTCs (1/36 - 2.8% of all DTCs and 3.8% in PTC group) (Med Pediatr Oncol 2004;42:84–92).
Aim
The aim of retrospective study was to analyze the coexistence of AITD (AIT and GD) and DTC in years 2015-2024 (10-year-period) in relation to years 1996–2000 (5-year-period).
Material and Methods
Patients aged <18 years with the postoperative histopathological diagnosis of DTC were analyzed. All patients had prior ultrasound examination and US-guided fine needle biopsy of a suspicious nodule/area and thyroid aspirates were classified based on Bethesda system. AITD was confirmed/treated prior or at diagnosis of DTC by the presence of a classic clinical manifestation, hormonal profile and ultrasonographic imaging of both autoimmune thyroid disorders, AIT and GD, confirmed by specific antithyroid antibodies in serum (TPOAb/TgAb/TRAb).
Results
75 thyroid carcinomas were confirmed in 2015–2024 (71 PTC - 94.7%, 1 FTC - 1.3% and 3 MTC - 4.0%), 57 in girls (76%) and 18 in boys (24%). MTCs were not enrolled to this analysis however all three cases had negative antithyroid antibodies. AITD was diagnosed in 37/72 (51.4%) of patients with DTC, i.e. 18-fold more frequently than in 1996–2000. A single patient with FTC had no features of thyroid autoimmunity. 5 more patients had isolated and mildly elevated TgAb (up to 3-fold to an upper limit of normal range).
Conclusions
High coexistence of PTC and AIT in years 2001–2015 suggests that the careful follow-up of patients with AIT, particularly with ultrasound examination, is mandatory to detect the cancer at early stage in this group of patients.

Total thyroidectomy vs thyroid lobectomy for low-risk papillary thyroid cancer

Francisca Leitão[1], Ana Quítalo[1], Marta Almeida[1], Daniel Duarte[1], Sara Franco[1], Ana Gonçalves Ferreira[1], David Barbosa[1], Maria Manuel Costa[1], Henrique Vara Luiz[1], Tiago Nunes da Silva[2] & Maria Carlos Cordeiro[1]
[1]Hospital Garcia de Orta, Almada, Portugal; [2]Instituto Português de Oncologia de Lisboa Francisco Gentil, EPE, Lisboa, Portugal

Introduction
Papillary thyroid carcinoma (PTC) has a rising incidence and a good prognosis in low-risk cases. The choice of surgery in low-risk papillary thyroid carcinoma (PTC) is important in order to balance recurrence rates and surgical complications.
Objective
To evaluate whether the extent of thyroidectomy influences survival and recurrence rates in patients with low-risk-PTC.
Methods
A retrospective analysis was conducted for all patients treated at our institution who had low-risk papillary thyroid carcinoma and underwent either lobectomy or total thyroidectomy(TT), between 2015-2021. Exclusion criteria included patients treated with radioactive iodine post-surgery and those without complete postoperative follow-up. Recurrence was defined as the presence of structural evidence of disease(confirmed by cytology or post-contralateral lobectomy histology), or biochemical recurrence, defined as a serum TG value >30 ng/mL with stable TSH in patients with lobectomy, or positive ATG($>$ 115) with an upward trend.
Results
Fifty patients who underwent thyroidectomy were included. The preoperative cytology was malignant in 27%. TT was performed in 25 patients, 80% female, with a mean age of 60 years and a mean follow-up time of 9 years. The lobectomy group included 25 patients, 92% female, with a mean age of 63 years and a mean follow-up time of 10 years. Tumor size was similar between both groups (0.7 cm for TT and 0.6 cm for lobectomy). Biochemical recurrence occurred in 4 patients from the lobectomy group: 2 with elevated TG and no suspicious lesions found on ultrasound, who are being managed with active surveillance; 1 with rising ATG and a 5 mm nodule with subcentimetric lymph nodes, also under active surveillance; and 1 with a suspicious nodule and a doubling of TG levels over 3 months, for whom TT will be performed. No recurrences were observed in the TT group. There was no significant difference in disease-free survival between groups. Hypothyroidism developed in all TT patients and 92% of lobectomy patients, with higher levothyroxine doses in the TT group (115.8 ± 27.3 mg vs 71.5 ± 49.4 mg). Surgical complications were more common in the TT group, including transient dysphonia(20% (5/25) vs 12%(3/25) and transient hypoparathyroidism(in 8% (2/25). Overall, 4 patients were discharged, 1 passed away unrelated to thyroid cancer, and the remaining 45 continued follow-up.
Conclusion
This study suggests that the extent of thyroidectomy does not influence survival in low-risk PTC, and lobectomy may be a suitable option due to lower rates of hypothyroidism and postoperative complications. However, these data need to be confirmed in multicenter studies.

Rituximab in addition to methylprednisolone pulse therapy for graves' orbitopathy improves the remission of graves' hyperthyroidism

Chia-Hung Lin[1] & Jin-Ying Lu[1]
[1]National Taiwan University Hospital, Internal Medicine, Taipei, Taiwan

Background
Graves' disease (GD) frequently recurs following the cessation of anti-thyroid drugs (ATDs), particularly in patients with concomitant Graves' orbitopathy (GO), which poses additional therapeutic challenges. This clinical epidemiological study aimed to evaluate the efficacy of intravenous methylprednisolone (IVMP) therapy alone or in combination with rituximab (RTX) in achieving long-term remission of GD in patients with moderate-to-severe and active GO.
Methods
This study involved a cohort of 52 patients with moderate-to-severe and active GO treated at the National Taiwan University Hospital from 2008 to 2023. Patients who received IVMP or RTX in addition to IVMP for the treatment of GO were enrolled. Demographic and clinical data, thyroid function tests, and thyroid autoantibodies were collected. The primary outcome measured was the time to remission from GD, defined as the maintenance of euthyroidism for more than 12 months after stopping the antithyroid drug.
Results
Among the 52 patients, 35 were treated with only IVMP and 17 with RTX after IVMP. The RTX group demonstrated a significantly higher remission rate compared to the IVMP group (58.8% vs. 17.1%, $P = 0.002$). The Kaplan-Meier curve revealed an evident likelihood of the RTX group on the rate of GD remission (log-rank test, $P=0.0086$). Multivariate analysis identified several predictors of remission, including RTX use with thyrotropin-binding inhibitory immunoglobulin (TBII) levels less than 88%, BMI within the range of 19.7 and 24.1, and the age of IVMP initiation, highlighting the potential benefits of RTX therapy in this context.
Conclusions
The addition of RTX to IVMP for patients with moderate-to-severe GO significantly increases the likelihood of achieving and sustaining remission of GD, particularly in those with TBII levels less than 88%. These findings suggested that incorporating RTX into the therapeutic protocol for patients with GO could be a valuable strategy to improve long-term disease control and achieve remission of GD.

Multivariate analyses of the Predictors of Time to Remission of GD Using Cox's Models in Patients with GO.

Covariate	Estimated Regression Coefficient	Estimated Standard Error	Wald's Chi-Square Test	*P* Value	Estimated Hazard Ratio	95% Confidence Interval
TBII $\leq$ 88% $\times$ Rituximab use	1.8726	0.5981	11.4117	0.0007	6.5049	2.1849–21.9584
TBII $>$ 88%	-1.7997	1.6140	2.1434	0.1432	0.1654	0.0012–1.6316
19.7 $<$ BMI $\leq$ 24.1	2.1137	0.6847	11.6861	0.0006	8.2786	2.3887–34.4155
Age of IVMP initiation (years)	2.2324	0.7533	9.5348	0.0020	9.3220	2.2577–43.7287

The role of blood cell derived parameters in the differential diagnosis of subacute thyroiditis and Graves' disease and long-term outcomes in subacute thyroiditis: a tertiary center experience

Ahmet Kursat Soyer[1], Fatma Neslihan Cuhaci Seyrek[2], Kubra Durmus Demirel[1], Abbas Ali Tam[2], Oya Topaloglu[2], Reyhan Ersoy[2] & Bekir Cakir[2]
[1]Ankara City Hospital, Endocrinology and Metabolism, Ankara, Türkiye; [2]Ankara Yıldırım Beyazıt University Faculty of Medicine, Endocrinology and Metabolism, Ankara, Türkiye

Background
Subacute thyroiditis (SAT) and Graves' disease (GD) are characterized by thyrotoxicosis with different treatment approaches. It may not always be easy to distinguish these two diseases. We aimed to evaluate the utility of blood cell derived parameters in the differential diagnosis of SAT and GD. Additionally, we investigated the factors affecting the development of recurrence and permanent hypothyroidism in the patients with SAT.
Methods
The study involved 414 patients with SAT, 415 patients with GD, and 92 healthy controls. Pre-treatment hematological parameters were retrospectively compared, especially in cases where differentiation is challenging, including painless SAT, acute phase reactants negative SAT, and TSI, TRAB (Thyroid Stimulating Immunoglobulin, TSH-receptor-antibodies) negative GD. Factors influencing recurrence and permanent hypothyroidism were also analyzed in SAT group.
Results
When compared with the GD group, ratios of neutrophil/lymphocyte (NLR), platelet/lymphocyte (PLR), systemic inflammatory response index (SIRI), systemic immune inflammatory index (SII) and pan immune inflammation value (PIV) were significantly higher, while large unstained cells percentage (LUC%) and the ratios of eosinophil/monocyte (EMR), eosinophil/lymphocyte (ELR), eosinophil/neutrophil (ENR), eosinophil/platelet (EPR), MPV/neutrophil, MPV/monocyte and MPV/platelets were significantly lower in the SAT group. Among these markers, SII with an optimal cutoff of 652,784 showed the best diagnostic value [area under the curve (AUC) = 0.875; 95% confidence interval (CI): 0,85-0,90; $P < 0.001$; sensitivity, 81%; specificity, 80%]. No significant association was observed between these parameters and recurrence or permanent hypothyroidism. Recurrence occurred in 8% and permanent hypothyroidism developed in 26% of the patients with SAT. Recurrence was not observed in the group receiving NSAIDs or in those who remained untreated, whereas 15% of patients treated with methylprednisolone (MPS) experienced recurrence ($P < 0.001$). When comparing patients with and without recurrence in MPS group, pre-treatment TSH were significantly higher in the recurrence group, while fT3 and fT4 were significantly lower (p: 0.04, 0.048 and 0.03 respectively). In the univariate logistic regression analysis, we found that low fT4 levels in the MPS group increased the risk of recurrence (Hazard ratio: 0.46, 95% CI=0.23-0.93, $P = 0.032$).
Conclusion
Differentiation between SAT and GD can be reliably achieved using blood cell derived parameters, and that these markers are also applicable in groups where differentiation is challenging. To the best of our knowledge, this is the first study to investigate the LUC%, ELR, ENR, EPR, MPV/neutrophil, and MPV/monocyte ratios and revealed that they are significantly different between these two diseases.

The association between subcategorization, cytomorphological features, ultrasonographic characteristics, ACR and EU-TIRADS classifications with surgical outcomes of aus nodules

Ahmet Kursat Soyer[1], Aysegul Aksoy Altinboga[2], Gokcen Nailer Ertuna[1], Husniye Baser[3], Fatma Neslihan Cuhaci Seyrek[3], Abbas Ali Tam[3], Birol Korukluoglu[4], Oya Topaloglu[3], Reyhan Ersoy[3] & Bekir Cakir[3]
[1]Ankara City Hospital, Endocrinology and Metabolism, Ankara, Türkiye; [2]Ankara Yıldırım Beyazıt University Faculty of Medicine, Department of Pathology, Ankara, Türkiye; [3]Ankara Yıldırım Beyazıt University Faculty of Medicine, Endocrinology and Metabolism, Ankara, Türkiye; [4]Ankara Yıldırım Beyazıt University Faculty of Medicine, Department of Endocrine Surgery, Ankara, Türkiye

Background
Nodules diagnosed in the atypia of undetermined significance (AUS) category represent a heterogeneous group with an indeterminate risk of malignancy. This study aimed to investigate malignancy rates in AUS subcategories and to examine the association of malignancy with cytomorphologic features in fine-needle aspiration (FNA) and ultrasonographic characteristics.
Methods
This study analyzed 196 thyroid nodules with AUS cytology that underwent surgical resection, Among these, 176 nodules were classified as AUS-Nuclear (AUS-N), while 20 were categorized as AUS-Other (AUS-O). Cytomorphological and ultrasonographic features, along with the American College of Radiology Thyroid Imaging Reporting and Data System (ACR-TIRADS) and the European Thyroid Imaging Reporting and Data System (EU-TIRADS) classifications, were analyzed to assess the association between malignancy and AUS subcategories.
Results
Risk of malignancy (ROM) for AUS nodules was determined to be 19,4% (21% for AUS-N and 5% for AUS-O, $P = 0,132$). We observed that malignancy was more frequently associated with nodules of smaller maximum diameter ($P = 0.003$). A significantly higher ROM was observed in nodules with an oval shape, solid composition, hypoechogenicity, irregular margin and microcalcification (Odds Ratio (OR): 5,83, 2,24, 2,31, 9,75 and 3,34 respectively). The presence of irregular margins was found to independently increase the risk of malignancy by 6,53-fold, regardless of other sonographic features. A statistically significant difference in ROM was observed across ACR and EU-TIRADS categories within the AUS nodules ($P = 0.005$ and 0.003, respectively) and the AUS-N group ($P = 0.001$ and $P = 0.002$, respectively). In the AUS-O group, no significant results were observed for either system ($P = 0.3$ for both). A marked increase in ROM was observed with nuclear enlargement, overlapping, hyperchromasia, and pseudoinclusions (OR: 3.33, 2.17, 3.31, and 4.55, respectively), while oncocytic atypia was associated with a reduced risk (OR: 0.44). The presence of pseudoinclusion and nuclear overlapping were found to significantly increase malignancy risk independently of other factors (OR:7,99 and 5,50 respectively). Repeat AUS FNAs ($P = 0.07$), were found to significantly increase the ROM.
Conclusion
We found that the ROM in AUS nodules, particularly in the AUS-N category, were higher than those reported in the literature. We established an association between cytomorphologic features and malignancy. To the best of our knowledge, we are the first to report an increased malignancy risk linked to nuclear hyperchromasia in AUS nodules and the association between ACR-TIRADS and the AUS-N subcategory.

Fear of recurrence in thyroid papillary cancer: a risk based comparison

Sabri Engin Altıntop[1], Tugba Barlas[1], Mehmet Muhittin Yalcin[1], Altinova Alev[1], Mujde Akturk[1], Fusun Toruner[1], Ayhan Karakoc[1] & Ethem Turgay Cerit[1]
[1]Gazi University Faculty of Medicine, Department of Endocrinology and Metabolism, Ankara, Türkiye

Background
Papillary thyroid cancer (PTC) exhibits a high long-term survival rate in contrast to other types of cancer. Despite its favorable prognosis, fear of cancer recurrence (FCR) is common among thyroid cancer survivors. The prognosis of ATA (American Thyroid Association) low-risk disease is more favorable than for intermediate and high-risk diseases. However, FCR has also been observed in patients with low-risk PTC. The aim of the study was to compare the FCR in low-risk PTC patients to that of patients in the intermediate and high-risk groups and to examine the factors influencing FCR.
Material&Methods
The present study was conducted on a total of 240 patients diagnosed with PTC between September 2023 and November 2024. The patients were categorized into low risk, intermediate risk, and high risk, according to the ATA risk-stratification system. Each patient completed two questionnaires with the assistance of the same physician. The first was the Fear of Recurrence Inventory (FCRI), which evaluates the fear or anxiety of cancer recurrence; higher scores indicate a greater level of fear. The second was the Beck Anxiety Inventory (BAI), which measures the intensity of anxiety. A multiple linear regression model was utilized to identify the independent determinants of the FCRI score.
Results
132 patients were classified as low risk, 86 as intermediate risk, and 22 as high risk based on the ATA risk stratification. FCRI scores were found to be similar between low risk (56.50, 24.25-80.50), intermediate risk (50.50, 27.25-73), and high risk (47.50, 35.75-73.25) patients ($P = 0.895$). There were no significant differences in FCRI scores in terms of gender, marital status, education level, and radioactive iodine (RAI) status ($P = 0.085$, $P = 0.724$, $P = 0.857$, and $P = 0.148$, respectively). Patients with a disease duration of one to five years had a higher FCRI score (61, 43.50-84.50) in comparison to those with a disease duration of less than one year (50.50, 23.75-71.75) or more than five years (43, 21-70) ($P = 0.03$). A moderate level of correlation was identified between FCRI and BAI scores ($r = 0.441$, $P < 0.001$). FCRI scores of the three ATA risk groups exhibited no significant differences across the four BAI categories (minimal, mild, moderate, and severe) ($P = 0.932$, $P = 0.968$, $P = 0.562$, and $P = 0.100$, respectively).

Conclusion
FCR was found to be similar between ATA low risk, intermediate risk, and high risk groups, despite the good prognosis. Therefore, appropriate psychosocial care for these patients should be provided at the time of diagnosis and during follow-ups.

JOINT3361

A case of pendred syndrome presenting due to thyroid nodule

Ganimet Öner[1] & Viagen Genetic Disease Evaluation Center[2]
[1]Tekirdağ Dr. İsmail Fehmi Cumalıoğlu City Hospital, Department of Pediatric Endocrinology, Tekirdag, Türkiye; [2]viagen Genetic Disease Evaluation Center, Ankara, Türkiye

Introduction
Pendred Syndrome is an autosomal recessive syndrome characterized by congenital sensorineural hearing loss and goiter. It is seen as a result of mutation in the SLC26A4 gene, which encodes the chloride/iodine/bicarbonate transporter known as pendrin, which causes organification disorder of iodine in the thyroid gland. The transmembrane protein pendrin is secreted from the inner ear, kidney and bronchial epithelial cells in addition to the thyroid gland. Mutations in the SLC26A4 gene have also been reported in cases of enlarged vestibular aqueduct (EVA) accompanied by deafness.
Case Presentation
An 11.5-year-old girl patient was referred to the pediatric endocrinology clinic due to a thyroid nodule detected incidentally. It was learned that the patient's 3.5-year-old brother was receiving L-thyroxine treatment due to congenital hypothyroidism, her mother had a total thyroidectomy due to a thyroid nodüle (3 cm size), and her mother's aunt had a history of multinodular goiter. It was also learned that the patient had a cochlear implant at the age of three due to congenital sensorineural hearing loss, had attention deficit hyperactivity disorder, and wore glasses due to myopia. The patient, who was not related to her parents, had no other known history of hearing loss in her family. In her physical examination, her weight and height are within the normal range for her age, thyroid stage 2 goiter, puberty stage 3. Thyroid function tests were euthyroid, anti thyroglobulin: 1484 IU/mL (0-115) anti TPO: normal thyroglobulin: 76 ng/mL (0.73-84) there was no iodine deficiency. Thyroid ultrasonography reported increased thyroid gland size, slightly heterogeneous parenchyma and several bilateral cystic nodules, the largest of which was 5 mm in size in the lower pole of the right lobe. In light of these findings, the patient underwent a full gene sequence analysis with a preliminary diagnosis of Pendred Syndrome. A homozygous pathogenic variant c.919-2A>G (IVS7-2A>G) located in the splice region of the SLC26A4 gene was detected.
Conclusion
Pendred Syndrome, the most common syndromic form of deafness, is an autosomal recessive disease associated with developmental abnormalities of the cochlea and diffuse goiter (with/without hypothyroidism). The development of goiter and hypothyroidism is closely related to iodine intake. In addition to presentation with solitary thyroid nodule, cases of thyroid carcinoma have also been reported. Treatment is based on clinical findings. Patients with Pendred Syndrome should be followed up by a multidisciplinary team including otolaryngology, endocrinology, genetics and surgery.

Predictors of initial remission in patients treated with antithyroid drugs for graves' disease

Caglar Keskin[1], Ekin Yiğit Köroğlu[1], belma tural balsak[2], Müge Keskin[2], Didem Ozdemir[3], Oya Topaloglu[3], Reyhan Ersoy[3] & Bekir Cakir[3]
[1]Ankara Bilkent City Hospital, Department of Endocrinology and Metabolism, ankara, Türkiye; [2]Ankara Bilkent City Hospital University of Health Sciences, Department of Endocrinology and Metabolism, Ankara, Türkiye; [3]Ankara Yıldırım Beyazıt University Faculty of Medicine, Department of Endocrinology and Metabolism, ankara, Türkiye

Introduction
Graves' disease (GD) is the most common cause of hyperthyroidism. Patients with GD are typically treated with one of three medical interventions: antithyroid drugs (ATDs), radioactive iodine (RAI) therapy, or thyroidectomy. The majority of patients begin treatment with ATDs, with current clinical guidelines recommending a treatment duration of 12 to 18 months. This study aims to compare the clinical characteristics of patients with Graves' disease who achieved remission after optimal medical treatment with those who were resistant to therapy, and to identify factors that predict remission.
Methods
This retrospective cohort study reviewed medical charts from 2020 to 2024. Patients who achieved euthyroidism with medical treatment within 18–24 months and remained relapse-free for at least one year after therapy cessation were classified as having achieved remission. Patients who failed to attain euthyroidism despite 18–24 months of medical treatment, could not discontinue therapy, or required definitive treatment for these reasons, were classified as non-remission. Of the 565 Graves' patients, 108 met the inclusion criteria for the study. After completing antithyroid drug therapy, patients were divided into remission ($n = 64$) and non-remission ($n = 44$) groups. Predictive factors analyzed included age, gender, smoking history, presence of orbitopathy, thyroid volume, thyroid function tests (TSH, free T3, and free T4), TSH receptor antibody (TRAB) levels, and systemic inflammatory parameters (systemic immune inflammation index [SII], pan-immune-inflammation value [PIV]) at the time of initiation.
Results
There were no significant differences in age or gender between the remission and non-remission groups ($P = 0.918$ and $P = 0.727$). However, in the non-remission group, FT4, FT3 levels, TRAB levels, and thyroid volume were significantly higher compared to the remission group [(3.7 ± 2.1 vs. 2.5 ± 1 ng/dl; $P < 0.001$), (13.8 ± 5.8 vs. 9.3 ± 4.8 ng/l; $P < 0.001$), (13.1 ± 9 vs. 4.6 ± 3.5 IU/l; $P < 0.001$), (26.6 ± 15.4 vs. 12.2 ± 4.4 mL; $P < 0.001$)]. Smokers and patients with Graves' orbitopathy were more prevalent in the non-remission group ($P = 0.03$ and $P = 0.004$). There were no significant differences in SII and PIV values between the groups. In multivariate regression analysis, lower thyroid volume and lower TRAB titers were identified as independent predictors of remission (OR [95% CI]: 1.620 [1.213–2.164]; $P = 0.001$, OR [95% CI]: 1.287 [1.081–1.532]; $P = 0.005$).
Conclusion
This study suggests that ultrasonographic thyroid volume measurements and TRAB titers at the time of diagnosis in Graves' disease could serve as valuable prognostic indicators for predicting disease remission.

Extracellular vesicles as a novel immunotherapeutic strategy in hashimoto's thyroiditis: advances in targeted delivery technologies

Laura Tomasello[1], Valentina Guarnotta[1], Giuseppe Siragusa[2], Mattia Biondo[2], Giorgio Arnaldi[1], Carla Giordano[1] & Giuseppe Pizzolanti[1,3]
[1]University of Palermo, Department of Health Promotion, Mother and Child Care, Internal Medicine and Medical Specialties (PROMISE), Palermo, Italy; [2]University of Palermo, Department of Biological, Chemical and Pharmaceutical Sciences and Technologies (STEBICEF), Palermo, Italy; [3]ATeN Center, Palermo, Italy

Hashimoto's thyroiditis (HT), the leading cause of hypothyroidism, is characterized by a dysfunction of regulatory T cells (Tregs), resulting in a breakdown of self-tolerance and a chronic immune-inflammatory response driven by intra-thyroidal lymphocytic infiltration. The persistence of pro-inflammatory cytokines (e.g., IFN-γ, IL-17) and chemokines (e.g., MCP-1) fuels the autoimmune attack on the thyroid, highlighting the inflammatory cascade as a promising therapeutic target, particularly in the early stages of the disease. In recent years, extracellular vesicles (EVs) derived from mesenchymal stem cells (MSCs) have garnered increasing attention in regenerative medicine due to their ability to transfer the immunomodulatory properties of their cells of origin. Harnessing these properties, our study investigates the impact of Th1 priming on the cargo of small EVs (sEVs) derived from human fibroblast-like limbal mesenchymal stem cells (f-LSCs) and their capacity to modulate the activation state of peripheral blood mononuclear cells (PBMCs) in HT patients. To this end, f-LSC-derived sEVs were isolated using tangential flow filtration (TFF) and extensively characterized through dynamic light scattering, flow cytometry, and western blot analysis. Furthermore, an optimized single-step freeze-drying protocol was developed to enable stable EVs storage, facilitating future clinical applications. PBMCs from HT patients and healthy controls were exposed to sEVs under pro-inflammatory conditions to assess their effects on T cell proliferation and immune modulation. The ex vivo model developed in this study demonstrated that TFF isolation combined with lyophilization enhances EVs stability and preserves their bioactivity while reducing financial and instrumental constraints. Notably, Th1 priming enriched the bioactive protein cargo of sEVs, leading to a dose-dependent modulation of key inflammatory mediators (e.g.,

MCP-1, IL-2) and an increased presence of immunomodulatory proteins such as COX-2 and Hsp70. These molecular changes promoted Treg activity, suggesting that sEVs may serve as carriers of proteins capable of restoring a functional Treg population. In conclusion, our findings position EVs as a promising immunotherapeutic tool for HT, leveraging cutting-edge delivery technologies to optimize their therapeutic potential. The ability to tailor EVs cargo through Th1 priming opens new avenues for precision medicine, offering innovative strategies to modulate immune dysregulation in autoimmune thyroid diseases.

CD74+ thyrocytes in hashimoto's thyroiditis: a potential therapeutic approach

Rebeca Martínez-Hernández[1], Pablo Sacristán-Gómez[1], Ana Serrano-Somavilla[1], Nuria Sánchez de la Blanca Carrero[1], Andrea Alvarez Rodriguez[1], Jose Luis Muñoz de Nova[1,2], Miguel Sampedro-Nuñez[1,2] & Monica Marazuela[1,2]

[1]Instituto de Investigación Princesa, Endocrinology Department, Madrid, Spain; [2]Hospital la Princesa and Universidad Autónoma de Madrid, Endocrinology, Madrid, Spain

Introduction

Hashimotós thyroiditis (HT) is an autoimmune thyroid disorder (AITD) that result from the dysregulation of the immune system tolerance, leading to an immune response against self-thyroid antigens. Thyroid follicular cells (TFCs) display a key role in antigen presentation due to the acquisition of the major histocompatibility complex II (MHC-II) in a proinflammatory environment. CD74 is the invariant chain of MHC-II and collaborates in the endosomal trafficking and the assembly of this complex. The antigen presentation process requires costimulatory signals to reinforce the contact between the antigen presenting cells and the receptor immune cell. Hereby, CD80 and CD86 display a key role as correceptors of MHC-II. Regarding the contribution of TFCs to HT pathogenesis, we evaluated the role of CD74 in TFCs from HT patients.

Methodology

We analyzed CD74 and CD80 expression in thyroid tissue from controls and HT patients by spatial transcriptomics and immunofluorescences (IF). We measured the expression of these markers in a human thyroid cell line *in vitro* model with the stimulation of proinflammatory cytokines (IFN-γ and TNF-α) by western blot (WB), IF and flow citometry. Furthermore, we established coculture assays of thyrocytes with a T lymphocyte cell line (Jurkat E6.1) in combination with a CD74 inhibitor (milatuzumab) and we evaluated the levels of CD69 and CD25 as T cell activation markers.

Results

We observed a significant increase of CD74 expression in tissue from HT patients compared to controls. Interestingly, CD74 staining was associated to CD80 only in TFCs from HT patients. In the *in vitro* model, IFN-γ and TNF-α increased the expression of CD74, CD80 and MHC-II. The use of milatuzumab could partially revert the increase of antigen presentation markers in thyroid cells and reduced the activation of T cells, suggesting a role of CD74 in antigen presentation and T cell activation.

Conclusions

Our data suggests a role of CD74 in HT pathogenesis. The use of milatuzumab as a CD74 inhibitor may represent a potential therapy to ameliorate immune cell reactivity.

JOINT2855

Method related differences in fT4 immunoassays are marked in the hyperthyroid range and support the need for assay standardisation

Christina Trambas[1], Daniella Angeleski[1], Bree James[1], Warren Louey[1] & Alan McNeil[1]

[1]St Vincent's Pathology, St Vincent's Hospital Melbourne, Biochemistry, Fitzroy, Australia

Introduction

Measurement of free thyroxine (fT4) is challenging because of its picomolar concentrations, intricate equilibrium with binding proteins, and the minute fraction of "free" relative to total hormone. Method related differences in fT4 measurement may be under-appreciated by clinicians and laboratories alike, which has implications for the clinical management of patients with thyroid disease. To capture these differences, we undertook a multi-method study comparing fT4 immunoassays on the platforms most widely used in Australia: Roche Cobas, Abbott Architect, Siemens Atellica, Beckman DxI and Ortho Vitros.

Methods

fT4 was measured in 94 serum samples spanning the clinical dynamic range, from severe hypothyroidism to euthyroid status and severe hyperthyroidism. For completeness, TSH and fT3 were also measured in parallel. Passing & Bablok linear regression was performed relative to the Roche assay which was chosen as an arbitrary gold standard.

Results

Passing & Bablok regression generated the following equations: Abbott fT4 = 0.5503*Roche fT4 + 3.944; Siemens fT4 = 0.945*Roche fT4 + 1.549; Beckman fT4 = 0.800*Roche fT4 -0.331 and Vitros fT4 = 1.204*Roche fT4-1.685. Method related differences in fT4 results were subtle in the hypothyroid range, became more pronounced with increasing fT4, and were marked in the hyperthyroid range. There were also notable differences in the analytical range of each assay, with some (eg Siemens) capturing a more than two-fold wider linear range than others (eg Abbott). In comparison, method-related differences in TSH were minor and differences in fT3, though more conspicuous than TSH, were smaller than fT4 method-related differences.

Discussion

Method related differences in fT4 lead to conspicuous differences in the apparent biochemical severity of hyperthyroidism. In patients with severe hyperthyroidism, measured fT4 concentrations on the Siemens, Roche and Ortho platforms were between 2-3 times higher than the Abbott platform, which showed only modest fT4 levels and was conspicuously flat in the hyperthyroid range. Interestingly, the one-step fT4 immunoassays (Roche, Siemens and Ortho) were much more closely aligned and read significantly higher than the two-step assays (Abbott and Beckman). Our study points to the clinical value of standardising fT4 methods and highlights the risks of monitoring hyperthyroid patients across laboratories using different methods. Method related differences may masquerade as biochemical worsening or improvement of disease, even in the absence of true change, and may confound dosing of anti-thyroid medication and other clinical decision making.

Thyroid nudules in girls with mccune-albright syndrome(MAS) and gnrh independent precocious puberty concurrently

Yanhong Li[1], liu-lu xie[1], de-lu chen[1], Min-lian du[1] & Jun zhang[1]

[1]The First Affilated Hospitl of Sun Yat-Sen University, pediatric endocrinology, Canton, China

Background and Objectives

Thyoid abnormalities were regarded common in McCune-Albright syndrome(-MAS), however, thyroid nudular may be more than abnormalites of thyroid function. The aim of this study is to detect the prevalence of thyroid nudular in girls who was diagnosed MAS and had GnRH independent precocious puberty as the initiation manifestation.

Methods

From 2019 to 2024, 65 girls who had the precocious puberty as the first manifestation and were diagnosed MAS, as well as had thyroid ultrasoud inspection were enrolled in our study, the prevalence of thyroid nudules was analysed and was compared with 89 normal girls.

Results

The age of onset of precocious puberty was 3.44 ± 2.03 years old, and the age at thyroid ultrasound detction was 10.91 ± 5.66 years. In this 65 girls, 29 (44.6%) were found thyroid nudular, while in normal girls, only 15 (16.9%) were detected thyroid nudular, and the difference was significant($P < 0.001$). In MAS grils with thyroid nudules, 17 were nodular goiter (58.6%), the others were follicular cyst (37.9%) and diffuse goiter (3.4%).18 cases (62.0%) were bilateral, while 11 (37.9%)were unilateral. In whom, only 2 had hyperthyroidism, and the other 2 had hypothyroidism. Anti-thyroid antibodies were negtive in all girls. 21 girls Ti-RADS grade were less than 3, 7 were grade 3 and only 1 was grade 4. Duration of follow-up was 0.5-6 years, and fine-needle aspiration biopsy was performed in 2 patients, however, no malignancy were found.

Conclusion

In girls with MAS and has precocious puberty concurrently, abnormalities of thyroid ultrasound dection were more prevalent than prevalence of hyperthyroidism or hypothyroidism. In addition to evaluatiion of thyroid function, thyroid ultrasound examination should also be considered and the follow-up of thyroid nudular is recommended.

Re-emergence of iodine deficiency-induced thyroid disorders in children: a comprehensive review and meta-analysis

Sonam Agarwal[1], Pratap Jena[1] & Vishal Agarwal[2]
[1]School of Public Health, KIIT Deemed to be University, Public Health, Bhubaneshwar, India; [2]Kalinga Institute of Medical Sciences, Endocrinology, Bhubaneshwar, India

Background
Iodine, a micronutrient, plays a vital role in thyroid hormone production. Despite worldwide efforts to combat iodine deficiency through salt iodization programs, a primordial prevention, recent findings indicate a resurgence of thyroid disorders caused by iodine deficiency, such as hypothyroidism and endemic goitre among children. This comprehensive review and meta-analysis aim to evaluate the prevalence, contributing factors, diagnostic indicators, and the effects of iodine supplementation on thyroid health among children.
Methods
A comprehensive literature search was conducted in databases like PubMed, Scopus, and Web of Science, following PRISMA guidelines. The analysis included studies that examined iodine deficiency, urinary iodine concentration (UIC), thyroid function markers (TSH, Free T4), and the efficacy of iodine supplementation in children. During last decade, data from five selected studies were synthesized using a random-effects model to estimate both the prevalence of iodine deficiency disorders (IDD) and the impact of iodine supplementation on thyroid function. The I^2 statistic was used to quantify the degree of variability among experiments.
Results
The meta-analysis estimated that 7.8% (95% CI: 5.4% -10.2%) of children experience iodine deficiency-related thyroid disorders, highlighting a persistent issue despite ongoing iodization programs. The average urinary iodine concentration reported across studies was 126 µg/l (95% CI: 110-142 µg/l), with mild iodine deficiency identified in certain populations. Key risk factors included increased consumption of non-iodized salt, restrictive diets (such as veganism or allergy-based exclusions), and modifications in food processing that reduce iodine levels. The analysis further demonstrated that iodine supplementation significantly lowered TSH levels by 3.2 mIU/l (95% CI: 1.8 - 4.5 mIU/l, $P < 0.01$) and increased free T4 levels by 0.6 ng/dl (95% CI: 0.3-0.9 ng/dl, $P < 0.05$), confirming its effectiveness in reversing thyroid dysfunction. The heterogeneity analysis indicated moderate variation among studies ($I^2 = 45\%$), underscoring the need for further extensive research.
Conclusion
Findings suggest a concerning resurgence of iodine deficiency-related thyroid disorders in children, particularly in populations with dietary restrictions or decreased intake of iodized salt. Iodine supplementation has proven beneficial in restoring thyroid function, yet public health measures must be strengthened to ensure sufficient iodine consumption through continuous food fortification, dietary assessment, and educational initiatives. Future large-scale epidemiological studies and controlled trials are required to refine iodine supplementation approaches and prevent a further rise in IDD cases.

Genetic characterization of congenital hypothyroidism with gland *in situ*: findings from a cohort of italian pediatric patients

Elisa Bortolamedi[1,2], Valeria Di Natale[2], Soara Menabò[3], Egidio Candela[1,2], Federico Baronio[2], Rita Ortolano[2] & Alessandra Cassio[1]
[1]Department of Medical and Surgical Sciences, Alma Mater Studiorum, University of Bologna, Bologna, Italy; [2]Pediatric Unit, IRCCS Azienda Ospedaliero-Universitaria di Bologna, Bologna, Italy; [3]Genetic Unit, Department of Medical and Surgical Sciences, IRCCS S.Orsola-Malpighi University Hospital, Bologna, Italy

Over the past few decades, the diagnosis of congenital hypothyroidism with a thyroid gland *in situ* (CH-GIS) has significantly increased, partially due to the widespread implementation of newborn screening programs. Although recent advancements in genetic research have enabled the identification of a genetic etiology in approximately 40-60% of CH-GIS cases, the etiology of this condition remains not completely understood.
Methods
In this study, we performed Targeted Next Generation Sequencing (NGS) of 18 thyroid-related genes in 78 pediatric patients with CH-GIS identified through newborn screening in Emilia-Romagna, Italy, from 2003 to 2021. All patients were diagnosed with permanent CH after diagnostic reevaluation. The goal was to genetically characterize this cohort, identify pathogenic variants, and explore the correlation between genotype and clinical phenotype.
Results
NGS analysis revealed 72 potentially pathogenic allelic variants (AVs) in 44 out of 78 patients, distributed across 10 genes: DUOX2, DUOXA2, GLIS3, IYD, NKX2-5, SLC26A4, TG, TPO, THRB, and TSHR. Of these, 78% were in genes involved in thyroid hormone synthesis, with DUOX2 being the most frequently affected gene (34.7%). We identified 25 AVs not previously reported, mostly missense mutations (18/25). A monogenic inheritance pattern was suggested for 22 patients: 8 with a single variant in a dominant gene and 14 with two variants in the same gene. Nine patients exhibited two or more variants in different genes, suggesting oligogenic inheritance. Additionally, 13 patients had a single variant in genes with autosomal recessive inheritance. Regarding the genotype-phenotype relation, the 14 patients with two AVs on the same gene presented a more severe phenotype, with median blood TSH levels of 200 µU/mL at diagnosis (significantly higher than other groups, $P = 0.006$), lower fT4 levels ($P = 0.002$) and an increased need for levothyroxine at 36 months of age.
Conclusion
NGS is a valuable diagnostic tool for the etiological characterization of CH-GIS. The confirmation of a relationship between genotype and clinical phenotype found in our population allows us to state that the early application of NGS can help define the etiologic diagnosis and plan appropriate follow-up. Despite this, in line with what has already been reported in the literature, abou half of the cases in our sample remain partially or completely genetically unsolved, highlighting the need for further investigation into alternative etiopathogenetic mechanisms.

JOINT3871

Improving hormonal balance in the treatment of pediatric congenital hypothyroidism: the role of combined LT4-LT3 therapy

Luisa Del Giacco[1], Marco Abbate[1], Gaia Vincenzi[1], Ilenia Teresa Petralia[1], Giulia Tarantola[1], Cristina Santagiuliana[1], Sara Zanelli[1] & Maria Cristina Vigone[1]
[1]IRCCS Ospedale San Raffaele, Department of Pediatrics, Milan, Italy

Introduction
Congenital hypothyroidism (CH) is managed with levothyroxine (LT4) to normalize TSH levels. However, LT4 monotherapy does not always ensure adequate tissue euthyroidism due to variability in peripheral conversion of thyroxine (T4) to triiodothyronine (T3). The FT3/FT4 ratio has emerged as a sensitive marker of thyroid hormone balance, with a persistently low ratio suggesting suboptimal T3 availability, as T3 is the biologically active hormone primarily generated from peripheral T4 conversion. This study investigates whether the addition of liothyronine (LT3) to standard LT4 therapy can restore a physiological FT3/FT4 ratio in pediatric CH patients.
Methods
15 pediatric CH patients with an altered FT3/FT4 ratio, despite normal or high-normal TSH and FT4 levels, were enrolled. Notably, 53% of patients had TSH and FT4 within range but with FT4 value at the upper limit and TSH at the high-normal threshold, making LT4 dose adjustments challenging. LT3 was introduced gradually, targeting an LT4:LT3 dose ratio between 10:1 and 20:1 to approximate physiological hormone production. Thyroid function tests (TSH, FT4, FT3, FT3/FT4 ratio) were evaluated according to age-specific reference ranges and measured at baseline, within six months of LT3 initiation, upon FT3/FT4 ratio normalization, and at a subsequent stability evaluation.
Results
At baseline, all patients exhibited an altered FT3/FT4 ratio, suggesting inadequate conversion of T4 to T3. Following LT3 introduction, FT4 levels decreased significantly ($p=0.0005$), while FT3 increased modestly, leading to progressive normalization of the FT3/FT4 ratio. The 92% of patients who achieved a normalized FT3/FT4 ratio, remained stable at the final follow-up ($p<0.0096$). Correlation analysis suggested that even small LT3 doses contributed significantly to optimizing thyroid balance.

Parameters	Pre-therapy w/LT3	1° evaluation	2° evaluation	3° evaluation	p-value
TSH (mcU/mL)	5.49(1.27-7.58)	2.53(0.70-8.13)	2.64(0.78-5.48)	2.16(2.16-3.6)	*0.349*
FT4 (pmo/l)	25.67(±6.32)	21.40(±3.00)	19.31(±2.7)	19.11(±2.33)	**0.0005**
FT3 (pmol/l)	6.69(±0.63)	9.96(±0.70)	6.92(±0.70)	7.04(±0.72)	*0.230*
FT3/FT4	0.29(±0.04)	0.36(±0.03)	0.38(±0.02)	0.39(±0.05)	**0.0037**

Conclusion
Our results suggest that the addition of LT3 to standard LT4 therapy can help restore a physiological FT3/FT4 ratio in pediatric CH patients with altered peripheral conversion. This approach may provide a more physiologic thyroid hormone balance, where LT4 monotherapy fails to optimize tissue hormone availability. While these results highlight the potential benefits of combination therapy, careful titration dose and monitoring therapy remain crucial. Future studies with larger cohorts and long-term follow-up are needed to refine treatment strategies and personalize the management of CH.

Metabolic dysfunction-associated steatotic liver disease and the risk of thyroid cancer: a complication of systemic metabolic disorder

Sang Yi Moon[1], Minkook Son[2] & Sunghwan SUH[3]
[1]Dong-A University College of Medicine, Department of Internal Medicine, Busan, South Korea; [2]Dong-A University College of Medicine, Department of Physiology, Busan, South Korea; [3]Samsung Changwon Hospital, Sungkyunkwan University School of Medicine, Department of Internal Medicine, Changwon, South Korea

Background
Metabolic dysfunction–associated steatotic liver disease (MASLD) represents a hepatic manifestation of metabolic syndrome. This study investigated the association between MASLD and the risk of thyroid cancer in a Korean population.
Methods
After excluding individuals with a history of liver disease or malignancy, we analyzed a cohort of 214,502 Korean adults aged 40 and above who participated in the National Health Screening Program from 2009 to 2010. Participants were categorized into four groups; no SLD without a cardiometabolic risk factor (CMRF), no SLD with at least one CMRF, MASLD, and metabolic and alcohol related/associated liver disease (MetALD). SLD was diagnosed using a fatty liver index threshold of $\geq$30. The primary outcome was the diagnosis of new thyroid cancer during the follow-up period. We examined the relationship between CMRF/SLD and thyroid cancer incidence using the Cox proportional-hazards model with adjustments for multiple variables.
Results
A total of 2,761 participants (1.3%) were newly diagnosed with thyroid cancer over an average follow-up of 9.61 years. Compared with participants without CMRF and SLD, those with CMRF (hazard ratio [HR] 1.33, 95% CI 1.16-1.52), those with MASLD (HR 1.36, 95% CI 1.17-1.58), and the MetALD group (HR 1.40, 95% CI 1.04-1.88) exhibited a significantly higher risk of thyroid cancer. In addition, MetALD significantly associated with thyroid cancer incidence solely in men.
Conclusion
In addition to CMRF, MASLD and MetALD was associated with an increased risk of thyroid cancer in the Korean population. This study is the first to demonstrate the association between thyroid cancer and the CMRF-MASLD-MetALD continuum.

Grave's orbitopathy: an atypical presentation

Lina Ghram[1], Meriem Adel[1], Cyrine Chehaider[1], Marwa Chiboub[1], Manel Jemel[1] & Ines Kammoun[1]
[1]National Institute of Nutrition Tunisia, University of Tunis El Manar, Faculty of Medecine of Tunis, 1007, Endocrinology, Tunis, Tunisia

Introduction
Grave's orbitopathy (GO) is an autoimmune disorder most commonly associated with Graves' disease (GD). It is typically manifested by exophthalmos, chemosis, and palpebral retraction. We report the case of a patient with GO presenting without exophthalmos and with normal MRI findings.
Observation
A 25-year-old female patient was referred for further management of GO. Hyperthyroidism was diagnosed in the presence of diplopia. The initial ophthalmological examination revealed partial paralysis of the medial branch of cranial nerve III, ptosis, and paralysis of the right superior rectus muscle, without exophthalmos. Initial cerebro-orbital MRI was unremarkable, showing intact oculomotor muscles and normal appearance of the optic nerves and chiasm. The initial thyroid function tests revealed FT4 at 68 pmol/l (reference range: 13-24 pmol/l) and TSH $<$0.01 mU/l (reference range: 0.5-5 mU/l). The patient was started on methimazole and oral corticosteroids. However, there was no improvement in the ophthalmological examination. A second cerebro-orbital MRI showed hypertrophy and inflammation of the inferior right oculomotor muscle, with T2 hyperintensity, T1 isointensity, and strong enhancement following gadolinium administration. The patient received three doses of methylprednisolone (1 g daily for three consecutive days), with a marked improvement in her diplopia at the two-week follow-up.
Conclusion
This case highlights the diagnostic challenges of GO, which may mimic other conditions and present in atypical forms. It should be considered in any patient with an oculomotor abnormality, particularly in young women. Repeated imaging is recommended even when initial imaging results are normal.

Management of low-risk differentiated thyroid carcinomas in nuclear medicine: a retrospective study of 280 cases

Moussa Nacer Khodja[1], Sofiane Rahal[1], Souleimane Meza[1] & Myriam Medjaher[1]
[1]Central Hospital Of The Army., Nuclear Medicine, Algiers, Algeria

Introduction
The risk stratification for recurrence of differentiated thyroid carcinomas, as outlined by the 2015 American Thyroid Association (ATA) guidelines, has enabled a therapeutic de-escalation, particularly for patients classified as low-risk for recurrence.
Materials and Methods
This monocentric retrospective study held within the Nuclear Medicine Unit of the Central Military Hospital of Algiers, follows a total of 280 patients, initially classified as low-risk according to the 2015 ATA criteria (pT1bN0/NxMx, pT2N0/NxMx), who after total thyroidectomy, received 1.1 GBq (30 mCi) of iodine-131 after thyrotropin stimulation (with either of the follwoing processes: rhTSH or thyroid hormone withdrawal) for ablation purposes. Thyroglobulin (Tg) and anti-thyroglobulin antibodies (ATg) levels were measured after thyrotropin stimulation, along with a cervical ultrasound, conducted 9 to 12 months post-treatment for all patients.
Results
Out of the 280 patients, 265 showed a complete biological response and a normal cervical ultrasound, resulting in a success rate of 94.6%.
- A cranial metastasis was identified in one patient.
- Four patients presented loco-regional metastasis (metastatic cervical adeonpathies).
- Ten patients presented an incomplete biochemical response with a negative cervical ultrasound and responded well to a second course of iodine-131 treatment.
Discussion
The results of our study are consistent with those of the ESTIMABL 1 study (98% remission), which allowed us to avoid overtreatment in more than 97% of patients. Additionally, dose reduction minimizes treatment-related side effects and has a considerable economic and organizational impact.
Conclusion
The use of low-dose iodine 131 (1.1Gbq), demonstrate excellent outcomes, yielding comparable results to higher dose treatment in low-risk differentiated thyroid carcinoma, ensuring optimal patient care, all the while reducing the economic and the organizational burden associated with former protocols.

JOINT1555

A study on the correlation between hyperthyroidism and bone metabolism & bone mass in children

Yi Liu[1] & Yu Yang[1]

[1]Jiangxi Provincial Children's Hospital, Department of Endocrinology, Genetics and Metabolism, Nanchang, China

Objective
To explore the alterations in bone metabolism and bone mass in children with hyperthyroidism, both before and during puberty.
Methods
Children newly diagnosed with hyperthyroidism from January to December 2024 were recruited and categorized into two groups: pre-pubertal and pubertal. A control group of healthy children from the same period was also included. Bone metabolism markers, including bone glaprotein (BGP), type I procollagen amino-terminal propeptide (PINP), type I collagen carboxy-terminal (β-CTX), alkaline phosphatase (ALP), 25-hydroxyvitamin D (25(OH)D), and bone mineral density (BMD), were measured in both untreated hyperthyroid children and healthy controls.
Results
Pre-pubertal hyperthyroid children: Significant differences were observed in BGP (167.33±79.21), PINP (1062.96±151.36), ALP (298.28±74.19), β-CTX (1.10±0.35), and 25(OH)D (79.67±19.11) compared to the control group ($P < 0.05$). However, no significant difference was found in BMD ($P > 0.05$). Pubertal hyperthyroid children: Significant differences were observed in BGP (151.81±81.23), ALP (252.71±87.90), β-CTX (1.14±0.56), and 25(OH)D (66.12±19.27) compared to the control group($P < 0.05$). No significant difference was found in PINP ($P > 0.05$). However, a significant difference was observed in BMD (-1.19±1.47) compared to the control group ($P < 0.05$).
Conclusion
Pre-pubertal children with hyperthyroidism exhibit increased bone metabolism. Pubertal children with hyperthyroidism experience bone loss.
Key Words
Hyperthyroidism, bone metabolism, bone mass, pre-pubertal children, puberty.

JOINT1818

Levothyroxine absorption test with daily levothyroxine dose: preliminary results in patients with refractory hypothyroidism

Charlotte Tudor[1], Grunenwald Solange[1] & Philippe Caron[1]
[1]CHU Larrey, Department of Endocrinology and Metabolic diseases, Toulouse, France

Introduction
Levothyroxine is the mainstay treatment of hypothyroidism. However, more than 15% of levothyroxine-treated patients failed to achieve the recommended serum TSH, due to either malabsorption, increased metabolism of thyroxine (T4) or non-adherence to treatment. A levothyroxine absorption test can differentiate true malabsorption from non-adherence or pseudo-malabsorption. Multiple protocols of levothyroxine absorption test have been published with differences in test doses, formulations, test duration, frequency of blood collection, absolute or relative peak or increments of total or free T4, and thresholds for normal absorption.
Patients and Methods
143 patients (109 women), mean (±SE) age 42±1 years, body mass index 25.5±0.5 kg/m^2, were treated after total thyroidectomy for benign ($n = 71$) or malignant ($n = 41$) diseases, autoimmune thyroiditis ($n = 29$), congenital ($n = 5$), central ($n = 4$) and post-radioiodine ($n = 3$) hypothyroidism, with levothyroxine alone ($n = 137$) or in association with liothyronine ($n = 6$). The mean daily dose of levothyroxine was 3.27±0.9 μg/kg. After an overnight fast, the first blood sample (baseline) was taken; then patients absorbed the daily levothyroxine dose and blood samples were drawn every 2 hours during 24 hours. Serum TT4 and FT4 concentrations were evaluated in all samples, TSH concentrations were measured before and 24-hour after levothyroxine absorption.
Results
Prior intake of levothyroxine, baseline TT4, FT4 and TSH concentrations were 7.6 ± 0.2 μg/dl, 12.5 ± 0.4 pg/ml and 25.1 ± 3.3 mU/l respectively, demonstrating refractory primary hypothyroidism ($n = 139$). After orally levothyroxine intake, TT4 and FT4 concentrations increased at 9.4 ± 0.2 μg/dl and 15.8 ± 0.5 pg/ml ($P < 10^{-3}$), respectively. TT4 and FT4 levels peaked after 4.2 ± 0.2 and 4.3 ± 0.3 hours, respectively. TT4 increments were diminished in chronic gastritis ($n = 19$, 1.20 ± 0.23 μg/dl, $P < 0.01$), Helicobacter pylori infection ($n = 15$, 1.58 ± 0.2 μg/dl, $P = 0.02$) and proton pump inhibitor treatment ($n = 9$, 1.74 ± 0.2 μg/dl, ns) attesting decreased levothyroxine absorption in such patients. There were no adverse events reported by the patients during the levothyroxine absorption test.
Conclusion
Levothyroxine absorption test can be achieved via the absorption of daily dosage of levothyroxine with the evaluation of TT4/FT4 levels over 4 – 6 hours follow-up. The test is clinically well tolerated. In clinical practice, more studies are necessary in patients with refractory hypothyroidism due to either factors interfering with levothyroxine absorption or T4 metabolism or to pseudo-malabsorption.

JOINT2692

Familial thyroid hormone resistance: a case series of two sisters with THRß mutation

Dovile Denaite[1], Edward Visser[2], Marcel Meima[2], Giedre Mockeviciene[1] & Ruta Navardauskaite[1]
[1]Lithuanian University of Health Sciences, Department of Endocrinology, Kaunas, Lithuania; [2]Academic Center for Thyroid Disease, Erasmus Medical Center, Department of Internal Medicine, Rotterdam, Netherlands

Introduction
Resistance to thyroid hormone beta (RTHβ) is a rare, typically autosomal dominant genetic disorder, caused by mutations in the *THRB gene*, encoding thyroid hormone receptor beta (TRβ*)*, leading to impaired responsiveness to thyroid hormone in tissues expressing TRβ. While affected individuals often present with elevated circulating free thyroxine (FT4) and free triiodothyronine (FT3) alongside non-suppressed thyroid-stimulating hormone (TSH), clinical manifestations, ranging from overt symptoms to asymptomatic presentations, complicate diagnosis. This case series highlights phenotypic variability and management of RTHβ in two sisters.
Case Report
The older sister, a 24-year-old woman, was referred to an endocrinologist during her first pregnancy at 26 weeks of gestation for elevated FT3: 4.19 pmol/mL (N 1.58–3.91) with other thyroid function tests normal. Thyroid ultrasound suggested possible autoimmune thyroiditis. She was started on L-thyroxine (50 mg daily), but follow-up two months later showed elevated FT4: 26.05 pmol/l (N 7.87–20.3) and FT3: 6.56 pmol/l (N 3.34–5.14) and non-suppressed TSH: 3.9 mU/l (N 0.4–3.6). Thyroid antibodies were negative. After delivering a healthy baby, L-thyroxine was discontinued. During her second pregnancy, she again had elevated FT4: 30.54 pmol/l and FT3: 6.65 pmol/l with a non-suppressed TSH: 3.52 mU/l. No treatment was initiated, thyroid hormone levels were monitored throughout pregnancy. Genetic testing confirmed a pathogenic heterozygous mutation in the *THRB* gene (c.1291A>T, p.Ile431Leu). She delivered another healthy, lower-birth-weight non-carrier baby. The younger sister, a 17-year-old female, underwent genetic testing after her sibling's diagnosis. Asymptomatic with no thyroid dysfunction on examination, she showed elevated FT4: 30.19 pmol/l and FT3: 7.13 pmol/l, with a non-suppressed TSH: 2.80 mU/l and negative thyroid antibodies (antiTPO, antiTg, antiTSH). Genetic testing confirmed the same *THRB* (c.1291A>T, p.Ile431Leu) mutation. Clinical management focused on monitoring thyroid function without initiating thyroid hormone suppression or beta-blocker therapy due to the absence of symptoms. Functional testing using a luciferase reporter assay in Jeg-3 cells showed reduced affinity of TRβ2-I341L (EC0 I341L vs WT: 9.1 [7.8-10.6] vs 0.71 [0.69-0.74] nM, $p<0.001$). The T3-affinity of the mutant was significantly reduced, as evident from a ~13-fold higher EC50 for T3 compared to wild-type in the reporter assay.
Conclusion
This family case demonstrates the phenotypic variability of RTHβ, ranging from pregnancy-associated thyroid dysfunction to an asymptomatic carrier state. It underscores the importance of familial genetic screening in diagnosing RTHβ and highlights the need for individualized, symptom-based management strategies to avoid overtreatment while ensuring appropriate monitoring for potential complications.

Differentiated thyroid cancer in acromegaly: increased risk, unaltered outcomes

Sinem Başak Tan Öksüz[1], Esra Eraslan Aydemir[1], Özge Baş Aksu[1], Rıfat Emral[1] & Sevim Güllü[1]
[1]Ankara University, Faculty of Medicine, Department of Endocrinology and Metabolism, Ankara, Türkiye

Introduction
Acromegaly is associated with an increased risk of cancer compared to the general population. Differentiated thyroid cancer (DTC) has been reported to be the most common type of malignancy in acromegaly. Whether DTC in patients with acromegaly are more aggressive is controversial.
Methods
The data of 14 acromegaly patients diagnosed with DTC and 42 non-acromegaly patients with DTC matched for age and sex (1:3) were retrospectively analyzed.
Results
In a cohort of 184 patients diagnosed with acromegaly, DTC was diagnosed in 14 (7.6%) patients. The mean age at DTC diagnosis was 49 ± 6.12 years. The

Table 1: Comparison of pathological and clinical features of acromegaly patients with DTC and non-acromegaly patients.

Parameter	DTC with acromegaly ($n = 14$)	Control group ($n = 42$)	*P* value
Tumor diameter (mm)	12.5 (IQR: 4.50 – 27.25)	7.0 (IQR: 4.75 – 11.25)	0.122
Multifocality (n, %)	5 (%35)	18 (%43)	0.638
Extracapsular invasion (n, %)	6 (%42)	7 (%17)	0.054
Lymph node metastasis (n, %)	2 (%14)	13 (%31)	0.223
Stage (n, %) -Stage 1 -Stage 2	13 (%93) 1 (%7)	40 (%95) 2 (%5)	0.732
RAI (n, %)	7 (%50)	18 (%43)	0.642
Total RAI dose (mCİ)	100 (IQR: 100 – 100)	100 (IQR: 75 – 131.25)	0.986
Response (n, %)			0.588
-Excellent response	13 (93%)	36 (%86)	
-Biochemical incomplete response	1 (7%)	3 (%7)	
-Structural incomplete response	0 (%)	3 (%7)	

median time from diagnosis of acromegaly to DTC was 36 months (IQR: 8.25 - 71.75). Two patients were diagnosed with PTC 12 months and 44 months before diagnosis of acromegaly, respectively. Five (37%) of the patients with acromegaly have active disease at the time of DTC diagnosis, 7 (50%) of them was in remission. Regarding the histological subtypes, 7 (50%) of them were classical subtypes, 6 (43%) of them were follicular subtypes and one (7%) of them was an oncocytic subtype Comparison of pathological and clinical features of acromegaly patients with DTC and non-acromegaly patients with DTC is summarized in table 1.

Conclusion

The incidence of thyroid cancer is increased in patients with acromegaly when compared to the general population. This phenomenon may be attributed to enhanced awareness, screening, and early detection bias. Our study concluded that patients with acromegaly did not demonstrate a more aggressive course. A longer follow-up period and the inclusion of a higher number of DTC patients may support the long-term validity of the present data.

JOINT2084

Association of extra-thyroidal abnormalities and genetic variants in congenital hypothyroidism: a single-centre study

Hakan Birinci[1], Hayrullah Manyas[2], Berna Eroğlu Filibeli[1], Eren Er[1], Özgür Kırbıyık[3], Kadri Erdoğan[3] & Bumin Nuri Dündar[4]
[1]Izmir City Hospital, Pediatric Endocrinology Clinic, Izmir, Türkiye, Izmir, Türkiye; [2]Sanlıurfa Training and Research Hospital, Pediatric Endocrinology, Sanlıurfa, Türkiye; [3]Izmir City Hospital, Medical Genetics Clinic, Izmir, Türkiye, Izmir, Türkiye; [4]Izmir Katip Celebi University, Faculty of Medicine, Department of Pediatric Endocrinology, Izmir, Türkiye, Pediatric Endocrinology, Izmir, Türkiye

Introduction

Extra-thyroidal abnormalities are common in congenital hypothyroidism (CH). This study aimed to investigate the frequency of extra-thyroidal abnormalities in CH cases and the relationship between extra-thyroidal disease and the genetic causes of CH.

Methods

Patients with CH were screened for non-thyroid congenital anomalies, and a thyroid genetic panel was analyzed using next-generation sequencing. The panel included the following genes: *NKX2-5, PAX8, PHEX, POR, SERPINA7, SLC16A2, SLC26A4, SLC26A7, SLC5A5, ALB, DIO1, DIO2, DIO3, DUOX1, DUOX2, DUOXA2, FOXE1, GLIS3, GNAS, IGSF1, SLC6A4, TG, THRA, TPO, TRH, TRHR, TSHB, TSHR, TTR, ZNF607, THRB*. Patients' data were obtained retrospectively from hospital records.

Results

The study included 77 patients (29 females and 48 males) diagnosed with CH. Among CH patients, 5 had central and 72 had primary hypothyroidism. The most common etiology was dyshormonogenesis (89.6%). Fifty-one variants were detected in 43 of the 77 patients who requested a genetic panel for CH etiology. *TG* variants were found in 10 patients, *ALB* in 8 patients, *TSHR* in 8 patients, *TSHB* in 5 patients, *TPO* in 4 patients, *THRA* in 4 patients, *POR* in 3 patients, *SLC26A4* in 2 patients, *PAX8* in 2 patients, *DUOX2, GNAS, PHEX, SLC16A2, THRB* variants in 1 patient each. The genetic panel detected pathogenic variants in 10 patients (13%), likely pathogenic variants in 14 patients (18.2%), variants of uncertain significance in 19 patients (24.7%), and no variants in 34 patients (44.2%). L-thyroxine treatment was discontinued in 14% (6 patients) of patients in whom a genetic variant was detected. In contrast, the withdrawal rate was 47.1% (16 patients) in cases without variants ($P = 0.002$). In the screening for anomalies accompanying CH, 26 patients (33%) had congenital anomalies. Cardiac anomalies were found in 8 patients, genitourinary anomalies in 7, central anomalies in 7, dysmorphic features in 5, musculoskeletal anomalies in 3, gastrointestinal anomalies in 1, and ocular anomalies in 2. Multiple system anomalies were observed in four patients. Genetic variants were reported in 16 of 26 patients with congenital anomalies, whereas 10 patients with extra-thyroidal anomalies had no genetic variants.

Conclusion

This study has showed that about one third of CH patients had non-thyroidal abnormalities, most commonly cardiac abnormalities. Identifying genetic mutations that cause CH may help elucidate the phenotype-genotype relationship of extra-thyroidal disorders and contribute to early diagnosis and feasible and appropriate treatment for these patients.

Chronotype and daytime sleepiness in patients with hashimoto's thyroiditis

Ivana Škrlec[1], Davor Lešić[2], Zrinka Biloglav[3,4], Jasminka Talapko[1], Vera Cesar[1,5] & Darko Katalinić[1]
[1]Faculty of Dental Medicine and Health, Josip Juraj Strossmayer University of Osijek, Osijek, Croatia; [2]Fizio Educa, Osijek, Croatia; [3]Department of Medical Statistics, Epidemiology and Medical Informatics, School of Public Health Andrija Štampar, Zagreb, Croatia; [4]School of Medicine, University of Zagreb, Zagreb, Croatia; [5]Department of Biology, Josip Juraj Strossmayer University of Osijek, Osijek, Croatia

Introduction

The hypothalamic–pituitary–thyroid axis controls the circadian clock via the suprachiasmatic nucleus. Chronotype refers to a person's natural preference for sleep-wake cycles and twenty-four-hour activity patterns. Daytime sleepiness, constant fatigue, and increased daytime sleepiness are common in many diseases, including Hashimoto's thyroiditis (HT). The evening chronotype may be associated with higher thyrotropin (TSH) levels and a higher risk of hypothyroidism. Concurrently, sleep disorders have become a serious public health problem as they impair endocrine function. The aim of the study was to estimate the association between thyroid status, chronotype, and daytime sleepiness among HT patients.

Material and Methods

The study included 115 patients, 106 women and nine men (43 ± 12 years of age) with clinical, ultrasound, and laboratory-confirmed HT. We used the short Morningness-Eveningness Questionnaire (rMEQ) to assess chronotype and the Epworth Sleepiness Scale (ESS) to evaluate daytime sleepiness. Based on chronotype, patients were categorized into intermediate + morning chronotype ($rMEQ > 11$) and evening chronotype ($rMEQ \leq 11$) groups. Patients were, based on the ESS, further categorized into those with normal daytime sleepiness ($ESS \leq 10$) and those with increased daytime sleepiness ($ESS \geq 11$).

Results

Most patients had normal daytime sleepiness (71.3%), and most of them had an intermediate chronotype (60.9%), while only one patient had a morning chronotype (0.9%). Age was significantly associated with chronotype ($\chi2 = 499.278$; $P = 0.012$), with younger patients tending to have an evening chronotype. A significant association was observed between chronotype and thyroglobulin antibodies (TgAb) ($\chi2 = 898.614$; $P = 0.008$) and TSH levels ($\chi2 = 833.323$; $P = 0.033$). Daytime sleepiness was also significantly associated with TgAb ($\chi2 = 1667.721$; $P = 0.050$), TSH ($\chi2 = 1531.095$; $P = 0.050$) and fT3 ($\chi2 = 618.605$; $P = 0.024$). Free triiodothyronine (fT3) levels were significantly higher in patients with intermediate + morning chronotype than in the evening ones ($Z = -2.160$; $P = 0.031$), while no significant differences in thyroid parameters were found between normal and increased daytime sleepiness.

Conclusion

Only 38.3% of patients had an evening chronotype, and only 28.7% had increased daytime sleepiness. The evening chronotype is associated with a higher rate of HT. Sleep affects the secretion of thyroid hormones and leads to a decrease in the amplitude of the circadian rhythm for TSH. The underlying mechanisms are not fully understood and require further investigation. Grant No. IP-FDMZ-2024.2025-09.

Objective
The *NRAS* Q61R variant is frequently observed in a range of thyroid tumors, including benign nodules, low-risk neoplasms, and malignant tumors such as follicular thyroid carcinoma (FTC) and papillary thyroid carcinoma (PTC). The presence of the Q61R variant alone makes it challenging to distinguish between benign and malignant lesions.
Methods
This study investigated miRNA expression profiles in 12 PTC, four FTCs, five low-risk carcinomas, 11 benign nodules, and 12 healthy thyroid tissues free of genetic alterations. The miRNA libraries for NGS sequencing were prepared from RNA isolated from fresh-frozen thyroid tissues using the QIAseq miRNA Library Kit (Qiagen). To compare miRNA expression between *NRAS* benign and malignant tissues, as well as between *NRAS*-positive and healthy tissues the miRge3.0 tool and DESeq2 package in R were used.
Results
NRAS-positive samples displayed significant miRNA expression changes compared to healthy tissues, with 125 miRNAs altered (50 upregulated, 75 downregulated). Noteworthy upregulated miRNAs included hsa-miR-221-3p, hsa-miR-221-5p, hsa-miR-222-3p. When comparing *NRAS*-positive benign nodules to malignant tumors, we identified significant changes in the expression of 33 miRNAs. Malignant samples showed marked increases in miRNAs such as hsa-miR-520a-5p and hsa-miR-519d-3p, while hsa-miR-9-5p significantly decreased.
Conclusion
These data suggest distinct miRNA expression profiles that may help differentiate benign from malignant thyroid tumors with the *NRAS* Q61R variant. *Supported by AZV NU21-01-00448 and MH CZ RVO 00023761..*

Unraveling clinical clues for deciphering thyroid nodule malignancy

Nicholas Angelopoulos[1], Ioannis Androulakis[1], Dimitrios Askitis[1], Nicolaos Valvis[1], Rodis Paparodis[1,2], Valentina Petkova[1], Anastasios Boniakos[1], Dimitra Zianni[1], Andreas Rizoulis[1], Sarantis Livadas[1], Dimitra Bantouna[1] & Juan Carlos Jaume[2]
[1]Hellenic Endocrine Network, Athens, Greece; [2]Loyola University Medical Center Maywood, IL and Edward Hines, Jr. VA Hospital, Hines, IL, USA, Endocrinology, Chicago, United States

Background
While most nodules are benign and asymptomatic, certain characteristics may indicate malignancy, prompting fine needle aspiration biopsy. Factors like age and gender affect cancer risk, complicating ultrasound-based risk systems. We aimed to determine whether the cytological malignancy rate of thyroid nodules could be adjusted for several clinical parameters.
Methods
Data from patients aged 18 and above with thyroid nodules assessed via Fine Needle Aspiration (FNA) were retrospectively reviewed. Malignancy classification was based on cytopathology and histopathology Results The study examined how various clinical parameters, adjusted for the ACR TI-RADS category, affected thyroid nodule malignancy rates, including age, sex, Body Mass Index (BMI), nodule size, presence of autoimmunity, and thyroxine therapy. Additionally, we analyzed the performance of ACR TI-RADS in predicting malignant cytology across different age subgroups of thyroid nodules.
Results
The study included 1128 thyroid nodules from 1001 adult patients, with a median age of 48 years and predominantly female (76.68%). Univariate analysis revealed age, sex, and nodule size as risk factors for malignant cytology. For each year of age, there was a 2.33% reduction in the OR for malignant cytology (95% CI: 1.1%-3.1%; P = <0.001). Male sex and nodule size were risk factors for malignant cytology with OR of 1.47(95% CI: 1.10 – 1.95; $P = 0.009$) and 0.94 (0.93 - 0.96; $P < 0.00$), respectively. The multivariate logistic regression analysis involving 1128 thyroid nodules, adjusted for ACR TI-RADS categories, sex, and nodule size, showed a 2.5% reduction in the OR for malignant cytology for each year of age. cIntragroup analysis was performed in each group of ACR TI-RADS (TR3, TR4, and TR5) nodules ($n = 705$) where FNA was indicated. In ACR TI-RADS 3 category nodules, only age strongly predicted malignancy. ROC analyses revealed a diameter of >34 mm as the cut-off value with the best sensitivity and specificity (Youden index 0.564, Sensitivity 83.3 %, and Specificity 73.1%). There was a 4.3% decrease in the odds of malignancy for each year of age increase in patients in the ACR TI-RADS 4 category. For every one-year increase in age, there was a 2.1% decrease in the odds of malignancy for patients in the ACR-TIRADS 5 category.
Conclusion
Raising the size threshold for recommending FNA of TR3-3 nodules and incorporating patients' age and gender into the evaluation process could enhance the system's accuracy in assessing thyroid nodules and guiding clinical management decisions.

JOINT3163

Differences between pediatric and adult treatment protocols in differentiated thyroid carcinoma: need for transitional guidelines for adolescents

Sarah Clement [1], Teske Kroondijk[1], Mark van Treijen[2] & Hanneke van Santen[1]
[1]Wilhelmina Children's Hospital, Utrecht, Netherlands; [2]University Medical Center Utrecht, Utrecht, Netherlands

Introduction
The presentation and outcome of differentiated thyroid carcinoma (DTC) differ significantly between pediatric and adult patients, leading to distinct guidelines for each group. Adolescents may receive different treatment on either pediatric or adult protocols, raising the question whether this distinction is justified or if a dedicated guideline for adolescents is needed. A critical first step in addressing this issue is a systematic comparison of pediatric and adult DTC guidelines to identify key differences.
Methods
A national review of Dutch pediatric (2020)[1] and adult (2024)[2] DTC guidelines was conducted, categorizing differences as concordant, discordant or partially concordant.
Results
Of the recommendations in both guidelines, 32% are concordant, 47% are discordant, and 21% are partially concordant. The main difference is a more de-escalating approach to managing adult DTC patients, guided by a validated risk classification system. In contrast, no such validated risk classification system exists for pediatric DTC patients. For pediatric cases, total thyroidectomy followed by radioactive iodine treatment is recommended for all patients with tumors >1 cm. In adults, this approach is clearly indicated only for high-risk DTC patients.
Conclusions
The management of DTC differs significantly between pediatric and adult patients, which can result in adolescents receiving vastly different treatment strategies depending on whether they are classified under pediatric or adult protocol at diagnosis. Relying solely on age may not be appropriate, as other factors beyond age are increasingly recognized to play a critical role in determining the most appropriate treatment strategy. The next step is to collaborate with a multidisciplinary team to develop evidence-based guidelines for adolescents (15-25 years), identify research gaps, and plan further studies to develop tailored recommendations for more personalized treatment strategies.

Table 1. Overview of the management of DTC in a 17-year old- vs 18-year old patient.

2 cm tumor and no signs of lymph node or distant metastasis		
Age:	17 years old	18 years old
Surgery:	Total thyroidectomy *Thyroid hormone replacement therapy*	Hemithyroidectomy *Categorized as low risk*
RAI therapy:	Yes	No
TSH level:	0.5-1.0 mU/l	0.5-2.0 mU/l
Re-stratification	No	Yes, one year after initial treatment Excellent response: TSH level normal reference

Abbreviations: RAI: Radioactive iodine; TSH: Thyroid stimulating hormone.

A novel biallelic intronic variant in the TG gene associated with thyroid dyshormonogenesis and fetal goiter

Zehra Yavas Abali[1,2], Esra Dirimtekin[3], Mehmet Eltan[4], Bilgen Bilge Geçkinli[3], Tugba Kalayci[5], Serap Turan[1] & Zehra Oya Uyguner[5]
[1]Marmara University School of Medicine, Department of Pediatric Endocrinology, Istanbul, Türkiye; [2]Istanbul University, Institute of Health Sciences, Istanbul University, Institute of Health Sciences, Genetics, Istanbul, Türkiye; [3]Marmara University School of Medicine, Department of Medical Genetics, Istanbul, Türkiye; [4]Sancaktepe Research and Training Hospital, Pediatric Endocrinology Unit, Istanbul, Türkiye; [5]Istanbul University, Istanbul Faculty of Medicine, Department of Medical Genetics, Istanbul, Türkiye

Background
Biallelic pathogenic variants in the *Thyroglobulin*(*TG*) gene have a well-established correlation with congenital hypothyroidism (CH) due to thyroid dyshormonogenesis (TDH), frequently associated with congenital goiter. The phenotypic spectrum is highly variable. Here, we describe a novel homozygous intronic *TG* variant in a family with recurrent congenital goiter and demonstrate its pathogenic impact through its transcript analysis.
Case Report
The proband, a 15.5-year-old male, was referred for a thyroid nodule. He had a prenatal diagnosis of goiter and was started on L- thyroxine postnatally due to CH. Born at term (3100 g) via spontaneous delivery, he required intensive care due to respiratory distress. He has been on L-thyroxine since infancy, with age-appropriate neurodevelopment. His parents were first-degree cousins, and his mother had a previous pregnancy complicated by fetal goiter. At presentation, his height and weight were 164.5 cm(-1.1SDS), and 73.5kg(0.8SDS), respectively. The thyroid gland was enlarged, and systemic examination was unremarkable. Thyroid ultrasound showed diffuse heterogeneity with fine septations and a 9 mm solid nodule. During follow-up, the iso-hypoechoic nodule increased to 14×9.5 mm. Fine needle aspiration biopsy (FNAB) initially indicated atypia of undetermined significance (Bethesda 3), later raising suspicion for follicular/-Hurthle cell neoplasm (Bethesda 4). Right lobectomy and isthmectomy revealed adenomatoid hyperplasia with oncocytic changes and reduced colloid. The presence of congenital goiter in both the proband and sibling with fetal goiter raised suspicion of TDH. Serum TG levels were markedly low (0.2 ng/mL;range: 3.5–77 ng/mL). Targeted next-generation sequencing identified a *novel* homozygous *TG* variant (NM_003235): c.5686+3A>C/p.(?) Parents were heterozygous. This variant was classified as a variant of uncertain significance (VUS) (PP3, Pm^2) according to ACMG criteria. *In silico* prediction tools defined a splice-altering effect, with strong pathogenicity scores. The variant was absent from gnomAD. A prenatal ultrasound in the mother's new pregnancy detected fetal goiter, prompting in-utero L-thyroxine. Segregation analysis confirmed the homozygous variant. To assess its splicing impact, RNA from peripheral blood (proband and affected sibling) was reverse-transcribed into cDNA, amplified by PCR, and sequenced. The splicing analysis confirmed aberrant exon skipping, specifically predicted in-frame skipping of exon 30 leading to c.5549_5686del/-p.(Leu1851Cys (;)1852_1896del) with loss of 45 residues from type IIIA and type IIIB repeat regions (UniProt).
Conclusion
This study identifies a novel *TG* splice-site variant, expanding the genetic landscape of CH. Functional RNA analysis confirmed its pathogenicity by demonstrating aberrant splicing. Our findings underscore the importance of early genetic diagnosis in dyshormonogenesis, enabling timely genetic counseling.

Antithyroid drug therapy for pediatric graves' disease: a dose-effect relationship study of initial dose and short-term efficacy

Yang Li[1], Gong chunxiu[1], Mu-Qiao Yan[1] & Yan-ning Song[1]
[1]Beijing Children's Hospital, Capital Medical University, National Center for Children's Health, Beijing, China

Purpose
To investigate the optimal initial dose of methimazole (MMI) in the treatment of pediatric Graves' disease (GD).
Methods
A retrospective analysis was conducted on clinical data from GD patients treated at our hospital between December 2015 and August 2023. Patients were further divided into low-dose (< 0.5 mg/kg/d) and high-dose (≥ 0.5 mg/kg/d) groups. A restricted cubic spline logistic regression analysis was used to assess the nonlinear relationship between the initial dose and the probability of normalizing free thyroxine (FT_4) within 30 days.
Results
The 324 GD patients ranged in age from 2.1 to 16.1 years. The mean initial doses for the mild, moderate, and severe groups in the low-dose and high-dose groups were 0.32±0.09 *vs.* 0.73±0.19, 0.39±0.08 *vs.* 0.71±0.18, and 0.35±0.09 *vs.* 0.73±0.17 mg/kg/d, respectively. There was no significant difference in the time to normalize FT_4 between the low-dose and high-dose groups for different severity categories ($P > 0.05$); however, the results of linear analysis showed that thyroid volume, initial dose and disease severity affected the days for FT_4 to return to normal. After adjusting for these factors, there was a nonlinear relationship between the initial MMI dose and the probability of normalizing FT_4 within 30 days, with the probability increasing until reaching a plateau at a dose of 0.58 mg/kg/d.
Conclusion
For patients with mild disease, an initial dose of 0.3 mg/kg/d is recommended. For those with moderate to severe disease, an initial dose of 0.5 to 0.6 mg/kg/d is recommended.

Objective
Thyroid tumours are more often diagnosed and prognosticated using molecular testing. Accounting for approximately 85-88% of cases, papillary thyroid

carcinoma (PTC) is the most common subtype of thyroid cancer. The *BRAF* p.(Val600Glu) variant is the most prevalent genetic alteration in PTC or papillary thyroid microcarcinoma (PTmC) and is associated with aggressive clinicopathological features and an increased risk of disease-related mortality. However, many of these aggressive features can only be identified postoperatively on histological specimens. The miRNA expression profile is an additional tool that is being explored in the diagnosis of thyroid cancer to help fill this gap in our knowledge.
Methods
In this study, we examined the expression profiles of miRNAs in PTC samples harbouring the *BRAF* p.(Val600Glu) variant, focusing on comparing the group of *BRAF*-positive PTC cases with indolent tumour behaviour (patients with T1/T2N0M0 without angioinvasion, persistence or recurrence) with more aggressive PTC cases (e.g. patients with lymphatic or distant metastases, angioinvasion, extrathyroidal invasion or radioiodine-refractory PTC). The QIAseq miRNA Library Kit (Qiagen) was used to generate miRNA libraries from fresh frozen thyroid tissue samples and for the bioinformatic comparison of the expression profiles, the miRge3.0 tool and the DESeq2 package in R were used.
Results
In *BRAF*-positive samples, a total of 80 miRNAs showed significantly altered expression (44 upregulated, 36 downregulated) compared to healthy thyroid tissue. The expression of 10 miRNAs exhibited significantly altered expression in more aggressive PTC cases - 7 miRNAs were significantly upregulated and 3 miRNAs were significantly downregulated. The most significant findings were upregulated expression of hsa-miR-642a-5p, hsa-miR-205-5p, hsa-miR-150-5p and downregulated expression of hsa-miR-520a-5p, hsa-miR-181d-5p and hsa-miR-3065-5p.
Conclusion
In conclusion, knowledge of the expression of miRNAs could be a useful tool for better prognosis. Our data suggest that the indolent and aggressive behaviour of PTC cases can be differentiated using miRNA expression profiles. Verification using a different method and the analysis of a larger set of samples are to follow.

Objective
The Q61R variant is the most frequent genetic alteration in the *HRAS* gene. It is observed in benign nodules, low-risk neoplasms and even malignant tumors including medullary thyroid carcinoma (MTC). Pathogenic variants in the *HRAS* gene are the ones most frequently detected in *RET*-negative MTC, but their prognostic significance is still unclear due to their occurrence across both benign and malignant thyroid tissue. Also, the presence of the Q61R variant alone makes it difficult to distinguish MTC from thyroid tumors derived from follicular cells in fine needle aspiration biopsy (FNAB) samples.
Methods
This study investigated miRNA expression profiles in 12 MTC, 12 papillary thyroid carcinoma (PTC) and 6 benign nodules with *HRAS* Q61R variant. The miRNA libraries for NGS sequencing were prepared from RNA isolated from fresh-frozen thyroid tissues using the QIAseq miRNA Library Kit (Qiagen). To compare miRNA expression of *HRAS*-positive MTC with *HRAS*-positive benign tissues and *HRAS*-positive PTC the miRge3.0 tool and DESeq2 package in R were used.
Results
In *HRAS*-positive MTC, a significant change in expression was found for 238 miRNAs compared to *HRAS* positive benign thyroid nodules and for 232 miRNAs compared to *HRAS*-positive PTC. Some miRNAs with significant expression changes in MTC were the same compared to *HRAS*-positive benign thyroid nodules and *HRAS*-positive PTCs (e.g., increased expression of hsa-miR-224-5p, hsa miR-132-3p, hsa-miR-132-5p, hsa-miR-769-5p, hsa-miR 10a 3p and decreased expression of hsa-miR-181a-2-3p and hsa-miR-126-5p), others were unique and were only changed compared to *HRAS*-positive benign thyroid nodules (e.g., increased expression of hsa-miR-137-3p, hsa-miR-10a 5p and decreased expression of hsa-miR-190a-5p, hsa-miR-130b-5p) or *HRAS*-positive PTCs (e.g., increased expression of hsa-miR-212-3p, hsa-miR-330-3p and decreased expression of hsa miR 130a-3p, hsa-miR-551b-3p, hsa-miR-30a-5p).
Conclusion
These data indicate the presence of distinct epigenetic alterations, manifesting in the form of altered miRNA expression profiles that may distinguish MTC from thyroid nodules derived from follicular cells in FNAB with the *HRAS* Q61R variant. Subsequent to the present study, verification will be undertaken using an alternative method, and an analysis of a larger set of samples will be conducted.

The impact of dry eye disease on magnetic resonance imaging findings and quality of life in patients with graves' orbitopathy
Anastasia Nikolopoulou[1], Sofia Chatzi[1], Vasiliki Georgakopoulou[1], Sofia Akrivou[1] & Georgios Boutzios[1]
[1]Department of Pathophysiology, National and Kapodistrian University of Athens, Laiko General Hospital, Athens, Greece

Introduction
Graves' orbitopathy (GO) is an autoimmune manifestation of Graves' disease (GD) affecting the orbit and the periorbital tissues. Among its other manifestations, an important percentage of patients experience symptoms of Dry eye disease (DED). The aim of this study was to investigate a possible association between DED and clinical, demographic, and imaging parameters of GO.
Material and Methods
This is a single-center observational study in an outpatient clinic of autoimmune endocrinopathies at a Tertiary, General, University Hospital between 09.2022-12.2024. Sixty-seven patients with GO were included in the study. We evaluated GO activity and severity parameters, functional and psychological well-being scores as assessed by the EUGOGO- GO Quality of Life Questionnaire, TSI levels. All patients underwent orbital MRI. Tear secretion was measured in all patients by applying a Schirmer test strip. Depending on the measured value, patients were divided into 4 subgroups: normal tear secretion (>15 mm), mild dry eye (10- 15 mm), moderate dry eye (5- 10 mm) and severe dry eye (<5 mm). Statistical analysis was performed using IBM SPSS Statistics version 26 and statistical significance was set at $P < 0.05$.
Results
Mean age was 52.34 $\pm$ 12.04 years (range 30–85 years) and 79.1% were females. We found that tear dysfunction severity was significantly associated with eye muscle involvement in MRI ($P = 0.005$), which was evident in all patients in the severe dry eye subgroup. IV contrast enhancement in MRI, indicative of active inflammation, was also positively correlated with dry eye severity ($P = 0.037$). Moreover, dysthyroid optic neuropathy (DON) was significantly associated with Schirmer categories ($P = 0.029$), with DON present in 25% of severe cases and 16.7% of moderate cases. Patients with moderate DED were older (mean $= 59.37$ $\pm$ 11.51 years) compared to those with normal tear function (mean $= 46.38$ $\pm$ 9.71 years, $P = 0.003$). Functional well-being scores were lower in severe dry eye cases (mean $= 13.08$ $\pm$ 3.25) compared to moderate cases (mean $= 17.78$ $\pm$ 4.78, $P = 0.039$).
Conclusion
In our study, we showed that there is a significant association between DED severity and older age, evident orbital MRI findings, DON and lower quality of life scores among patients with GO. Further prospective studies are needed to

confirm a possible correlation between DED severity and GO parameters, such as disease activity and TSI levels.

Risk of psychiatric disorders in patients with graves' disease: a nationwide population-based analysis

Seo Young Sohn[1], Jeong Heo[1], Jiyeon Ahn[1], Min Kyung Lee[1], Jae Hyuk Lee[1], Yunjin Kim[2] & Sung Woo Cho[3]

[1]Myongji Hospital, Hanyang University College of Medicine, Division of Endocrinology, Department of Internal Medicine, Goyang, South Korea; [2]Hanyang University College of Medicine, Biostatistics Lab, Medical Research Collaborating Center, Seoul, South Korea; [3]Inje University Ilsan Paik Hospital, Inje University College of Medicine, Cardiology, Goyang, South Korea

Background

Graves' disease (GD) is an autoimmune hyperthyroidism and is associated with various psychiatric symptoms, such as irritability, mood changes, and insomnia. However, the epidemiological risk of psychiatric disorders among individuals with GD remains unclear. This study aimed to investigate whether a diagnosis of GD is associated with an increased incidence of various psychiatric disorders at a nationwide level.

Methods

This study was a retrospective cohort study using data from the Korean National Health Insurance Claims database. We identified 20,851 patients with newly diagnosed GD and 46,008 age- and sex-matched controls. Cox proportional hazards models were used to estimate the risk of incident psychiatric disorders in patients with GD compared to controls. We further analyzed the hazard ratios (HRs) by follow-up period (<2 years, ≥ 2 years) since the diagnosis of GD.

Results

Patients with GD exhibited a higher risk of developing psychiatric disorders compared to controls. The risk for incident depression (HR: 1.34, 95% CI: 1.24-1.44), bipolar disorder (HR: 1.57, 95% CI: 1.31-1.89), anxiety disorder (HR: 1.52, 95% CI: 1.43-1.63), and sleep disorder (HR: 1.44, 95% CI: 1.32-1.58) was significantly elevated. This increased risk for various psychiatric disorders, except schizophrenia, persisted even two years after the GD diagnosis. The association between GD and schizophrenia was not statistically significant.

Conclusions

This large-scale, population-based study demonstrates a significant association between GD and an increased risk of developing depression, bipolar disorder, anxiety disorder, and sleep disorder. The findings underscore the importance of long-term monitoring for psychiatric disorders in patients with GD.

Simultaneous occurrence of subacute thyroiditis and graves' disease

Zlata Kovacevic[1,2], Emir Muzurovic[1], Sanja Medenica[1], Dušan Đurić[3] & Slavica Novosel[4]

[1]Clinical Center of Montenegro, Faculty of Medicine, University of Montenegro, Endocrinology, Podgorica, Montenegro; [2]Clinical Center of Montenegro, endocrinology, Podgorica, Montenegro; [3]Clinical Center of Montenegro, Hematology, Podgorica, Montenegro; [4]Clinical Center of Montenegro, Oncology, Podgorica, Montenegro

background

Subacute thyroiditis (SAT) is a transient, post-viral inflammatory disorder of the thyroid gland characterized by transient thyrotoxicosis, neck pain, and eventual recovery of thyroid function. In some cases, hypothyroidism may develop due to glandular damage. The coexistence of SAT and Graves' disease (GD) is extremely rare, with only a few cases reported in the literature.

Patient findings

We report a case of the simultaneous occurrence of SAT and GD with active orbitopathy in a 46-year-old woman. The patient presented with malaise, generalized weakness, nausea, vomiting, neck pain, and orbitopathy symptoms persisting for approximately one month. Physical examination revealed a heart rate of 100 beats per minute, a diffusely enlarged and tender thyroid gland, conjunctival redness, eyelid swelling, and mild exophthalmos. Laboratory findings included: Thyrotropin (TSH) <0.01 mIU/l, Free thyroxine (FT4) $>$ 64.4 pmol/l, Free triiodothyronine (FT3) >30.7 pmol//l, Thyroglobulin 1038.52 ng/mL, Thyiroglobulin antibody 1.1 IU/mL, Thyroperoxidase antibody 19.1 IU/mL, Thyroid-stimulating hormone receptor antibody 19.1 IU/mL, Thyroid-stimulating hormone receptor antibody >40 IU/l, Erythrocyte sedimentation rate 85 mm/h, C-reactive protein 11.9 mg/dl and Interleukin-6 82 pg/mL. Thyroid ultrasound showed an enlarged, heterogeneous gland with hypervascularity. Ophthalmological examination confirmed active Graves' orbitopathy with a Clinical Activity Score (CAS) of 4–5/7 based on EUGOGO criteria. The patient was treated symptomatically with thyrosuppressive therapy and pulse corticosteroids for 12 weeks.

Conclusion

The simultaneous occurrence of SAT and GD, especially with active Graves' orbitopathy, is exceedingly rare. In this case, SAT-induced autoimmune alterations may have triggered the development of GD in a predisposed individual. This case highlights the importance of considering overlapping thyroid pathologies in complex clinical presentations.

JOINT2986

Angioinvasion and multifocality in papillary thyroid cancer: identifying prognostic biomarkers

Angelika Buczyńska[1], Maria Kościuszko[1], Adam Krętowski[1] & Anna Popławska-Kita[1]

[1]Medical University of Bialystok, Bialystok, Poland

Papillary thyroid carcinoma (PTC) represents the most prevalent malignancy of the thyroid gland and is generally associated with a favorable clinical trajectory. Nevertheless, a subset of cases exhibits a markedly more aggressive phenotype, often distinguished by angioinvasion and multifocality, both of which are significant prognosticators of increased locoregional invasion, heightened recurrence rates, and a greater propensity for distant metastases. These pathological features are strongly correlated with adverse clinical outcomes. Consequently, the identification of reliable molecular markers associated with angioinvasion and multifocality is paramount for refining risk stratification models and optimizing therapeutic decision-making, particularly in guiding the implementation of more extensive surgical interventions and early adjuvant radioiodine (RAI) therapy. Among the emerging molecular determinants implicated in tumor progression and neovascularization, thioredoxin (Thx) and tetraspanin 30 (CD63) have garnered significant attention. Thx, a critical modulator of redox homeostasis, has been linked to tumor proliferation, immune evasion, and metastatic dissemination, whereas CD63, a member of the tetraspanin superfamily, plays a pivotal role in tumor-endothelial interactions and vascular invasion. Given the established relationship between oxidative stress and poor prognosis in aggressive PTC variants, Thx and CD63 have emerged as promising biomarkers with potential mechanistic relevance to both angioinvasion and multifocality. This study included 20 patients diagnosed with PTC who exhibited both multifocality and angioinvasion. The reference cohort consisted of 45 patients without evidence of angioinvasion or multifocality, representing a very low-risk group following thyroidectomy. Serum levels of Thx and CD63 were quantified and analyzed for their association with aggressive histopathological features, followed by an assessment of their diagnostic performance using area under the curve (AUC) analysis. Both biomarkers were significantly elevated in patients with angioinvasive and multifocal PTC (Thx: $P < 0.001$, CD63: $P = 0.025$). Logistic regression analysis demonstrated a strong correlation between these biomarkers and aggressive tumor characteristics, supporting their potential role in vascular invasion and multifocality. Furthermore, multivariate regression confirmed their independent predictive value. Notably, a combined biomarker panel incorporating Thx and CD63 further improved the accuracy of risk stratification (AUC $= 0.87$), highlighting its potential clinical applicability in prognostication and personalized therapeutic decision-making for high-risk PTC cases.

C cell hyperplasia and multifocal papillary thyroid microcarcinoma in a patient with remarkably elevated basal and stimulated calcitonin levels

Nata Joksimovic[1], Mirjana Stojkovic[1,2], Bojan Markovic[1], Tamara Janic[1], Jovana Babic[1], Ivana Djurkovic[1], Biljana Nedeljkovic Beleslin[1,2] & Milos Zarkovic[1,2]
[1]Clinic for Endocrinology, Diabetes and Metabolic Diseases, University Clinical Centre of Serbia, Belgrade, Serbia; [2]Faculty of Medicine, University of Belgrade, Belgrade, Serbia

Introduction
Medullary thyroid carcinoma (MTC) is calcitonin (CT) secreting tumor, originating from parafollicular thyroid cells. Serum basal and stimulated CT levels are helpful for early detection of MTC, while it is still a matter of debate whether it can differentiate between MTC, reactive and neoplastic C cell hyperplasia (CCH). According to the growth pattern CCH is subclassified into focal, diffuse and nodular. Neoplastic CCH -which is mostly nodular- precedes familial MTC, and often accompanies sporadic MTC with uncertain preneoplastic significance. Physiological CCH is associated with various conditions. It is not always possible to distinguish between these two based on C cell morphology. CCH is often found near differentiated thyroid lesions, and hypercalcitoninemia is not shown to be indicative of PTC.
Case Presentation
A 56 years old man was admitted to our hospital due to raised basal CT of 58.6 pg/mL, associated with incidentally discovered hypoechoic thyroid nodule measuring 9 mm by ultrasound. He had history of hypertension and hypokalemia, coxarthrosis, basal cell carcinoma and suspicion of polycythemia vera (PV). He was not obese, denied alcohol consumption and taking PPI. Basal CT in our institution was 34 pg/mL, CEA was normal. Calcium stimulation test was performed and the peak CT value of 893 pg/mL was highly suggestive of MTC. Laboratory analysis were consistent with the diagnosis of PV and hypokalemia with no other abnormalities. Thyroid-specific antibodies were negative and he was euthyroid. Thoracal CT scan, done for 6 mm pulmonary nodule on prior X ray scan, showed voluminous body of left adrenal gland. Autonomous cortisol secretion and catecholamine excess were excluded. Testing for primary aldosteronism was postponed and patient underwent total thyroidectomy. Histopathological examination revealed two bilateral microfoci of papillary thyroid carcinoma (1.5 and 0.5 mm), modest nodular hyperplasia, as well as focal, diffuse and nodular C cell hyperplasia (Calcitonin +) in both lobes of the thyroid. Testing for RET germline mutation is ongoing.
Conclusion
There are still no appropriate cut offs for discriminating MTC and neoplastic CCH from reactive forms, while it is sometimes hard to distinguish between reactive, neoplastic CCH and micro-MTC on histological evaluation. Thorough pathological search of whole specimen in cases with high CT levels is of great importance.

JOINT1257

Re-considering wolff chaikoff effect in paediatrics

Rosemary Brungs[1], Simon Chapman[1,2], Ved Bhushan Arya[1,2], Pankaj Agrawal[1] & Ritika R Kapoor[1,2]
[1]King's College Hospital NHS Foundation Trust, Paediatric Endocrinology, London, United Kingdom; [2]King's College London, Paediatrics, London, United Kingdom

The Wolff-Chaikoff effect refers to the temporary inhibition of thyroid peroxidase synthesis of thyroid hormone following excessive iodine exposure. Primary hypothyroidism has been reported in neonates, particularly very low birth-weight, following the use of iodine-based antiseptics and contrast agents. Thyroid function tests (TFTs) are not routinely monitored in this population. This case series describes 3 paediatric patients where severe hypothyroidism was (incidentally) detected following iodine exposure. Although typically transient, hypothyroidism can persist and evidence-based management protocols are lacking.
Cases
Three paediatric patients were referred to the Paediatric Endocrinology service for primary hypothyroidism following iodine exposure (cases summarised in table 1). All had prior TFTs, which were repeated post procedure for unrelated reasons. Cases 1 & 2 had iodine antiseptic exposure during laparotomy and bowel resection, while case 3 was exposed to an iodine-containing contrast agent (Omnipaque 240). Cases 1 & 3, with pre-exposure TSH elevation, were treated with thyroid hormone replacement due to persistent hypothyroidism.

Table 1

	Case 1	Case 2	Case 3
Gestation at birth	32+4	34	23+6
Iodine exposure procedure	Iodine antiseptic	Iodine antiseptic	Iodine contrast
Age at procedure in weeks (CGA)	14 (47/40)	154	13 (36/40)
TPO antibodies	ND	Negative	Negative
NBST for congenital hypothyroidism	NS	NS	NS
TFTs pre-exposure		Autoimmune encepha-	
Rationale for test	Pituitary screen	litis	Pituitary screen
Days prior to exposure	2	114	2
TSH mU/l (0.27-4.2)	10	0.1	15.4
fT4 pmol/l (11-21.2)	16.7	16.9	13.5
TFTs post exposure results (days)		Pituitary screen for	
Rationale for test	Prior TFTs abnormal	hypotension	Prior TFTs abnormal
First abnormal	2	2	3
Peak abnormal	5	5	10
First normal TSH	15	11	26
TFTs post-exposure (peak abnormal)			
TSH mU/l (0.27-4.2)	58.2	37	70.6
fT4 pmol/l (11-21.2)	5.2	5.5	9.7
Management			
Type Day commenced	L3/l4	-	L3/l4
post exposure	7	-	12
Treatment duration (months)	3 +	-	37 +
Current dose (mg/kg)	3	-	5

CGA Corrected gestational age; NBST New-born screening test; NS Not Suspected; ND No data; L3 liothyronine sodium; L4 levothyroxine; + Ongoing.

Conclusion
Wolff-Chaikoff effect should be considered in paediatric cases following high-dose iodine exposure. Although congenital hypothyroidism's neurodevelopmental impact is well-known, the effect of transient hypothyroidism is less understood, raising uncertainty about management. This series highlights two neonatal cases with pre-existing TFT derangements where hypothyroidism persisted beyond the typical period following iodine exposure. This underscores the need for careful iodine use and peri-exposure monitoring particularly in patients where thyroid abnormalities are already detected.

Variable phenotype of resistance to thyroid hormone due to a pathogenic THRA gene variant in a mother and her two daughers

Elise Nauwynck[1], Sofie Ryckx[2], Daniel Klink[2], Sietske Vermaning[2], Marije Meuwissen[3], Lisa Billion[4] & Jean De Schepper[1]
[1]UZ Brussel, Pediatric Endocrinology, Brussels, Belgium; [2]ZAS Paola-kinderziekenhuis, Pediatric Endocrinology, Antwerpen, Belgium; [3]UZ Antwerpen, Center of Medical Genetics, Antwerpen, Belgium; [4]Heilig Hart Ziekenhuis, Endocrinology, Lier, Belgium

Background
Resistance to thyroid hormone (RTH) alpha is caused by pathogenic variants in the thyroid hormone receptor alpha (*THRA*) gene. Diagnosis is frequently delayed due to its rarity, association with near-normal thyroid function tests and variable nature of its clinical presentation. This report describes three family members exhibiting variable clinical and hormonal manifestations of RTH due to a heterozygous missense variant in the *THRA* gene.
Case Presentation
Two sisters, aged 5 and 2.5 years, presented with short stature and developmental delay. The oldest sister was born at 40 weeks of gestation with an average birth weight, length, and head circumference (HC). Between 6 and 20 months, she experienced faltering growth, although weight gain remained normal. She had chronic constipation and delayed language development with dysarthric speech. The younger sister was born at 38 5/7 weeks gestation, with a birth weight of -1.4 SDS, birth length of -1.2 SDS, and HC of -0.7 SDS. Postnatally, she exhibited limited catch-up growth, but a significant BMI increase after the age of 6 months. She had delayed tooth eruption, general hypotonia, and a delayed motor and language development. The mother had a history of learning problems, dysarthric speech, heart rhythm disorder, insulin resistance with hepatic steatosis. Her height was 159 cm and weight 105 kg. Her serum TSH (0.72 U/l) and fT4 (14.8 pmol/l) were normal. Clinical examination revealed in both sisters short stature (-3.8 SDS and -2.5 SDS), relative macrocephaly (HC +0.2 SDS and +0.9 SDS), and increased BMI (+1.5 SDS and +1.3 SDS), global hypotonia and hypermobility and additionally a facial dysmorphism (round face, full

cheeks, and an upturned nose) in the oldest girl. Biochemical testing showed low fT4, elevated fT3, normocytic anemia, and elevated serum copper in the youngest and normocytic anemia, normal serum FT4 but an elevated FT3/FT4 ratio and a normal serum copper in the oldest girl. Whole-exome sequencing revealed a maternally inherited, pathogenic missense variant (c.1207G > A, p.(Glu403Lys)) in the *THRA* gene in both sisters and the mother.

Conclusion

Missense variants in the *THRA* gene can result in a mild RTH phenotype with normal serum FT4 concentrations and remain undiagnosed during childhood. A familial history of delayed neurodevelopment, clinical signs such as relative macrocephaly, delayed language development and global hypotonia, and biological findings such as a persistent normocytic anemia and increased serum copper should raise suspicion for RTH due to *THRA* variants.

Hidden impact of high-dose hook effect: a case report on cross-reactivity of human chorion gonadotropin on thyroid function

Nick Narinx[1,2], Pieter-Jan Martens[3], Toon Van Gorp[4], Jaak Billen[2], Marie Bex[3] & Leen Antonio[1,3]

[1]KU Leuven, Department of Chronic Diseases and Metabolism, Leuven, Belgium; [2]University Hospitals Leuven, Department of Laboratory Medicine, Leuven, Belgium; [3]University Hospitals Leuven, Department of Endocrinology, Leuven, Belgium; [4]University Hospitals Leuven, Department of Gynecologic Oncology, Leuven, Belgium

Introduction

The high-dose hook effect is a well-described yet sometimes overlooked lab artifact when using immunoassays in the clinical laboratory. Extremely high analyte levels could produce false low or undetectable results, with potential impact on clinical decisions and treatment. We present a case of severe hyperthyroidism in which the high-dose hook effect played a central role in the diagnostic work-up.

Case Report

A 36-year-old female was referred for worsening thyrotoxicosis, diagnosed 11 weeks prior after presenting with hematuria and urinary retention, caused by a pelvic mass. Her medical history included endometriosis and a complete molar pregnancy, successfully treated with chemotherapy. At presentation the patient had a sore throat, suggesting viral thyroiditis, due to absence of thyroid-stimulating hormone (TSH) receptor and thyroid peroxidase antibodies and a normal thyroid ultrasound. Thyrotoxicosis persisted despite initial therapy with thyrostatics (methimazole 30mg daily) and subsequent corticosteroids (methylprednisolone 32mg daily, tapered down to 12mg over 4 weeks). One week prior to referral, scintigraphy revealed high technetium uptake, possibly indicating antibody-negative Graves' disease, and methimazole was resumed. Further investigation identified the pelvic mass as malignant gestational trophoblastic disease, characterized by high human chorionic gonadotropin (hCG) levels, which were initially valued at 6.769 IU/l. hCG can however, due to structural similarities and at high doses, cross-activate the TSH receptor, causing hyperthyroidism with high isotope uptake, similar to Graves'. Upon initiating chemotherapy, hCG levels unexpectedly rose to > 1.000.000 IU/l, a paradoxical increase instated due to high-dose hook effect. Dilution of the pre-chemotherapy sample revealed much higher hCG levels (2.883.000 IU/l). As chemotherapy progressed, hCG levels decreased, improving thyroid function and resolving thyrotoxicosis.

Conclusion

This case underscores the impact of hCG on thyroid function and especially its ability to stimulate thyroid activity when circulating in high levels. Although rare, measuring hCG in unexplained thyrotoxicosis cases is advisable. Furthermore, in case of immunoassay diagnostic testing for hCG, the potential impact of high-dose hook effect must be considered *in situ*ations where one would clinically expect extremely elevated levels of hCG, despite being (falsely) low on the lab report. Recognizing this phenomenon is crucial for accurate interpretation of immunoassay results in similar clinical contexts.

Clinical profile and incidence of childhood graves' disease in brunei darussalam

Chen Yun Tok[1], Liana Omar[1] & Chun Yen Wee[1]

[1]Raja Isteri Pengiran Anak Saleha Hospital, Bandar Seri Begawan, Brunei Darussalam

Introduction

Graves' disease (GD) is the most common cause of hyperthyroidism in children, however there is limited data on the epidemiology and clinical profile of GD in Bruneian children. Hence, our study aimed to describe the incidence, clinical characteristics and biochemical profile of GD in the paediatric population aged 12 years and younger in Brunei Darussalam.

Methods

A national population-based retrospective medical record review of children aged 12 years and younger diagnosed with GD was conducted from January 2017 to July 2024 in Brunei Darussalam.

Results

A total of 18 patients diagnosed with GD were included in this study, with female (77.8%) and Malay ethnicity (77.8%) predominance. The mean age at diagnosis was 8 ± 2.64 years. Frequently reported symptoms include eye symptoms (75.0%), neck swelling (66.7%), palpitations (54.5%), weight loss (37.5%), heat intolerance (30%) and diarrhoea (12.5%). Common clinical signs were goitre (88.9%), tachycardia (77.8%), fine tremors (33.3%) and hypertension (22.2%). None of the children presented in a thyroid storm while 11 patients had Graves' orbitopathy. More than half (56.3%) had a first degree relative with thyroid disease and only 1 patient had associated Type 1 Diabetes Mellitus. All of the children had presence of Thyroid Stimulating Hormone (TSH) receptor antibody, with suppressed TSH and elevated free Thyroxine (FT4) levels. There were 17 patients (94.4%) positive for anti-thyroid peroxidase antibody and 15 patients (83.3%) positive for anti-thyroglobulin antibody. All patients were on Carbimazole with no complications but only 5 patients received additional Propanolol treatment to relieve thyrotoxic symptoms. The mean duration to FT4 normalisation from treatment initiation was 80.43 ± 52.05 days with 55.6% of the patients reported a history of non-compliance to treatment. None of the patients underwent radioactive iodine therapy or thyroidectomy. Only one patient achieved remission at the end of the study. The mean annual incidence of GD from 2017 to 2023 in children aged 12 years and younger in Brunei Darussalam was 2.9 per 100,000.

Conclusion

There is a higher incidence of GD reported in Bruneian children compared to western countries which ranges from 0.79 to 2 per 100,000. However, female predominance and major presenting symptoms were similar to other international studies on children with GD. Half the patients had history of non-compliance to treatment which may contributed to the low rate of remission. Further research is necessary to determine possible genetic or environmental factors accounting for the higher incidence of GD in Bruneian children.

JOINT1704

Visual functioning and physical appearance quality of life (QoL) scores of Thyroid Eye Disease (TED) patients seen in a multidisciplinary consultation

Cléa Baron-Joly [1], Grunenwald Solange[1], Céline Dekeister[1], Lucien Cadilhac[1], Philippe Imbert[1] & Philippe Caron[1]

[1]CHU Larrey, Department of Endocrinology and Metabolic diseases, Toulouse, France

Thyroid Eye Disease (TED) is frequent in Graves' disease and rare in Hashimoto' thyroiditis patients, with conjunctival redness, swelling of the eyelids, diplopia and proptosis. TED severely affects the Quality of Life (QoL) of patients, evaluated using visual functioning and physical appearance GO-QoL scores, and higher scores reflecting better QoL. Treatment of TED is based on severity (mild, moderate to severe, sight threatening) and activity (Clinical Activity Score, CAS) of the disease: for active disease (CAS > 3/7) intravenous glucocorticoids are the mainstay treatment, for inactive phase (CAS < 3/7) surgical rehabilitation (orbital decompression, diplopia correction, eyelid procedures) should improve visual function and esthetic. In our endocrine department, TED patients are seen and managed by a multidisciplinary (endocrinologist, ophthalmologist, maxillo-facial surgeon) team. Of the 136 TED patients evaluated with GO-QoL, 110 were women, mean (±SE) age was 53±1 years and 28 patients presented smoking at diagnosis. Graves' disease patients ($n = 130$) were treated with antithyroid drugs, and after recurrence with total thyroidectomy ($n = 71$) or radioiodine therapy ($n = 26$). Other patients had autoimmune thyroiditis treated with levothyroxine or clinical followed up. At the active phase, TED patients were treated with intravenous glucocorticoids according to EUGOGO protocol ($n = 74$), orbital radiotherapy ($n = 25$) or others medical treatments (rituximab $n = 6$, tocilizumab $n = 4$, teprotumumab $n = 1$). At the inactive phase, surgical rehabilitation consisted of orbital decompression ($n = 78$), oculomotor surgery ($n = 22$) and eyelid procedures ($n = 26$). At the first visit (V1), visual functioning (55.2±2.5) and physical appearance (52.4±2.4) GO-QoL scores were

decreased, and negatively associated with the CAS (visual functioning $P = 0.001$, physical appearance $P = 0.03$). Physical appearance score was more decreased in women (49.6 ± 2.6) than in men (64.6 ± 4.8) ($P = 0.01$). Visual functioning and physical appearance scores were more affected in older ($P = 0.01$) and in younger ($P = 0.0001$) patients, respectively. At the last visit (V2) after mean 24 ± 1 months of medical and/or surgical follow-up, CAS (V1 = 2.63 ± 0.13, V2 = 1.19 ± 0.07, $P < 0.001$), proptosis ($P < 0.0001$) and diplopia (V1 $n = 81$, V2 $n = 62$, $P < 0.0001$) decreased, visual functioning (V2 = 77.5 ± 2.1, $P = 0.014$) and physical appearance (V2 = 70.5 ± 2.2, $P < 0.01$) GO-QoL scores increased significantly, with the exception of physical appearance score in smoking patients ($n = 13$). In conclusion, visual functioning and physical appearance GO-QoL scores are decreased in TED patients, and improved after medical and/or surgical treatment in our multidisciplinary consultation. GO-QoL scores should be included in the clinical evaluation of TED patients, as severity and activity of the orbital disease, and should be considered as an indicator of treatment results in order to improve QoL of TED patients.

Iron deficiency and thyroid dysfunction: impact of iron supplementation on tsh levels in women of reproductive age in ajara georgia

Liana Jashi[1], Tamar Peshkova[2], tamar shervashidze[3], Mukhamed Artmeladze[1], Koba Kamashidze[4], Nino Gorgiladze[1] & Ana Kotorashvili[1]
[1]AVICENNA – Batumi Medical University, Batumi, Georgia; [2]Batumi Shota rustaveli State University, Batumi, Georgia; [3]David Agmashenebeli University of Georgia, Tbilisi, Georgia; [4]Univesity of Georgia, T'bilisi, Georgia

Background
Iron deficiency is frequently linked to thyroid dysfunction, particularly subclinical hypothyroidism. This study evaluates the effect of iron supplementation on thyroid-stimulating hormone (TSH) levels over six weeks in women with varying iron levels.
Methods
A retrospective analysis was conducted on 17 women aged 35 to 44 years. Baseline measurements included serum ferritin, TSH, free thyroxine (FT4), and anti-thyroid peroxidase antibodies (AT-TPO). TSH levels were reassessed after six weeks of iron supplementation.
Results
At baseline, lower ferritin levels (<15 ng/mL) correlated with elevated TSH, suggesting subclinical hypothyroidism. After six weeks of iron therapy, TSH levels declined in most patients. Those with ferritin levels between 8–11 ng/mL experienced a significant TSH reduction (e.g., from 7.1 to 3.2 μIU/mL and 8.1 to 3.1 μIU/mL). Patients with ferritin >20 ng/mL showed minimal TSH fluctuations. However, participants with high AT-TPO exhibited persistent or increased TSH despite iron therapy (e.g., AT-TPO 890 IU/mL, TSH increased from 4.7 to 10.2 μIU/mL).
Conclusion
Iron supplementation effectively reduces TSH levels in iron-deficient individuals, underscoring its role in thyroid hormone metabolism. However, in autoimmune thyroiditis (elevated AT-TPO), TSH levels remained high or worsened, indicating a complex interaction. Regular iron status monitoring is crucial in managing thyroid dysfunction, particularly in individuals at risk of hypothyroidism. Further research is needed to explore the underlying mechanisms.

Antithyroid arthritis syndrome in pediatric graves' disease: a rare adverse methimazole reaction

Eloisa Rizzotto[1,2], Francesco d'Aniello[1], Marco Francesco Natale[1], Armando Grossi[1] & Graziamaria Ubertini[1]
[1]Bambino Gesù Children's Hospital, Endocrinology and Diabetology Unit, Rome, Italy; [2]University of Rome 'Tor Vergata', Rome, Italy

Antithyroid arthritis syndrome (AAS) is a rare but significant adverse reaction linked to antithyroid therapy. We present a case of an 8-year-old girl with celiac disease and newly diagnosed Graves' disease who developed arthritis and systemic symptoms 22 days after starting methimazole (5 mg three times a day; 0,46 mg/kg). The patient presented with arthralgia and swelling of both wrists and the third finger of the right hand. She also had difficulty walking due to right hip pain. She reported a one-week history of an urticarial rash on her trunk and upper limbs, along with systemic symptoms, including diarrhea, abdominal pain, vomiting, and loss of appetite. During hospitalization, she developed a fever. Laboratory tests showed a normal complete blood count, elevated inflammatory markers (CRP 2.68 mg/dl, ESR 31 mm/h), and mildly elevated liver enzymes. Physical examination revealed tenderness on flexion-extension of both wrists (worse on the right), swelling of the right wrist, pain on mobilization of the right hand's proximal interphalangeal JOINT, and tenderness with limited range of motion of the hip JOINT. The rheumatologist confirmed arthritis. Microbiological tests were negative. A JOINT ultrasound confirmed bilateral synovitis. Due to persistent fever, whole-body CT and bone scintigraphy were performed and were negative. As thionamide arthritis was suspected, methimazole therapy was reduced to 5 mg twice daily (0,31 mg/kg) and ibuprofen (300 mg three times daily) was administered for 10 days, followed by a further 10 days as required. The fever resolved on the 10th day of hospitalization and the patient was discharged; after 20 days the patient had no further clinical signs of arthritis and laboratory tests were completely normalized. The patient subsequently discontinued thionamide therapy after 6 months from the start, with normal thyroid function tests and negative TSH-receptor antibodies. The patient remained stable with no recurrence of arthritis or systemic symptoms. The close timing between methimazole initiation and the onset of arthritis and systemic symptoms and the exclusion of other causes, strongly suggest AAS. This case highlights the importance of recognizing this rare adverse drug reaction in pediatric patients receiving antithyroid therapy. To the best of our knowledge, this is the first case of AAS in pediatric patients, probably due to an underestimation of this side effect and the rarity of Basedow's disease in pediatrics. Early recognition and reduction of thionamide are crucial for resolution of symptoms, highlighting the need for vigilance when prescribing in pediatric populations.

AI-driven EMR integration in functional thyroid dysfunction: advancing diagnosis and management

CheowPeng Ooi[1], Norlela Sukor[2], Norlaila Mustafa[3], Norasyikin Abdul Wahab[3], Saravanan Muthaiyah[4] & Lokman Hakim[5]
[1]IMU University, Internal Medicine, Kuala Lumpur, Malaysia; [2]Pusat Perubatan Universiti Kebangsaan Malaysia, Endocrine Unit, Department of Medicine, Kuala Lumpur, Malaysia; [3]Pusat Perubatan Universiti Kebangsaan Malaysia, Endocrine Unit, Internal Medicine, Kuala Lumpur, Malaysia; [4]IMU University, School of Business and Technology, Kuala Lumpur, Malaysia; [5]IMU University, Institute of Research, Development and Innovation, Kuala Lumpur, Malaysia

Introduction
Functional thyroid dysfunction (FTD) refers to medical conditions that alter thyroid hormone balance, ranging from mild hypothyroidism to severe hyperthyroidism. The prevalence varies globally, driven by demographic and diagnostic criteria. Hypothyroidism affects 3–7% and hyperthyroidism 0.5–2% of individuals. Subclinical hypothyroidism and hyperthyroidism are more common, accounting for 10% and 5%, respectively. This highlights the need for a patient-centred approach to diagnosis and management. Artificial intelligence (AI), including machine learning (ML), deep learning (DL), natural language processing (NLP), and computer vision (CV), is advancing healthcare by offering tools to analyze intricate datasets. Electronic medical records (EMRs), the cornerstone of modern clinical practice, store both structured data, such as laboratory values and prescription information, and unstructured data, including clinician notes. The integration of AI with EMRs holds the potential to improve the work performance of healthcare professionals, thereby improving patient outcomes.
Objective
We summarised the highlights of AI's advancements in EMR systems for the management of FTD.
Methods
A systematic review of medical literature from January 2015 to December 2024 was conducted targeting studies on AI- EMR integration for FTD care. Priority was given to research detailing AI methodologies applicable to FTD, emphasizing data quality, developmental stage, and EMR applications.
Results
AI and EMR synergy has led to innovative algorithms that enhance diagnostic precision by integrating imaging with EMR data, customizing levothyroxine regimens, and predicting complications and comorbidities through longitudinal data analysis. Despite the potential to improve FTD diagnosis and management, personalise treatment, and enhance patient care pathways, its adoption in clinical

practice remains limited, highlighting a gap between innovation and real-world application.
Discussion
Translating AI-EMR synergy to practical thyroid care faces challenges, including validation issues that limit generalizability, no standardized and fragmented EMR data infrastructure, and the opacity of AI decision-making processes. Emerging solutions like explainable AI (XAI), federated learning, and hybrid human-AI workflows are promising steps forward.
Conclusion
AI-EMR systems have the transformative potential to shift thyroid care from reactive to proactive, precision-driven, patient-centred, safe, and equitable strategies. Addressing the current limitations through data standardization and harmonization, equity-focused safe AI frameworks, and accelerated real-world validation through prospective clinical trials is crucial. Achieving this vision demands urgent collaborative multidisciplinary efforts among professionals and researchers in endocrinology, clinical practice, data science, epidemiology, and policy-making in FTD care. By prioritizing patient-centred design and rigorous validation, AI-EMR integration can evolve from experimental to essential in optimizing FTD care.

Utility of sPD-l1 and sPD-1 as biomarkers for assessing clinical activity in moderate-to-severe thyroid eye disease

Katarzyna Cieplińska[1], Emilia Niedziela[2,3], Agata Kopacz-Rdzanek[1], Anna Słuszniak[1], Magdalena Chrapek[4], Iwona Pałyga[2,3] & Aldona Kowalska[2,3]
[1]Holy Cross Cancer Center, Department of Tumor Markers, Kielce, Poland; [2]Holy Cross Cancer Center, Department of Endocrinology, Kielce, Poland; [3]Jan Kochanowski University, Collegium Medicum, Kielce, Poland; [4]Jan Kochanowski University, Department of Mathematics, Faculty of Natural Sciences, Kielce, Poland

Introduction
T cell activation plays a crucial role in the pathogenesis of thyroid eye disease (TED). The programmed cell death-1 (PD-1)/programmed cell death ligand-1 (PD-L1) pathway, as an immune checkpoint, regulates T cells responses, including to self-antigens. PD-L1, primarily expressed on antigen-presenting cells during inflammation, binds to PD-1 on B and T cells. Soluble forms of these molecules (sPD-L1 and sPD-1) maintain the ability to bind to membrane counterparts. As their interaction affects immune tolerance, regulation of this pathway is an attractive therapeutic option. However, there are limited data on the relevance of sPD-1 and sPD-L1 in TED. The aim of this study is to assess the role of sPD-1 and sPD-L1 in the pathogenesis of TED and to evaluate their potential as biomarkers to improve disease diagnosis and the assessment of disease activity.
Methodology
This is a single-center, prospective study on patients diagnosed with moderate-to-severe TED associated with Graves' disease, who were qualified for intravenous corticosteroid treatment (IVGC) according to the European Group on Graves' Orbitopathy (EUGOGO) guidelines. Blood samples were collected from patients before and 12 weeks after starting IVGC treatment. Levels of thyrotropic hormone (TSH), free thyroxine, free triiodothyronine, thyroid-stimulating immunoglobulin, TSH receptor antibodies, and interleukin-6 were measured using immunoassays. Enzyme-linked immunosorbent assays (ELISA) were used to measure sPD-1 and sPD-L1 concentrations in peripheral blood serum. Disease activity was assessed using the Clinical Activity Score (CAS). Correlations between the studied molecules and CAS before and after IVGC treatment were investigated. Concentrations of sPD-1 and sPD-L1 were compared with those of healthy controls (HC).
Results
Thirty patients were enrolled. Statistical analysis revealed a positive correlation between sPD-L1 and CAS before (rho $= 0.42$, $P = 0.0194$) and after (rho $= 0.37$, $P = 0.0412$) 12 weeks of IVGC treatment. sPD-1 also positively correlated with sPD-L1 before (rho $= 0.93$, $P < 0.0001$) and after (rho $= 0.88$, $P < 0.0001$) treatment. However, no correlation was observed between sPD-1 and CAS. Baseline serum levels of sPD-1 and sPD-L1 did not significantly differ between patients with TED and HC. The decreases in sPD-1 and sPD-L1 levels after 12 weeks of IVGC treatment were not significant.
Conclusion
Our results showed that sPD-L1 levels may serve as a novel immunological marker for disease activity and the monitoring of treatment response in patients with TED. However, sPD-1 may not play a significant role in the pathogenesis of TED.

JOINT2514

Microwave ablation therapy of an intrathyroid parathyroid adenoma

José Vicente Rocha[1], Marta Vaz Lopes[1], Francisca Delfim[2], Carolina Peixe[1], Ana Gomes[1], Leonor Fernandes[2], João Leitão[2] & EMA PAULA RICCA LACERDA NOBRE M CAETANO[1]
[1]ULS Santa Maria, Rheumatology Department, Lisbon, Portugal; [2]ULS Santa Maria, Radiology, Lisbon, Portugal

Introduction
Primary hyperparathyroidism (PHPT) is a disorder of calcium metabolism most frequently due to a parathyroid adenoma. Parathyroidectomy is the treatment of choice. However Microwave Ablation Therapy (MWA) has been applied for the treatment of primary hyperparathyroidism. The incidence of ectopic parathyroid glands ranges from 10% to 22% with an intrathyroid parathyroid adenoma (IPA) being a possible cause of PHPT (0.7-6.7%). The best treatment for IPAs is still in debate.
Case Report
A 47-year-old woman was referred to the endocrinology clinic following an incidental finding of PHPT. The patient had no personal history of bone fractures or nephrolithiasis. Biochemical analysis demonstrated elevated serum calcium (11.9 mg/dl), low serum phosphate (2 mg/dl), and elevated parathyroid hormone (PTH) levels (199 pg/mL). A [99mTc]Tc-MIBI scintigraphy scan showed slight persistent uptake in the inferior third of the left thyroid lobe and neck ultrasound identified a mixed predominantly solid and slightly hypoechoic nodule, measuring $2.1 \times 1.8 \times 1.5$ cm (LxT×AP). Fine-needle aspiration biopsy (FNAB) confirmed IPA. MWA of the IPA in the left thyroid lobe was performed with no complications. A 90% nodule volume reduction and a reduction of serum calcium and PTH values at 6 months were obtained, no longer reaching surgical criteria.
Discussion and Conclusion
To our knowledge this is the first reported microwave ablation of an IPA. Literature review identified a total of 5 patients that had IPAs treated with radiofrequency ablation. MWA ablation may be a viable alternative to surgery in the treatment of IPAs.

A multimodal large language model as an end-to-end classifier of thyroid nodule malignancy risk: practical or potential?

Gerald Sng[1,2], Yi Xiang[3], Daniel Lim[1], Joshua Tung[1], Jen Hong Tan[1] & Chiaw Ling Chng[2]
[1]Singapore General Hospital, Department of Endocrinology, Singapore, Singapore; [2]Singapore General Hospital, Data Science and Artificial Intelligence Laboratory, Singapore, Singapore; [3]National University of Singapore, Institute of Systems Science, Singapore, Singapore

Introduction
Thyroid nodules are a prevalent problem in the general population. To date, commercial applications of artificial intelligence (AI) solutions for nodule risk classification have used traditional machine-learning models. Large Language Models (LLMs), especially those equipped for multimodal tasks combining text and image data, have shown promise in various applications, including medical diagnostics. Importantly, they can potentially offer flexibility for application in different imaging classification tasks. This study investigates the effectiveness of a multimodal vision-language model in the ultrasound-based risk stratification of thyroid nodules using the ACR TI-RADS risk stratification system, exploring the model's accuracy, consistency, and the influence of prompt engineering.
Methods
We utilized Microsoft's open-source LLaVA model and its instruction-tuned model LLaVA-Med, to assess 192 thyroid nodules from ultrasound cine-clip images with ACR TI-RADS descriptors. The study involved analyzing the output of the model and the effect of the use of basic and modified prompts, and images with and without radiologist-annotated regions of interest. The analysis measured the accuracy of the LLM outputs against manual assessments, and the consistency of outputs.
Results
Out of 4,608 responses, 83.3% were deemed valid, with prompt engineering improving frequency of valid responses. The LLaVA-Med model demonstrated higher accuracy in classifying individual TI-RADS components including composition (42.1% vs 20.3%, $P < 0.001$) and echogenicity (57.3% vs 49.9%, $P = 0.004$) compared to the base model, but overall TI-RADS classification

accuracy remained low for both models (31.9% vs 38.9%, $P = 0.004$). The use of labelled images improved accuracy in classifying nodule margins (58.2% vs 53.0%, $P = 0.040$). Prompt engineering improved the consistency of the overall TI-RADS classification (52.1% vs 26.6%, $P < 0.001$), but its effect on accuracy varied across different components.
Conclusion
The study explores the use of open-source, multimodal LLMs as a resource-efficient method of end-to-end thyroid nodule risk stratification, including commonly-employed methods of performance optimization. However, the mixed results highlight the challenges in achieving clinically meaningful performance in their current form. The results suggest that while instruction-tuning and prompt engineering can enhance model output, the inherent technical limitations in image interpretation and model stochasticity restrict their clinical utility. Future developments should build on these findings to explore efficient prompting techniques to improve their accuracy and consistency in clinical applications.

Thyroid artery embolization for compressive goiter in high surgical risk patients

Karla Mariaca Riveros[1], Federico Vazquez San Miguel[2], Jaume Sampere Moragues[3], Diego Ignacio Tovar Felice[1], Anna Oliva Ortiz[1] & Jordi Lluís Reverter[1]
[1]Hospital Universitari Germans Trias i Pujol, Badalona, Badalona, Spain; [2]Hospital Universitari Germans Trias i Pujol, Badalona, Endocrinology and nutrition, Badalona, Spain; [3]Hospital Universitari Germans Trias i Pujol, Badalona, Spain

Introduction
Endothoracic goiter can lead to mediastinal invasion and compression of vital structures: trachea, esophagus, and large vessels. Surgery is the first line treatment, yet in some cases may require sternotomy, increasing significantly morbidity and mortality. In elderly frail patients or those with severe comorbidities, surgery may be contraindicated due to high surgical risk. In such cases thyroid artery embolization (TAE) is presented as a safe and effective alternative.
Material and Methods
Since 2022, 15 patients (81.1% women, 80(71-91)) with symptomatic endothoracic goiter, not candidates for surgery due to high surgical risk underwent palliative TAE. Dysphagia was reported in 54.5%, dyspnea in 27.3% and both symptoms in 18.2%. Regardless of thyroid function, 33.3% of patients had previous hyperthyroidism. Deviation of the vascular bundle, esophagus and trachea was reported in 36.4% of the patients and 63.6% had tracheal stenosis. Initial calculated volume was 131 ± 114 ml. During follow-up, all patients were assessed clinically, analytically, and radiologically.
Results
Median follow-up of was 10.5 ± 5 months. Total volume significantly decreased over time, reducing from an initial 131 ± 114 ml to 56 ± 111 ml at 3 months and 72 ± 85 ml at 12 months of follow-up. A progressive reduction was evident, with a 45% decrease from the initial volume at 3 months and a 59% reduction at 12 months. No patient showed a significative increase during follow up. All patients reported improvement of obstructive symptoms. Among patients who reported dysphagia or weight loss, follow-up showed an average weight gain of 3.5 ± 3.7 kg. Transient hyperthyroidism was reported in 81% with a median duration of 30 days but was not clinically significant. The peak mean FT4 level was 2.8 mg/dl (DS 1.6-3.9). Eventually, all patients with normal thyroid function normalized their values during follow-up. Among patients with pre-existing hyperthyroidism, hyperfunction was controlled in 3 out of 5 cases and no patient developed new onset hypothyroidism. Two major complications were recorded, possibly associated with the procedure (stroke with ad integrum recovery, bronchospasm).
Conclusion
In our series of patients, thyroid artery embolization (TAE) in symptomatic endothoracic goiter is an effective and safe procedure in patients who are not candidates for surgery, being a minimally invasive procedure with rapid recovery.

A case of autonomous hot thyroid nodule

Behiye Sarıkaya Özdemir[1], Şenay Savaş Erdeve[1], Erdal Kurnaz[1], Melikşah Keskin[1], Keziban Aslı Bala[1], Nazlı Altun Yoloğlu[2], Saffet Öztürk[3], Ömer Bayır[4] & Yasemin Dere Günal[3]
[1]Ankara Etlik City Hospital, Pediatric Endocrinology Clinic, Ankara, Türkiye; [2]Ankara Etlik City Hospital, Pediatric Surgery Clinic, Ankara, Türkiye; [3]Ankara Etlik City Hospital, Pediatric Endocrinology Clinic, Ankara, Türkiye; [4]Ankara Etlik City Hospital, Ear, Nose and Throat Surgery Clinic, Ankara, Türkiye

Introduction
In adults, thyroid autonomous adenomas causing hyperthyroidism are relatively common and are mostly due to mutations that increase the structural activity of the thyroid-stimulating hormone receptor (TSHR). However, in children with hyperthyroidism, autonomous adenomas are exceptional, and reports on their clinical and molecular characteristics are scarce. In this report, a case of an autonomous hot thyroid nodule is presented, and its management is shared. **Case Report:**A 14-year-and-9-month-old female patient presented with swelling in the neck. It was learned that the patient had complaints of hair loss for the last 3–4 months but no complaints of palpitations, weight loss, or hand tremors. Her personal and family history revealed that she was born at term via cesarean section with a birth weight of 3040 g. On physical examination, her height was 177.2 cm (2.71 SDS), weight was 86 kg (3.59 SDS), body mass index (BMI) was 27.3 kg/m^2 (2 SDS), blood pressure was 110/70 mmHg, and pulse was 88 bpm.A 3x3 cm palpable mass was detected in the left thyroid lobe. Pubertal development was at Tanner stage 5, and other systemic examinations were normal. Thyroid function tests showed **free T4 (sT4): 1.84 ng/dl (0.98-1.63)**, **free T3 (sT3): 7.15 ng/l (2.56-5)**, and **thyroid-stimulating hormone (TSH): <0.005 mIU/l (0.51-4.3)**. Anti-thyroid peroxidase antibody, anti-thyroglobulin antibody, and TSH receptor antibody were negative. **Thyroid ultrasonography (USG):** Right lobe: 50x19x14 mm (6.65 mL) Left lobe: 50x25x32 mm (20 mL) **Total volume: 9.6 SDS**.A well-defined, approximately **35x30x24 mm** semisolid nodule with cystic components, a hypoechoic halo, and internal vascularity detected by color Doppler ultrasonography was observed, almost completely covering the left lobe. **Thyroid scintigraphy** showed a hyperactive nodular area in the left lobe (Figure 1). The patient was started on **propranolol and low-dose methimazole**. Based on clinical, laboratory, and imaging findings, the patient was diagnosed with an **autonomously functioning hot nodule**. To rule out malignancy, a **fine-needle aspiration biopsy (FNAB)** was performed, and the nodule was reported as **benign**. The patient was referred to pediatric surgery, and after achieving a euthyroid state, **left lobectomy** was performed. The lobectomy pathology report indicated **nodular hyperplasia**. Postoperatively, all treatments were discontinued.A **TSHR gene analysis** was planned to investigate the etiology.
Conclusion
In cases of hot nodules causing hyperthyroidism, surgical removal is recommended after achieving a euthyroid state with antithyroid treatment. Studies have reported that hot nodules in children have a **higher malignancy risk**, with **2-18% of these nodules being malignant**. In this report, the management of a case with a hot thyroid nodule was discussed.

Evaluation of the effects of antithyroid drug therapy on body mass index in children and adolescents with graves' disease

Aslıhan Araslı Yılmaz[1], Behiye Sarıkaya Özdemir[1], Melikşah Keskin[1], Erdal Kurnaz[1,2], Keziban Aslı Bala[1] & Şenay Savaş Erdeve[1]
[1]Ankara Etlik City Hospital, Pediatric Endocrinology Clinic, Ankara, Türkiye; [2]Ankara Etlik City Hospital, Pediatric Endocrinology Clinic, Ankara, Türkiye

Introduction
Graves' Disease (GD) is the most common cause of primary hyperthyroidism in children and adolescents and is associated with weight loss before treatment. During treatment, weight gain is frequently observed. This study aims to evaluate weight fluctuations in newly diagnosed GD patients receiving pharmacological treatment.
Materials and Methods
The records of 27 newly diagnosed GD patients who started pharmacological treatment (methimazole) between October 2022 and January 2024 were retrospectively reviewed. Patients who had started treatment before their first endocrinology visit, had thyroid malignancies, or had incomplete records were

excluded from the study. Patients with a body mass index (BMI) percentile of 85-95 at diagnosis were classified as overweight, while those above the 95th percentile were classified as obese. The patients were divided into two groups: those who were overweight/obese and those who were not. The groups were compared in terms of age, gender, puberty status, BMI at diagnosis, BMI standard deviation score (SDS) at diagnosis, BMI and BMI-SDS at 6 and 12 months, thyroid function tests, TSH receptor-blocking antibody levels (TRAB), thyroid volume, follow-up duration, duration of antithyroid drug use, and initial methimazole dose. Changes in BMI over the first year were expressed as Δ BMI-SDS (0-12).

Results

The median age of the patients was 14.11 years, 74.1% were female, and only one patient was prepubertal. A family history of thyroid disease was present in 66.7% of the patients. The most common presenting symptoms were palpitations (33.3%), weight loss (25.9%), and hand tremors (14.8%). Among patients with a history of weight loss, 71% were in the normal weight group. There were no significant differences between the groups in terms of age, thyroid function tests, thyroid volume, thyroid volume SDS, follow-up duration, initial methimazole dose, or duration of antithyroid drug use ($P > 0.05$). The increase in BMI and BMI-SDS at 6 and 12 months after diagnosis was significantly greater in the non-obese and non-overweight groups. Δ BMI-SDS (0-12) was correlated with weight, BMI, BMI-SDS, ST3-ST4, and TRAB levels at diagnosis.

Conclusion and Discussion

Our study highlights the importance of weight management in the treatment of GD alongside the regulation of thyroid function. Weight management should be a focal point for all patients receiving antithyroid drugs to minimize the development of obesity and mitigate the harmful effects of weight gain. Particularly, obese and overweight patients who are at high risk for metabolic syndrome and cardiovascular complications should be monitored more closely.

Evaluation of ultrasonographic and clinicopathological features of gallium-68 DOTA-TATE uptake in the thyroid gland

Beril Turan Erdogan[1], Fatma Dilek Dellal Kahramanca[1], Gulsum Karahmetli[1], Şeyda Türkölmez[2], Fazlı Erdogan[3], cevdet aydin[4], Oya Topaloglu[4], Reyhan Ersoy[4] & Bekir Cakir[4]

[1]Ankara Bilkent City Hospital, Department of Endocrinology and Metabolism, Ankara, Türkiye; [2]Ankara Yildirim Beyazit University Faculty of Medicine, Department of Nuclear Medicine, Ankara, Türkiye; [3]Ankara Yildirim Beyazit University Faculty of Medicine, Department of Pathology, Ankara, Türkiye; [4]Ankara Yildirim Beyazit University Faculty of Medicine, Department of Endocrinology and Metabolism, Ankara, Türkiye

Background

Gallium-68 DOTA-TATE PET/CT is a widely utilized imaging modality for neuroendocrine tumors (NETs) due to its sensitivity for somatostatin receptors (SSTRs). However, incidental uptake in the thyroid is increasingly noted, raising questions about its clinical significance. This study analyzes ultrasonographic and clinicopathological features of patients with thyroid Ga-68 DOTA-TATE uptake.

Methods

This retrospective study included 39 patients who underwent Ga-68 DOTA-TATE PET/CT imaging from April 2019 to November 2023, exhibiting thyroid uptake categorized as focal, diffuse, or heterogeneous. Ultrasonographic evaluations, fine-needle aspiration biopsies (FNAB), and laboratory tests, including thyroid function and autoimmune markers, were reviewed. Statistical analyses assessed relationships between uptake patterns, SUVmax, and clinical parameters.

Results

Focal uptake was noted in 59% of patients, diffuse in 17.9%, and heterogeneous in 23.1%. Focal Ga-68 DOTA-TATE uptake in the thyroid gland remains a potential indicator of malignancy. Although no cases of carcinoma were confirmed in this cohort, the observed focal uptake emphasizes the importance of vigilant follow-up and thorough diagnostic evaluations such as ultrasonography and FNAB. FNAB was performed on 82% of patients with suspicious nodules; 33.3% yielded non-diagnostic Results Diffuse uptake correlated with benign conditions like Hashimoto's thyroiditis. The mean SUVmax was 7.35 ± 3.08.

Ultrasonographic Findings

87.2% of patients had nodular or multinodular goiter. Of these, 20.5% showed chronic thyroiditis. Mixed nodule structure predominated (68.6%), and 48.6% exhibited isoechoic patterns. FNAB results were benign in 46.7% and atypia of undetermined significance (AUS) in 17.8%, with one case identified as follicular neoplasm.

Discussion

Focal Ga-68 DOTA-TATE uptake in the thyroid may signify malignancy risk, underscoring the need for systematic evaluation. Diffuse uptake aligns more commonly with benign thyroid diseases, particularly autoimmune conditions. An inverse relationship between SUVmax and BMI hints at metabolic and inflammatory influences on SSTR expression. High non-diagnostic FNAB rates indicate challenges in conclusive diagnoses, warranting further studies.

Table: Ga-68 DOTA-TATE Thyroid Uptake Analysis.

Parameter	Value
Focal uptake	59%
Diffuse uptake	17.9%
Heterogeneous uptake	23.1%
SUVmax	7.35 ± 3.08
Non-diagnostic final FNAB results	33.3%
Nodular/multinodular goiter	87.2%
Chronic thyroiditis (isolated)	10.3%
Isoechoic nodule patterns	48.6%
Mixed nodule structures	68.6%

Conclusion

Focal Ga-68 DOTA-TATE uptake is a potential marker of malignancy, while diffuse uptake often suggests benign pathology. Comprehensive diagnostic approaches, including ultrasonography and FNAB, are critical for incidental thyroid findings on Ga-68 DOTA-TATE PET/CT imaging. Further research on SUVmax correlations with metabolic factors is needed to refine patient management strategies.

JOINT1703

Lymph node ratio predicts persistence/recurrence in medullary thyroid cancer

Esra Canavar[1], Sinem Başak Tan Öksüz[1], Rıfat Emral[1] & Sevim Güllü[1]

[1]Ankara University Faculty of Medicine, Department of Endocrinology and Metabolism, Ankara, Türkiye

Introduction

The lymph node ratio (LNR) is defined as the number of metastatic lymph nodes or divided by the number of resected lymph nodes. LNR has been suggested as a predictive factor in various cancer types; however, the data regarding medullary thyroid cancer (MTC) is limited. The aim of the study is to evaluate LNR as a risk factor for persistence/recurrence in patients with MTC.

Methods

Medical records of 52 patients treated for MTC in a single tertiary center between 2001 and 2023 were retrospectively reviewed. Persistent and recurrent diseases were defined as those detected within the first 12 months of diagnosis or during subsequent follow-up periods, respectively. To identify risk factors influencing persistence/recurrence, univariable and multivariable Cox proportional hazard models were used.

Results

Persistent and recurrent disease was identified in eight and seventeen patients, respectively. The median follow-up period was 86.5 months (IQR:30.75 - 165). The characteristics of patients with a persistence/recurrence and remission status are outlined in Table 1. In univariable analysis, lymphovascular invasion, postoperative serum calcitonin and carcinoembryonic antigen (CEA) levels, and LNR were significant ($p < 0.05$) predictors of persistence/recurrence. In multivariable analysis persistent/recurrent disease was independently associated with the LNR value and was accurately predicted by a cut-off value of 0.22 (area under the curve = 0.97; sensitivity 90%, specificity 91%).

Table 1: The characteristics of patients with a persistence/recurrence and remission status.

Parameter	Persistence/Recurrence ($n = 25$)	Remission ($n = 27$)	*P* value
Age, y (mean ± SD)	42 ± 13	50 ± 17	0.053
Gender, female *n.* (%)	11 (44)	19 (70.4)	0.054
RET positivity *n.* (%)	6 (24)	10 (37)	0.663
Tumor size (mm), mean ± SD	2.6 ± 1.5	2 ± 1.4	0.074
Multifocal tumor, *n.* (%)	6 (24)	8 (29.6)	0.647
Lymphovascular invasion, *n.* (%)	12 (48)	3 (11.1)	0.003
Extracapsular invasion, *n.* (%)	5 (20)	1 (3.7)	0.94
Metastatic lymph node, n (median, IQR)	6 (2.5 -13)	0 (0 - 3)	<0.001
Lymph node ratio, n (median, IQR)	0.36 (0.25 - 0.64)	0 (0 - 0.14)	<0.001
Postoperative calcitonin, pg/mL (median, IQR)	216 (29.5 - 497)	3.8 (0.6 - 9.4)	<0.001
Postoperative carcinoembryonic antigen, ng/mL (median, IQR)	3.8 (1.9 - 16.1)	2.1 (1.3 - 4.3)	0.029

Conclusion
LNR can potentially predict persistence/recurrence as a quantitative evaluation tool for lymph node metastasis in patients with MTC.

Clinicopathological evaluation of advanced thyroid cancer

Deniz Türküm Atikcan Şimşek[1], Ozlem Turhan Iyidir[1], Mustafa Senturk[1], Aslı Nar[1] & Neslihan Bascil Tutuncu[1]
[1]Baskent University, Ankara, Türkiye

Introduction
Advanced thyroid cancer is a rare disease with heterogeneous clinical and pathological characteristics. There is insufficient knowledge regarding this condition. The aim of our study is to investigate the clinicopathological features of advanced-stage thyroid cancer cases at our center.
Method
This retrospective, single-center study identified patients with advanced-stage thyroid cancer through medical records and electronic hospital systems. Demographic data, comorbidities, preoperative ultrasonographic findings, pathological results, treatments, and follow-up information were recorded. Clinicopathological evaluation was performed using descriptive statistics.
Results
A total of 16 patients were included in the study. The mean age of the patients was 61 (±17). 56.3% of the patients were female. Preoperative ultrasonographic examination was available for 8 patients. The average largest nodule diameter was 5 (±3) mm. Hyperechogenicity was found in 12.5%, cystic areas in 25%, hypoechoic halo in 12.5%, and calcifications in 37.5% of the patients, while 12.5% had a well-defined border. 37.5% underwent total thyroidectomy only, while remaining had total thyroidectomy combined with neck dissection. Papillary thyroid carcinoma(PTK) was diagnosed in 9 (56.3%) cases, medullary carcinoma in 2 cases, while anaplastic thyroid carcinoma(ATC)+papillary microcarcinoma, ATC+PTK, follicular carcinoma+papillary microcarcinoma, follicular carcinoma, and Hurthle cell carcinoma were each identified in 1 case. The average tumor size was 37 mm (± 23). Among pathological high-risk features, lymphovascular invasion was present in 61.5% and extrathyroidal extension in 63.6%. A papillary carcinoma case exhibited Tall-cell variant, perineural invasion, and BRAFV600E mutation. Distant organ metastasis was present in 5 patients, with lung and bone being the most common. According to the ATA risk score, 12.5% of patients were classified as low, 50.0% as intermediate, and 37.5% as high risk. 75.0% (12 patients) received radioactive iodine (RAI) therapy. The patients who received RAI had a total average dose of 278 mCi (±220). Residual tissue was observed in 4 (30.8%) patients on post-surgical 131-Iodine whole-body scan (WBS). DOTA-PET was used in medullary cancer post-surgery, and FDG-PET in other types, with 3 (18.8%) patients showing uptake. 2 cases showed WBS positive and PET negative results, while 3 cases showed PET positive and WBS negative. 25% of the patients received targeted therapy. The median overall survival after surgery was 97 months.
Conclusion
In our country, advanced thyroid cancer most commonly presents with a papillary histology. 131-Iodine whole-body scan and PET scans may yield false-negative results during follow-up. Targeted therapy is an important treatment option. The survival rate and response to treatment are favorable.

JOINT2647

Thyrotoxic hypokalaemia periodic paralysis-

Umer Qazi[1]
[1]Norfolk and Norwich University hospital, Diabetes and Endocrinology, Norwich, United Kingdom

Background
Thyrotoxic hypokalemic periodic paralysis (THPP) is a rare complication of hyperthyroidism, primarily reported in Asian populations, affecting about 2% of hyperthyroid individuals. In non-Asian populations, its incidence is considerably lower, estimated at 0.1% to 0.2%. THPP typically presents with muscle weakness and hypokalemia, predominantly in males aged 20 to 40.
Case Presentation
We describe a 38-year-old male patient of African descent who presented to the Accident and Emergency department with progressive weakness of the lower limbs, which subsequently affected his upper limbs. Neurological examination revealed diminished reflexes in the lower limbs, while reflexes in the upper limbs were normal, with no other neurological deficits observed.
Investigations
Laboratory tests indicated a critically low serum potassium level of 2.2 mmol/l, signifying severe hypokalaemia. Thyroid function tests showed undetectable thyroid-stimulating hormone (TSH), elevated free thyroxine (T4) at 30 pmol/l, and undetectable high free triiodothyronine (T3). Diffuse thyroid enlargement was noted, prompting further evaluation for autoimmune thyroiditis, Grave's thyrotoxicosis with thyroid antibody testing pending.
Discussion
This case illustrates the atypical presentation of THPP in a non-Asian patient and emphasizes the importance of timely diagnosis. The combination of acute muscle weakness and specific laboratory findings should prompt clinicians to consider THPP in hyperthyroid patients, particularly in the context of acute paralysis. This is a condition which can cause significant morbidity with muscular paralysis and respiratory arrest secondary to respiratory muscular paralysis. Our patient did not have any reparatory issue on admission. He was treated with antithyroid medications, betablockers and Potassium.
Conclusion
The rarity of THPP in non-Asian populations highlights the need for increased awareness among healthcare providers. Prompt recognition and management of this condition can improve patient outcomes and prevent complications related to hypokalemia and thyroid dysfunction. Further research is needed to enhance understanding and treatment strategies for THPP across diverse populations.

Radioiodine therapy in pediatric graves' disease: insights from a single-center study of 35 cases

Anna Rothenfusser[1], Ana Chiesa[1,2], Andrea Arcari[1,2] & Patricia Papendieck[1,2]
[1]CEDIE, Centro de Investigaciones Endocrinologicas "Dr. Cesar Bergada", Hospital de Ninos Ricardo Gutierrez, Buenos Aires, Argentina, Division Endocrinologia, Buenos Aires, Argentina; [2]Hospital de Ninos, Ricardo Gutierrez, Division de Endocrinologia, Buenos Aires, Argentina

Introduction
Pediatric Graves' disease (PGD) is marked by hyperthyroidism and antithyroid receptor antibodies (TRAb). Low antithyroid treatment (ATD) remission rates, side effects and poor adherence require alternative therapies.
Objective
To describe outcome to radioiodine treatment (RAI) in PGD at a single institution.
Material and Methods
Retrospective analysis of 35 PGD patients followed between 2006 and 2024 treated with RAI. Data describing outcome and adverse effects were retrieved. RAI dose was calculated by formula using thyroid size by palpation or sonography and 24 hours-RAI uptake (100-250 μ Ci).
Results
Hispanic PGD cohort, 89% females, with a median age of 12 years (y) (range (r): 2–17.2). Thyroid disease was familial in 46% and 14% had other autoimmune conditions. Two had Down syndrome; one had osteogenesis imperfecta. All but one received ATD in a titration regimen and one with hepatic failure (autoimmune hepatitis) underwent RAI as first option. Median ATD duration was 1.3 y (r: 0.1–6.5). RAI was indicated for 14 patients (40%) due to exacerbation under low-dose ATD, 11 (31%) for adverse reactions, 9 (26%) for poor compliance, and 1 (3%) for flare-up after ATD discontinuation. Median age at RAI indication was 14.6 years (r: 5.8–19.9y). Median goitre size at indication was 45g (r: 30–80g). Median RAI dose was 10 mCi (r: 5–20) for the first dose, equivalent to 0.26 mCi/g thyroid tissue (r:0.25-0.36). Three patients required a second dose for persistent hyperthyroidism at a mean of 0.7years (SD ± 0.14); the mean total dose of RAI was 0,4 mCi/g thyroid tissue (SD ± 0,14). All achieved hypothyroidism (elevated TSH, normal/low thyroid hormones) at a median time of 0.3 years (r: 0.1–5.1) after RAI. Beta-blockers were used in all but two patients for transient tachycardia post-RAI and 8 patients needed ATD for transient hyperthyroidism (23%). No adverse events were reported. Median post-RAI follow-up was 3 y (r: 0.4–11.6).
Conclusions
RAI was an effective and save definitive treatment for PGD patients who presented adverse reactions or failure to ATD with high chances to achieve hypothyroidism in 3-4 months.

[1]Institute of Endocrinology, Department of Molecular Endocrinology, Prague, Czech Republic; [2]2nd Faculty of Medicine, Charles University in Prague and Motol University Hospital, Department of Ear, Nose, and Throat, Prague, Czech Republic; [3]2nd Faculty of Medicine, Charles University in Prague and Motol University Hospital, Department of Nuclear Medicine and Endocrinology, Prague, Czech Republic; [4]2nd Faculty of Medicine, Charles University in Prague and Motol University Hospital, Department of Pathology and Molecular Medicine, Prague, Czech Republic; [5]3rd Faculty of Medicine, Charles University in Prague and University Hospital Kralovske Vinohrady, Department of Otorhinolaryngology, Prague, Czech Republic; [6]3rd Faculty of Medicine, Charles University in Prague and University Hospital Kralovske Vinohrady, Department of Pathology, Prague, Czech Republic; [7]3rd Faculty of Medicine and Military University Hospital, Department of Otorhinolaryngology and Maxillofacial Surgery, Prague, Czech Republic; [8]3rd Faculty of Medicine and Military University Hospital, Department of Pathology, Prague, Czech Republic

Objectives
Molecular testing of thyroid tumors is increasingly being used for the diagnosis and prognosis of patients. In some cases, however, the same gene variant may be present in both benign and malignant thyroid tissue. There is 42.1% positive predictive value for our preoperative samples of thyroid nodules with pathogenic variants in *HRAS* gene, respectively 52.6% with low-risk neoplasms included. Currently, it is not possible to distinguish whether a preoperative fine-needle aspiration biopsy sample with *HRAS* pathogenic variant is a benign or malignant nodule.
Methods
The study consisted of 12 *HRAS* Q61R-positive papillary thyroid carcinomas (PTCs), six *HRAS* Q61R-positive benign nodules and 12 healthy thyroid tissues (with no genetic alteration). The miRNA libraries for NGS sequencing were prepared from RNA containing miRNA extracted from fresh-frozen thyroid tissues using the QIAseq miRNA Library Kit (Qiagen). Bioinformatics used the miRge3.0 tool and the DESeq2 package in R to compare cohorts of *HRAS* benign vs. malignant tumors.
Results
The focus was on comparing follicle-derived nodules with the detected *HRAS* Q61R pathogenic variant. The expression of miRNAs in benign and malignant thyroid tumors was compared. A total of 11 miRNAs were found to be significantly increased in expression in *HRAS*-positive PTCs in comparison to benign thyroid nodules (e.g. hsa-miR-31-5p, hsa-miR-34c-5p, hsa-miR-149-5p), whereas expression of four miRNAs were found to be significantly downregulated in the *HRAS*-positive PTCs (hsa-miR-371a-5p, hsa-miR-372-3p, hsa-miR-373-3p, hsa-miR-548ap/548j-5p).
Conclusion
In summary, the combination of genetic testing at the DNA level and measurement of epigenetic changes in miRNA expression could be a useful tool for better diagnostics and prognostics. Especially, miRNA expression analysis could be useful in the preoperative diagnosis of nodules in which *HRAS* variants are found and malignancy is not sufficiently clear. Verification with another method and analysis of a larger sample set will follow. *Supported by AZV NU21-01-00448 and MH CZ RVO 00023761.*.

JOINT501

Laboratory patterns differ between patients with severe vs milder forms of congenital hypothyroidism

Lisa Corker[1] & Iris Gutmark-Little[1]
[1]Cincinnati Children's Hospital Medical Center, Cincinnati, United States

Purpose
Congenital hypothyroidism (CH) is the most common congenital endocrine disorder, affecting approximately 1 in 2-4,000 newborns. Consensus guidelines recommend rapid normalization of thyroid-stimulating hormone (TSH) levels for neurodevelopmental protection. However, this approach may lead to elevated free thyroxine (fT4) levels, raising concerns about overtreatment despite persistently elevated TSH. This lab pattern has been anecdotally noted to be more frequent and persistent in individuals with severe CH, complicating levothyroxine dose titration. We hypothesize that individuals with severe CH require higher levels of fT4 to appropriately suppress TSH compared to those with mild CH, suggesting a potential difference in the thyroid feedback loop between the two groups. A better understanding of this relationship could inform treatment strategies and improve outcomes.
Methods
Patients were included based on a diagnosis code for congenital hypothyroidism, with associated TSH and fT4 (measured by direct dialysis) values extracted. Patients were divided into two subgroups: (1) severe CH (at least one documented TSH >60); (2) mild CH (all TSH values <25). A Student's t-test with a fixed effects model was used to compare the levels of fT4 relative to TSH between these two groups.
Results
A significant difference in fT4 relative to TSH was observed between the groups, indicating that for the same TSH value, individuals with severe CH have significantly higher fT4 levels compared to those with mild CH ($t_{(2910)} = -3.69$, $P = 0.0002$). Additionally, a significant difference was found in the rate at which fT4 changes in response to TSH (i.e., the slope of the relationship between fT4 and TSH) for the two groups ($t_{(2910)} = -9.21$, $P < 0.0001$). Individuals with severe CH exhibited a more attenuated response in TSH to changes in fT4, indicating reduced sensitivity to fT4 compared to those with mild CH.
Conclusions
This study demonstrates that individuals with severe CH require higher free T4 to achieve similar TSH suppression, suggesting differences in thyroid regulatory mechanisms. Additionally, the rate at which fT4 changes with respect to TSH differs significantly between the two groups; individuals with severe CH are less responsive to shifts in fT4, further highlighting the variability in thyroid feedback. These findings underscore the importance of understanding variability in thyroid function in order to optimize clinical management. Tailored treatment strategies could be developed based on the severity of CH, ultimately improving long-term outcomes for affected individuals.

JOINT1332

Thyroid nodule of tuberculous origin: a delayed and unexpected diagnosis - a case report

Adele Bodieu Chetcha[1], Cecilia Fomenky Njiandock[2], Mesmin Dehayem[1], Jean Claude Mbanya[1], Eugene Sobngwi[1], Jean Taguebue[3] & Martine Etoa[1]
[1]Central Hospital of Yaounde, Yaounde, Cameroon; [2]Bamenda Regional Hospital, University of Bamenda, Bamenda, Cameroon; [3]Mother and Child Center/Chantal Biya Foundation, YAOUNDE, Cameroon

Introduction
According to the WHO, Cameroon located in Central Africa, is ranked among the 30 high Tuberculosis (TB) burden countries in the world. Moreover, in 2021, more than 22000 people were infected with TB and 5.1% of cases concerned children aged 0-14 years. Thyroid nodules in children are rare and usually benign. However, in regions where TB is endemic, rarer causes like tuberculous thyroiditis must be considered. This condition accounting for less than 1% of extra-pulmonary TB can present as a painless nodule and may be misdiagnosed as a benign abscess or adenoma. Diagnosis is often delayed requiring a combination of clinical, laboratory and histopathological findings. This case highlights the diagnostic challenges and the need for a high index of suspicion for TB in pediatric thyroid nodules.
Case Presentation
A 4-year old boy was referred for endocrine consultation before planned thyroid surgery due to a year long history of neck pain and an enlarged thyroid. Initial tests showed no signs of thyroid dysfunction but a high WBC count (26.675×10^9/l with neutrophil predominance of 84%). Thyroid abscess was suspected and was treated with antibiotics. Symptoms recurred with pain and after stronger antibiotics failed, fistulization occurred prompting surgery. FNA was refused and a CT scan revealed a nodule. Further questioning revealed the mother had chronic cough, weight loss and night sweats raising concern for tuberculosis. Her sputum was positive for *Mycobacterium tuberculosis* leading to suspicion of tuberculous thyroiditis in the child. A chest X-ray and gastric lavage for *Mycobacterium tuberculosis* testing were both negative in the child. Empirical antiTB treatment was initiated with favorable response and the child remained well at 1year follow-up.
Discussion
Symptoms including enlarging nodules, neck pain, fever, weight loss may mimic other thyroid conditions delaying diagnosis. In this case, failure to respond to antibiotics, symptom recurrence, mother's history and a positive sputum culture for *Mycobacterium tuberculosis* prompted consideration of tuberculous thyroiditis.

Fistulization further suggested TB. In paediatric patients a thorough history including exposure to adults with active pulmonary TB is crucial for making the diagnosis and in many cases, surgical intervention is not required once the underlying TB infection is effectively treated. The diagnosis requires high clinical suspicion and while FNA is the gold standard.
Conclusion
Tuberculous thyroiditis, though rare, should be considered in pediatric thyroid nodules especially in TB endemic areas. This case highlights the importance of a detailed patient history including potential TB exposure.

Neuropsychological and growth outcomes in congenital hypothyroidism: impact of timing of thyroid hormone supplementation

Bhanu Nalluri[1], Akhila Aitha[2], Neelaveni K[3] & Rakesh Sahay[3]
[1]Osmania General Hospital, Department of Endocrinology, Hyderabad, India; [2]Nirmal Neuro Hospital, Nirmal, India; [3]Osmania General Hospital, Departement of Endocrinology, Hyderabad, India

Background
Congenital hypothyroidism (CH) is a leading cause of preventable intellectual disability and growth failure. Early detection and initiation of thyroxine therapy are crucial for optimizing neuropsychological and physical outcomes. The timing of treatment initiation and initial thyroxine (T4) levels significantly influence neurocognitive and physical development in children with CH[1,2].
Methods
A cross-sectional study was conducted at a tertiary care hospital from January 2017 to December 2018. Sixty children aged >3 years with CH were evaluated using the Binet Kamat Scale for Intelligence to assess IQ[3] and the Child Behavior Checklist (CBCL) to measure behavioral outcomes, including Withdrawal, Anxiety/Depression, Social Problems, Thought Problems (WAST), Attention Deficit, and Aggression (ADA). Height SDS (standard deviation score) was recorded. Statistical analysis was performed using SPSS v20, with a p-value $<$ 0.05 considered statistically significant.
Results
Females constituted 53% of the study cohort, while males (47%) exhibited more severe biochemical abnormalities (lower T4 and higher TSH levels at diagnosis). IQ was significantly influenced by the timing of therapy initiation: children treated within the first month of life had a mean IQ of 79, compared to 59.5 for those treated between 1 and 6 months, and 61.1 for those treated after 6 months. Severe CH, indicated by lower T4 levels, was associated with greater IQ deficits. Height SDS and behavioral scores (WAST and ADA) showed no significant correlation with therapy timing, though elevated WAST and ADA scores were observed.
Conclusions
Early initiation of thyroid hormone therapy (<1 month) significantly improves IQ in children with CH. However, the timing of therapy does not appear to impact height SDS or behavioral outcomes. These findings highlight the importance of neonatal screening and timely intervention to improve neurocognitive outcomes[1,3].

Prevalence of hypothyroidism in children with nephrotic syndrome: a systematic review and meta-analysis

Sarthak Das[1], Soumi Kundu[1], Saroj Tripathy[1], Archana Malik[1], Saurabh Varshney[1] & Pratima Gupta[1]
[1]All India Institute of Medical Sciences, Deoghar, Deoghar, India

Background
Nephrotic syndrome (NS) is among the most prevalent renal glomerular diseases in children. Nephrotic syndrome (NS) is characterized by glomerular damage, leading to a significant loss of proteins in the urine specifically thyroxine-binding globulin (TBG) and thyroxine. Subclinical or overt hypothyroidism in this population may exacerbate the disease burden, complicate management, and impair long-term outcomes.
Objective
The objectives are: (1) to determine the pooled prevalence of hypothyroidism in children with nephrotic syndrome(2) Pooled prevalence of Clinical and Subclinical hypothyroidism in nephrotic syndrome and (3) to explore factors influence.
Methodology
This systematic review was registered in the PROSPERO database under the identifier CRD42023455277. The authors conducted searches across databases, including EMBASE, Web of Science, Cochrane CENTRAL, Scopus, and CINAHL and Google. The keyword search was limited to titles and abstracts, employing Boolean operators such as "OR" and "AND" where applicable. The search terms included Nephrotic syndrome, prevalence, hypothyroidism, children, thyroid stimulating hormone, and thyroxine.
Statisical analysis
The Quantitative Analysis includes Pooled prevalence with 95% Confidence Interval (CI) was calculated using OpenMeta software. The Heterogeneity were assessed using I^2 statistic test. Publication Bias was evaluated using funnel plots and Egger's test.
Result
26 studies were included in the review, with 19 studies included in the meta-analysis. The pooled prevalence rate is 41.45% with 95% confidence interval 32.896 to 50.287. The funnel plot does not show significant asymmetry, suggesting there is no substantial publication bias or small-study effects. The pooled prevalence of hypothyroidism among steroid resistant nephrotic syndrome(SRNS) is 38.140. The pooled prevalence of clinical hypothyroidism is 15.31% with a 95% confidence interval of 8.463 to 23.736. The pooled prevalence of sub clinical hypothyroidism was 25.96% with a 95% confidence interval of19.456 to 33.044. The standardized mean difference of TSH value between nephrotic syndrome with and without hypothyroidism group is 1.86 suggesting a moderate to large effect size. And $I^2 = 93.62\%$ indicates substantial variability among the studies and $P < 0.01$ suggests that the heterogeneity is statistically significant. In Regression analysis there is a weak downward trend between age and proportion.
Conclusion
This systematic review and meta-analysis highlights the significant burden of hypothyroidism in patients with nephrotic syndrome, with notable differences across subtypes and severity of thyroid dysfunction. Elevated TSH levels in nephrotic syndrome compared to control groups further underscore the impact of this renal condition on thyroid physiology. These findings call for routine thyroid function monitoring, particularly in high-risk subgroups like SRNS.

OCT and OCTA evaluation of neurovascular structures in pediatric graves' disease without active ophthalmopathy

Tuğçe Dursun Yılmazşamlı[1], Semra Tiryaki Demir[1], Ahmet Uçar[2], Aydilek Dağdeviren Çakır[2], Ecrin Çakır[1] & Sümeyra Keleş Yeşiltaş[1]
[1]University of Health Sciences, Şişli Hamidiye Etfal Health Practices and Research Centre, Ophthalmology, Istanbul, Türkiye; [2]University of Health Sciences, Şişli Hamidiye Etfal Health Practices and Research Centre, Pediatric Endocrinology and Diabetes, Istanbul, Türkiye

Purpose
To investigate retinal and choroidal neurovascular structures in children and adolescents with Graves' disease(GD) but without active ophthalmopathy using OCT and OCTA.
Patients and Methods
In this prospective, cross-sectional, observational study, GD patients without ophthalmopathy were assessed between September 2022 and 2023. Retinal and choroidal neurovascular structures in the macula and peripapillary retinal neurovasculature were quantitatively analyzed using OCT and OCTA and compared to age-matched healthy controls. Statistical significance was set at a *P*-value less than 0.05.
Results
Thirty patients with Graves' disease (mean age 14.3 $\pm$ 2.3 years) and 30 age-matched healthy controls. The GD group exhibited significantly lower vessel densities in both the superficial and deep capillary plexuses of the fovea ($P < 0.05$

for all) and significantly larger foveal avascular zone diameters compared to controls ($P = 0.002$). Central foveal thickness (CFT) and choroidal thickness (CT) were significantly lower in the GD group ($P = 0.036$ and $p \leq 0.01$ for all; respectively). No significant differences were found between groups regarding choriocapillaris flow area, choroidal vascularity index, peripapillary retinal nerve fiber layer thickness (pRNFLT), or radial peripapillary capillary plexus vessel densities ($p > 0.05$ for all).
Conclusion
In pediatric GD patients without active ophthalmopathy, macular microvascular changes appear to precede optic disc changes. Alterations in CFT and CT may occur before changes in pRNFLT. Reduced macular vessel density, thinner CFT, and decreased CT may be important biomarkers for monitoring pediatric GD patients.

Thyroid lymphoma presented as a painful cervical mass: a diagnostic dilemma

Maria Chrysoulaki[1], Vasiliki Daraki[2], Fotis Mermigas[2], Panagiotis-Nikolaos Tsakalomatis[2], Evangelia Pissadaki[2], Angelos Matheakakis[3], Maria Psyllaki[3], Aikaterini Andrianaki[4], Paraskevi Floroskoufi[5], Helen Papadaki[3,6] & Paraskevi Xekouki[2]
[1]Medical School, University of Crete, Heraklion, Crete, Greece; [2]University of Crete, School of Medicine, Endocrinology, Diabetes and Metabolism Clinic, Heraklion, Greece; [3]University Hospital of Heraklion, Department of Hematology, Heraklion, Crete, Greece; [4]Irodotos Medical Center, Heraklion, Crete, Greece; [5]Venizelio General Hospital, Department of Endocrinology, Heraklion, Crete, Greece; [6]University of Crete, Heraklion, Crete, Greece

Introduction
Thyroid lymphoma, though rare, can be classified as either primary thyroid lymphoma (PTC) or secondary thyroid lymphoma. PTC typically arises from the thyroid gland and may later spread to the lymph nodes and other organs, often in individuals with preexisting Hashimoto's thyroiditis. Secondary thyroid lymphoma, on the other hand, originates in lymph nodes or other organs, with subsequent involvement of the thyroid. We present a case of thyroid lymphoma that posed significant diagnostic challenges.
Case Presentation
A 49-year-old male presented with a rapidly enlarging left thyroid mass, dysphagia, and hoarseness. Laboratory tests and thyroid antibodies were normal. Ultrasound revealed a 7x5x6 cm mass with increased blood flow and reactive cervical lymph nodes, raising concern for either thyroid cancer or subacute thyroiditis. A fine needle aspiration (FNA) was inconclusive due to hemorrhage, and a lymph node biopsy suggested reactive lymphadenopathy. Due to the diagnostic uncertainty and significant patient discomfort, a total thyroidectomy was performed, revealing diffuse large B-cell lymphoma (DLBCL). Postoperatively, the patient developed permanent hypoparathyroidism requiring ongoing calcium supplementation. Staging with PET/CT and CT scans revealed involvement of regional lymph nodes, stomach, and pancreas, but not the bone marrow. The lymphoma was classified as stage IV (Lugano) with an International Prognostic Index (IPI) score of 3 and Central Nervous System-IPI score of 3.
Treatment and Outcome
The patient was treated with six cycles of Polatuzumab, Rituximab, Cyclophosphamide, and Methylprednisolone (Pola-R-CHP) every 21 days. Post-treatment PET/CT scans showed no evidence of disease.
Conclusion
Although rare, thyroid lymphoma should be considered in the differential diagnosis of rapidly enlarging thyroid masses. Early recognition and timely intervention are critical for improving prognosis, particularly in cases without a prior history of Hashimoto's thyroiditis. This case highlights the diagnostic complexity of thyroid lymphoma and the importance of comprehensive staging and tailored treatment.

The impact of levothyroxine treatment on T lymphocyte gene expression in Hashimoto's thyroiditis

Péter Kaltenecker[1,2], Viktória Temesfői[1,2], Anna Nörenberg[1,2], Tímea Serény-Litvai[1,2], József Kun[2,3], Péter Urbán[2,3], Attila Gyenesei[2,3] & Emese Mezősi[2,4]
[1]Szentágothai Research Centre, University of Pécs, Pécs, Hungary; [2]National Laboratory on Human Reproduction, University of Pécs, Pécs, Hungary; [3]Hungarian Centre for Genomics and Bioinformatics, Szentágothai Research Centre, University of Pécs, Pécs, Hungary; [4]First Department of Medicine, Clinical Center, Medical School, University of Pécs, Pécs, Hungary

Hashimoto's thyroiditis (HT) is a common autoimmune disorder of the thyroid gland. The appearance of anti-thyroid antibodies (ATAs) against thyroid peroxidase (TPO) and thyroglobulin (TG), and the infiltration of the thyroid gland by mononuclear cells are characteristic markers of HT. Although it is not obligatory, HT can lead to hypothyroidism at an advanced stage of the disease (indicated by the increased level of thyroid-stimulating hormone, TSH), against which levothyroxine replacement therapy has been proved to be beneficial. Since HT is considered to be a T cell-mediated disease primarily, we designed a transcriptome analysis experiment (RNA-seq) to examine gene expression alterations in T lymphocytes in HT and the effect of levothyroxine treatment. Peripheral blood samples were collected from ATA+ hypothyroid HT patients (TPO and TG antibody positivity, abnormal elevated TSH level) before and after levothyroxine replacement therapy and from the age-matched healthy controls. T cells were isolated from the blood by magnetic separation and then total RNA was purified. Whole transcriptome sequencing (bulk) was performed using the Illumina NovaSeq 6000 platform, with QuantSeq 3' mRNA library preparation and single-end sequencing with 75bp read length, in order to screen for differentially expressed (DE) genes. Following the identification of DE genes, we carried out a functional enrichment analysis to investigate which biological processes and signaling pathways are affected by these changes. Our screen revealed that the vast majority of DE genes were up-regulated in T lymphocytes in HT, approximately 85 percent, compared to the healthy control. Interestingly, the contrary could be observed in the same disease patients after levothyroxine treatment, where 262 of the 308 DE genes were down-regulated in T cells. Between the control and the treated groups, DE genes were present in a notably lesser amount. By examining changes between the healthy vs Hashimoto and the Hashimoto vs treated comparisons, we found 181 identical genes that exhibited a clear switch in their expression pattern from an up-regulated to a down-regulated state. Several upstream regulators, such as interleukin-1A (IL-1A), IL-1B and tumor necrosis factor (TNF) were activated in HT and became inhibited following levothyroxine addition. In addition, we observed a similar activation-inactivation phenomenon in many signaling pathways (IL-4 and IL-13, IL-6, IL-17, TNF, nuclear factor-kappa B and transforming growth factor beta signaling), suggesting that altered immunological processes characteristic of the disease may be reversed by applying levothyroxine therapy.

Diagnostic performance of ultrasound-based risk stratification systems for follicular thyroid carcinoma

Boram Kim[1], Myoung-Kyoung Kim[2], Ji-Hyun Yoo[1], Da-Eun Leem[1], Sun-Wook Kim[1], Jae-Hoon Chung[1], Jung Hee Shin[2], Soo Yeon Hahn[2] & Tae-Hyuk Kim[1]
[1]Samsung Medical Center, Endocrinology, Seoul, South Korea; [2]Samsung Medical Center, Radiology, Seoul, South Korea

Background
In the evaluation of thyroid nodules, an ultrasound-based risk stratification system(RSS) is useful for identifying patients with a high likelihood of thyroid cancer and determining the need for fine needle aspiration biopsy (FNAB). However, these systems are primarily focused on diagnosing papillary thyroid carcinoma(PTC), the most common type of thyroid cancer. A new ultrasound-based RSS for the diagnosis of follicular thyroid carcinoma(FTC) has recently been proposed, known as F-TI-RADS. In this study, we compared this new system with existing systems for diagnosing thyroid cancer.
Methods
This retrospective study included 385 patients: 194 diagnosed with follicular thyroid carcinoma(FTC) and 191 diagnosed with follicular adenoma(FA), who underwent surgery for follicular neoplasms at Samsung Medical Center. Preoperative ultrasound examinations of the FA and FTC groups were reviewed and evaluated using K-TI-RADS, ACR TI-RADS, and F-TI-RADS. Additionally, we compared the usefulness of each system in screening for high-risk FTC by incorporating TERT promoter mutation information based on the WHO classification.
Result
The factors required to evaluate each RSS on preoperative ultrasound for all patients were compared between the FTC and FA groups. There were no

significant differences in size ($P = 0.685$), composition ($P = 0.054$), or orientation ($P = 0.349$) between the two groups. However, significant differences were observed in the presence or absence of lobulation ($P < 0.001$), echogenicity ($P < 0.001$), margin characteristics ($P = 0.003$), calcification ($P < 0.001$), and trabecular formation ($P < 0.001$). When comparing the area under the curve (AUC) values of the TI-RADS systems, the AUC values were 0.635 for K-TI-RADS, 0.646 for ACR TI-RADS, and 0.658 for F-TI-RADS, with no statistically significant differences between these RSSs. Next, the patients were divided into two groups to evaluate the usefulness of the systems in screening for high-risk FTC. Group 1 included patients with FA, minimally invasive (MI) FTC, or encapsulated angioinvasive (EA) FTC with wild-type (WT) TERT, comprising 292 patients. Group 2 included patients with encapsulated angioinvasive (EA) FTC with TERT mutation or widely invasive (WI) FTC, comprising 28 patients. The AUC values for the RSSs in each group were as follows: 0.751 for K-TI-RADS, 0.783 for ACR TI-RADS, and 0.846 for F-TI-RADS.

Conclusion

When comparing the FTC and FA groups, the performance of the three RSSs was similar, However, F-TI-RADS demonstrated superior performance compared to the other RSSs in detecting high-risk FTCs.

JOINT2886

The coexistence of graves' disease and thymic hyperplasia: a case report

Megi Lekbello[1], Marjeta Kermaj[1] & Dorina Ylli[2]
[1]University Hospital "Mother Tereza", Endocrinology, Tirana, Albania; [2]University of Medicine, Tirana, Albania

Introduction

Thymic hyperplasia is frequently observed in patients with Graves' disease. The association between Graves' disease and thymic hyperplasia was first described in 1912, and up to 38% of patients with Graves' disease exhibit histological thymic abnormalities. However, the exact mechanism underlying the development of thymic hyperplasia in these patients remains unclear.

Case Report

We present a case report of a 23-year-old female medical student who presented to the outpatient clinic with complaints of palpitations, tachycardia, tremors, anxiety, and a weight loss of 5 kg over three months. She had no eye symptoms. On physical examination, her vital signs were as follows: blood pressure of 110/70 mmHg, heart rate of 130 beats per minute, respiratory rate of 18 breaths per minute, weight of 49 kg, and height of 160 cm (body mass index of 19.14 kg/m^2). Laboratory tests revealed a suppressed TSH level of $<$0.005 μIU/mL (reference range: 0.27–4.2 μIU/mL), elevated free T4 of 4.47 ng/dl (reference range: 0.93–1.7 ng/dl), thyroperoxidase antibody of 397 IU/mL (reference range: 0–34 IU/mL), and thyrotropin-binding inhibitory immunoglobulins of 37 IU/l (reference range: 0–115 IU/l). The anti-TSH receptor antibody was also elevated at 20.5 IU/l (reference range: $<$1.22 IU/l). A thyroid ultrasound showed a heterogeneous and hypoechoic thyroid gland with increased vascularization. Additionally, a heterogeneous structure was observed below the left thyroid lobe. A CT scan of the neck and chest confirmed the presence of a hyperplastic thymus measuring 27 mm, located below the thyroid gland. Following a neurological evaluation, electromyography (EMG) was performed, and myasthenia gravis was ruled out. The patient was started on Methimazole 5 mg twice daily (2-0-2). After six weeks, she returned for follow-up with no symptoms of hyperthyroidism and a weight gain of 1.5 kg. Laboratory results showed TSH at 0.45 μIU/mL and free T4 at 1.1 ng/dl. A follow-up neck CT scan was scheduled for three months later.

Conclusion

Thymic hyperplasia is a common finding in patients with Graves' disease. It is important to consider this diagnosis in patients with thyrotoxicosis and a mediastinal mass to prevent unnecessary interventions that could lead to harm. The prognosis is excellent, and treatment with methimazole has been reported to contribute to thymic mass reduction.

Case report: misleading increase in thyroid-stimulating hormone receptor antibodies during pregnancy in graves disease: value of functional, cell-based assays

Astrid Claessens[1], Katrien Clotman[2], Evy De Witte[1] & Jan Monballyu[1]
[1]KU Leuven, Leuven, Belgium; [2]UA, Antwerpen, Belgium

Introduction

Graves disease is an autoimmune endocrinopathy caused by thyroid-stimulating hormone receptor antibodies (TSH-R-Ab). Classically, this results in hyperthyroidism as thyroid-stimulating autoantibodies (TSAb) predominate. Nevertheless, these antibodies can also exhibit blocking (TBAb) or neutral activity. The net activity determines the clinical presentation and approach. Specific consideration and monitoring in pregnancy is suggested due to TSH-R-Ab's ability to migrate transplacentally and affect the fetus' thyroid gland. However, conventional thyroid receptor binding tests detect all types of thyroid hormone receptor antibodies without differentiating between them.

Case Report

A 36-year-old woman with Graves disease without ocular involvement had been treated for 56-months with propylthiouracil (PTU) and L-T4 replacement therapy. The TSH-R-Ab titer, measured with two different chemiluminescence immunoassays during follow-up, remained persistently elevated. During the first trimester of her twin pregnancy, we noticed a tendency toward hypothyroidism and a remarkably increased TSH-R-Ab titer, considering the difference in immunoassay. The quantity and functional properties of TSH-R-Ab can be altered during gestation due to immunological changes. In classical Graves caused by TSAb, these antibodies will usually decrease during pregnancy. However, the antibodies may become blocking or neutral in rare cases. In consideration of hypothyroidism, the dose of PTU was reduced incrementally. L-T4 was associated given the low-to-normal T4-titer, where we aimed for higher values to sustain neurological fetal development. Ultimately, PTU was stopped and L-T4 progressively increased according to thyroid testing every two weeks. Development of both fetuses was normal with no evidence of hypo- or hyperthyroidism. Considering the appearance of TBAb would imply a risk of hypothyroidism in the fetuses, a functional TSH-receptor-antibody assay was requested to differentiate between all types of TSH-R-Ab. This test was performed by Prof. Dr. Kahaly at Johannes Gutenberg University. We concluded that neither thyroid-stimulating nor thyroid-blocking antibodies were present. Therefore, the measured antibodies were neutral. A favorable result given that these antibodies do not affect thyroid function, neither the mother's nor the fetuses'.

Conclusion

When observing a switch between hyper- and hypothyroidism in patients with known Graves disease, it is important to screen for functional TSH-R-Abs. This distinction is important during pregnancy because inadequate maternal L-T4 levels could irreversibly impair fetal neurological development. Other indications for screening could include Graves disease with positive TSH-R-Abs persisting after 18 months of block-replacement therapy, before pregnancy when there is a known history of auto-immune thyroid disease addressed with thyroidectomy or radioactive iodine and autoimmune thyroid dysfunction secondary to immune reconstitution therapy.

Thyroid dysfunction in children with nephropathic cystinosis- single center experience

Noha Aly[1], Asmaa Abd Elhakeem[2], Mona Abdullatif[3], Fatma M Atia[1], Rasha Helmy[1], Rasha Selim Mahmoud[1] & Neveen A Soliman[1]
[1]Children's Hospital, Faculty of Medicine, Cairo University, Endocrine, Diabetes and Metabolism Pediatric Unit (DEMPU), Cairo, Egypt; [2]Children's Hospital, Faculty of Medicine, Cairo University, Cairo, Egypt; [3]Kasralainy Hospital, Faculty of Medicine, Cairo University, Chemical and clinical pathology, Cairo, Egypt

Background

Nephropathic cystinosis is a rare genetic disease characterized by defective lysosomal cystine transport due to mutation in CTNS gene and consequently increased lysosomal cystine. Hypothyrodism is a known complication of nephropathic cystinosis but the pathogenesis of thyroid dysfunction appears to be more complex than merely thyroid gland destruction by lysosomal cysteine.

Methodology

Prospectively fifteen patients with infantile nephropathic cystinosis had been recruited from Cystinosis Clinic, Children's Hospital, Cairo University. Laboratory assessment of thyroid profile included free T4, free T3, TSH, thyroid autoantibodies (anti-thyroglobulin antibodies, anti-peroxidase antibodies) were measured. Thyroid ultrasound was done to all patients by a single operator.

Results

The age of recruited patients ranged from 5 to 10 years with mean age of 7.87 + 1.7 years. The frequency of hypothyroidism among our cohort was 8 patients (53.3%). Most of the affected patients were males 75% with their mean age was 8.25 + 1.17 years old. However, the age of diagnosis of thyroid dysfunction ranged from 1 to 8 years old with mean age of 4.87 + 2.08 years. All patients

(100%) had negative anti- peroxidase antibodies (TPO). As regards anti thyroglobulin antibodies (TG), 2 patients among euthyroid group had positive titer and only 1 patient among hypothyroid group had borderline titer. All patients with hypothyroidism were on thyroid hormone replacement therapy in the form of Levothyroxine. The dose of replacement therapy ranged from 50 to 150 (μg/day) with mean dose of 71.8 +34.08(μg/day). Only 5 patients were compliant to treatment and well controlled but the remaining 3 patients were not controlled. Thyroid ultrasound revealed very small thyroid gland for age among both euthyroid and hypothyroid group.
Conclusion
Hypothyroidism is a frequently reported complication among our cohort of patients with nephropathic cystinosis. There is no role of autoantibodies (anti-thyroglobulin, anti-peroxidase) in the pathogenesis of thyroid gland destruction. Patients with nephropathic cystinosis have small volume thyroid gland regardless of their thyroid status.

Risk factors, clinical characteristics, and outcomes of pediatric thyroid cancer: an egyptian single center experience

Yasmine Abdelmeguid[1], Laila Farawila[2] & Shady Fadel[3]
[1]Faculty of Medicine, Alexandria University, Pediatric Endocrinology and Diabetology, Alexandria, Egypt; [2]Faculty of Medicine, Alexandria University, Pediatric Department, Alexandria, Egypt; [3]Faculty of Medicine, Alexandria University, Pediatric Oncology, Alexandria, Egypt

Introduction
Thyroid cancer is rare in childhood and adolescents representing about 0.7% of all malignant tumors in children. The incidence rate of pediatric thyroid cancer has been increasing over the last years. However, in comparison to adults, the pathophysiology, presentation, management, and long-term outcomes in children is different and not fully-known.
Aim of the work
The aim of this study is to describe clinical, laboratory, and radiological characteristics of pediatric thyroid cancer patients in a specialized tertiary-care center in Egypt. In addition, risk factors for thyroid cancer and its recurrence, treatment and outcomes were assessed.
Patients and Methods
This study was a retrospective cohort enrolling 17 children diagnosed with thyroid cancer at Alexandria Pediatric Oncology Center at age <18 years. Informed consent was obtained from parents of included children after approval of Alexandria University Ethical committee. Data was extracted from medical records of patients over a 5-year period. The following data was recorded: demographic characteristics, family history of malignancy or autoimmune thyroid disease and history of radiation exposure. Anthropometric measurements, clinical presentation, laboratory, and radiological findings, pathology results, treatment and outcomes were also reviewed.
Results
The patients' age at diagnosis ranged between 5-17 years (mean 10.41 yrs). Almost 53% were females, while 47% were males. One patient (5.8%) was exposed to neck radiotherapy, 5 patients (29.4%) had family history of autoimmune diseases, while 3 patients (17.6%) had family history of malignancy (other than thyroid cancer). Three patients had Hashimoto's thyroiditis with positive thyroid autoantibodies. All patients presented with neck swelling. At diagnosis, only one patient was short (-3.4 SD) and had severe hypothyroidism (TSH 106 mIU/ml), while 7 patients (41.1%) were obese. Sixteen patients (94.1%) had unilateral affection, with predilection to right side (82.3%). Fifty eight percent had nodal metastases, while 35.29% (6/17) had distant metastases including lungs. Surgery was performed in all patients; categorized into hemithyroidectomy (5.88%), total thyroidectomy (29.4%), and total thyroidectomy with nodal dissection (64.7%). The majority of patients had papillary carcinoma (94%), except one patient had follicular variant of papillary carcinoma. All patients received radioactive iodine therapy. Forty seven percent of patients developed hypoparathyroidism following surgery. As regards outcome, 4 patients (23.5%) had persistent/recurrent thyroid cancer.
Conclusion
Our study describes the outcomes of a cohort of pediatric thyroid cancer patients in a specialized center in Egypt. Children and adolescents are more likely to have more severe stages of disease with higher recurrence rate, compared to adults.

JOINT3016

Spindle epithelial tumor with thymus-like differentiation: A rare thyroid entity

Sam Emmanuel Sabu[1], Jayakrishnan C[1], Dipin K R[2] & Aiswarya Pradeep[3]
[1]Jubilee Mission Medical College & Research Institute, Endocrinology, Thrissur, India; [2]Jubilee Mission Medical College & Research Institute, Surgical Oncology, Thrissur, India; [3]Jubilee Mission Medical College & Research Institute, Pathology, Thrissur, India

Introduction
Spindle epithelial tumor with thymus-like differentiation (SETTLE) is a rare thyroid malignancy with fewer than 50 cases reported worldwide. Typically arising in children and young adults, it is believed to originate from remnants of the branchial pouch or thymic tissue. It is often misdiagnosed as medullary thyroid carcinoma (MTC) or differentiated thyroid malignancies. Despite its indolent growth, SETTLE has a notable propensity for late metastasis, necessitating early recognition and long-term monitoring.
Case Description
A 14-year-old boy presented with a left-sided neck swelling that rapidly increased in size over three weeks. Prior to presentation at our center, an ultrasound and fine-needle aspiration cytology (FNAC) were performed, which showed spindle cells and was reported as MTC. On examination, apart from the neck mass, the child had a marfanoid habitus. There was no significant family history. Based on these findings, we suspected Multiple Endocrine Neoplasia type 2B and proceeded with the estimation of calcitonin, carcinoembryonic antigen (CEA), and plasma fractionated metanephrines, all of which were within the normal range. Since non-secretory MTC is rare, we reviewed slides of the FNAC performed outside and also conducted a fresh FNAC, which was again reported as MTC. Imaging done to stage the tumor did not reveal any evidence of metastasis. We proceeded with a total thyroidectomy with central compartment lymph node dissection. Histopathological examination of the resected specimen showed a biphasic tumor with spindle cells and cystic areas lined by mucinous columnar cells, with no extrathyroidal extension. Immunohistochemistry showed positivity for CK7, CK5/6, vimentin, BCL2, and CD117. Tumor cells were negative for TTF1, calcitonin, and chromogranin. This led to a diagnosis of SETTLE, and the child is under follow-up.
Discussion
SETTLE is a rare thyroid neoplasm that poses a significant diagnostic challenge. Despite its indolent course, SETTLE carries a significant risk of late metastases, especially to the lungs, occurring years after the initial diagnosis. Definitive diagnosis often requires immunohistochemical examination of resected tissue. Complete surgical resection with long-term follow-up is the mainstay of treatment. Given the potential for late recurrence, close follow-up with periodic imaging is essential.

Using TSH-receptor antibody testing to guide antithyroid drug withdrawal reduces the early relapse rate - a population-based study

David Fisher[1,2], Nitzan Sagie[3], Merav Fraenkel[1,2] & Uri Yoel[1,2]
[1]Soroka University Medical Center, Endocrinology department, Beer Sheva, Israel; [2]Soroka University Medical Center, Clinical research center, Beer Sheva, Israel; [3]Ben-Gurion University of the Negev, Faculty of Health Sciences, Beer Sheva, Israel

Background
Cessation of methimazole treatment in Graves' Disease (GD) often leads to relapse. In February 2023, Clalit Healthcare Services (CHS), the largest health maintenance organization in Israel, began to provide thyrotropin receptor antibody (TRAb) testing for patients with GD to help guide when to withdraw methimazole treatment. This nationwide retrospective cohort study evaluated whether using TRAb testing to guide methimazole withdrawal reduces relapse rates compared to clinical judgment alone.
Methods
Using the MDClone platform, we identified CHS-insured patients diagnosed with GD between 01/2013 and 09/2023. The first day of remission was established three months following the last purchase of methimazole if euthyroid or hypothyroid thyroid function test results were documented during this timeframe. Exclusion criteria included prior thyroidectomy or radioactive iodine treatment, pregnancy, and elevated liver transaminases ($\geq$3 times the upper limit of normal), or neutropenia ($\leq 1{,}000 \times 10^3/\mu L$) within six months of methimazole cessation. Patients were grouped into two cohorts; one where TRAb titer was tested and

measured <2.5 UI/l (seronegative) within three months of the last purchase of methimazole ('TRAb assisted cohort'), and one where TRAb was not measured in this time period ('clinical assessment cohort'). Baseline characteristics and the primary outcome - GD early relapse, defined as subsequent thyrotoxicosis during one-year follow-up were compared. A frailty Cox regression assessed the association between TRAb seronegative status immediately prior to methimazole cessation and disease relapse, adjusting for potential confounders.
Results
The study included 3420 clinical episodes; 84 in the TRAb assisted cohort and 3336 in the clinical assessment cohort. Age (median 49 years, $P = 0.47$), gender (75% female, $P = 0.8$) and socioeconomic status (score of 3 when using a five-point scale, $P = 0.46$) were similar in the two cohorts. At the time of GD diagnosis, free triiodothyronine (T3) was above the upper limit of normal in 73% of patients in the TRAb assisted cohort and 66% in the clinical assessment cohort ($P = 0.4$). The proportion of patients with TSH above or within the normal range prior to methimazole cessation was similar (87% in both cohorts, $P > 0.99$). During one-year follow-up, 49/84 (55%) in the TRAb assisted cohort and 2606/3336 (78%) patients in the clinical assessment cohort relapsed ($P = 0.002$). TRAb seronegative status prior to stopping methimazole reduced the risk of relapse by 38% compared to clinical assessment alone (HR 0.62, CI 0.46-0.84, $P = 0.002$).
Conclusion
Seronegative TRAb status reduces the one-year relapse risk by 38% amongst patients presumed to be in remission.

JOINT2591

Trapping-only nodules – are they higher risk for malignancy?

Helena Urbano Ferreira[1], Luísa Torres[1], Juliana Gonçalves[1], Sandra Belo[1] & Paula Soeiro[1]
[1]ULS São João, Porto, Portugal

Introduction
Trapping-only nodules, or "discordant" nodules, are thyroid nodules that exhibit increased uptake of radioiodine and decreased uptake of technetium-99m on thyroid scans. Unlike regular "hot" nodules, which actively synthesize and secrete thyroid hormones, trapping-only nodules simply trap the iodine but there is no organification or increased hormone synthesis, and consequently there is no hyperfunction. It has previously been proposed that this trapping-only phenomenon might be associated with higher risk of malignancy, and thus, these nodules often require careful evaluation.
Aim
Evaluate the risk of malignancy of trapping-only nodules.
Methods
All thyroid scans performed in our center from January 2020 to June 2024 reporting trapping-only nodules were reviewed ($n = 133$). Subsquently, pathology results from all the nodules that underwent fine-needle aspiration cytology and/or surgery were examined ($n = 41$). Characteristics of the nodules on ultrasound were also collected.
Results
Thirty-nine patients with 41 trapping-only nodules were included, 66.7% were female and the mean age was 59.0 ± 12.9 year. Thirty-one (75.6%) had subclinical thyrotoxicosis, and TSH nadir was 0.17 ± 0.13 mU/l. Twenty-five (64.1%) had uni- or multinodular toxic goiter and 8 (20.5%) had Graves' disease. Regarding ultrasound characteristics, the mean size of the nodules was 21.2 ± 9.9 mm, and most were classified as EU-TIRADS 3 (56.1%) and EU-TIRADS 4 (36.6%). Of the 33 nodules that underwent fine-needle aspiration cytology, 26 (78.8%) were benign, 5 (15.2%) were nondiagnostic, and 2 (6.0%) were suspicious for malignancy, according to the Bethesda system. Of the 14 patients that underwent surgery, 6 (75.0%) had pathology findings consistent with thyroid follicular nodular disease, 1 (12.5%) had a single adenomatous nodule, and 1 (12.5%) had a hyalinizing trabecular tumor, which is a low-risk follicular cell-derived neoplasia. Six nodules had both results from aspiration cytology and surgical histology. Of note, of the two patients with nodules suspicious for malignancy, one had follicular nodular disease and the second had the hyalinizing trabecular tumor.
Conclusion
Trapping-only nodules do not appear to carry an increased risk of malignancy, and their evaluation should be similar to "cold" nonfunctioning nodules. Larger studies are needed to assess the true prevalence of thyroid malignancy among trapping-only nodules.

JOINT2821

From thyroid storm to cardiac recovery: the impact of hyperthyroidism on heart function

Marta Almeida[1], Ricardo Capitão[1], Daniel Duarte[1], Francisca Henriques[1], Ana Quitalo[1] & Maria Cordeiro[1]
[1]Hospital Garcia de Orta, Almada, Portugal

Introduction
Hyperthyroidism is a systemic disorder with significant cardiovascular implications, including arrhythmias and structural heart changes. We report a case of a 27-year-old male with untreated hyperthyroidism presenting with thyroid storm and severe cardiovascular complications.
Case Description
A 27year-old male presented to the emergency room with worsening asthenia, palpitations, myalgia, diarrhea, and fever (39-40°C) over the past week. He was diagnosed with hyperthyroidism in 2019 but had not been taking any medications nor attending follow-up appointments. His clinical history included 25 kg weight loss, episodic palpitations, sweating, anxiety, and extremity tremor since 2019. On admission, he was alert, reactive, with marked exophthalmos and goiter. His blood pressure was 90/73 mmHg, heart rate of 180 bpm, corresponding to atrial fibrillation. Laboratory findings indicated severe hyperthyroidism: TSH <0.01 mUI/l (RV 0.27-4.20), T3 577 ng/dl (RV 80-200), fT4 6.03 ng/dl (RV 0.93-1.70); hepatocellular injury (ALT 167 UI/l, AST 126 UI/l, total bilirubin 1.7 mg/dl), mild systemic inflammation (CRP 3.47 mg/dl) and positive TRABs (17.7 UI/l). A diagnosis of thyroid storm was made (85 points on the Burch-Wartofsky Point Scale), and the patient was admitted to the intensive care unit, where treatment with propylthiouracil, hydrocortisone, potassium iodide, and propranolol was initiated. However, due to worsening hepatic cytolysis, therapy was switched to methimazole. A transthoracic echocardiogram revealed a severely dilated left atrium and severe mitral regurgitation, attributed to annular dilation, posterior leaflet hypomobility, and pseudo prolapse of the anterior leaflet (EROA 0.52 cm^2, regurgitant volume 63 mL). Right ventricular systolic function was impaired, and a mobile hypoechoic mass was noted near the superior vena cava, raising suspicion of thrombus formation. Anticoagulation therapy was initiated, and additional studies were performed to rule out other potential etiologies or complications. No other significant findings were identified. Heart rate control was challenging, necessitating additional digoxin before stabilizing with beta-blockers after euthyroidism was achieved. Follow-up echocardiography showed an improvement in mitral regurgitation severity from severe to mild-moderate.
Discussion
This case underscores the profound effects of hyperthyroidism on cardiovascular function, emphasizing the necessity of early diagnosis and intervention to avert life-threatening complications. The improvement in structural heart changes, such as mitral regurgitation, after achieving euthyroidism highlights the dynamic cardiovascular impact of thyroid dysfunction and reinforces the need for comprehensive endocrine and cardiac management.
Conclusion
Thyroid dysfunction can significantly impact cardiac structure and function. Early recognition and treatment of hyperthyroidism are crucial to prevent cardiovascular deterioration and improve patient outcomes.

Decoding elevated tsh with normal free t4: a comprehensive guide to differentiation, genetic insights, and diagnostic strategies

Ashraf Soliman[1], Nada Alaaraj[1], Abir Ali[1], Noor Hamed[1], Shayma Ahmed[1] & Fawzia Alyafei[1]
[1]Hamad Medical Corporation, Doha, Qatar

Background
Elevated thyroid-stimulating hormone (TSH) levels with normal free T4 can result from a variety of physiological or pathological causes. Differentiating these causes is crucial for effective diagnosis and management. Genetic factors further complicate this landscape, requiring careful evaluation using clinical and laboratory data.
Objective
To summarize key genetic factors, physiological and pathological causes, and diagnostic steps associated with high TSH and normal free T4, based on current studies.
Methods
Data from multiple studies were analyzed to identify genetic contributions, differentiate causes, and outline diagnostic steps. Key findings were summarized into structured tables.

Results

Table 1: Genetic and Differentiation Causes.

Category	Focus	Frequency	Key Studies (n)
Genetic Factors	TSHR, DUOX2, PAX8 mutations	Rare	15 studies (n = 3,150)
	Deiodinase polymorphisms (DIO1, DIO2)	10–15%	8 studies (n = 1,100)
	Thyroglobulin mutations (TG)	Rare	4 studies (n = 700)
Physiological	Transient elevation, lab variability	10–20%	18 studies (n = 3,200)
Pathological	Subclinical hypothyroidism, autoimmune	20–35%	28 studies (n = 3,500)

Table 2: Differentiation of Causes.

Cause Type	Specific Cause	Description
Physiological	Stress, lab variability	Non-pathological causes such as stress or circadian changes in TSH levels.
Pathological	Autoimmune, medications	TSH elevation due to thyroid dysfunction, drug side effects, or pituitary issues.

Table 3: Diagnostic Steps.

Step	Action	Purpose
Autoantibody Testing	Measure anti-TPO and anti-thyroglobulin antibodies	Detect autoimmune thyroid disease
Ultrasound	Evaluate for structural abnormalities	Identify nodules or Hashimoto's thyroiditis
Thyroid Function Tests	Repeat TSH and free T4 levels	Rule out transient changes
Family History & Genetics	Investigate familial patterns and genetic mutations	Uncover hereditary causes
Exclude Secondary Causes	Review medications and iodine exposure	Identify non-thyroidal factors

Conclusion

Elevated TSH with normal free T4 is multifactorial, encompassing physiological, pathological, and genetic components. Differentiation relies on targeted diagnostic steps including antibody testing, imaging, and genetic analysis. A structured approach aids in accurate classification and management.

Ultrasonography and cytology previous results analysis in patients that have undergone thyroid surgery

Laia Capdevila Torrents[1], Marta Carrasco Marín-Blasco[1], Mari Cruz de la Fuente Juárez[2], Maite Santamaría Gómez[2], Alba Dalmau Vila[1], Carolina López Cano[1] & Ferran Rius Riu[1]
[1]Hospital Universitari Arnau de Vilanova de Lleida, Endocrinology and Nutrition, Lleida, Spain; [2]Hospital Universitari Arnau de Vilanova de Lleida, General Surgery, Lleida, Spain

Objectives

To review the final pathological results in thyroid nodular disease surgeries and compare them with the previous ultrasonographic and cytological Results.

Patients and Methods

Among the patients that underwent surgery between January 2019 and June 2024, in our database we had at least one ultrasonography and one valid cytology of 304 nodules. EU-TIRADS classification has been used for ultrasound characteristics and the Bethesda system for cytology results.

Results

Among those 304 nodules, 229 (75.3%) had a non-malignant result and 75 (24.7%) malignant. Eleven out of 135 (8.1%) EU-TIRADS 3 were malignant, 22 out of 92 (23.9%) EU-TIRADS 4 and 40 out of 66 (60.6%) EU-TIRADS 5. None of 17 (0%) Bethesda I were malignant, 6 out of 90 (6.7%) Bethesda II, 11 out of 117 (9.4%) Bethesda III, 4 out of 21 (19%) Bethesda IV, 28 out of 34 (82.4%) Bethesda V and 26 out of 26 (100%) Bethesda VI. Combining the two classifications, it can be highlighted that among Bethesda V-VI nodules, 3 out of 7 (42.9%) EU-TIRADS 3 were malignant, 17 out of 19 (89.5%) EU-TIRADS 4, and 32 out of 32 (100%) EU-TIRADS 5. On the other hand, in Bethesda II-III nodules, 7 out of 111 (6.3%) EU-TIRADS 3 were malignant, 3 out of 63 (4.8%) EU-TIRADS 4, and 7 out of 29 (24.1%) EU-TIRADS 5.

Conclusions

The cytology results are highly reliable in our centre (equal or better than the theoretical in Bethesda I and Bethesda III-VI). The apparent high malignancy percentage among Bethesda II nodules can be explained because the reasons why these nodules undergo surgery may give them a higher malignancy risk than those that do not. The interactions between ultrasound and cytology classifications could be used to better assess the indication for surgical treatment.

Thyroid peroxidase antibodies and their role in predicting outcomes in graves' disease treatment

Klara Gewert[1,2], Geriolda Topi[1,2], Jan Calissendorff[3,4] & Tereza Planck[1,2]
[1]Department of Clinical Sciences, Lund University, Malmö, Sweden; [2]Department of Endocrinology, Skåne University Hospital, Malmö, Sweden; [3]Department of Endocrinology, Karolinska University Hospital, Stockholm, Sweden; [4]Department of Molecular Medicine and Surgery, Karolinska Institutet, Stockholm, Sweden

Introduction

Graveś disease (GD) is the predominant cause of hyperthyroidism. Treatment options include antithyroid drugs (ATD), surgery, and radioactive iodine ablation (RI). After treatment with ATD, both relapse and development of hypothyroidism are common. Although thyroid peroxidase antibodies (anti-TPO) are prevalent in patients with GD, their role in driving relapse or hypothyroidism after treatment in patients with GD remains unclear. This study aimed to determine if patients with anti-TPO at GD diagnosis are more likely to relapse after ATD or RI treatment, and if patients with anti-TPO are at increased risk of developing hypothyroidism post-ATD treatment.

Methods

This was an observational, non-interventional retrospective registry study, which included 712 patients treated for GD at a single center in Sweden during 2002-2018.

Results

After therapy with ATD, there was no difference in relapse rate between patients with (37.0%) or without (38.4%) anti-TPO at GD diagnosis. Age <40 years was a risk factor for relapse after ATD ($P < 0.0001$). Presence of anti-TPO at diagnosis was associated with reduced relapse rate after RI (13.9% vs. 24.6%; $P = 0.049$). Development of hypothyroidism after discontinuation of ATD did not correlate with anti-TPO status at diagnosis (with anti-TPO: 17.3%; without anti-TPO: 20.8%).

Conclusion

Anti-TPO positivity at diagnosis of GD did not affect the relapse rate after ATD treatment but could be associated with a better effect of RI. Anti-TPO did not increase the risk of hypothyroidism post-ATD. Understanding these and other risk factors can facilitate treatment choices and help physicians individualize management and follow-up strategies for patients with GD.

Admission and follow-up characteristics of pediatric and adolescent patients with hyperthyroidism

Ceren Yüceer Pelioğlu[1], Merih Berberoğlu[2], Ayşegül Ceran[2], Elif Özsu[2], Zehra Aycan[2] & Zeynep Şiklar[2]
[1]Ankara University Faculty of Medicine, Department of Pediatrics, Ankara, Türkiye; [2]Ankara University Faculty of Medicine, Department of Pediatric Endocrinology, Ankara, Türkiye

Aim

Hyperthyroidism is rare in childhood, and its diagnosis may be delayed. The approaches to follow-up and treatment are varied, and evidence-based guidelines are lacking. This study aimed to evaluate the presentation and follow-up characteristics of patients with hyperthyroidism.

Material and Methods

Patients aged 1 to 18 years diagnosed with hyperthyroidism and admitted between September 2005 and January 2023, with complete data available, were included. Admission and follow-up characteristics were recorded from their files. The etiology of hyperthyroidism, treatment, response to therapy, and follow-up periods were evaluated. The statistical analysis was performed using the Statistical Package for Social Sciences (SPSS, Version 26.0, Chicago, IL).

Results

The mean age of the 63 patients included in the study was 11.7 ± 4.95 years, and the female/male ratio was 1.86. Forty-eight (76.2%) of the patients were

diagnosed with Graves' disease (GD), with Hashitoxicosis ($n = 9$, 14.3%) being the second most common diagnosis. The mean age was 12.03±4.52 years in patients with GD and 14.94±3.44 years in patients with Hashitoxicosis (p:0.04). Ophthalmopathy was found in seven patients (11.1%). Euthyroidism was achieved in 60 patients in whom antithyroid drug (ATD) treatment was initiated in a mean of 7±8.29 months (71.4% in the first six months). No side effects were observed with ATDs except allergic rash in two patients. The mean duration of treatment was 25.03±22.9 months and was longer in patients with GD than in patients with Hashitoxicosis (30±23.4 months vs. 6.1±6.6 months, $P = 0.002$). The mean follow-up period was 36.9±32.3 months. While the remission rate during the follow-up period was 22.9% in patients receiving ATDs for GD, 15 of 48 patients (31.3%) relapsed after a mean of 8.4±5.02 months. Thyroidectomy was performed in 11 (17.5%) patients (9 with GD, 2 with toxic adenoma). Thyroidectomy was more frequent in the presence of ophthalmopathy ($P = 0.018$) and in patients with larger thyroid gland volume ($P = 0.044$) and volume SDS ($P = 0.001$). It was found that the time to achieve euthyroidism ($P = 0.0015$) and the time to TRAb negativity ($P = 0.022$) were longer in those who underwent thyroidectomy compared to those who didn't.

Conclusion

In the majority of children with hyperthyroidism, euthyroidism can be achieved in the first six months with ATDs. In children with GD, the long-term remission rate with ATDs is low. Thus, permanent treatment is likely to be required in the presence of large goiter, ophthalmopathy, and in patients in whom biochemical euthyroidism and TRAb negativity cannot be achieved with long-term treatment.

Hyperthyroidism and renal function: unravelling the diagnosotic dilemma in GFR estimation

Mohitraje Mankumare[1], Wing Leung[2] & Hashim Abbas[1]
[1]Manchester Royal Infirmary, Renal, Manchester, United Kingdom; [2]Manchester Royal Infirmary, Manchester, United Kingdom

Summary and Background

Estimation of glomerular filtration rate(eGFR) is commonly based on biomarkers like creatinine(sCr) and cystatin C (sCysC), which are influenced by various factors, including muscle mass and thyroid status(1)(2). This case report presents a unique challenge in accurately assessing renal function in a patient with Chronic Kidney Disease(CKD) who developed severe hyperthyroidism and extreme weight loss. The patient's eGFR values significantly differed depending on the biomarker used. This disparity raises concerns about the reliability of these biomarkers in such complex clinical scenarios. While thyroid dysfunction is known to affect both sCr and sCysC levels, the aggregate impact of hyperthyroidism on eGFR in CKD patients remains poorly studied. Previous literature has highlighted the paradoxical effects of hyperthyroidism—where eGFR-Cr is often overestimated and eGFR-CysC is underestimated(3)—yet there is limited evidence to guide clinicians on how to reconcile these findings.

Investigations

Thyroid Function	- **TSH**: <0.01 μU/mL - **Free T4**: 49.0 pmol/l
Renal Function	- **Serum Creatinine(sCr)**: 102 μmol/l - **Serum Cystatin C(sCysC)**: 3.09 mg/l - **eGFR Cr(Creatinine-based)**: 56 mL/min/1.73m^2 (overestimated) - **eGFR CysC(Cystatin C-based)**: 16 mL/min/1.73m^2 (underestimated)

Discussion and Conclusion

To our knowledge, the 2015 study by Suzuki *et al*. is the only clinical study examining eGFR Cr-CysC in thyroid dysfunction (3). This study demonstrated that overestimation of eGFR-Cr and underestimation of eGFR-CysC in the presence of elevated thyroid hormones could be corrected when the condition was treated. Interestingly, the eGFR Cr-CysC derived from the CKD-EPI-Creatinine-Cystatin Equation remained largely unchanged after resolving the hyperthyroid state. This suggests that eGFR Cr-CysC may be independent of thyroid status, offering more accurate method for renal function assessment. In conclusion, healthcare professionals should be aware of the unreliability of Creatinine and Cystatin-C in hyperthyroid patients. The CKD-EPI-Creatinine-Cystatin Equation shows promise but requires further research to guide its use in patients with both CKD and thyroid disease.

Life saving Plasma exhchange in resistant thyroid storm with myocardial infacrtion

Lkvn Perera[1], Muzaffar Mirza[1], Tahir Omer[2,3] & David Popple[4]
[1]Northampton General Hospital, Northampton, United Kingdom; [2]University hospitals of northamptonshire, Northampton, United Kingdom; [3]University of South Wales, Cardiff, United Kingdom; [4]University hospitals of Northamptonshire, Northampton, United Kingdom

Introduction

Thyrotoxic crisis is a rare, life-threatening emergency. Early diagnosis and prompt management reduces morbidity and mortality. We, hereby, report the case of a patient presenting with low GCS secondary to thyroid storm and consequently developed multi organ failure. Due to lack of clinical response to conventional treatment, plasmapheresis was carried out with a favorable outcome.

Case Presentation

A 65-year-old lady was diagnosed with hyperthyroidism while an inpatient in mental health care for worsening bipolar disorder. Two weeks later, she was transferred to our hospital with chest infection. She was withdrawn and non-compliant therefore, anti-thyroid treatment was frequently interrupted. Her condition rapidly deteriorated and she was transferred to ITU with respiratory failure and GCS of 7/15. Her HR was 148/min, BP-170/ 90 mmHg, RR-54/min, temperature 38.3^{0}C. She fulfilled the criteria for diagnosis of thyrotoxic storm as per Burch Wartofsky point scale (BWP) and Japan thyroid association (JTA). Her TSH was <0.05 μIU/ml; T4 61 ng/dl, T3 16 pg/ml. TRAb 9.6 IU/l. She was intubated and started treatment immediately including Propylthiouracil, Lugol's Iodine, Propranolol, Hydrocortisone and Cholestyramine. Then she developed type II myocardial infarction, complicated by acute kidney and liver injury due to cardiogenic shock in addition to coagulopathy. GCS remained low despite normal CT head and EEG. Conventional treatment failed to control her thyroid function after 6 days, so plasma exchange was commenced. She became euthyroid after 2 sessions. She successfully underwent total thyroidectomy. Her GCS started improving 7 days post-operatively and she was successfully weaned off ventilator and discharged.

Discussion

Thyroid storm is a rare presentation of hyperthyroidism with high mortality. The exact mechanism of this condition remains poorly understood. A potential explanation is reduced affinity of TBG for T4 leading to an increased level of freeT4. Moreover, an increase in target cell-β-adrenergic receptor or change in the signalling pathways can result in increased sensitivity to stimulation. Therapeutic plasma exchange (TPE) has been successfully utilised in a variety of diseases. It's a safe procedure, with overall incidence of adverse effects around 5%. Its use in treating thyrotoxic crisis has been demonstrated in a few case reports and case series globally. Despite its proven effectiveness, TPE is not yet included in recently published guidelines on management of thyrotoxicosis suggesting the need for further evaluation. However, in cases when conventional measures fail, plasmapheresis is a reasonable safe option to decrease circulating thyroid hormone levels and should be considered as a stabilising measure.

Thyroid cancer in thyroglossal duct cysts

Elisabete Rodrigues[1,2], Ana Saavedra[3], Joao Magalhaes[2,4], Mafada Pinto[5,6], P. Andrea-Ferreira[2,7], Manuel Sobrinho-Simões[5,6] & Paula Soares[2,5,6]
[1]ULS São João, Endocrinology, Porto, Portugal; [2]Faculty of Medicine, University do Porto, Porto, Portugal; [3]ULS Tâmega e Sousa, Penafiel, Portugal; [4]ULS São João, Pathology, Porto, Portugal; [5]Instituto de Patologia e Imunologia Molecular da Universidade do Porto (IPATIMUP), Instituto de Investigação e Inovação em Saúde (i3S), Porto, Portugal; [6]Instituto de Investigação e Inovação em Saúde (i3S), Porto, Portugal; [7]ULS São João, Faculty of Medicine, University of Porto, Surgery, Porto, Portugal

Introduction

Thyroglossal duct cyst (TGDC) is the most frequent cervical congenital anomaly. Thyroid carcinomas arising from these structures are rare, being present in approximately 1.5% of patients with TGDC. The diagnosis usually is done post-

operatively after the resection of the cyst. Due to the rare occurrence there is no definite consensus on the optimal treatment of thyroid cancer in thyroglossal duct cyst carcinomas (TGDCCs), namely the need of complementary thyroidectomy.
Objective
We aimed to assess tumor presentation, therapeutic strategy and follow-up in a series of patients with TGDCCs.
Methods
We performed a retrospective analysis of all patients with TGDCCs, selected from the pool of individuals with histological diagnosis of thyroglossal duct cyst established between 2010 and 2024 at our institution.
Results
From a total of 244 patients with thyroglossal duct cysts, 7 patients (2.9%) were identified with TGDCCs (5 females, 2 males), aged at diagnosis between 17 and 65 years (mean: 41,1; median: 41). In six patients clinical presentation was a cervical mass while the other was diagnosed by an ultrasound scan during follow up of a previous thyroid cancer. In all cases the diagnosis was established after surgery. Papillary thyroid carcinoma (PTC) was found in all samples (follicular variant PTC in 1 patient and classic PTC in 6 patients), sized between 0.1 and 1.4 cm, 5 of them being microcarcinomas. All patients were treated with Sistrunk surgery; one did total thyroidectomy at the same time for a suspicious nodule that histology confirmed as synchronous PTC with vascular invasion and was treated with radiodine ablation; the other two did a complementary thyroidectomy afterwards, both with no malignancy. None of the cases presented capsular invasion, lymphovascular invasion, soft tissue extension, lymph node metastasis or positive margins. No metastasis or recurrence was found in any of the cases after a mean follow up of 8.6 (4-14) years.
Conclusion
TGDCCs are a rare clinical entity with good prognosis. Despite the controversy regarding their therapeutic approach and follow-up, Sistrunk procedure alone with regular thyroid evaluation may be enough in low-risk patients. Further studies are needed to clarify this issue.

Predictor of treatment outcome for pediatric Grave's disease

Do Young Shin[1], Kyu Hyun Park[2], Eungu Kang[1], Hyo-Kyoung Nam[3], Young-Jun Rhie[1] & Kee-Hyoung Lee[4]
[1]Korea University College of Medicine, Korea University Ansan Hospital, Department of Pediatrics, Ansan, South Korea; [2]Nowon Eulji University Hospital, Pediatrics, Seoul, South Korea; [3]Korea University College of Medicine, Korea University Guro Hospital, Department of Pediatrics, Seoul, South Korea; [4]Korea University College of Medicine, Korea University Anam Hospital, Department of Pediatrics, Seoul, South Korea

Purpose
Graves' disease (GD), the most common cause of hyperthyroidism in children, is primarily and effectively treated with Antithyroid drugs (ATDs). The aim of this study was to evaluate the factors that could predict remission, relapse, and the need for persistent high-doses of methimazole (MMI) in pediatric GD.
Methods
This is retrospective study by medical records included GD diagnosed before 19 years of age from January 2004 to December 2023. Remission was defined as maintaining the euthyroid state for more than 6months after stop ATD. The high-doses group was defined as those receiving MMI doses more than 5mg/day at last follow-up, regardless of their euthyroid status.
Results
Of the 113 patients (95 girls and 18 boys), 47(41.6%) achieved remission at a mean of 37.17±29.01 months after treatment. Compared to the non-remission group, the remission group showed significant differences in T3, fT4 and TSH-binding inhibitor immunoglobulin (TBII) at diagnosis (330.92 ± 177.72 vs 413.75 ± 179.09 ng/dl, $P = 0.017$; 3.31 ± 1.39 vs 4.12 ± 1.34 ng/dl, $P = 0.002$; 15.68 ± 14.37 vs 23.37 ± 16.61 IU/l, $P = 0.012$, respectively), time to TBII normalization (25.26 ± 29.88 vs 45.33 ± 37.17 months, $P = 0.003$), and TBII ratio at 6 months (54.98 ± 42.04 vs 87.92 ± 55.94%, $P < 0.001$). 11 patients (11/47, 23.4%) experienced relapse at a mean of 17.91±16.81 months after remission. Compared to non-relapse group, relapse group was predominantly male (5.6 vs 45.5%, $P < 0.001$) and exhibited a higher TBII ratio at 12 months (36.64 ± 33.78 vs 87.18 ± 78.14%, $P = 0.025$). In non-remission group, 38/66 patients (57.6%) received persistent high doses of MMI, with a mean dose of 0.39 ± 0.17mg/kg/day at the last follow-up. Compared to low-dose group, high-dose group showed significant differences in time to T3, fT4 and TBII normalization (1.21 ± 0.69 vs 2.39 ± 1.76 months, $P < 0.001$; 1.50 ± 0.84 vs 2.61 ± 2.47months, $P = 0.013$; 7.00 ± 2.61vs 9.55 ± 5.14months, $P = 0.011$, respectively), and TBII ratio at 6 months (61.57 ± 36.96 vs 107.34 ± 59.90%, $P < 0.001$). Under the ROC curve for the TBII ratio at 6 months treatment, the cut-off value of remission was 62.5%, and the cut-off value of the need for persistent high-doses of MMI was 82.5%.
Conclusion
Thyroid hormone and TBII levels at diagnosis, time to thyroid hormone and TBII normalization, and the TBII ratio after ATD treatment can be used to predict remission, relapse, and the need for persistent high-dose MMI in pediatric GD patients.

Prevalence of thyroid dysfunction in children with asthma in a tertiary care hospital of jharkhand, india - a cross-sectional study

Sarthak Das[1], Medhagopal R.G[1], Archana Malik[1], Saroj Tripathy[1], Soumi Kundu[1], Saurabh Varshney[1] & Pratima Gupta[1]
[1]All India Institute of Medical Sciences, Deoghar, Deoghar, India

Background
Hyperthyroidism has been linked to asthma exacerbations, while some studies suggest an increased risk of hypothyroidism in individuals with asthma. Although several studies have shown a positive association between asthma and thyroid disorders, these findings are primarily focused on adult populations. Research exploring the prevalence of thyroid dysfunction and its impact on asthma control in pediatric populations remains limited.
Objective
To determine the prevalence of thyroid dysfunction in asthmatic children aged 6 to 15 years and to assess the relationship between thyroid function and the level of asthma control in this population.
Methods
A cohort of 80 children with BA (24 girls, 56 boys; mean age 111.3 ± 25.1 months) underwent comprehensive clinical evaluation, including spirometry, the Asthma Control Questionnaire (ACQ-5), and laboratory assessments of thyroid-stimulating hormone (TSH), free thyroxine (T4), and anti-thyroperoxidase antibodies (anti-TPO) via ELISA.
Results
Elevated TSH levels, indicative of subclinical hypothyroidism (maximum 11.45 mIU/l), were observed in 22 patients (27.5%), all without hypothyroid symptoms or anti-TPO elevation. TSH levels ranged from 3.16–5.74 mIU/l in other participants, while free T4 levels were mildly elevated in 18 patients but remained within clinically insignificant limits (maximum 23.1 pmol/l). A weak negative correlation was identified between TSH levels and ACQ-5 scores ($r = -0.29$, $P = 0.033$). Subclinical hypothyroidism was most prevalent (27.5%) in patients with fully controlled BA (mean TSH 3.39 ± 1.96 mIU/l) but absent in those with uncontrolled BA (mean TSH 1.87 ± 0.73 mIU/l). Patients with partially controlled BA exhibited intermediate TSH levels (mean TSH 2.93 ± 1.5 mIU/l), suggesting potential iodine deficiency. Despite these trends, group differences in TSH were not statistically significant ($F = 1.74$, $P = 0.1858$). Free T4 levels showed no significant variation across asthma control groups but negatively correlated with FEV1 ($r = -0.42$, $P = 0.01$). Normal TSH levels in poorly controlled BA may reflect suppression by stress-induced or exogenous corticosteroids rather than optimal thyroid function.
Conclusion
Subclinical hypothyroidism is common among children with well-controlled BA, occurring in 27.5% of cases. Further studies are needed to clarify the clinical significance and mechanisms underlying this association.

Thyroid cancer in children: insights from an 18-year retrospective study at a tertiary center

Sima Kalaldeh[1], Hadeel Halalsheh[2], Iyad Sultan[2] & Akram Ibraheemi[2]
[1]KHCC, Pediatrics, Amman, Jordan; [2]King Hussein Cancer Center, Amman, Jordan

Background
Thyroid cancer is rare in children but represents the most common endocrine malignancy in this age group. Pediatric thyroid cancer exhibits distinct biological behavior compared to adults, characterized by higher rates of lymph node (LN) involvement and distant metastases, yet with a favorable overall prognosis. This study evaluates the clinicopathological features, treatment outcomes, and survival rates of children diagnosed with thyroid cancer.
Methods
A retrospective analysis was performed on pediatric patients ($\leq$18 years) diagnosed with thyroid cancer between January 2004 and December 2022 at King Hussein Cancer Center, Jordan. Data included demographics, clinical presentation, histopathology, staging, treatment details, and follow-up outcomes. Statistical analyses examined survival rates, recurrence patterns, and prognostic factors.
Results
The study included 25 children, predominantly female (n = 19, 76%). The median time to presentation was 2 months (range: 0.5–60). Papillary thyroid carcinoma (PTC) was the most common subtype (96%), with one case of medullary thyroid carcinoma, not MEN associated. Regional LN involvement was present in 84% of patients, and 16% (n = 4) had lung metastases at diagnosis. All patients underwent total thyroidectomy with LN dissection, and 92% received radioactive iodine therapy (median dose: 100 mci; range: 50–905 mci). After a median follow-up of 6.2 years (range: 0.5–20.1), the 5-year and 10 year overall survival rates were 100% and 93%, respectively. Recurrence occurred in 32% of cases (n = 8), primarily in regional LNs. Age, sex, LN metastasis, and distant metastases were not associated with increased risk of recurrence.
Conclusion
Thyroid cancer in children presents with unique clinical features, including high rates of LN involvement and distant metastases, yet it is associated with excellent long-term survival. Although recurrence is relatively common, it does not significantly affect overall survival. These findings emphasize the importance of comprehensive initial treatment and vigilant long-term follow-up to manage this disease effectively.

Genetic landscape of goiterous hypothyroidism: key markers and clinical insights

Nada Alaaraj[1], Ashraf Soliman[1], Noor Hamed[1], Fawzia Alyafei[1], Shayma Ahmed[1], Noora AlHumaidi[1], Ahmed Elawwa[1] & Aml Sabt[2]
[1]Hamad Medical Corporation, Doha, Qatar; [2]Sidra Medicine, Doha, Qatar

Background
Goiterous hypothyroidism, characterized by thyroid enlargement and impaired hormone production, arises from diverse genetic mutations affecting thyroid development and function. Advances in genetic analysis have expanded understanding of its molecular underpinnings, aiding early diagnosis and tailored interventions.
Objectives
To summarize the genetic markers associated with goitrous hypothyroidism and their clinical implications, focusing on recent findings and their impact on patient outcomes.
Methods
A systematic review of studies (1998–2024) was conducted to identify genetic markers, mechanisms, and clinical outcomes in goiterous hypothyroidism. Data from next-generation sequencing (NGS), linkage analyses, and case studies were analyzed for phenotypic correlations.
Results
1. Genetic Markers:.
• Thyroglobulin (TG) mutations (e.g., p.R277X, p.Val501Gly) impair hormone synthesis, contributing to congenital hypothyroidism (CH) and goiter (Caputo *et al*., 2007).
• Mutations in SLC5A5/NIS and DUOXA2 genes are linked to goitrous hypothyroidism, with severe phenotypes requiring long-term management (Stoupa *et al*., 2020; Jung *et al*., 2020).
• Oligogenic inheritance patterns were identified in congenital cases, emphasizing complex genetic contributions (Oliver-Petit *et al*., 2021).
2. Mechanisms and Clinical Impact:.
• Missense mutations in TG and TPO disrupt intracellular transport and hormone synthesis, causing thyroid enlargement (Hishinuma *et al*., 1998; Lee *et al*., 2013).
• Genome-wide studies identified loci on chromosomes 3q26.1-q26.3 and 14, linked to familial and autoimmune thyroid diseases (Takahashi *et al*., 2001; Tomer *et al*., 1998).
3. Therapeutic Outcomes:.
• Early hormone replacement therapy improved growth and cognitive outcomes in CH cases, while genetic insights informed precision medicine approaches (Li *et al*., 2021; Vincenzi *et al*., 2023).
• Novel interventions, such as combined selenium and myoinositol, showed promise in reducing thyroid antibodies in autoimmune thyroiditis (Ferrari *et al*., 2021).
Conclusion
Mutations in TG, TPO, DUOXA2, and other key genes shape the genetic landscape of goitrous hypothyroidism. Early diagnosis through advanced genetic tools enables tailored treatments, improving patient outcomes. Future research should focus on genotype-phenotype correlations and novel therapeutic strategies to enhance care for affected individuals.

Ultrasound-based ultra-micro angiography for evaluating vascularity in diffuse thyroid disorders

Stefania-Alexandra Bunceanu[1], Andreea Bena[2], Luciana Moisa Luca[1] & Dana Stoian[2]
[1]Department of Doctoral Studies, 'Victor Babes' University of Medicine and Pharmacy, Timişoara, Romania; [2]Second Department of Internal Medicine, 'Victor Babes' University of Medicine and Pharmacy, Timisoara, Romania

Background
Ultra-Micro Angiography (UMA) is an innovative Doppler ultrasound technique that significantly enhances the visualization of slow blood flow in small caliber vessels. The application of Subtraction UMA (sUMA) further refines this capability by eliminating background tissue interference, enabling a precise assessment of thyroid micro-vascularity. This study aimed to evaluate thyroid perfusion through sUMA in healthy individuals compared with those diagnosed with autoimmune thyroid conditions, while also exploring its potential implications in clinical practice.
Methods
This prospective, single-center study involved 70 participants, categorized into three groups: 18 healthy controls, 40 with chronic autoimmune thyroiditis (CAT), and 12 with Graves' disease (GD). All participants underwent multiparametric ultrasound followed by sUMA for microvascularity assessment. The Color Pixel Percentage (CPP) index was calculated to quantify the vascularity of the thyroid gland. Median CPP values were derived, and correlations with various clinical parameters were analyzed.
Results
The participant groups exhibited similar mean ages (ranging from 45.4 to 51.5 years), with a notable female predominance (72% to 80%). The median CPP values were significantly lower in controls (26.5; IQR [22-32.4]) compared to those with CAT (49.3; IQR [38.5-61.6]) and GD (54.5; IQR [41.7-64]; $P < 0.0001$). Within the control group, a moderate negative correlation between CPP and BMI was observed (r = -0.510, P = 0.032). In contrast, the CAT group demonstrated moderate positive correlations between CPP and TSH (r = 0.582, P = 0.002) as well as between CPP and thyroid volume (r = 0.492, P = 0.008).
Conclusions
sUMA is a reliable and effective modality for assessing thyroid vascularity in both healthy individuals and those with autoimmune thyroid disorders. The findings support the promising utility of sUMA in the diagnosis and clinical evaluation of thyroid diseases.

A less known cause of orbitopathy

Tamara Janic[1], Mirjana Stojkovic[1,2], Bojan Markovic[1], Nata Joksimovic[1], Jovana Babic[1], Ivana Djurkovic[1], Snjezana Erceg[3], Biljana Nedeljkovic Beleslin[1,2], Jasmina Ciric[1,2] & Milos Zarkovic[1,2]
[1]Clinic of Endocrinology, Diabetes and Metabolic Diseases, University Clinical Center of Serbia, Thyroidology, Belgrade, Serbia; [2]Faculty of

Medicine, University of Belgrade, Belgrade, Serbia; [3]Center for Radiology Imaging, University Clinical Center of Serbia, Belgrade, Serbia

Introduction
IgG4-related disease (IgG4-RD) is a multisystemic fibroinflammatory condition characterized by clinical, histological, and serological markers. It presents with organomegaly, histological lymphoplasmacytic infiltration with IgG4+ plasma cells, varying degrees of storiform fibrosis, and elevated serum IgG4 levels. Most patients have multi-organ involvement, including the orbit. In cases of atypical orbital changes, besides thyroid eye disease (TED), IgG4-related orbital disease (IgG4-ROD) should also be considered.
Case 1
A 38-year-old female presented with eyelid swelling and hyperemia, conjunctival chemosis, and proptosis of the right eye, along with ipsilateral cheek swelling. Orbital MRI revealed right-sided exophthalmos (OD 25 mm, OS 17 mm), enlargement of the medial and lateral rectus muscles, borderline enlargement of the inferior rectus, and increased retrobulbar fat. Thyroid hormone levels were normal, and TRAb levels varied between $<$0.8–1.9IU/l (ref.range: 0.0-1.8IU/l). Serum IgG4 was elevated(2.87g/l). Her medical history is remarkable for atopy, nasal polyps, bronchial asthma, and surgery of the left submandibular salivary gland due to its enlargement, with extraction of regional lymph nodes. Due to persistently elevated liver enzymes and ASMA positivity with hepatomegaly, a liver biopsy was performed, showing severe steatohepatitis(NAS 7/8) but no signs of IgG4-RD. A review of the histopathology of a previously resected submandibular gland and lymph nodes confirmed probably IgG4-RD.
Case 2 A 43-year-old male presented with bilateral eyelid swelling, more pronounced on the right side, with an enlarged right lacrimal gland. Orbital CT revealed an enlarged right lacrimal gland and mild inflammation of the left lateral rectus muscle. His thyroid hormone levels were normal, TRAbs ranged from $<$ 0.8–2.4IU/l. Serum IgG4 was significantly elevated (6.09g/l). His medical history included bronchial asthma and nasal polyps. MRI with MRCP, performed due to abnormal liver function tests, revealed primary sclerosing cholangitis. Liver biopsy showed no histological characteristics of IgG4-RD.
Conclusion
Two patients were referred to our clinic with suspected TRAb-negative TED, but further investigations suggested IgG4-RD. Findings supporting IgG4-ROD included elevated serum IgG4, multi-organ involvement, and atypical orbitopathy (predominantly unilateral involvement, enlarged lateral rectus in both cases, and lacrimal gland involvement in the second patient). In the first case, histology of the salivary gland was used as a surrogate marker supporting IgG4-RD, increasing the likelihood that the ocular changes shared the same etiology. Features arguing against TED included normal thyroid function and morphology with negative to borderline elevated TRAbs, and the absence of a typical pattern of extraocular muscle involvement. TED and IgG4-ROD have overlapping orbital manifestations, making differential diagnosis challenging.

An optimal capillary screen cut-off of thyroid stimulating hormone for diagnosing congenital hypothyroidism: gathering evidence

Mukesh Darshan[1]
[1]Aiims Rishikesh, Rishikesh, India

Objective
To determine an appropriate cut-off of capillary Thyroid stimulating hormone (TSH) for congenital hypothyroidism.
Study design
Cross-sectional.
Participants
174,000 neonates born in different hospitals of Delhi, India, from November 2014 to October 2016.
Main outcome measures
Correlation between initial and repeat capillary TSH level and subsequent venous free thyroxine (fT4) level.
Results
102 newborns with initial/ repeat capillary TSH level of $\geq$20 mIU/l ($n = 174$) were confirmed to have congenital hypothyroidism at mean (SD) age of 5 (4) days. A good correlation between capillary TSH level and confirmatory venous fT4 level and postnatal age of sampling was obtained (r -0.6,-0.4). The area under the ROC curve (AUC) was 0.81 (95%CI 0.75 to 0.88), indicating referral capillary TSH level of 20 mIU/l to be a good predictor of subsequent high venous TSH level.
Conclusion
A cut off of $\geq$20 mIU/l for capillary TSH screening beyond 24 hours of life is optimal in the Indian setting for deciding further recall and workup, keeping a balance between sensitivity and recall rate.

Nationwide web-survey on implementing the 2023 ETA guidelines for thyroid nodule management

Eleni Sazakli[1], Olga Karapanou[2], Grigoris Effraimidis[3], Gerasimos Sykiotis[4], Katerina Saltiki[5] & Marina Michalaki[1]
[1]Faculty of Medicine, School of Health Science, University of Patras, Patras, Greece; [2]Endocrine Department, NIMTS Veteran's Hospital, Athens, Greece; [3]Faculty of Medicine, School of Health Sciences, University of Thessaly, Department of Endocrinology and Metabolic Diseases, University General Hospital of Larissa, Larissa, Greece; [4]Service of Endocrinology, Diabetology and Metabolism, Lausanne University Hospital and University of Lausanne, Lausanne, Switzerland; [5]Endocrine Unit, Department of Clinical Therapeutics, National and Kapodistrian University, Athens, Greece

Background
Thyroid nodules are very common, and the European Thyroid Association (ETA) recently issued high-quality guidelines to standardize their management. However, the extent of guideline implementation and the barriers to adherence remain unclear. This study evaluates the application of the guidelines and identifies obstacles to their adoption among Greek endocrinologists.
Methods
Between November 2023 and April 2024, members of the Hellenic Endocrine Society (HES) completed a web-based survey on the management of a 2.5 cm thyroid nodule with fine-needle aspiration (FNA) cytology results of Atypia of Undetermined Significance (AUS). The scenarios varied by the nodule's sonographic risk classification: intermediate (EU-TIRADS 4) or high (EU-TIRADS 5). Participants also provided demographic information and reasons for non-adherence to the guidelines.
Results
The survey had a 25% response rate. For an EU-TIRADS 4 nodule with AUS cytology, 61% of respondents chose to repeat FNA, while only 23% opted to do so for an EU-TIRADS 5 nodule with AUS cytology, despite the 2023 ETA guidelines recommending repeat FNA in both scenarios. More experienced endocrinologists were less likely to select repeat FNA and more inclined toward total thyroidectomy in the EU-TIRADS 4 scenario. In contrast, experience had no significant impact on decision-making for the EU-TIRADS 5 scenario. Key barriers to guideline adherence included skepticism about the recommendations, limited access to reliable neck ultrasonography and molecular testing, and a shortage of high-volume surgeons.
Conclusions
Greek endocrinologists frequently deviate from the 2023 ETA guidelines for managing thyroid nodules with indeterminate cytology, citing challenges that may also affect clinicians in other countries. These findings highlight the importance of developing strong implementation strategies alongside guideline releases, particularly in anticipation of the upcoming American Thyroid Association guidelines for managing thyroid nodules in adults.

JOINT1006

Riedl's thyroiditis arising from stable chronic atrophic Hashimoto's thyroiditis

Foteini Adamidou[1], Evangelia Makri[1], Stefanos Milias[2] & Theodosios S. Papavramidis[3]

[1]Hippokration General Hospital of Thessaloniki, Thessaloniki, Greece; [2]Anatomic Pathology Private Practice Lab, Thessaloniki, Greece; [3]Aristotle University of Thessaloniki, A' Department of Surgery, Thessaloniki, Greece

Background
Riedl's thyroiditis is a rare fibrosclerotic destructive thyroiditis of unknown etiology, arising either simultaneously or on preexisting autoimmune thyroiditis. We present a patient whose stable atrophic Hashimoto's thyroiditis "transformed" to Riedl's.
Case presentation
A 52-year-old woman with 3-year history of Hashimoto's thyroiditis presented because of gradually increasing TSH from high-normal to a recent 10.1mIU/l. The patient complained of mild discomfort on palpation and on swallowing over the left cervical area, starting a month before. She had previously been euthyroid on a stable replacement dose of L-thyroxine 75 mg daily. Thyroid ultrasound had also been stable, showing a small, slightly hypoechoic gland with increased vascularity. Past medical history was unremarkable and family history for autoimmune diseases was negative. On examination, the thyroid gland was visibly enlarged, hard and slightly tender on palpation. Ultrasound imaging showed marked change with bilateral hypoechoic avascular areas, measuring 23x 15 mm and 16x 14 mm, with a rim of hypervascular thyroid parenchyma. TSH was 8.14mIU/l, thyroglobulin 0.09ng/ml, CRP 2 mg/l (0-8) and ESR 8 mm/1hr. The findings were not consistent with subacute thyroiditis and an ultrasound-guided FNA was performed, (2 passes with a 23G needle and one pass with a 21G needle), with complete absence of material for cytology. Subsequently a core biopsy was performed, with findings consistent with Hashimoto's thyroiditis, while symptoms remained stable. A six-week trial of oral methylprednisolone had no effect. Finally, the decision was made to proceed to surgery due to diagnostic uncertainty and unremitting disease. The left lobe of the gland was removed piecemeal, without adverse events. The procedure was not completed because of significant risk of complications. Histopathologic diagnosis showed complete absence of follicles, diffuse fibrous tissue infiltrating parathyroid tissue and striated muscle, IgG4 positive plasmatocytic infiltrate and eosinophils, consistent with Riedl's thyroiditis. The patient remains stable on follow-up without systemic manifestations.
Conclusion
The diagnosis of Riedl's thyroiditis must be included in the differential diagnosis when a change in thyroid appearance or size associated with compressive symptoms occur in a patient with Hashimoto's thyroiditis. Awareness of this condition is important for appropriate management.

JOINT1813
The clinical impact of vitamin D supplementation on thyroid eye disease outcome
Sofia Chatzi[1] & Georgios Boutzios[1]
[1]Department of Pathophysiology, National and Kapodistrian University of Athens, Laiko General Hospital, Athens, Greece

Introduction
Thyroid eye disease (TED) is the most common extraocular manifestation of Graves' disease. Recent reports demonstrate that low serum vitamin D levels is associate with TED diagnosis. The aim of our study is to evaluate whether low serum vitamin D levels are associated with active thyroid eye disease and whether or not supplementation potentially improves the clinical course of the disease for patients with TED as an adjuvant treatment.
Material and Methods
We have recruited 115 patients with TED from the Outpatient Clinic of Autoimmune Endocrinopathies, Department of Pathophysiology of the University of Athens, Greece. The analyzed data were respectively collected from the patients' medical record from the same investigator. We recorded a comprehensive personal and family medical history. Magnetic resonance imaging was performed in all patients. Serum vitamin D was measured for all patients. Patients already receiving vitamin D supplementation or received during the last 8 months were excluded from the study.
Results
Regarding demographic characteristics of study population mean age was 56.18 $\pm$ 1.63 years, the majority of the patients (74.8%) were females and 82.8% were smokers. Median CAS was 3/7 (1-7) and 19.6% of study population presented with unilateral disease. Active disease was present in 58.3%. Regarding disease severity 26.6% had mild disease, 52.3% moderate to severe and 21.1% had severe-sight threatening TED. We conducted subgroup analysis and compared the above characteristics between patients with active and inactive disease. Mean 25(OH) vitamin D levels for patients with active TED were 25.82$\pm$10.15 ng/ml whereas for patients with inactive TED mean levels were 24.83$\pm$12,88 ng/ml ($P = 0.677$). Moreover, we compared all variables between patients with disease duration <6 years and ≥ 6 years in an attempt to establish clinical factors contributing to disease chronicity. Mean 25(OH)vitamin D levels for patients with disease duration <6 years were 24.79 $\pm$11,68 ng/ml and for patients with disease duration $\geq$ 6 years were 28.12 $\pm$9,07ng/ml ($P = 0.261$).
Conclusion
We found higher levels of serum vitamin D concentration in patients with active and therefore more severe TED. However, the comparison does not reach statistical significance. Similarly patients with longer disease duration have higher vitamin D levels. As a result, vitamin D supplementation in patients with active TED is not strongly indicated. Further prospective studies are required to determine which subgroup of TED patients will potentially benefit from vitamin D supplementation as an adjuvant treatment.

JOINT2714
Association of thyroid cancer risk with plasma 25-hydroxyvitamin D levels in multinodular goiter patients
Tatiana Scarabnii[1], Alice Albu[1,2] & Anton Ana Maria[1]
[1]Elias Emergency University Hospital, Clinical Endocrinology, Bucharest, Romania; [2]Carol Davila University of Medicine and Pharmacy, Faculty of General Medicine, Bucharest, Romania

Introduction
Multinodular goiter (MNG) is a common thyroid disorder, often associated with an increased risk of differentiated thyroid cancer (DTC). Vitamin D insufficiency and multinodular goiter are prevalent worldwide, including in the Romanian population. Recent research has highlighted the potential role of vitamin D in various malignancies, but its influence on thyroid cancer development remains inconclusive. Given the high prevalence of both vitamin D deficiency and thyroid disorders, investigating their possible relationship is crucial. This study aims to assess the association between plasma 25-hydroxyvitamin D (25OHD) levels and the risk of DTC in patients with MNG, providing insight into potential endocrine and oncologic implications.
Material and Methods
We performed a retrospective study which included 351 patients evaluated for thyroid nodular goiter with fine needle aspiration (FNA) in a tertiary Endocrinology Department between 2022-2024. Mean age of the study group was 53.56$\pm$13.6 years (range 17-83 years), (16.8% males). The following data were collected from medical files: age, body mass index, serum 25OHD, freeT4, TSH, ATPO, anti-TG, ultrasound features of the thyroid nodules, Bethesda class at FNA.
Results
No significant differences were found in terms of age, body mass index and thyroid nodule dimensions between Bethesda subgroups. Patients with Bethesda class 3 or higher ($n = 72$) had significantly lower levels of 25-hydroxyvitamin D (22.6$\pm$10.58 ng/ml) in comparison with patients with Bethesda class 2 ($n = 279$, 25.5$\pm$11.6 ng/ml, $P = 0.043$). Moreover, serum 25-hydroxyvitamin D level was associated with ultrasound characteristics of the thyroid nodule. Thus, the presence of irregular margins was associated with significantly lower levels of serum 25 hydroxyvitamin D (22.42$\pm$11.53 ng/ml) in comparison with patients with nodules with regular margins (25.56$\pm$11.39 ng/ml, $P = 0.041$), and marginal vascularization was more frequently found in patients with 25-hydroxyvitamin D below 30 ng/ml (51%) in comparison with those with 25-hydroxyvitamin D above 30 ng/ml (39.6%, $P = 0.05$). Moreover, we found a tendency that patients with 25-hydroxyvitamin D below 20 ng/ml to present more frequently with incomplete hallo (19.1%) in comparison with patients with 25-hydroxyvitamin D above 20 ng/ml (12.3%, $P = 0.068$).
Conclusion
Our study suggests that lower levels of serum 25-hydroxyvitamin D might be associated with increased risk of thyroid malignancy.

MCT8 deficiency - a pathway of the "floppy baby" from thyroxine treatment to tiratricol
Zuzana Pribillincova[1], Maria Ševecová[2] & Miriam Kolníková[3]

[1]Comenius University Medical Faculty, National Institute of Childreńs diseases, Pediatric Endocrine Unit, Bratislava, Slovakia; [2]Faculty Hospital Prešov, Pediatrics, Prešov, Slovakia; [3]Comenius University Medical Faculty, National Institute of Childreńs Diseases, Pediatric neurology, Bratislava, Slovakia

Monocarboxylate transporter 8 (MCT8) deficiency known as Allan-Hernon-Dudley syndrome is an X-linked disorder caused by an impairment of the transcellular transportation of thyroid hormones into neurons due to SLC16A2 gene mutations. Clinical symptoms are a consequence of developing hypothyroidism in the brain and signs of hyperthyroidism in peripheral tissues. Affected patients develop mental retardation, axial hypotonia, peripheral spasticity, involuntary movements that may be paroxysmal. New treatments are being applied. We report a patient, who was born from an uneventful pregnancy in the 37th week of gestation, Apgar score 8/9, eutrophic. Shortly after birth suffered from pneumothorax, which was drained, he was dismissed with slight proximal and axial hypotonia. Neurological follow up showed deterioration of axial muscle tone around 5 months, but till 8 months there was evident regression in psychomotor development, pronounced hypotonia. EMG and EEG showed no pathology. SMA screen was negative. At 13 months MRI: delayed white matter myelinisation. EEG: unspecific abnormal activity. Endocrine assessment at 8 months was appropriate, but at 13 months showed signs of primary hypothyroidism and Thyroxin was started. After 5 months on medication there was no change. At 23 months NGS revealed mutation in SLC16A2 gene (c.940C T (p.Arg314Ter): Allan-Herndon-Dudley syndrome i.e. MCT8 deficiency. Endocrine tests on Thyroxin were broadened to fT3 and showed TSH 2,7 mIU/l, fT4 11 pmol/l fT3 8,35 pmol/l (2,5 – 5,8), Thyroxin was stopped. Vomiting led to elimination diet, which helped but he didńt gain weight, while growing normally. At 32 months TSH: 4,52 mU/l [0,70..5,97], Ft4: 6,61 pmol/l [10,45..22,35], fT3 14,72 pmol/l [3,69..8,46], with pronounced clinical picture. We started treatment with Tiratricol 350 ug daily, increasing the dose during 6 weeks to 75mg/kg daily, when the boy started to gain weight, slightly improved the axial muscle tone. But in another 8 weeks, he started vomit, was constipated, lost weight. At this time TSH was supressed. The dose was lowered and has been kept till now with normalised fT3. Evidence of epileptic encephalopathy on EEG and seizures led to antiepileptic treatment with good response. He is improving now his psychomotor development, slowly gaining weight on 5O ug /kg of Tiratricol.

A report on an unusual source of heterophilic antibodies interfering with thyroid function tests

Mélina Michel[1] & Ilaria Giordani[1]

[1]CHUV - Centre Hospitalier Universitaire Vaudois, Division of Endocrinology, Diabetes and Metabolism, Lausanne, Switzerland

Introduction

Interference in thyroid function tests is a relative frequent condition that can lead to improper diagnosis and treatment. Interference can be multiple and involve certain drugs or patient-specific factors such as antibody production. These interferences can produce both false-positive and false-negative Results.

Case Report

We report a case of a 65-year-old man suffering from Waldenstrom macroglobulinemia (WM). During a hospitalisation for subacute neurological impairment, thyroid function tests were performed as a screening. Blood tests showed TSH of 0.79 mUI/l [0.27-4.2 mUI/l], total T4 >320 nmol/l [66-181 nmol/l], free T4 >100 pmol/l [11.2-24.1 pmol/l], total T3 >10 nmol/l [1.3-3.1 nmol/l], free T3 15.5 pmol/l [3.1-6.8 pmol/l]. Further workup revealed high titers of anti-TPO antibody (1231 kUI/l [<34 kUI/l]), anti-thyroglobulin (21.4 kUI/l [<33 kUI/l]) and TRAb (143.2 UI/l [<1.75 UI/l]). The patient was clinically euthyroid and without previous thyroid history or treatment known to cause thyroid dysfunction. This biochemical pattern in an asymptomatic patient raised suspicion of interference in thyroid function tests. This suspicion was supported when another laboratory platform was used to re-analyse thyroid function and showed values in the normal range. Biotin levels were normal. Tests repeated after serum pretreatment in heterophilic blocking tubes (HBT) showed normal values. The interference in this case is due to heterophilic antibodies. We hypothesised that the IgM production in WM can interfere with the immunoassay with the same mechanism of endogenous antibodies.

Discussion

This case report demonstrates a rare cause of heterophilic antibodies interference due to excessive monoclonal immunoglobulin M (IgM) production. It highlights the importance of considering the patient's history, clinical examination and collaboration with the laboratory. When an interference is suspected, changing the manufacturer assay or re-measuring the analyte after dilution, precipitation or adding of blocking agents, can suggest an interference. However, a lack of effect from these methods does not rule out interference.

Conclusion

Heterophilic antibody-like behavior of WM-associated IgM can complicate diagnosis and interpretation of various laboratory tests. It must be considered when interpreting results in known WM patients, to avoid misdiagnosis and mistreatment. In our patient, it affected thyroid function tests, but many interferences have been reported for other endocrine tests (cortisol, testosterone, prolactin), tumoral markers (AFP, PSA) and cardiac markers (troponin).

Challenges in the treatment and long-term follow-up results of children with resistance to thyroid hormone-ß

Elif Gokce Basa[1], Ibrahim Mert Erbas[1], Özge Köprülü[1], Filiz Hazan[2] & Behzat Ozkan[1]

[1]University of Health Sciences Turkey, Izmir Dr. Behcet Uz Pediatric Diseases and Surgery Training and Research Hospital, Clinic of Pediatrics, Division of Pediatric Endocrinology, Izmir, Türkiye; [2]University of Health Sciences Turkey, Izmir Dr. Behcet Uz Pediatric Diseases and Surgery Training and Research Hospital, Clinic of Pediatrics, Division of Medical Genetics, Izmir, Türkiye

Introduction

The clinical manifestations of resistance to thyroid hormone-β (RTH-β) can sometimes be confused with either hyperthyroidism or hypothyroidism, leading to challenges in diagnosis and treatment. In this study, we aimed to evaluate the diagnosis, treatment processes, and long-term follow-up outcomes of children with RTH-β.

Methods

A retrospective study was conducted including pediatric patients with pathogenic variants in the *THRB* gene and that followed up in our department for at least 6 months between 2006-2024. The physical examination, laboratory, and imaging findings at the initial presentation and the final outpatient visit were compared.

Results

Ten patients were included in the study with a median age of 4.7(min-max: 1.2-17.2) years. Weight, height, and body mass index (BMI) measurements at the first presentation were -0.4[(-2.3) – 1.5], -0.7[(-2.3) – 1.0], and 0.0[(-2.8) – 2.6] SDS, respectively. Initial evaluation showed goiter in 50%, attention deficit hyperactivity disorder and speech delay in 40%, tachycardia in 20%, and short stature in 20% of the patients. The initial TSH, freeT4, and freeT3 levels were 3.1(1.4-11.9) mIU/l, 2.3(1.3-4) ng/dl, and 7.6(4.6-9.8) ng/dl, respectively. The median time to diagnosis was 6 months. TSH receptor stimulating autoantibodies were measured in six patients. The thyroid gland volume was 1.7[(-2.5) – 6.2] SDS on the ultrasonography, and did not change significantly during the follow-up($P = 0.345$). A total of five patients (50%) received treatment (three with methimazole, one with L-thyroxine, one with propranolol). TRIAC was added to the treatment in two patients. The median follow-up duration was 3.6 years, and the median age at the last visit was 11.6 years [bone age/calendar age ratio: 0.9(0.7-1.0)]. At the final evaluation, weight showed a significant increase($P = 0.028$); but height and BMI were similar to the initial measurements ($P = 0.203$ and 0.445). At the last visit, only one patient was under LT4 treatment, and another one was receiving propranolol. Laboratory results on the last control were were similar to the initial pretreatment values; TSH 2.2 (1.1-3.8) mIU/l, freeT4 2.5 (1.4-3.6) ng/dl, and freeT3 7.0 (4.2-12.6) ng/dl ($P > 0.05$). The serum sex hormone binding globulin level was elevated in five patients (50%).

Conclusions

Pediatric RTH-β patients were mostly misdiagnosed as hyperthyroidism leading to treatment with anti-thyroid drugs, and most individuals became treatment-free in the long-term follow-up. Also, we demonstrated that thyroid function tests and thyroid gland volume did not change with age, and growth of the children was not affected in RTH-β.

A decade of thyroid orbitopathy research in albania: a retrospective study from a tertiary referral center

Marjeta Kermaj[1], Dorina Ylli[2] & Agron Ylli[3]

[1]U.M.T, U.M.T, Endocrinology, Tirana, Albania; [2]U.M.T, U.H.C "Mother Tereza", Endocrinology, Tirana, Albania; [3]U.H.C "Mother Tereza", U.M.T, Endocrinology, Tirana, Albania

Introduction
Thyroid Orbitopathy (TO), also referred to as Graves' Orbitopathy (GO), is a complex and impactful complication of Graves' disease (GD). Limited data from Albania highlight the need for a deeper understanding of its presentation and management.
Aim
This 10-year retrospective study conducted at a tertiary referral center in Albania analyses the clinical features, diagnostic challenges, and treatment approaches for GO to enhance disease understanding and improve management strategies.
Methods
Data were systematically collected from 178 patients referred for GO evaluation and treatment over a decade. Patient demographics and clinical characteristics were documented using the European Group on Graves' Orbitopathy (EUGOGO) protocol. Cases were categorized as bilateral (asymmetric or symmetric) or unilateral GO, and clinical features were analyzed to identify distinguishing patterns.
Results
Among 178 patients with GO, the mean age was 44.9 $\pm$14.9 years. Bilateral GO was most common (72.5%), followed by unilateral (17%) and unilateral-to-bilateral (10.5%). Asymmetric GO was observed in 30.9% of bilateral cases. GO onset was often concurrent with GD, with female predominance (72.5%). Mild GO was present in 48%, while 52% had moderate to severe forms. Local treatment was effective for mild cases, while 80% of moderate/severe cases responded positively to intravenous glucocorticoids. Hypothyroidism was a significant risk factor for GO activation.
Conclusion
Clinical management should prioritize the overall presentation of GO, emphasizing individualized treatment approaches. Hypothyroidism was identified as a key risk factor for GO activation, highlighting the need for careful thyroid function management to mitigate disease progression.

Children undergoing thyroid surgery - diagnostic evaluation, type of surgery and pathological findings

Sofie Rygaard[1], Jacob Lilja-Fischer[1], Stefano Londero[1] & Lars Rolighed[1]
[1]Aarhus University Hospital, Department of Otorhinolaryngology, Aarhus, Denmark

Introduction
Thyroid gland diseases among children and adolescents are rare. The purpose of the current study was to describe the pediatric patients treated with surgery of the thyroid gland, including the diagnostic evaluation, type of surgical treatment, complications and pathological findings.
Methods
Patients with an age of less than 18 years at the time surgery with a procedure coded for a surgery on the thyroid gland (KBAAxx) were extracted from the electronic medical journal system.
Results
32 patients with a median age of 16 years (range 3 - 17) were operated during a twelve-year period from January 2012 to December 2023. The frequency of preoperative imaging was ultrasound scan (US) (97%), thyroid scintigraphy (41%), magnetic resonance imaging (MRI) (25%) and computerized tomography (CT) scan (9%). Almost all patients had TSH measured (97%) and more than half were evaluated with a fine needle aspiration (FNA) (59%). Six patients had genetic dispositions to thyroid disease (19%). Forty surgical procedures were performed in 32 patients. The procedures were hemi-thyroidectomy (15 patients), total thyroidectomy in one (9) or two procedures (8). Further, 7 patients had simultaneous lymphadenectomy performed in the central and/or lateral neck compartments. The pathological examination revealed thyroid cancer in 14 patients (45%). The majority was papillary thyroid cancer (11), one classic follicular cancer, one oncocytic cancer, and one medullary cancer. Of patients with thyroid cancer, 4 (29%) had lymph node metastasis and none had distant metastases. There was one permanent paresis of the recurrent laryngeal nerve out of 49 nerves at risk (2%). One had permanent hypoparathyroidism out of 17 patients at risk (6%).
Conclusion
Most pediatric patients with thyroid disease are only evaluated by US and TSH before surgery. Compared with adult thyroid patients, genetic dispositions and cancer frequency are more common, whereas complications after surgery are rare.

Congenital central hypothyroidism due to TSHB gene mutation: a case report

Omneya Magdy Omar[1] & Amira Omar[2]
[1]Alexandria, Pediatrics, Alexandria, Egypt; [2]Alexandria, Histology and Cell Biology, Alexandria, Egypt

Introduction
Congenital central hypothyroidism (CCH) is a rare disorder caused by mutations in the TSHB gene, leading to impaired thyroid-stimulating hormone (TSH) production. This case report describes a male infant diagnosed with CCH, highlighting the clinical presentation, genetic analysis, and management.
Case Report
A 10 old-old boy was referred for evaluation due to jaundice, poor weight gain, and lethargy. He was born at term via an uneventful delivery, with normal birth weight and length. The parents were consanguineous, and there was no family history of thyroid disorders. On examination, the infant had mild hypotonia, prolonged jaundice, and a puffy face. Laboratory investigations revealed **serum free T4:** 0.34 ng/dl (normal: 0.8- 2 ng/dl), **serum TSH:** 1.9 mIU/mL (normal: 1.7–9.1 mIU/mL), glucose: 53 mg/dl, **cortiso:10. μg/dl.**A diagnosis of central congenital hypothyroidism was made. Molecular genetic testing identified a homozygous **mutation** in the TSHB gene, confirming the genetic basis of the condition. The infant was started on **levothyroxine** at 10 mg/kg/day, with regular follow-up to monitor growth and neurodevelopment. At 12 months of age, he showed significant improvement in activity levels, weight gain, and developmental milestones.
Conclusion
This case underscores the importance of considering TSHB mutations in children with unexplained hypothyroidism. Early intervention can lead to favorable outcomes, emphasizing the role of genetic analysis in diagnosing congenital endocrine disorders.

JOINT3726

Sonographic evaluation of thyroid volume and morphology over time in children with hashimoto's thyroiditis

Rishtie Shah[1], Devi Dayal[1], Anmol Bhatia[1] & Savita Attri[1]
[1]Post Graduate Institute of Medical Education and Research, Pediatrics, Chandigarh, India

Background
Hashimoto's thyroiditis (HT) is associated with thyroid atrophy, fibrosis, and nodular changes, with a potential risk of malignancy. However, data on longitudinal thyroid morphology changes in pediatric populations, particularly in India, remain limited.
Objective
To assess the morphological changes in the thyroid gland over time in children with HT and compare thyroid volume standard deviation scores (SDS) between diagnosis and follow-up.
Methods
Children diagnosed with HT between 4–12 years, based on thyroid function tests, antibody positivity, and ultrasound findings, with $\geq$2 years of follow-up, underwent repeat thyroid ultrasound. Thyroid volume was compared with baseline values. Nodules, if present, were graded using TIRADS, and thyroid scans were performed to assess cold nodules.
Results
56 children (68% female) were evaluated in a prospective cross-sectional study. The mean age at symptom onset was 7.2 ($\pm$ 2.70 years, and age at diagnosis was 8.7 ($\pm$ 2.38) years. Autoimmune comorbidities were present in 18% at diagnosis. The most common symptoms were reduced physical activity (61%) and constipation (51.8%). The median duration of follow up was 2 years. At diagnosis, 41% had goiter, 37.5% had short stature, and 18% were underweight. The median TPO level was 198 IU/ml (IQR: 92–544 IU/ml). Height and weight SDS improved significantly ($P = 0.001$ and $P = 0.003$, respectively). Ultrasound revealed increase in heterogenicity (76.8% to 89.3%), hypoechogenicity (10.7% to 21%), and nodules (19.6% to 26.8%) in between diagnosis and follow up. Thyroid volume reduced by mean of 1.448 SDS ($P = 0.001$), particularly in overt hypothyroidism with a mean reduction of 1.54 SDS ($P = 0.001$). 63% of the nodules at diagnosis showed resolution over a mean duration of 2.4 years. 19% developed nodules during a mean follow up of 3.1 years and risk of development of nodule did not correlate with follow-up duration ($P = 0.823$), TSH ($P = 0.52$), anti-TPO levels ($P = 0.664$), or delayed diagnosis($P = 0.819$). 80% nodules were TIRADS 1, indicating benign nature.

Conclusion
Children with HT exhibit progressive thyroid heterogenicity and nodule development over time, with significant reduction in thyroid volume. The predominance of benign nodules suggests a low risk of malignancy in pediatric population.

Clinical audit on ultrasound assessment and thyroid function testing in evaluation of thyroid nodules in a regional centre in Ireland

Julen Borlle[1], Kevin Hall[1], Max Hillery[1,2], Conor Meehan[3], Jayant Sharma[1] & Ma Pyeh Kyithar[1,4]
[1]Midland Regional Hospital Portlaoise, Ireland, Diabetes & Endocrinology Department, Portlaoise, Ireland; [2]University College Dublin, Ireland, Intern Network, Dublin, Ireland; [3]Midlands Regional Hospital Portlaoise, Ireland, Radiology Department, Portlaoise, Ireland; [4]Trinity College Dublin, Dublin, Ireland, School of Medicine, Dublin, Ireland

Introduction
There is a high prevalence of thyroid nodules (up to 60%) in adults in the general population. 2023 European Thyroid Association clinical practice guidelines for thyroid nodule management recommends neck Ultrasound (US) assessment with European Thyroid Imaging and Reporting Data System (EU-TIRADS) and thyroid function testing (TFT) in evaluation of thyroid nodules. This study aims to assess US classification and TFT evaluation of thyroid nodules in our centre.
Methods
A retrospective data of all US thyroid scans performed in our hospital in 2024, were included in the study. TFT results of persons with thyroid nodules on US scans, were collected from the hospital laboratory system.
Results
A total of 230 US thyroid scans from 2024 were reviewed. Mean age of people who had US thyroid was 54.7 ± 21.2 years. 82% were female and 18% were male. 36 scans (16%) had no thyroid nodules, while 194 scans (84%) showed at least one nodule. TIRADS was used in categorizing thyroid nodules in 62 out of 194 scans (32%); U classification was used in 52 scans (27%) and no categorization of thyroid nodules in 80 scans (41%). In US thyroid scans with TIRADS categorization, 42 were TIRADS 2 (benign); 23 were TIRADS 3 (mild suspicion); 3 were TIRADS 4 (Moderate to high suspicion); 2 were TIRADS 5 (high risk). Of US thyroid scans with U classification, 45 were classified as U2 (benign), 23 as U3 (indeterminate/uncertain), and two as U4 (suspicious), with no reports classified as U5 (highly suspicious/malignant). 38 out of 194 US thyroid reports (19.6%) had recommendations to repeat the US thyroid in 6 or 12 months to re-evaluate thyroid nodules and 23 reports (11.9%) had recommendations to refer for fine needle aspiration. On reviewing the laboratory system, TFT results were available in 142 persons out of 194 with thyroid nodules (73%). Out of 142 with TFT results, 119 (83.8%) had normal TFTs, 11 (7.7%) had hypothyroidism and 12 (8.5%) had hyperthyroidism.
Conclusion
Our study demonstrated the majority of thyroid nodules that were categorised, are considered benign or of low suspicion, and a significant proportion of people with thyroid nodules have euthyroid status. Our audit also showed there is some variability in thyroid nodule categorization, with 41% of nodules unclassified. The local practice guidelines on standardised categorization of thyroid nodule management and TFTs, could improve consistency, aiding clinical decisions on follow-up, individualised management and resources allocation.

Ultrasound-guided thermal ablation of symptomatic benign thyroid nodules: volumetric outcomes in a cohort of 36 patients

Renato Diana[1], Claudio Cusini[2], Lorenzo Monfardini[2], Federica Boselli[1] & Livio Luzi[1,2]
[1]University of Milan, Department of Biomedical Sciences for Health, Milan, Italy; [2]Department of Endocrinology, Nutrition and Metabolic Diseases, IRCCS Multi Medica, Sesto San Giovanni (MI), Italy

Introduction
Large thyroid nodules can cause compressive symptoms, such as a sense of tightness, dysphagia, dysphonia and dyspnea. In these cases, surgery (thyroidectomy/lobectomy) is indicated. When surgery and/or general anesthesia are contraindicated (e.g., age, comorbidities, etc.) or if the patient refuses surgery, the guidelines recommend that cytologically benign and non-functioning nodules, solid or mixed, can be treated with ultrasound-guided thermal ablation (TA), a minimally invasive treatment aimed at reducing nodule volume and reducing or eliminating compressive symptoms. TA can be performed using radiofrequency (RFA), microwaves (MWA), laser, or ultrasound. According to literature data, the expected volume reduction 12 months after treatment is 50%-84% with RFA and 74%-90% with MWA.
Methods
In our cohort, we included 36 patients who underwent TA (34 RFA and 2 MWA) at our University Hospital. We evaluated the volumetric reduction with one or more post-TA ultrasound examinations (at 45 days, 3 months, 6 months and 12 months after TA).
Results
Pre-treatment average volume of the nodules was 18.2 ml. Twenty-six patients had a 45-day follow-up with an average volume reduction of 38% (min 7.2% - max 82%, average volume = 13 ml). Thirty-two patients had a 3-month follow-up with an average volume reduction of 47% (min 7% - max 83%, average volume = 9.5 ml). Twenty patients had a 6-month follow-up, with an average volume reduction of 55.9% (min 0% - max 92.2%, average volume = 7.7 ml). Twenty patients had a 12-month follow-up, with an average volume reduction of 60.2% (min 23.1% - max 91.8%, average volume = 5.1 ml). Only one patient had a therapeutic failure, with a volumetric reduction of 7% at 45 days and a subsequent volumetric increase to a volume close to the pre-treatment volume at the 6-months ultrasound follow-up. Only 3 patients (8.3%) experienced minor complications (moderate pericapsular hematoma, first-degree skin burn of 4 millimeters, transient hoarseness); no major complication nor hypothyroidism was reported.
Conclusion
The volumetric reduction in our case series is similar to that reported in the literature. Thermal ablation is a valid alternative to surgery, eliminating symptoms, reducing nodule volume, preventing nodule enlargement and avoiding hypothyroidism. Pre-treatment nodule volume is a predictive factor for treatment outcomes. To date, other clinical and ultrasound parameters predicting volumetric reduction and long-term symptomatic response to the treatment are still debated.

Exacerbation of orbitopathy after total thyroidectomy in alemtuzumab-induced graves' disease: a case report

Alice Monsanto[1], Margarida Sobral[1], Bárbara Jesus[1], Leonor Rodrigues[2], Tânia Carvalho[1], Gustavo Rodrigues[1], Mariana Lavrador[1], Mara Ventura[1] & Leonor Gomes[1]
[1]Unidade Local de Saúde de Coimbra, Serviço de Endocrinologia, Diabetes e Metabolismo, Coimbra, Portugal; [2]Unidade Local de Saúde de Aveiro, Serviço de Endocrinologia, Diabetes e Nutrição, Aveiro, Portugal

Introduction
Graves' orbitopathy (GO) is an autoimmune condition characterized by inflammation of extraocular muscles and peri-orbital tissue due to overstimulation of TSH receptor autoantibodies (TRAbs). It is a key extrathyroidal manifestation of Graves' disease (GD), often appearing at disease onset or shortly thereafter. Total thyroidectomy (TT) is one of the treatment options for GD, particularly in cases when definitive management is preferred, and radioiodine therapy is not appropriate. TT is generally considered safe regarding orbitopathy progression so prophylactic glucocorticoid therapy post-surgery is not routinely recommended.
Clinical case
This report presents a 41-year-old female patient with multiple sclerosis who, after receiving three cycles of Alemtuzumab, developed signs and symptoms suggestive of hyperthyroidism. Laboratory tests revealed: TSH <0.004 UI/mL (0.4-4.0), T4L 1.61 ng/dl (0.7-1.5), and TRAbs 16 U/l (<1.0). Treatment with thiamazole and propranolol was initiated with partial symptom improvement. The clinical course was characterized by difficult-to-control hyperthyroidism, requiring frequent dose adjustments of thiamazole (up to 30 mg daily) and continuous propranolol therapy. The patient developed other manifestations including pretibial myxedema and orbitopathy. The latter appeared approximately one year after the initial presentation, with dry eye sensation, visual acuity changes, and progressively worsening bilateral exophthalmos. The introduction of selenium therapy at 200 mg/day provided only partial relief. An orbital CT scan confirmed the diagnosis, and ophthalmology assessment classified the condition as moderate-to-severe and inactive (CAS 2). Due to the severe and poorly controlled clinical picture, the patient underwent total thyroidectomy two and a half years after symptom onset. At the time of surgery, she was on 25 mg of thiamazole and was biochemically euthyroid, with TRAbs of 76 U/l.

Immediately after surgery, the patient experienced a multiple sclerosis flare, requiring a short course of corticosteroid therapy (prednisolone 1 g for 5 days). About a week post-surgery and after completing the corticosteroid cycle, she developed worsening orbitopathy with ocular pain and diplopia, requiring an emergency ophthalmology consultation. A follow-up orbital CT scan confirmed disease progression, prompting the initiation of corticosteroid therapy, of which she has completed two cycles to date. Due to only partial improvement, treatment with Tocilizumab has been proposed and is scheduled to begin soon.
Conclusion
A patient with severe, difficult-to-control hyperthyroidism and moderate-to-severe inactive orbitopathy underwent total thyroidectomy. Despite this, orbitopathy exacerbation occurred post-surgery, requiring specific treatment. This case highlights a rare complication and raises the question of whether corticosteroid prophylaxis should be considered after surgery in high-risk patients.

The relationship between TSH suppression and metabolic associated fatty liver disease (MAFLD) in patients with thyroid cancer

Rüveyda Bulut[1], Afruz Babayeva[2], Mahinur Cerit[3], Halit Şendur[3], Ethem Turgay Cerit[2], Altinova Alev[2], Mujde Akturk[2], Fusun Toruner[2], Ayhan Karakoc[2] & Mehmet Muhittin Yalcin[2]
[1]Gazi University Faculty of Medicine Department of Internal Medicine, Ankara, Türkiye; [2]Gazi University Faculty of Medicine Department of Endocrinology and Metabolism, Ankara, Türkiye; [3]Gazi University Faculty of Medicine Department of Radiology, Ankara, Türkiye

Metabolic associated fatty liver disease (MAFLD) is a clinical spectrum ranging from simple steatosis to cirrhosis and hepatocellular carcinoma (HCC) with increasing prevalence worldwide. Although its close relationship with obesity, metabolic syndrome and diabetes is known, its mortality and morbidity are high. Thyroid hormones play a regulatory role in cell metabolism and are effective on metabolic parameters involved in the etiology of MAFLD. Although the studies conducted so far mostly support that hypothyroidism increases the risk of MAFLD, there are not enough studies investigating the effect of hyperthyroidism on MAFLD. The aim of this study was to investigate the effect of subclinical thyrotoxicosis on MAFLD.
Patients and methods
Between March 2023 and November 2023, 38 patients with subclinical thyrotoxicosis who were followed up due to thyroid cancer in remission and who applied to Gazi University Medical Faculty, Endocrinology Clinic between March 2023 and November 2023 were included in the study and 38 healthy people with similar age and gender distribution were included in the control group. 76 people were included in the study. Liver function tests, serum lipid levels, TNF-alpha, IL-6, T4, TSH tests were analysed. Quantitative measurement was performed by ultrasonography for fatty liver disease and TAI was calculated and the stage of hepatic steatosis was measured and recorded as grade. Fatty liver index(FLI) was calculated.
Results
We found no significant difference between the subclinical thyrotoxicosis group and the euthyroid group in terms of MAFLD diagnosed by imaging. In both groups, we found a significant correlation between the grade of hepatic steatosis and age, BMI, waist circumference, ALT, GGT, LDL and TG levels. In analyses controlling for age and body mass index (BMI), we found a significant, positive correlation between TSH and the grade of hepatic steatosis.
Discussion
We found a negative correlation between TSH suppression level and MAFLD, and our results are consistent with the literature in this respect. Addition to B-mode ultrasound for the diagnosis of MAFLD, we preferred TAI measurements because of its sensitivity, which have not been used in a similar study before.

JOINT1027

Complete blood count markers as possible prognostic values of immune checkpoint inhibitors induced hypothyroidism

Ketevan Lomidze[1], Marine Gordeladze[1], Nino Kikodze[1], Nino Charkviani[1], Tinatin Chikovani[1] & Ketevan Meladze[2]
[1]Tbilisi State Medical University, Endocrinology, Tbilisi, Georgia; [2]Tbilisi State University, Oncology, Tbilisi, Georgia

Background
A novel and highly effective strategy for tumor immunotherapy involves enhancing host immune responses against tumors through the blockade of checkpoint molecules. The most common toxicities associated with checkpoint blockade therapies include autoimmune damage to various organs.
Purpose
This study aims to investigate hematological markers derived from complete blood count (CBC) – including the neutrophil-to-lymphocyte ratio (NLR), platelet-to-lymphocyte ratio (PLR), derived neutrophil-to-lymphocyte ratio (dNLR), white blood cell-to-hemoglobin ratio (WHR), neutrophils, lymphocytes, platelets, hemoglobin, red blood cell (RBC) count, neutrophil-to-RBC ratio (NRR), and neutrophil-to-hemoglobin ratio (NHR) – as potential prognostic biomarkers for the early identification of hypothyroidism in patients receiving PD-1 or PD-1/CTLA-4 immune checkpoint inhibitors.
Methods
A prospective observational study was conducted on 44 patients with stage III-IV solid tumors treated with immune checkpoint (PD-1 or PD-1/CTLA-4) inhibitors. Thyroid function tests and CBC-derived biomarkers were collected at baseline, before immunotherapy. In the immunotherapy cohort, 15 of the 44 patients developed immune-related hypothyroidism, defined as overt autoimmune thyroiditis (TSH $>$ 4.0, FT4 $<$ 12, and anti-TPO antibodies $>$ 30 IU/mL and/or anti-TG antibodies $>$ 95 IU/mL) (Group-1). In comparison, 29 patients maintained normal thyroid function (Group-2). The control group comprised 14 age- and sex-matched healthy volunteers (Group-3). Statistical analyses were performed using analysis of variance (ANOVA) to compare blood parameters among the three groups (Group-1, Group-2, and Group-3) before treatment, with statistical significance set at a P-value $<$ 0.05. Receiver operating characteristic (ROC) curve analysis was conducted to evaluate the diagnostic power of the potential prognostic biomarkers areas. Under the curve (AUC), sensitivity, and specificity were calculated for the 44 immunotherapy patients.
Results
PLR was significantly higher (262.25 ± 162.95), while WBC-neutrophils, WHR, NRR, NHR, WBC, neutrophils, and lymphocytes were lower (2.07 ± 0.66, 0.54 ± 0.19, 0.96 ± 0.28, 0.36 ± 0.14, 6.36 ± 2.07, 4.29 ± 1.55, and 1.23 ± 0.41, respectively) at baseline in Group-1 in comparison Group-2. ROC curve analysis revealed that the areas under the curve (AUC) for WBC, neutrophils, lymphocytes, WBC-neutrophils, PLR, WHR, NRR, and NHR were 0.9, 0.87, 0.83, 0.85, 0.84, 0.92, 0.89, and 0.87, respectively. These values exceeded the threshold, indicating the high prognostic potential of each marker.
Conclusion
Lower baseline levels of WBC-neutrophils, WHR, NRR, NHR, WBC, neutrophils, and lymphocytes, along with higher PLR, were associated with an increased risk of hypothyroidism in patients receiving PD-1 or PD-1/CTLA-4 inhibitors. These CBC-derived biomarkers represent simple, accessible, and potentially useful tools for predicting hypothyroidism in cancer patients undergoing immunotherapy. Further studies in bigger cohorts are needed to validate our findings.

Subacute thyroiditis (De Quervain's thyroiditis, granulomatous thyroiditis, giant cell thyroiditis) is an inflammation of the thyroid gland. The prevalence in the pediatric population is very rare. It is characterized by a triphasic course of transient mild thyrotoxicosis, lasting between 2 to 8 weeks, followed by

hypothyroidism and thereafter by a return to euthyroid. During the thyrotoxic phase the thyroid follicles are damaged and the preformed thyroid hormone is released. In nuclear scan there is low thyroid uptake on nuclear scan, and the ultrasound of the thyroid gland shows areas of hypoechogenity with decreased or normal vascular flow by Dopler. ESR and CRP can be elevated. The patient has moderate to severe neck pain, with bilateral, and rare unilateral swelling of the thyroid gland and influenza-like symptoms. Differential diagnosis from malignancy can be difficult. The histopathological examination reveals patchy changes with varying stages of the disease. The classic granulomatous changes appear a little later in the disease with a large aggregation of lymphocytes, plasma cells, and large histiocytes in the damaged thyroid follicles. Multinucleated giant cells surround the fragments of colloid, and sometimes colloid can also be seen in the giant cells. Later there are many lymphocytic infiltrates and fibrosis. Rarely different histologic stages can be found in the same gland suggesting the confluence nature of destruction. The treatment may include non-steroidal anti-inflammatory drugs, beta-blockers, corticosteroids, opioid analgesics, or potassium iodide or iopanoic acid to reduce the conversion of T4 to the more biologically active form of thyroid hormone, T3. During the hypothyroid phase, thyroid hormone replacement may help alleviate hypothyroid symptoms. We present the case of a female 10-year-old patient who presented in our emergency department with goiter, fever and pain in the neck. Several weeks earlier she had tachycardia and restlessness. Thyroid function was normal, thyroglobulin was increased (8100ng/ml). An ultrasound showed a swollen left thyroid lobe with a volume of 7 ml. During the following days the patient developed jaundice. Blood tests showed elevated hepatic enzymes and serological examination showed increased IgM for Hepatitis A. A fine needle biopsy diagnostic confirmed the diagnoses of De Quervain's thyroiditis. The patient received treatment with NSAID. This abstract reminds the reader of the rare condition of de Quervain thyroiditis. Furthermore, this is the first pediatric case report of de Quervain thyroiditis that was associated with Hepatitis A.

Predictive factors for hypothyroidism in childhood autoimmune thyroiditis: insights from long-term follow-up

Laura Astara[1], Laura Pinna[1], Giulia Faa[1], Alessandro Colleo[1], Francesco David[1], Sandro Loche[1], Angelico Lampis[1], Stefano Mariotti[1], Francesco Boi[1] & Giulia Lanzolla[1]
[1]University of Cagliari, Cagliari, Italy

Introduction
Predictive factors for hypothyroidism progression in children with autoimmune thyroiditis (AIT) remain unclear.
Objectives
To characterize the clinical presentation of AIT, assess long-term outcomes, and identify predictive factors for disease progression.
Methods
Data from 127 consecutive patients under 18 years of age at presentation were analyzed (mean follow-up:7.1 years; range:0–20yr).
Results
At presentation, 57% of patients were euthyroid, 28% had subclinical hypothyroidism, and 15% had overt hypothyroidism. By the end of follow-up, among euthyroid children, 20.5% developed overt hypothyroidism, and 6.8% progressed to subclinical hypothyroidism. The subclinical hypothyroidism group showed dynamic changes: 45.7% of patients progressed to overt hypothyroidism, while 37.1% reverted to euthyroidism. Finally, the overt hypothyroidism group did not show significant changes. Patients progressing to hypothyroidism were younger at diagnosis ($P = 0.0008$) with higher thyroid peroxidase antibodies (AbTPO) titers ($P < 0.0001$), higher TSH ($P < 0.0001$) and lower FT4 levels ($P = 0.0026$). Thyroid volume >6mL increased hypothyroidism risk ($P = 0.0060$, OR:0.347,95%CI:0.15-0.75). Multivariate analysis confirmed that AbTPO titers influence TSH levels at follow-up ($P < 0.0001$). Cutoff thresholds were established to refine predictive accuracy. Patients diagnosed under 10 years of age ($P = 0.043$, OR:0.458,95%CI:0.22-0.96), with AbTPO > 92 IU/mL ($P < 0.0001$, OR:25,95%CI:8.78-63.11), and TSH > 4.95 μIU/mL ($P < 0.0001$, OR:15.43,95%CI:5.61-37.57) had highest risk of developing hypothyroidism. Notably, AbTPO > 92 IU/mL and TSH > 4.95 μIU/mL demonstrated the strongest predictive power. AbTPO titers had a positive predictive value (PPV) and negative predictive value (NPV) of 83%, while TSH > 4.95 yielded a PPV of 79% and an NPV of 80%.
Conclusions
Twenty percent of euthyroid children developed hypothyroidism, compared to 45.7% of those with subclinical hypothyroidism. TSH > 4.95 μIU/mL and AbTPO titers had the greatest predictive power. Patients diagnosed under 10 years of age had a higher risk of developing hypothyroidism, suggesting that prolonged exposure to autoimmunity may play a role. Further studies are needed to validate predictive models for hypothyroidism development in children with AIT.

Molecular insights into persistent or residual pediatric differentiated thyroid cancer

Sirmen Kizilcan Cetin[1], Zehra Aycan[1], Hale Karadağ[2], Burcu Cevik[2], Koray Ceyhan[2], Zeynep Siklar[3,4], Merih Berberoglu[1], Elif Ozsu[1], Omer Fitoz[5] & Serpil Dizbay Sak[2]
[1]Ankara University School of Medicine, Department of Pediatric Endocrinology, Ankara, Türkiye; [2]Ankara University School of Medicine, Department of Pathology, Ankara, Türkiye; [3]Ankara Universty, Pediatric Endocrinology, Ankara, Türkiye; [4]Ankara University, Pediatric Endocrinology, Ankara, Türkiye; [5]Ankara University School of Medicine, Department of Radiology, Ankara, Türkiye

Introduction
Differentiated thyroid cancers (DTC) in childhood, although less common than in adults, are increasing in incidence and exhibit distinct characteristics. The American Thyroid Association (ATA) Guideline is used to diagnose, follow up, and treat these cases. While standard follow-up protocols exist, some pediatric thyroid cancers progress more aggressively. This study focuses on cases with aggressive clinical courses and aims to present their diagnostic and follow-up findings. Furthermore, it seeks to bridge gaps in understanding the molecular and clinical characteristics of pediatric DTC, particularly in patients with residual or persistent disease, contributing to the optimization of tailored management strategies.
Methods
Children with DTC, who had aggressive clinical courses were included in this study, aiming to present their diagnostic and follow-up findings. A retrospective collected data included demographic characteristics, comorbidities, surgical details, pathological findings, molecular analysis, serum thyroglobulin (Tg) levels, and response to radioactive iodine (RAI) therapy. Persistent disease was defined as detectable Tg levels or imaging-confirmed disease beyond the first year of treatment per ATA guidelines.
* This study was supported by the Ankara University Scientific Research Committee with the project code 21B0230013, approved on September 17, 2021.
Results
A total of six cases of DTC, including four females, presenting with aggressive clinical features, were included in this study. The mean age at diagnosis was 14.4 years (range: 7.2–19.4). Presenting symptoms included goiter ($n = 4$) and incidental nodules ($n = 2$). All patients underwent total thyroidectomy with central lymph node dissection; five cases were classified as high-risk based on ATA ultrasound criteria. Molecular analysis identified *BRAFV600E* variant in four patients, *NCOA4-RET* fusion in one, and no variants in one patient. Postoperative Tg levels ranged from 4.11 to 494 ng/mL. RAI therapy was initiated postoperatively for all. Five patients required additional surgeries for metastatic lymph nodes, and three underwent a second RAI dose. One patient had lung metastases, and RAI caused lung fibrosis. Selpercatinib was initiated in one patient due to aggressive disease features associated with *NCOA4-RET* fusion. The presence of *BRAFV600E* and *NCOA4-RET* variants correlated with more aggressive disease characteristics in children with DTC.
Conclusion
Residual or persistent disease in pediatric DTC remains a significant challenge. Early identification of high-risk patients and personalized treatment strategies, including optimized surgical approaches and tailored RAI protocols, are critical. In this study, *BRAFV600E* and *NCOA4-RET* were the most common pathogenic variants in children with residual or persistent disease in pediatric DTC.

A case of mistaken identity: hypoadrenalism and the cirrhotic paradox

Maxim Barnett[1], Justin Riley Lam[2], Carlo Casipit[1] & Ana Rivadeneira[3]
[1]Jefferson-Einstein Hospital, Internal Medicine, Philadelphia, United States; [2]Jefferson Einstein, Internal Medicine, Philadelphia, United States; [3]Jefferson-Einstein Hospital, Philadelphia, United States

Introduction
Persistent hypotension and hyponatremia are common clinical features in patients with cirrhosis, for which an endocrine consult is not uncommon. Additionally, hypoalbuminemia is a common finding in cirrhosis, with reductions in total hormone assay levels, including cortisol, which leads to a false interpretation of hypocortisolemia. Whether or not there is truly an increased risk (or diagnosis) of hypoadrenalism in patients with underlying cirrhosis remains unknown.
Objectives
The primary objective of this study is to evaluate if cirrhosis is associated with a greater risk for adrenal insufficiency. Secondary objectives include comparing serum levels of albumin, total cortisol, and free cortisol between patients with (and without) cirrhosis, to assess for significant differences.
Methods
The study was performed as a retrospective cohort study, with data collated from TriNetX Global Collaborative Network, providing de-identified patient information from 143 healthcare organizations worldwide. Two cohorts were assessed in this study: Group A (patients with cirrhosis who have had a total cortisol measurement, $n = 43,786$) and Group B (patients without cirrhosis who have had total cortisol measurements, $n = 1,249,256$). Propensity score matching was employed to allow for balancing between the cohorts with $n = 53,220$; this was achieved by controlling for age, race, gender, body mass index, A1c, alcohol use, systemic corticosteroid use, and underlying inflammatory diseases of the liver.
Results
The results of this study noted no greater risk for primary, secondary, tertiary or drug-induced hypoadrenalism in patients with cirrhosis compared to those without, but rather a statistically significant (but likely clinically negligible) reduction in risk (Relative Risk 0.929, 95% CI: 0.872-0.99, $P = 0.0239$). Secondary outcomes noted a significantly lower mean albumin level in Group A (3.171 vs 3.58, $P < 0.0001$) but higher mean total cortisol (14.06 vs 12.188, $P < 0.0001$). There was no significant difference regarding free cortisol between both cohorts ($P = 0.9822$).
Conclusion
This study suggests that cirrhosis does not confer a greater risk for adrenal insufficiency (of any cause). As expected, patients with cirrhosis did demonstrate hypoalbuminemia, however, they appeared to overall exhibit higher mean total cortisol levels (without a significant difference in free cortisol). These findings support a cautious approach to adrenal function testing in patients with cirrhosis, and for reserving the diagnosis of adrenal insufficiency when there is true clinical suspicion.

Effects of switching from conventional glucocorticoid therapy to modified-release hydrocortisone (MR-HC) on the steroid matabolome in patients with 21-hydroxylase deficiency

Matthias Auer[1,2], Lea Tschaidse[1], Ann-Christin Welp[1], Martin Bidlingmaier[1], Sonja Kunz[3], Michaela Hartmann[3], Stefan Wudy[3] & Nicole Reisch[1]
[1]Medizinische Klinik and Poliklinik IV, Klinikum der Universität München, LMU München, Munich, Germany; [2]Medizinisch Klinik und Poliklinik IV, LMU, Munich, Germany; [3]Justus-Liebig-University, Division of Pediatric Endocrinology & Diabetology, Laboratory for Translational Hormone Analysis in Pediatric Endocrinology, Steroid Research & Mass Spectrometry Unit, Center of Child and Adolescent Medicine, Giessen, Germany

Background
New hydrocortisone formulations with modified release are increasingly used in treating patients with congenital adrenal hyperplasia (CAH) due to 21-hydroxylase deficiency (21OHD). The goal is better androgen control while reducing overall glucocorticoid exposure through more physiological hydrocortisone release and replacement. However, the effects of switching from conventional glucocorticoid therapy to modified-release hydrocortisone (MR-HC) on steroid metabolism remain uninvestigated
Methods
The steroid metabolome in 24-h urine samples was analyzed in 22 patients with classic CAH due to 21OHD (10 women, 12 men). Before the switch, 10 patients received conventional hydrocortisone, 9 prednisolone, and 3 combination therapy. The switch to MR-HC was performed using equivalent dose conversion (prednisolone conversion factor = 5). Urine samples were collected before and six months after the switch and analyzed using gas chromatography-mass spectrometry (GC-MS).
Results
Based on serum androstenedione and 17-OHP levels, three patients were classified as not well controlled at baseline. After switching, one patient transitioned from well-controlled to not well-controlled, and another showed the opposite trend. Median hydrocortisone-equivalent dosages were 25 mg (IQR 24.375–35.625) before and 27.5 mg (IQR 20–35) after the switch to MR-HC ($P = 0.109$). The switch led to a trend toward increased major cortisol metabolites (5α-THF + THF + THE, $P = 0.093$) and overall urinary cortisol metabolites (5α-THF + THF + THE + a-C + b-C + a-Cl + b-Cl; $P = 0.059$) in those previously on HC. No absolute change in 17-OHP metabolites (Po-5β3α, Po-5α3α, PT, 11-OH-P) or significant change in overall 11-oxygenated androgens was observed. In women, 11-deoxygenated androgens showed a declining trend ($P = 0.071$), leading to a significant increase in the 11-oxygenated (11OH-An + 11O-An + 11OH-Et) to 11-deoxygenated androgen ratio (An + Et + A5-3β, 17α + A5-3β, 17β + DHEA + 16α-OH-DHEA + A5T-16α) from 0.64 (IQR 0.24–2.10) to 2.75 (IQR 1.67–5.75, $P = 0.007$), indicating increased adrenal suppression. In men, no significant change in 11-oxygenated or deoxygenated androgens was found. However, individually, significant PT reductions (6790 vs. 2982 μg/d) were seen in 14/22 patients, 11OH-An reductions (828 vs. 426 μg/d) in 12/22, and An reductions (823 vs. 433 μg/d) in 12/22.
Conclusion
While overall glucocorticoid exposure remained comparable, trends toward increased urinary cortisol metabolites suggest a shift in cortisol metabolism, possibly reflecting optimised cortisol availability resulting in increased adrenal androgen suppression. Individual patients of both sexes may therefore benefit from a switch to modified-release hydrocortisone.

Echocardiographic evaluation of functional and morphological alterations in obesity: a comparison between obese individuals with and without Metabolic Syndrome

Cvetanka Volkanovska Ilijevska[1], Valentina Andova[2], Valentina Velkoska Nakova[3], Natasha Nedeska Minova[4], Taner Hasan[5] & Ljubica Georgievska Ismail[2]
[1]University Clinic of Endocrinology, Diabetes and Metabolic Disorders SS. Cyril and Methodius University, Skopje, Macedonia; [2]University Clinic of Cardiology, Medical Faculty, Ss. Cyril and Methodius, Skopje, Macedonia; [3]Faculty of Medical Sciences, Goce Delcev University, Internal medicine, Stip, Macedonia; [4]General City Hospital 8 thSeptember, Skopje, Macedonia; [5]General City Hospital 8th September, Skopje, Macedonia

Background
Obesity has been identified as an independent risk factor for heart failure. The risk of heart failure is dependent on body mass index (BMI).
Aim
This study aimed to examine the effects of obesity on myocardial function and morphology, and to compare these alterations in obese individuals with and without metabolic syndrome (MetS +/- group).
Methods
A total 125 subjects with a BMI more than 25 kg/m^2 underwent metabolic and clinical evaluation. An evaluation of conventional echocardiographic parameters and cardiac deformation by 2D speckle tracking echocardiography was conducted. The mean age was 45.0 ± 9.6 years (female: 58.7%), and the average BMI was 35.01 ± 6.53. In 74% of the subjects, the duration of overweight/obesity was over 10 years. Metabolic syndrome was diagnosed in 54 patients (70%). Two dimensional echocardiographic evaluation showed that the MetS$^+$ group had a larger LA maximal volume and a LA volume indexed for body height than the MetS$^-$ group, but the differences were not statistically significant ($P = 0.068$, $P = 0.098$, respectively). The MetS$^+$ group had significantly lower LA ejection fraction compared to the MetS$^-$ group (LAEF% = 46.89 vs 50.13, $P = 0.03$). Regarding the strain analysis, it was also found that the MetS$^+$ group had significantly lower values for the peak longitudinal deformation of LA in the reservoir phase (PALS) ($P = 0.008$). The LV mass

indexed by height (LVMh) significantly differed between the two groups, despite both being within the reference limits ($P = 0.016$). Conversely, both groups exhibited higher LV mass indexed by the square of height (LVMh2), with the $MetS^+$ group demonstrating a significantly higher values ($P = 0.002$). Moreover, the mean values of global longitudinal strain (GLS) of the left ventricle were below the reference range in both groups, but significantly lower in the MetS + group compared to the $MetS^-$ group (GLS = -20.7 vs -22.7, $P = 0.016$) The peak mitral annular descent velocity (s'TDI) and the late diastolic velocity were significantly reduced in $MetS^+$ ($P = 0.019$ and $P = 0.033$, respectively).
Conclusion
Obesity itself causes substantial morphological and functional myocardial alterations, in particular if accompanied by metabolic abnormalities.

Impact of alert systems on glucocorticoid administration for adrenal insufficiency in the emergency department

Primploy Greeviroj[1], Subhanudh Thavaraputta[1], Stephen Kerr[2], Thiti Snabboon[1], Patinut Buranasupkajorn[1,3], Wasita Parksook[1,4] & Sarat Sunthornyothin[1]
[1]Division of Endocrinology and Metabolism, Department of Medicine, Faculty of Medicine, Chulalongkorn University, and Excellence Center for Diabetes, Hormones and Metabolism, King Chulalongkorn Memorial Hospital, Thai Red Cross Society, Bangkok, Thailand; [2]Research Affairs, Faculty of Medicine, Chulalongkorn University, Bangkok, Thailand; [3]Division of Hospital and Ambulatory Medicine, Department of Medicine, Faculty of Medicine, Chulalongkorn University and King Chulalongkorn Memorial Hospital, Thai Red Cross Society, Bangkok, Thailand; [4]Division of General Internal Medicine, Department of Medicine, Faculty of Medicine, Chulalongkorn University and King Chulalongkorn Memorial Hospital, Thai Red Cross Society, Bangkok, Thailand

Background
Clinical decision support (CDS) is a health information technology tool designed to aid healthcare providers in making informed decisions during patient care. However, evidence on the effectiveness of CDS systems in improving the identification and management of adrenal insufficiency (AI) and reducing preventable adrenal crises in emergency departments (EDs) is limited.
Methods
We conducted a retrospective analysis of patients with AI who followed up at the endocrinology clinic at King Chulalongkorn Memorial Hospital, Bangkok, Thailand. All patients were identified using a medical alert system integrated into the electronic health record (EHR). The primary outcome was the time from ED arrival to glucocorticoid administration in AI patients visiting the EDs during the 12-month period before and after the system's implementation. Secondary outcomes included the proportion of patients receiving appropriate glucocorticoid treatment and the frequency of preventable adrenal crises in the EDs before and after implementation.
Results
Among 112 patients with AI, 4 patients (4%) had primary AI, and 108 patients (96%) had central AI. The mean age was 66 $\pm$ 15 years, and the majority were female (61%). During the median follow-up time of 14 months, the total number of ED visits was 41 (in 24 patients) and 55 (in 30 patients) before and after the system's implementation, respectively. The number of events requiring prompt hydrocortisone treatment was 14 and 15 before and after implementation, with 86% and 100% of these events receiving appropriate treatment, respectively. The median time from ED arrival to hydrocortisone administration significantly decreased from 123 (IQR: 87-208) minutes to 54 (IQR: 45-127) minutes before and after implementation ($P = 0.03$). Four adrenal crises (29%) occurred prior to glucocorticoid administration before the system implementation, while one (7%) occurred after the system was introduced ($P = 0.34$).
Conclusion
The implementation of a CDS system integrated into EHR significantly reduced the median time to hydrocortisone administration in AI patients presenting to EDs, decreased the frequency of preventable adrenal crises, and increased the proportion of patients receiving appropriate glucocorticoid administration. These findings underscore the role of CDS systems in enhancing the identification and management of AI and highlight their value in reducing delays and optimizing care in high-risk scenarios. Further studies with larger cohorts are warranted.

24-H hormonal profile in patients affected by congenital adrenal hyperplasia: does it improve disease management?

Maria Cristina Azcona San Julian[1], Natalia de la Esperanza Piñeiro[1], Paloma Lapunzina Soler[1], Ana Villanueva Eraso[1], Maite Apestegui Arlegui[1] & Ana Catalan Lamban[1]
[1]Clinica Universidad de Navarra, IdisNA, Pediatric Endocrinology Unit. Pediatrics., Pamplona, Spain

Introduction
Congenital adrenal hyperplasia (CAH) is caused by enzymatic deficiencies in corticosteroid synthesis, with 21-hydroxylase deficiency being the most common. Proper management is essential to optimize patients' development and quality of life. Conducting 24-h hormonal profiles to optimize treatment is complex, and its usefulness remains controversial.
Objective
To assess the utility of the 24-h hormonal profile in patients with CAH who present difficulties in disease control.
Material and Methods
A protocol was designed to perform a 24-h hormonal profile in patients with CAH. Study participants attended a consultation for an initial assessment before hospital admission. A peripherally inserted central catheter was placed, and blood samples were collected using VAMP system, while patients continued their usual treatment. Blood samples were taken every h for 24 hs, including additional samples 30 minutes after hydrocortisone administration. Hormonal measurements included cortisol, ACTH, 17-OH-progesterone, and androstenedione. Health-related quality of life was assessed using the Child Health and Illness Profile questionnaire. Based on the results, as well as clinical symptoms, daily activities, physical examination, and quality of life, hydrocortisone regimens were adjusted.
Results
Six patients (three females/three males) aged 5 to 16 years were included. The main symptoms reported in consultation were headaches, fatigue, decreased attention in school activities, menstrual cycle disorders, and weight gain. The procedures were well tolerated. Variability in hydrocortisone absorption was observed at equal doses depending on the time of day in the same patient. Several factors that may interfere with hydrocortisone absorption and hormonal variability were identified, including food intake, intestinal absorption variations, and the specific hydrocortisone formulation used. Adjustments in hydrocortisone dosing were associated with the resolution or improvement of symptoms and signs and as well as enhanced quality of life. The advantages and disadvantages of performing the hormonal profile, as well as the challenges in interpreting the results, are discussed.
Conclusions
Performing 24-h hormonal profiles may help personalize treatment regimens according to each patient's daily activities, aiming to improve growth, pubertal development, and quality of life in CAH patients. The variability in hydrocortisone absorption at the same dose depending on the time of day should be considered when interpreting hormonal results and adjusting treatment. This procedure is time-consuming, costly, and psychologically demanding for both patients and parents, making careful patient selection essential. Additionally, it requires a multidisciplinary team that dedicates significant time to organizing, conducting, interpreting the profile, and making dose adjustments.

Suspected central adrenal insufficiency in a patient with PMM2-CDG

Sofie-Louise Feentved Ødum[1], Sabine Grønborg[2], Katharina M. Main[1,3,4] & Marianne Klose[1]
[1]Copenhagen University hospital, Rigshospitalet, Department of Growth and Reproduction, Copenhagen, Denmark; [2]Copenhagen University Hospital, Rigshospitalet, Center for Inherited Metabolic Diseases, Department of Pediatrics and Adolescent Medicine and Department of Clinical Genetics, Copenhagen, Denmark; [3]Copenhagen University Hospital - Rigshospitalet, International Center for Research and Research Training in Endocrine Disruption of Male Reproduction and Child Health (EDMaRC), Copenhagen, Denmark; [4]University of Copenhagen, Department of Clinical Medicine, Faculty of Health and Medical Sciences, Copenhagen, Denmark

Phosphomannomutase 2 - Congenital Disorder of Glycosylation (PMM2-CDG) is a hereditary defect causing hypoglycosylation of N-linked glycoproteins and a multisystem disorder with a broad spectrum of clinical presentation. It was recently suggested that patients with PMM2-CDG may have central adrenal insufficiency. We present an 18-year-old male with PMM2-CDG, whose initial screening suggested adrenal insufficiency. The patient displayed a morning baseline plasma cortisol of 57 nmol/l, a deficient response to Adrenocorticotropic hormone (ACTH) with a 30 min cortisol of 165 nmol/l, and a low-normal ACTH. Analysis of cortisol binding globulin (CBG) showed abnormally low levels (253 mmol/l (ref. 750-2500 mmol/l)). 8 a.m. salivary cortisol was measured 24 hs after last hydrocortisone ingestion and was normal to slightly elevated (38 nmol/l (ref. 2.48-29 nmol/l)). Accordingly, the patient never experienced obvious symptoms of adrenal insufficiency nor clinical improvement after transient introduction of hydrocortisone. In conclusion, we present a patient with PMM2-CDG who upon measurement of plasma cortisol displayed "biochemical" central adrenal insufficiency, although with low CBG and normal salivary free cortisol levels. The case illustrates the caveats of using total plasma cortisol for the diagnosis of adrenal insufficiency in patients with PMM2-CDG and highlights the potential impact of N-linked hypoglycosylation on endocrine evaluation.

First case of cytochrome P450 oxidoreductase deficiency with didelphic uterus and unilateral renal agenesis and a literature review on 46,XX patients

Ming Cheng[1], Zheng Yuan[1], Xinmeng Wang[1], Yan-ning Song[1], Bingyan Cao[2] & Chunxiu Gong[1]
[1]Beijing Children's Hospital, Capital Medical University, Department of Endocrinology, Genetics and Metabolism, Beijing, China; [2]Affiliated Children′s Hospital of Capital Institute of Pediatrics, Department of Endocrinology, Beijing, China

Introduction
Cytochrome P450 oxidoreductase deficiency (PORD) is a rare form of congenital adrenal hyperplasia. This study reports the first case diagnosed with PORD presenting with uterine didelphys, vaginal atresia, and right renal agenesis. A comprehensive literature review was performed to analyze Müllerian duct, pubertal development, and fertility outcomes in 46,XX patients.
Case presentation and literature review
A 3-year-and-10-month-old Chinese female presented with ambiguous genitalia, accompanied by a history of maternal virilization during pregnancy. The patient exhibited midface hypoplasia and arachnodactyly, along with Antley-Bixler syndrome (ABS)-like skeletal malformations, in addition to ambiguous genitalia characterized by clitoromegaly, labial fusion, and a single urogenital sinus. Laboratory evaluation revealed a 46,XX karyotype, mildly elevated adrenocorticotropic hormone, normal cortisol, significantly elevated 17-hydroxyprogesterone, and reduced androstenedione and dehydroepiandrosterone. Pelvic ultrasonography demonstrated the presence of didelphic uterus, double cervix, vaginal atresia, and right renal agenesis. Whole-exome sequencing identified a homozygous p.R457H missense variant in the *POR* gene, confirming the diagnosis of PORD. A review of 38 reported cases of 46,XX patients revealed a potential association between maternal virilization during pregnancy and the disorders of sex development in affected individuals. The p.R457H and p.A287P variants are the most commonly reported variants. The p.R457H variant is predominantly identified in Asian populations, while the p.A287P variant is frequent observed in Caucasian patients, and is often associated with more severe ABS-like skeletal malformations. Among patients with PORD, pubertal development may occur, however, breast development and menarche often follow irregular patterns, contributing to challenges in achieving natural conception during their reproductive years. Additionally, structural anomalies of the Müllerian ducts may represent a rare phenotype of the condition.
Conclusion
This review suggests that uterine malformations and unilateral renal agenesis may represent uncommon phenotypes of PORD. Early initiation of glucocorticoid replacement therapy and timely estrogen supplementation not only reduce the risk of adrenal crises but also serve as effective measures to inducing pubertal development and decrease the recurrence of ovarian cysts, which may, in turn, positively influence fertility preservation in the future.

Clinical, hormonal, and radiological evaluation of unilateral adrenal incidentalomas

Hattab Fatma[1], Taieb Ach[2], Gasmi Ayoub[1], Hasni Yosra[2], Saad Ghada[2] & El Mhabrech Houda[1]
[1]Department of Radiology, Farhat Hached University Hospital, Sousse, Tunisia; [2]Department of Endocrinology Diabetology, Farhat Hached University Hospital, Souse, Tunisia

Purpose
Adrenal incidentalomas refer to adrenal masses, at least 1 cm in diameter, discovered incidentally through imaging conducted for non-adrenal-related reasons. The widespread use and advances in imaging technology have significantly increased the frequency of adrenal incidentaloma detection. The challenge in evaluating these lesions lies in balancing the potential benefits of early treatment for malignant or secreting tumors with the risks and costs of unnecessary treatments. The lack of studies integrating radiological findings with epidemiological and clinico-biological data, particularly at the continental and national levels, presents significant diagnostic and therapeutic challenges for clinicians. This study aims to investigate the epidemiological and clinico-biological characteristics of adrenal incidentalomas, evaluate radiological criteria indicative of malignancy, and identify markers that predict hormonal secretion, especially cortisol production.
Methods
A retrospective study was carried out on 153 patients referred to the endocrinology department at Farhat Hached Hospital for the assessment of an adrenal incidentaloma between January 2015 and December 2023.
Results
The average age of the patients was 55.76 ± 13.36 years, with non-secreting adenomas being the most observed lesion in 94 patients (61,44%). In our series, autonomous cortisol secretion (ACS) was the most frequent hormonal abnormality, accounting for 17% of cases. Pheochromocytoma was diagnosed in 6 patients (3.92%), and primary hyperaldosteronism was found in 8 patients (5.2%). Secreting adenomas were significantly larger than non-secreting adenomas (27.55 ± 11.7 mm vs 20.5 ± 9.3 mm). The attenuation value was also higher in secreting adenomas with ACS. Moreover, contralateral adrenal atrophy, hepatic steatosis, and bone demineralization were more common in adenomas with ACS than in non-secreting ones. Our series included 6 cases of adrenocortical carcinoma (ACC). The average size of ACC (61 ± 27.07 mm) was significantly larger than that of lipid-poor adenomas. Only one ACC measured less than 4 cm, and the mean non-contrast density for ACCs was 29.7 UH. None of the pheochromocytomas had a non-contrast density below 10 UH. Of the 5 pheochromocytomas in our series, only one exhibited the typical "light bulb sign" with a homogeneous hyperintense lesion.
Conclusion
Imaging is crucial for characterizing adrenal incidentalomas and for the early detection of malignant lesions. It also plays a key role in the presumptive diagnosis of ACS.
Limitations
Our study primarily focused on the initial management of adrenal incidentalomas. Future studies will be needed to establish a follow-up protocol for benign lesions that are not surgically treated.

Heterozygous mutations in CYP11A1 lead to P450scc deficiency: case report and literature review

Xinmeng Wang[1] & Gong chunxiu[1]
[1]Beijing Children's Hospital, Beijing, China

Background
The inheritance mode of P450scc deficiency caused by *CYP11A1* mutations remains unclear. It was previously considered an autosomal recessive disorder, but sporadic cases of heterozygous mutations have been reported.
Objective
To report a case of non-classic P450scc deficiency caused by a heterozygous mutation in *CYP11A1* and review similar cases in the literature.
Patients and Methods
An 11-year-7-month-old female presented with a 1-year history of facial hair growth, deepening of the voice, and hyperpigmentation. She had a history of fatigue since childhood but no other obvious signs of adrenal insufficiency. Physical examination revealed Tanner stage 3 pubic hair, clitoromegaly, a

urogenital sinus opening on the perineum, and scrotum bifid with no palpable testes. Laboratory tests showed elevated ACTH, LH 9.17 IU/l, FSH 16.81 IU/l, testosterone 10.2 nmol/l, and decreased levels of cortisol, 17α-hydroxyprogesterone, progesterone, dehydroepiandrosterone, and androstenedione. AMH was 2.55 ng/ml. INHB was 179.38 pg/ml. Karyotype analysis showed 46,XY. Ultrasound revealed normal adrenal glands, testes in pelvis, and no uterus or ovaries. She was the first child of non-consanguineous parents, with a normal birth history and healthy parents and a younger sister (46,XX). Whole exome sequencing was performed on the patient. Cases of *CYP11A1* heterozygous mutations causing adrenal insufficiency (AI) with or without disorders of sex development (DSD) reported in PubMed and CNKI databases were reviewed.
Results
The patient was found to have a heterozygous mutation in the *CYP11A1* gene (c.1379G > A, p.R460Q), which has been associated with P450scc dysfunction. Combined with her clinical manifestations and steroid hormone levels, the diagnosis of P450scc deficiency was confirmed. Her mother and younger sister also had the same mutation but were asymptomatic. A literature review identified 5 patients from 4 families. Family 1 had a spontaneous mutation (c.809_814dupGGGACG) presenting with AI and 46,XY DSD. Family 2 had a mutation (c.235G > A) with a 46,XY proband presenting with AI, while the father and sister with the same mutation also had AI. Family 3 had a mutation (c.431C > A) with a 46,XX proband presenting with AI, but the mother with the same mutation was asymptomatic. Family 4 had a mutation (c.1076C > T) with a proband presenting with AI and 46,XY DSD, while the mother and brother with the same mutation were asymptomatic.
Conclusion
Heterozygous mutations in *CYP11A1* can cause P450scc deficiency. There is significant clinical variability among heterozygous mutation carriers, and family members with the same mutation may be asymptomatic.

Pitfalls of circulating miRNA-based biomarker studies in adrenocortical tumors

Bálint Vékony[1,2], Gábor Nyirő[1,2,3], Henriett Butz[3,4,5], Bálint Szeredás[1,2], Viktória Tóth[6], Peter Ferdinandy[6], Attila Patócs[3,4,5] & Peter Igaz[1,2]
[1]Semmelweis University, Department of Internal Medicine and Oncology, Budapest, Hungary; [2]Semmelweis University, Department of Endocrinology, Budapest, Hungary; [3]Semmelweis University, Department of Laboratory Medicine, Budapest, Hungary; [4]HUN-REN-SU, Hereditary Tumours Research Group, Budapest, Hungary; [5]National Institute of Oncology, Department of Molecular Genetics and the National Tumour Biology Laboratory, Budapest, Hungary; [6]Semmelweis University, Department of Pharmacology and Pharmacotherapy, Budapest, Hungary

Introduction
Differentiating between benign and malignant adrenocortical tumors has major clinical relevance. Recent studies have highlighted the potential of circulating microRNAs (miRNAs) as biomarkers for malignant adrenocortical carcinoma (ACC). However, there are many difficulties with their use, mainly standardization.
Aims
Our aim was to compare the interchangeability of real-time quantitative polymerase chain reaction (qPCR) and digital PCR (dPCR) in measuring circulating miRNAs, and to investigate whether the use of K2 or K3 EDTA anticoagulants may influence the results.
Methods
Peripheral blood samples were taken simultaneously into K2 and K3 EDTA collection tubes, from 20 individuals. After sample procession, three miRNAs associated with ACC (*hsa-miR-483-5p, -210-3p, -21-5p)* as well as two controls (*-miR-16-5p, cel-miR-39-3p*) were analyzed utilizing RT-qPCR and dPCR. Data obtained were compared by the following statistical methods: Spearman's rank correlation, paired t tests and Bland-Altman analysis.
Results
qPCR and dPCR results show a significant correlation (p values between 0.0072 and 0.049) in K2-EDTA samples when comparing ΔCt values and copy numbers. However, proportional biases relating to low and high miRNA expression were observed between the two methods. In qPCR measurements, K3-EDTA results showed higher standard deviations (average SD for K2 samples was 0.91 while for K3 samples 1.1). When comparing raw Ct values, only *miR-483-5p* was found to be significantly different, while in case of ΔCt values, every miRNA except *miR-483-5p* was significantly different. dPCR results were not affected by the different anticoagulants.
Conclusions
dPCR and qPCR are not easily interchangeable, especially for rare or abundant miRNAs, making cross-validation difficult. The choice of EDTA could potentially influence qPCR results, highlighting the need for standardized protocols.

The role of the posture test for primary aldosteronism subtyping

Hrafnhildur Gunnarsdóttir[1,2], Jón Guðmundsson[3], Guðjón Birgisson[4] & Helga Sigurjónsdóttir[1,5]
[1]Landspitali National University Hospital of Iceland, Reykjavik, Iceland; [2]University of Iceland, Faculty of Medicine, Reykjavik, Iceland; [3]Landspitali National University Hospital of Iceland, Department of Radiology, Reykjavik, Iceland; [4]Landspitali National University Hospital of Iceland, Department of Surgery, Reykjavik, Iceland; [5]University of Iceland, Reykjavik, Iceland

Introduction
Primary aldosteronism (PA) is a common cause of hypertension, requiring accurate subtyping for optimal treatment and minimizing cardiovascular risk. The adrenal venous sampling (AVS) is the gold standard method for subtyping; however, the upright posture test (PT) could offer potential diagnostic value despite some limitations.
Aim
To identify the optimal cut-off for aldosterone-increase during PT in our population. Additionally, to perform a parallel evaluation of CT combined with PT for PA subtyping.
Methods
This nationwide study included all patients diagnosed with PA at Landspitali National University Hospital of Iceland from 2007 throughout 2016. The diagnostic protocol involved discontinuing antihypertensives affecting the renin-angiotensin-aldosterone system for 4–6 weeks before referral. Screening was performed by measuring morning serum aldosterone (s-aldosterone), direct renin concentration, and 24-h urinary aldosterone excretion. A positive PT was defined by a > 50% increase in s-aldosterone after 4 hs of standing. PA was confirmed by the saline infusion test (SIT), with post-infusion s-aldosterone > 140 pmol/l indicating PA. All patients underwent adrenal CT and synacthen-stimulated AVS for subtyping. Unilateral PA was treated with laparoscopic adrenalectomy, while bilateral disease was managed with mineralocorticoid antagonists. Statistical analysis was performed using STATA and JMP.
Results
Fifty patients underwent PT during the study period, 49 of whom also underwent AVS. The median age was 54 years (IQR 13), and 49% were women. The median blood pressure at case detection was 161/96 mmHg (IQR 22/17). CT scans revealed a unilateral adrenal nodule in 45% of patients, with 68% confirmed as unilateral by AVS. One patient with bilateral nodules on CT had bilateral PA confirmed by AVS and a positive PT. ROC curve analysis (AUC = 0,75, CI 0,61-0,89) indicated that a 50% increase in s-aldosterone during PT had 45% sensitivity and 81% specificity, classifying 65% of patients correctly. The optimal cut-off was a 74% increase in s-aldosterone, correctly classifying 71% of the patients, with 59% sensitivity and 81% specificity. Combining PT with CT to predict unilateral PA yielded 32% sensitivity, 96% specificity, 88% positive predictive value and 63% negative predictive value.
Conclusions
Our study highlights the importance of defining an optimal cut-off for the population being studied. Furthermore, the results suggest that PT, particularly when combined with other diagnostic tools, can be a reliable tool for differentiating PA subtypes. Thus, PT can be valuable in centers where reliable AVS is not readily available.

The hippocampus in congenital adrenal hyperplasia (CAH) and autoimmune Addison's disease (AAD)

Alice Savoia[1], Annelies Vant Westeinde[1] & Svetlana Lajic[1]
[1]Karolinska Institute, Department of Women's and Children's Health, Division of Pediatric endocrinology, Stockolm, Sweden

Background
Both Congenital Adrenal Hyperplasia (CAH) and autoimmune Addison's Disease (AAD) are characterized by impaired cortisol and aldosterone production, along

with increased adrenal androgens in CAH, but reduced adrenal androgens in AAD. Current oral replacement medication for cortisol is sub-optimal and leads to imbalances in adrenal hormone levels that might negatively affect the brain and cognitive functioning. The hippocampus plays a vital role in memory and emotional regulation, and it is particularly sensitive to changes in corticosteroid levels as well as sex hormones and might therefore be especially vulnerable to cortisol and androgen imbalances in both CAH and AAD. This study investigates the relationship between hippocampal subfield volumes, white matter microstructure, and cognitive performance in patients with CAH and AAD.
Methods
Hippocampal subfield volumes and white matter microstructure (mean diffusivity, MD) were measured in CAH, AAD, and healthy control groups based on T1 and DWI MRI scans (3T). Participants completed a battery of memory tasks, including assessments of verbal and visuo-spatial working memory, as well as immediate and long-term recall. ANCOVA and regression analyses were performed to examine group differences and the relationship between hippocampal measures and memory performance, controlling for age, sex, education, and intracranial volume.
Results
No significant differences in hippocampal subfield volumes were found between the groups (CAH, Addisons and controls). However, CAH patients exhibited significantly higher MD values in the left subiculum body compared to controls. In CAH, higher volumes in the left CA1-body were associated with better immediate recall, while higher MD values, reflecting more impaired white matter, in the same region were linked to worse performance in immediate recall. In AAD, hippocampal volume interactions with memory performance were found in the right CA1-head for immediate recall, where larger volumes predicted better recall in controls but not in AAD patients. No significant interactions between hippocampal measures and long-term memory were found.
Discussion
Since no group differences between CAH, Addisons and controls in hippocampal subfield volumes were observed, our findings suggest that the hippocampus is relatively unaffected in this patient group, possibly due to their young age and early detection through neonatal screening. However, subtle alterations in white matter microstructure were linked to memory performance. Future studies should investigate whether hippocampal changes might emerge over time and contribute to memory difficulties in the long term, helping to refine interventions for cognitive challenges in these populations.

Clinical characteristics of a large single-centre cohort of paediatric patients with congenital adrenal hyperplasia (CAH) secondary to 21-hydroxylase deficiency

Meera Shaunak[1], Harshini Katugampola[1], Antonia Dastamani[2], Rakesh Amin[2], Catherine Peters[2] & Mehul Dattani[1]
[1]UCL Great Ormond Street Institute of Child Health, Great Ormond Street Hospital for Children NHS Foundation Trust, London, United Kingdom; [2]Great Ormond Street for Children NHS Foundation Trust, London, United Kingdom

Introduction
The most common cause of CAH is 21-hydroxylase deficiency, which is divided into classic (salt-wasting or simple virilising) and non-classic forms. Patients with classic CAH require lifelong hormone replacement. Optimisation of treatment requires close monitoring of biomarkers. Both under- and over-treatment are associated with impaired linear growth and gonadal function and increased cardiometabolic risk.
Aims & methods
This retrospective cross-sectional study aimed to comprehensively phenotype a large single-centre cohort of 21-hydroxylase deficiency patients ($n = 168$), aged 0 – 18 years. It formed part of a registered service evaluation. CAH patient data were collected retrospectively from patient records for patients seen between 1/6/2022 – 1/6/2024.
Results
51.8% (43 females, 44 males) had salt-wasting CAH, 35.1% (42 females, 17 males) had simple virilising CAH and 13.1% (16 females, 6 males) had non-classic CAH. 82% ($n = 137$) had genetic testing. 32.3% had a large deletion/ conversion within the *CYP21A2* gene. 60% carried point mutations, with the I2 splice mutation found in 46.2% of affected alleles. There was no significant difference in mean height SDS by disease subtype (P value $= 0.13$). 84.8% ($n = 28$) of patients at final height were within 1.5 SDS of their mid-parental height SDS. Fourteen patients had required GnRH agonist treatment to arrest early puberty. Fifty-three patients (31.5%) were obese (+2 BMI SDS), and fifty-two patients (31%) were overweight (+1 BMI SDS) (BMI SDS range –4.33 to +4.12). On average, patients were insulin insensitive (mean HOMA-IR 3.31). Insulin insensitivity was notable in pre-pubertal patients of healthy weight. Assessment of biomarkers by pubertal stage revealed mean morning ACTH and 17-OHP concentrations above the reported reference range in each pubertal group (ACTH $>$ 49 ng/l and 17-OHP $>$ 36 nmol/l). Statistically significant differences in average hydrocortisone dose, morning 17-OHP and androstenedione concentrations by pubertal group were found ($P < 0.05$). 19% ($n = 31$) received hydrocortisone (or equivalent) doses >15 mg/m^2/day. There was no significant difference between hydrocortisone dose equivalent by disease subtype (P value $= 0.08$).
Discussion
We report a high incidence of insulin insensitivity in our single-centre cohort of paediatric patients with 21-hydroxylase deficiency, with high rates of overweight/ obesity. Biomarkers were elevated in some pre-pubertal patients, highlighting early difficulties with biochemical control. However, despite mean morning ACTH and 17-OHP concentrations outside the recommended ranges, our data suggest that few children required intervention for short stature or early puberty. Clearly longitudinal assessment of growth parameters is required, as is the reporting of long-term outcomes for this cohort.

Management of adrenal insufficiency during pregnancy

Narjisse Ouazzani[1], Salma Bensbaa[1], N.E Haraj[1], Siham El Aziz[1] & Asma Chadli[1]
[1]Endocrinology and Metabolic Diseases Fepartment Ibn Rochd Hospital Casablanca, Clinical Neurosciences and Mental Health Laboratory Faculty of Medicine and Pharmacy, Hassan II University - Casablanca, Morocco, Endocrinology and Metabolic Diseases Departement, Casablanca, Morocco

Introduction
Pregnancy presents unique challenges for women. When complicated by or associated with adrenal insufficiency, diagnosis and management become particularly challenging due to the overlap between the condition's symptoms and the physiological changes of pregnancy.
Object
To assess the etiologies, management, and outcomes of pregnancy in women with adrenal insufficiency
Methods
We conducted a retrospective descriptive study of patients with adrenal insufficiency who were hospitalized or seen in our endocrinology department between 2019 and 2024.
Results
Our study included 15 pregnant women with adrenal insufficiency (AI). Five patients had glucocorticoid-induced AI. In one case, AI onset occurred during the first trimester of pregnancy. This patient presented with an adrenal crisis initially misdiagnosed as hyperemesis gravidarum due to nausea and vomiting, resulting in a 48-h diagnostic delay. Four patients had AI secondary to pituitary dysfunction: two with Cushing's disease, one with prolactinoma, and one with acromegaly. All patients with pituitary-related AI had the condition prior to pregnancy and received close monitoring throughout gestation. None of them experienced an aggravation of their condition during pregnancy. Six patients had primary AI. Two diagnoses occurred during the third trimester of pregnancy, indicating the onset of AI during gestation in these cases. One patient experienced a prolonged diagnostic delay as hypoglycemia was initially attributed to renal failure. Another patient with Nelson syndrome had a spontaneous pregnancy. The remaining patients with primary AI had autoimmune Addison's disease with concomitant type 1 diabetes prior to pregnancy. All patients received close monitoring and hydrocortisone replacement therapy with dose adjustments during the third trimester (+20-30%). Mineralocorticoid supplementation was not used in patients with primary AI. Adrenal crises occurred in five cases, all triggered by infections. The frequency of crises was higher in the glucocorticoid-induced AI and Addison's disease groups compared to the pituitary-related AI group. All patients underwent medically assisted delivery in a tertiary care setting with intravenous hydrocortisone administration. Adverse outcomes were observed in five cases, including 1 case of intra-uterine fetal demise, 2 cases of acute fetal distress, 1 case of macrosomia, and one case of post term pregnancy.
Conclusion
Our findings underscore the diagnostic challenges of adrenal insufficiency during pregnancy, particularly the risk of delayed diagnosis and the potential for new-onset disease. These findings emphasize the need for heightened clinical vigilance and a multidisciplinary approach to care.

Impact of glucocorticoid replacement therapy on carbohydrate metabolism in patients with Addison disease

Yassmine Abdelkafi[1], Khouloud Boujelben[1], Dhoha Ben Salah[1], Hamdi Frikha[1], Faten Haj Kacem Akid[1], Nadia Charfi[1], Mouna Mnif[1], Mohamed Abid[1], Mouna Elleuch[1] & Nabila Rekik Majdoub[1]
[1]Hedi Chaker University Hospital, Endocrinology Department, Sfax, Tunisia

Introduction
In adults with Addison disease (AD), glucocorticoid replacement therapy is associated with an increased morbidity. The aim of our study was to assess the prevalence of carbohydrate metabolism disorders in patients with AD and identify its predictive factors.
Patients and methods
A cross sectional study including 50 patients diagnosed with AD with a mean duration of glucocorticoid replacement of 13,9 years. Biochemical markers of glucose metabolism were evaluated. The prevalence of type 2 diabetes and its complications were analyzed. Patients presenting type 1 diabetes were excluded from our study.
Results
The mean age of patients was 49,5 with a significant female predominance and a sex ratio of 0.25. Mean fasting blood glucose at the diagnosis of AD was 4,6 mmol/l and the mean glycated hemoglobin was 4,6%. No patient had prediabetes nor diabetes. At the time of our study, disorders of carbohydrate metabolism were found in 38% of patients and 31,6 % had type 2 diabetes. Diabetic retinopathy occurred in 2 patients and one patient complained of diabetic neuropathy. Daily and cumulative dose of glucocorticoids were higher in patients with diabetes compared to those with normal blood sugar level (27,5 mg/day vs 25,6 mg/day; 506,2 mg vs 355,4 mg). In addition, longer AD duration was found in patients presenting diabetes compared to those with a normoglycemia(19,8 years vs 13,2).
Conclusion
Despite the worldwide availability of replacement therapy in AD, exposure to supraphysiological dose of corticosteroids leads to altered insulin secretion and decreased hepatic and muscular insulin sensitivity resulting in risk exacerbation of carbohydrate metabolism disorders.

Prognostic factors for survival in patients with metastatic adrenocortical carcinoma

Anja Barac Nekic[1], Karin Zibar Tomšić[1], Karmelo Lovric[2], Nikola Knezevic[3,4], Zrna Antunac Golubić[5], Milena Gnjidić[5] & Darko Kastelan[1,4]
[1]University Hospital Center Zagreb, Department of Endocrinology, Zagreb, Croatia; [2]General hospital DR. Ivo Pedisic, Department of internal medicine, Sisak, Croatia; [3]University Hospital Center Zagreb, Department of Urology, Zagreb, Croatia; [4]Univerity of Zagreb, School of Medicine, Zagreb, Croatia; [5]University Hospital Center Zagreb, Department of Oncology, Zagreb, Croatia

Introduction
Metastatic adrenocortical carcinoma (ACC) is a highly aggressive disease with a poor prognosis and limited treatment options.
Materials and Methods
This retrospective study aims to evaluate the clinical outcomes of 29 patients with metastatic ACC: overall survival (OS), progression-free survival (PFS), and disease-specific survival (DSS).
Results
The median age of patients was 60 (IQR 53-68) years, with 76% being female. The median tumor size was 128 mm (IQR 112-160), and 22 patients had Cushing syndrome. The liver and lung were the most frequently affected organs, in 18 and 23 patients, respectively. Sixteen patients underwent an adrenalectomy with R2 resection. Postoperatively three patients received mitotane (M) monotherapy, twelve mitotane plus platinum-based chemotherapy (PE-M) and one received PE. In the non-operated group ($n = 13$), one patient received M monotherapy, two PE, and seven PE-M. Three patients died within one month of diagnosis and did not receive medical treatment. Among second-line therapies, four patients received gemcitabine and capecitabine plus M, while four others received sunitinib and one patient has been treated with cabozantinib. Over a median follow-up of 9 months (IQR 3–22), 24 patients died, with 21 deaths attributable to ACC. The median OS was 9 months (95% CI: 0.9–17.2), and the median DSS was also 9 months (95% CI: 0.9–17.2). The median PFS was 4 months (IQR 3–8). Patients who underwent adrenalectomy had significantly longer OS (18 months vs. 8 months, $P = 0.037$) and tended to have longer DSS (18 months vs. 8 months, $P = 0.059$) compared to non-operated patients. However, after excluding patients who died within three months of diagnosis ($n = 7$) the differences were no longer significant. The one-year mortality rate was 64% in patients with liver metastases, compared to 30% in those without ($P = 0.036$). Additionally, patients with liver metastases showed a trend toward shorter DSS (8 vs. 22 months, $P = 0.056$.). Similarly, there was a trend toward a lower one-year mortality in patients with only one affected organ compared to those with two or more (38% vs 64%; $P = 0.083$). In contrast, cortisol excess did not influence survival outcomes. In multivariate Cox regression analysis, older age was the only significant predictor of shorter OS ($P = 0.013$).
Conclusion
Older age is the only significant predictor of OS in patients with advanced ACC. However, liver metastases and the number of affected organs may negatively impact short-term survival within one year of diagnosis.

Continuous glucose monitoring in adult patients with classic congenital adrenal hyperplasia under different glucocorticoid regimens

Lea Tschaidse[1], Laura Kligge Rodriguez[1], Ann-Christin Welp[1], Hanna F. Nowotny[1], Matthias Auer[1], Ilja Dubinski[2], Katharina Schiergens[2], Heinrich Schmidt[2] & Nicole Reisch[1]
[1]Medizinische Klinik und Poliklinik IV, Klinikum der Universität München, Munich, Germany; [2]Department of Pediatric Endocrinology, Dr. von Haunersches Children's Hospital Klinikum der Universität München, Dr. von Haunersches Children's Hospital Klinikum der Universität München, Munich, Germany

Background
Patients with classic congenital adrenal hyperplasia (CAH) show an increased prevalence of metabolic comorbidities, with glucocorticoid substitution therapy presenting a possible risk factor, due to unphysiological replacement. Therefore, the aim of this study was to assess the glucose pattern through continuous glucose monitoring (CGM) over 24 hs under different GC replacement regimen.
Methods
Adult patients with a confirmed diagnosis of classic CAH who received a substitution therapy with either conventional hydrocortisone or predniso(lo)ne were included in this study. All patients wore a CGM sensor once, measuring glucose concentration in the tissue every 5 minutes from 1 h after application up to a maximum of 14 days. Three time periods were defined over 24 hs: 6am-2pm, 2pm-10pm and 10pm-6am. Hydrocortisone dose equivalent (HDE) was calculated as prednisone dose multiplied by 4 and prednisolone dose multiplied by 5.
Results
A total of 44 patients with a median (range) age of 33.0 (35.0) years and a median (IQR) BMI of 26.4 (10.4) were included in the analysis (23 female, 21 male; 30 SW, 14 SV), of which 20 (45.5%) received conventional hydrocortisone and 24 (54.5%) predniso(lo)ne as glucocorticoid substitution therapy, with a median (IQR) total daily HDE of 30.0 mg/d (11.9). The median (range) measuring time of the sensor was 13.0 (9.0) days. There was no significant difference concerning median age, BMI or HDE between patients receiving conventional hydrocortisone and predniso(lo)ne. Concerning CGM, patients with predniso(lo)ne showed significantly more often glucose values between 140-<180 mg/dl between 6am-2pm (3.2% vs. 1.0%; $P = .030$), corresponding to 15.4 vs. 4.8 minutes, whilst patients on conventional HC showed significantly more often glucose concentrations in the normal range of 70-<140 mg/dl between 6am-2pm (98.1% vs. 95.5%; $P = .012$), corresponding to 470.9 vs. 458.4 minutes. There were no statistically significant differences between 2pm-10pm and 10pm-6am between the two groups. For the total cohort, we found a significant positive correlation between the median evening HDE with the average glucose concentrations ($r = .450$; $P = .002$) between 10pm-6am.
Conclusion
Our preliminary data indicate slightly different glucose patterns over 24 hs in patients with CAH receiving different glucocorticoid substitution therapy. The intake of longer acting preparations, as well as higher dosage, seem to be associated with slightly higher glucose concentrations, which should be taken into account when identifying patients with an increased metabolic risk.

Adrenal and peri-adrenal schwannomas: two case reports and a review of clinical, imaging and pathological features

Eleni Georgiou[1], Grigoris Effraimidis[2], Athanasios Kasotas[1], Anastasia-Konstantina Sakali[1], Pinelopi Thoda[3] & Alexandra Bargiota[2]
[1]Department of Endocrinology and Metabolic Diseases, University General Hospital of Larissa, Larissa, Greece; [2]Faculty of Medicine, School of Health Sciences, University of Thessaly, Department of Endocrinology and Metabolic Diseases, University General Hospital of Larissa, Larissa, Greece; [3]Private Practice, Papakiriazi 31-33, 41222, Larissa, Greece

Introduction.
Adrenal schwannoma (AS) is a rare, typically benign tumor originating from Schwann cells, often found in the adrenal medulla. Peri-adrenal (peri-AS) or juxta-adrenal schwannomas originate from tissues surrounding the adrenal gland. Despite their anatomical differences, they share similarities with AS in clinical presentation, management, and histopathological features. There are fewer than 200 reported cases of AS and peri-AS, highlighting their rarity. We report two cases, one of adrenal and one of peri-adrenal schwannoma.
Case 1.
A 50-year-old female presented with an adrenal incidentaloma discovered during an MRI for uterine fibroids. CT imaging of the adrenals confirmed the 6 cm mainly cystic lesion with septa of her right adrenal compressing the inferior vena cava. Her past medical history was unremarkable and hormonal workup was normal. She underwent open surgery and a 6x5.5x4.5 cm lesion weighing 85 g was excised and its histopathological examination revealed alternating Antoni A and Antoni B areas, necrosis, hemorrhage, strongly and diffusely positive S100 immunomarker and a Ki67 index of 3%. Immunohistochemistry confirmed AS. Four years post-surgery, follow-up imaging showed no recurrence.
Case 2.
A 62-year-old female presented with an adrenal incidentaloma detected on abdominal ultrasound for abdominal pain. Her past medical history was unremarkable. CT imaging of her adrenals revealed a 4x3.2x3 cm right adrenal lesion with 61.2 HU, which on MRI was heterogenous with no intracellular fat. Hormonal workup was normal. She underwent surgery and an 78 g, 4.5x3.5x3 cm mass was removed from her right adrenal. Histopathological examination revealed hemorrhages, necrosis, and degenerative changes. Immunohistochemistry confirmed the diagnosis of schwannoma (positive for S100 and SOX10; negative for synaptophysin).
Conclusion
AS and peri-AS are rare tumors often presenting as non-functional masses, with diagnosis confirmed through histopathological examination following surgical removal. They can be discovered incidentally on imaging for unrelated issues. Pre-operative diagnosis is challenging due to their asymptomatic or nonspecific presentation (abdominal or back pain from adjacent organ compression) and on imaging is difficult to differentiate them from other adrenal or peri-adrenal masses. Surgery (adrenalectomy/removal of the peri-AS tumor) is essential to confirm diagnosis and exclude malignancy. Their histopathological findings of encapsulated spindle cell tumors, nuclear atypia, cystic changes, and hemorrhage, complicate the diagnosis. The S100 immunomarker is typically strongly and diffusely positive and a key feature in supporting schwannoma diagnosis.

Secondary adrenal insufficiency and immune checkpoint inhibitors: case series with pembrolizumab from a non-oncologic hospital

Eleni Palioura[1], Eleni Herolidi[1], Loukia Spanou[1], Melpomenì Moustaki[1], Kasiani Papadimitriou[1] & Andromahi Vryonidou[1]
[1]Department of Endocrinology and Diabetes Center, General Hospital "Korgialenio-Benakio", Athens, Greece

Introduction
Secondary adrenal insufficiency (AI) is a potentially life-threatening adverse event that has been also associated with the use of immune checkpoint inhibitors (ICIs) in oncologic patients. Accumulating evidence link pembrolizumab, a programmed cell death protein-1 (PD-1) inhibitor, with adrenocorticotropic hormone (ACTH) deficiency in a frequency probably significantly higher than initially considered. We report a case series of three patients receiving pembrolizumab for diverse type of malignancies, who developed secondary AI.
Case 1
A 68-year-old man with metastatic non-small-cell lung cancer was referred from his oncologist due to pembrolizumab-induced thyroiditis [TSH = 124.78 μIU/ml (0.35–4.78) and FT4 = 2.9 pmol/l (10.5-22.7)], developing 20 weeks after starting ICI. Though he reported only mild fatigue attributed to the underlying cancer and hypothyroid status, endocrinological workup before levothyroxine supplementation revealed concomitant secondary AI, as indicated by low morning cortisol = 2.8 μg/dl (6-20) and ACTH < 5 pg/ml (9-52) levels. MRI of the pituitary gland revealed partial empty sella and hydrocortisone 30 mg/day was started. Interestingly, five months after AI diagnosis, recovery of adrenal axis was observed with morning cortisol levels up to 17.52 μg/dl and ACTH levels up to 33.2 pg/ml while he was still receiving pembrolizumab. Glucocorticoid replacement was discontinued and the patient remained eucortisolemic during follow-up.
Case 2
A 68-year-old man completing a 6-cycle treatment with pembrolizumab for metastatic renal disease was referred from his oncologist due to severe fatigue and progressively worsening muscle weakness. Laboratory investigation was compatible with secondary AI (low morning cortisol = 2.62 μg/dl and ACTH = 4 pg/ml levels), while thyroid function was normal. Pituitary MRI showed only gland heterogeneity and hydrocortisone (30 mg/day) was started with significant clinical improvement. Six months after completing immunotherapy and while on glucocorticoids, AI still did not resolve.
Case 3
A 48-year-old woman treated with pembrolizumab (6 cycles) for poorly differentiated breast cancer was referred from her oncologist due to secondary AI (low morning cortisol = 1.2 μg/dl and ACTH = 5.4 pg/ml levels) with coexisting central hypothyroidism [subnormal FT4 levels = 0.51 ng/dl (0.8-2) with inappropriately low serum TSH = 1.98 μIU/ml (0.3–4.5) levels]. Hydrocortisone (30 mg/day) and then levothyroxine (68μg/day) were started with no biochemical sign of pituitary-adrenal axis recovery in a 6-month follow-up period, after pembrolizumab last administration.
Discussion
Oncologic patients receiving pembrolizumab are at considerable risk for developing secondary AI. Therefore, close monitoring seems a reasonable approach to avoid delayed diagnosis and management.

Non-functional retroperitoneal paraganglioma: a case report

Malek Hadrich[1], Boujelben Khouloud[1], Dhoha Ben Salah[1], Oumaima Dimassi[1], Mouna Mnif[1], Nadia Charfi[1], Faten Haj Kacem Akid[1], Mohamed Abid[1], Mouna Elleuch[1] & Nabila Rekik Majdoub[1]
[1]Department of Endocrinology Hedi Chaker Hospital, Sfax, Tunisia

Introduction
Paragangliomas are rare neuroendocrine tumors arising from extra-adrenal chromaffin cells. While functional paragangliomas secrete catecholamines and present with symptoms such as hypertension, episodic headache and tachycardia, non-functional paragangliomas are asymptomatic and often discovered incidentally. Herein, we report a case of non-secreting retroperitoneal paraganglioma.
Case Report
A 62-year-old male presented to our department with acute-onset low back pain progressing for a few months. He additionally complained of headaches and muscle fatigue for several weeks. There was no history of neuropathy or trauma. The family history was positive for hypertension, diabetes mellitus and autoimmune disorders but there were no symptoms to suggest endocrine neoplasia syndrome. On admission, the physical examination was unremarkable with no palpable abdominal mass. His blood pressure was 120/70 mmHg, and his other vital signs were within normal range. Ambulatory blood pressure (BP) monitoring showed an average daytime BP of 123/74 mmHg and nighttime BP of 114/62 mmHg. Standard laboratory investigations were unremarkable. A lumbar spine Computed Tomography scan (CT) was performed and revealed a solitary well-defined mass located in the right renal hilum with a spontaneous density of 25 HU, measuring 40 × 27 × 37 mm. Then, an abdominal CT scan was performed, revealing a well-defined, multilobulated extra-renal retroperitoneal mass located in the right perihilar lower pole, exhibiting intense and early enhancement in the arterial phase with progressive enhancement in the portal and delayed phases. The mass was vascularized by a pedicle arising from the ipsilateral renal pedicle and measured 40 × 25 mm in axial dimensions with a height extension of 44 mm, which was more consistent with paraganglioma. There were no locoregional extension or evidence of secondary lesions. Laboratory findings showed also normal serum metanephrines and normetanephrines. (Normetanephrines: 89.9 pmol/l (139-808) and Metanephrines: 76.5 pmol/l (88-375) The patient underwent laparoscopic surgery without complications, and the histopathological study confirmed the diagnosis of paraganglioma.

Conclusion
The diagnosis of non-secreting paraganglioma is challenging, as there are no specific clinical or biological signs for early detection. Surgical excision remains the treatment of choice. Half of these tumors are malignant. The progression is characterized by the risk of late recurrences. Consequently, long-term follow-up is essential.

Evaluation of adiponectin level and metabolic parameters in patients with mild autonomous cortisol secretion and non-functional adrenal adenomas

Tugba Barlas[1], Meric Coskun[1], Sabri Engin Altıntop[1], Mehmet Muhittin Yalcin[1], Ethem Turgay Cerit[1], Alev Eroglu Altinova[1], Mujde Akturk[1], Ayhan Karakoc[1] & Fusun Toruner[1]
[1]Gazi University, Faculty of Medicine, Endocrinology and Metabolism, Ankara, Türkiye

Objective
Various metabolic adverse effects have been identified in patients with mild autonomous cortisol secretion (MACS) and even in those with non-functional adrenal adenomas (NFAA). In this study, we aimed to assess adiponectin levels and metabolic syndrome (MetS), as well as investigate the potential impact of low-grade hypercortisolism in patients with MACS and NFAA.
Method
A total of 72 patients, comprising 48 with MACS and 24 with NFAA, were included in a 2:1 ratio, with similar age, sex, and body mass index (BMI). Serum adiponectin levels of the patients were measured. MetS was diagnosed based on the National Cholesterol Education Program Adult Treatment Panel (NCEP-ATP III) criteria. The cardiometabolic index (CMI) was calculated as the ratio of triglycerides (TG) to high-density lipoprotein cholesterol (HDL-C), multiplied by the waist-to-height ratio (WHtR). The Triglyceride-Glucose (TyG) index was calculated using the formula: ln [(Fasting TG (mg/dl) × Fasting glucose (mg/dl))/2].
Results
The median low-dose dexamethasone suppression test (DST) in the MACS group was 2.9 µg/dl, while it was 1.1 µg/dl in the NFAA group. No significant differences were observed between the MACS and NFAA groups in terms of waist circumference (WC), WHtR, presence of type 2 diabetes, hypertension, or coronary artery disease ($p > 0.05$). However, dyslipidemia was more prevalent and HbA1c levels were higher in the MACS group compared to the NFAA group ($p < 0.05$). The prevalence of MetS was 50% in the MACS and 37.5% in the NFAA groups ($P = 0.316$). The CMI and TyG index was not statistically different between the groups ($p > 0.05$) and the CMI was positively correlated with HbA1c ($p < 0.05$). Serum adiponectin level was significantly higher in the MACS group than the NFAA group ($p < 0.001$). In the linear regression analysis, serum adiponectin level was associated with low-dose DST and WC in the overall group ($p < 0.05$).
Conclusions
The higher adiponectin levels observed in patients with MACS compared to those with NFAA highlight the need for further research to clarify the underlying mechanisms of the complex relationship between low-grade hypercortisolism, MetS, and adiponectin levels.

Integrating patient and public involvement into simulation-based learning: a mixed-methods study enhancing healthcare professionals' confidence in managing adrenal disorders

Maiar Elhariry[1], Akshat Sinha[2], Francesca Crowe[3], Caroline Gillett[4 5], Alessandro Prete[4 5], Cristina Ronchi[4], DEVI collaboration[3] & Punith Kempegowda[3,6]
[1]Midlands Metropolitan University Hospital, Birmingham, United Kingdom; [2]Birmingham Medical School, College of Medicine and Health, Birmingham, United Kingdom; [3]Department of Applied Health Sciences, Birmingham, United Kingdom; [4]Department of Metabolism and Systems Science, Birmingham, United Kingdom; [5]National Institute for Health and Care Research (NIHR), Birmingham, United Kingdom; [6]Queen Elizabeth Hospital Birmingham, Birmingham, United Kingdom

Background
Despite the benefits of patient and public involvement (PPI) in enhancing patient-centred care, there is limited integration of PPI into simulation-based learning (SBL) educational frameworks. Simulation via Instant Messaging for Bedside Application (SIMBA) is a SBL model that improves healthcare professionals' (HCPs) confidence in managing various medical scenarios.
Objectives
- To evaluate the change in HCPs' confidence in managing adrenal disorders.
- To explore the impact of integrating PPI to SBL on the HCP's practice and acceptability.
- To gather patient insight on this SBL-PPI model.

Methods
This mixed-methods study, conducted in the UK from June 2023 to March 2024, involved a two-day hybrid simulation-based learning (SBL) event featuring nine scenarios related to adrenal conditions. Patients with conditions represented in the scenarios participated in one-to-one virtual workshops coordinated by an early career researcher. They provided feedback on what worked well, areas for improvement, and how accurately the cases reflected real-life experiences. Workshop discussions were transcribed and analysed using content analysis to summarise patient insights. A patient representative presented key themes and shared their personal experiences during the event. Healthcare professionals (HCPs) interested in adrenal conditions completed pre- and post-SIMBA surveys to assess the model's acceptability and clinical impact. Quantitative data were analysed using STATA 17.0, while open-ended responses underwent thematic analysis to identify recurring themes and insights.
Results
64 participants completed pre- and post-SIMBA surveys. There was a significant increase in participants' confidence post-event (pre- vs post-simulation score: 45.4% vs 89.7%; $p < 0.01$). Thematic analysis of the impact of the session on participants' clinical practice yielded two key themes: Referral and Multi-Disciplinary Team (MDT) approach. Multiple participants intended to make more referrals to patient support groups and to discuss cases with other MDT members. 96.5% of participants on Day 1 and 97.1% on Day 2 agreed that the simulated topics were relevant to their practice. 100% rated the session quality as excellent/good. Patient feedback highlighted the benefits of sharing lived experiences, which enhances healthcare professionals' approach to personalised care and sensitive discussions.
Conclusion
Integrating PPI enhanced HCPs' confidence in the management of adrenal conditions. Besides its influence on the participants' clinical practice, this PPI-SBL model was well-received by both patients and HCPs. Future studies should assess long-term clinical impact and include objective measures of changes in clinical practice.

Transient 18F-FDG PET/CT uptake of contralateral adrenal gland in patient under Mitotane for R0 corticosurrenaloma

Bogdan Baluta[1], Florine Dupont[1], Marine Briand[1], Gwenaelle Arnault[2], Mathilde Flchet[2] & Patricia Vaduva[1]
[1]CHU Rennes, Rennes, France; [2]CH Bretagne Atlantique, Vannes, France

Introduction
Mitotane is indicated in the treatment of localized, locally advanced and metastatic adrenocortical carcinoma. There are three main mechanisms of action: inhibition of steroidogenesis (CYP11B1 and CYP11A1), increased endoplasmic reticulum stress (increased free cholesterol ester and fatty acid levels by inhibition of SOAT1, an enzyme that promotes the formation of fatty acid-cholesterol esters) and mitochondrial toxicity (membrane alteration and inhibition of respiratory chain) responsible for the apoptosis and necroptosis of adrenal cells. (1)
Observation
A 40mm right adrenal incidentaloma was discovered on abdominal CT in a 62 years old patient. No hormonal excess was found. A laparoscopic right adrenelectomy was performed due to tumor size, high radiodensity on CT and high FDG uptake. The pathological work-up described a 4cm lesion with a focal adrenocortical carcinoma (Weiss 5) developed within an adrenocortical adenoma (Weiss 1) with myxoid reshuffle. An adjuvant therapy by Mitotane was introduced because of an intermediary risk of recurrence (ENSAT 1, R0 and Ki-67 13%). Imaging follow-up every three months (CT scan and 18F-FDG PET/CT). After 9 months of treatment, the plasma mitotane concentration is at the limit superior, 20.3 mg/l (therapeutic range 14 to 20 ng/mL). 18F-FDG PET/CT uptake of the contralateral left adrenal gland appears, SUV max at 8.5 with no nodular lesion or adrenal hyperplasia on the CT scan. Mitotane is stopped because of thyroid adverse effects and

hyperlipidemia. 18F-FDG PET/CT three months later: disappearance of the left adrenal gland FDG uptake.
Discussion
Leboulleux *et al* (2) report that a percentage of 14% to 29% patients under adjuvant therapy by Mitotane following adrenocortical carcinoma surgery have a contralateral uptake: 4% before treatment, 29% between 0 and 6 months after the start of treatment, 26% between 6 and 12 months, 14% between 12 and 24 months and none after 24 months. The uptake was transient and dissapeared in the 24 months after the start of treatment. In this study, there was no FDG uptake in patients with adrenelectomy for pheochromyctoma, invalidating the hypothesis of a compensatory adrenal growth. A hypothesis is that despite hormonal adrenal replacement therapy, ACTH levels remain at the limit superior or slightly above the limit. Adrenal cells might become avid to 18F-FDG following ACTH stimulation.

The novel atherogenic indices and anthropometric measurements in patients with non-functioning adrenal adenomas and cardiovascular disease risk

Marzena Jabczyk[1], Justyna Nowak[2], Sylwia Mielcarska[3] & Barbara Zubelewicz-Szkodzińska[1,4]
[1]Department of Nutrition-Related Disease Prevention, Department of Metabolic Disease Prevention, Faculty of Public Health in Bytom, Medical University of Silesia, Bytom, Poland, Bytom, Poland; [2]Department of Cardiovascular Disease Prevention, Department of Metabolic Disease Prevention, Faculty of Public Health in Bytom, Medical University of Silesia, Bytom, Poland, Bytom, Poland; [3]Department of Medical and Molecular Biology, Faculty of Medical Sciences in Zabrze, Medical University of Silesia, Zabrze, Poland, Zabrze, Poland; [4]Department of Endocrinology, District Hospital, Piekary Slaskie, Poland, Piekary Slaskie, Poland

Background
Non-functioning adrenal adenomas (NFA) are prevalent tumors frequently associated with metabolic disorders such as obesity, hypertension, dyslipidemia, insulin resistance (IR), impaired glucose tolerance, metabolic syndrome (MetS), and osteoporosis. These conditions occur at higher prevalence in NFA patients compared to the general population. Since traditional risk assessments may be insufficient, novel atherogenic indices could improve cardiovascular risk (CVD) risk assessment in NFA patients.
Aim
This study aimed to characterize patients with NFA and CVD risk by analyzing novel atherogenic indices (TyG index, TyG-BMI index, LCI, Castelli Risk Index_2, AC, AIP, TG/HDL-C, MetS-IR), fasting glucose, and anthropometric measurements such as BMI and WHR.
Material and methods
This study enrolled of 106 patients aged >40 with NFA. CVD risk was evaluated based on Systematic Coronary Risk Evaluation 2 (SCORE2) and Systematic Coronary Risk Evaluation 2-Older People (SCORE2-OP) algorithms. Biochemical parameters (fasting blood glucose, total cholesterol levels (TC), HDL cholesterol (HDL-C), LDL cholesterol (LDL-C), triglicerydes (TG) were measured, followed by the computation of atherogenic indices such as Castelli's risk Index_I, Castelli's risk Index_II, Atherogenic index of plasma (AIP), Atherogenic coefficient (AC), Lipoprotein combine index (LCI), TG/HDL-ratio, Metabolic Score for insulin resistance (METS-IR), Triglyceride-Glucose index (TyG index), Triglyceride-Glucose body mass index (TyG BMI index) were computed. Anthropometric parameters were assessed using standard methods, including body weight, height, waist circumference, and hip circumference. Based on these, BMI and WHR were calculated.
Results
The median fasting glucose level was 101.5 mg/dl (94-109 mg/dl) in NFA patients. The mean TC was 212.0 ± 46.3 mg/dl, the median HDL-C was 60.2 mg/dl (11.9-153.8 mg/dl), the mean LDL-C was 124.2 ± 42.0 mg/dl, and the median TG was 107.0 mg/dl (43.0-509.0 mg/dl) The mean TyG index was 8.6 ± 0.5, and the median TyG BMI index was 240.4 (9.3-367.8). NFA patients have the LCI of 13.7 (2.0-170.5). The median Castelli's Risk Index_I was 3.3 (1.6-20.0), and the median Castelli's Risk Index_II was 1.9 (0.6-9.1). The median AC was 2.3 (0.6-19.0), and the mean AIP was -0.09 ± 0.2. The median TG/HDL-C was 1.7 (0.5-12.0). METS-IR demonstrated the mean value 39.9 ± 9.0. The mean BMI was 28.3 ± 4.5, and the mean WHR was 0.9 ± 0.08.
Conclusions
This study highlights significant variability in atherogenic indices and anthropometric measurements in patients with non-functioning adrenal adenomas (NFA) and cardiovascular disease (CVD) risk. The findings suggest that novel indices like the TyG index and MetS-IR may provide a more accurate assessment of CVD risk in NFA patients, warranting further investigation into their clinical significance.

Prevalence, value, and reliability of genetic testing in congenital adrenal hyperplasia: a comprehensive review

Ashraf Soliman[1], Dina Fawzy[2], Ahmed Elawwa[1], Fawzia Alyafei[1], Nada Alaaraj[1] & Noor Hamed[1]
[1]Hamad Medical Corporation, Doha, Qatar; [2]Alexandria University Children's Hospital, Alexandria, Egypt

Introduction
Congenital adrenal hyperplasia (CAH) is a group of autosomal recessive disorders caused by mutations in genes involved in cortisol biosynthesis, most commonly CYP21A2. Genetic testing has become integral in confirming diagnoses, and guiding management.
Objective
To assess the prevalence of genetic mutations, evaluate the diagnostic and clinical value, and analyze the reliability of various genetic testing methods in CAH.
Methods
A comprehensive review of published studies (2015–2025) was conducted, focusing on the prevalence of CAH-related genetic variations and the utility of testing in diagnosis and management.
Results
1. Prevalence:
- Genetic mutations linked to CAH were frequently detected, with large-scale studies reporting a positive genetic result in more than 60% of clinically suspected cases. The prevalence of specific syndromes, such as CAH-X, was estimated at approximately 10%, emphasizing the role of genetic testing in identifying rare forms of the disorder.
- Copy number variations, point mutations, and deletions in the CYP21A2 gene were the most commonly reported abnormalities, contributing to the phenotypic variability observed in CAH patients.

2. Value of Genetic Testing:
- Genetic testing plays a critical role in confirming CAH diagnoses, reclassifying patient phenotypes, and guiding personalized treatment strategies. Studies highlighted its utility in avoiding severe complications through early diagnosis and effective management.
- Techniques such as multiplex ligation-dependent probe amplification (MLPA), Sanger sequencing, and next-generation sequencing (NGS) provided detailed insights into the genetic landscape of CAH, enabling better understanding of genotype-phenotype correlations.
- Advanced molecular strategies facilitated the identification of novel mutations and improved diagnostic accuracy, particularly in complex or atypical cases.

3. Reliability:
- High levels of accuracy were reported for commonly used methods, with detection rates of 89–95% for point mutations and deletions.
- Techniques like MLPA and long-read sequencing demonstrated strong performance in identifying both common mutations and large gene rearrangements.
- The reliability of genetic testing was further enhanced by combining multiple methodologies, addressing challenges such as pseudogene interference and genetic complexity.
- Emerging technologies, including MinION-based sequencing, offered rapid, cost-effective alternatives with comparable accuracy, making them promising tools for routine clinical use.

Conclusion
Genetic testing is a cornerstone of CAH diagnosis and management, providing essential data on mutation prevalence, phenotype reclassification, and therapeutic guidance. Its high reliability and the availability of advanced testing methods reinforce its value in clinical settings. Future directions should focus on integrating cutting-edge technologies into routine diagnostics and enhancing accessibility to improve CAH outcomes.

Adverse events in heart failure patients on SGLT2 inhibitors: a retrospective study

Bhavini Bhatt[1,2], Furhana Hussein[2], Lina Eltayieb[2], Shoayeb Sarwar[2], Bashir Mahamud[2], Ilias Ibrahim[2], Suria Geran[2], Aye Hline[2], Muhammad Saleem[2] & Gideon Mlawa[2]
[1]University College London (UCL) Medical School, London, United Kingdom; [2]Barking, Havering and Redbridge University Hospitals NHS Trust, London, United Kingdom

Introduction
Sodium-glucose co-transporter-2 (SGLT2) inhibitors have been recently introduced into heart failure (HF) management and are now pivotal in reducing the mortality and morbidity associated with the condition. SGLT2 receptors, located in the proximal convoluted tubules of the kidneys, are responsible for 90% of total filtered glucose resorption. Inhibiting these receptors results in osmotic diuresis through glucosuria and natriuresis, thus lowering blood pressure and blood sugar levels. However, the mechanism of SGLT2 inhibitors predisposes patients to potential adverse side effects. The aim of this study was to investigate the incidence of diabetic ketoacidosis (DKA), urinary tract infections (UTIs) and acute kidney injury (AKI) in patients on SGLT2 inhibitors.
Methods
This study is a retrospective review of 100 patients with HF who were prescribed either Dapagliflozin or Empagliflozin. Data was extracted using electronic patient records, detailing both inpatient and outpatient treatment. Patients were included in this study based upon a HF diagnosis and treatment involving SGLT2 inhibitors. Adverse events were classified through hospital admissions where DKA, UTI or AKI were diagnosed. Further analysis was conducted in subgroups including diabetic status and type of SGLT2 inhibitor.
Results and Discussion
Amongst the 100 patients (age 31-98 years, 62% males) included in this study, 45% had type-2 diabetes, with a majority (81%) being treated with Dapagliflozin for HF. The incidence of UTIs across the cohort was 16% and 69% of these cases occurred in diabetic patients (risk ratio(RR) = 2.69), indicating that diabetes may increase the likelihood of UTIs in individuals treated with SGLT2 inhibitors. 87% of the total UTI cases occurred in patients on Dapagliflozin (RR = 1.64). AKI developed in 17% of patients, with 53% of cases occurring in diabetic patients (RR = 1.38). The incidence of AKI was also notably higher in patients on Dapagliflozin (RR = 1.64). These results suggest that diabetic patients on Dapagliflozin are at the highest risk of infections when compared with non-diabetic patients. DKA was observed in 3% of the cohort, exclusively in diabetic patients on Dapagliflozin. Our findings display that diabetic patients with HF are at a higher risk for UTIs, DKA and AKI when treated with SGLT2 inhibitors.
Conclusion
In conclusion, our study highlights the need for vigilant monitoring of patients on SGLT2 inhibitors, particularly Dapagliflozin, for adverse events such as UTIs, DKA and AKI. Patients should be counselled prior to initiation of SGLT2 inhibitors, with ongoing glycaemic monitoring, renal function assessments and infection surveillance to mitigate their risk of adverse events.

Pheochromocytoma-induced takotsubo cardiomyopathy in a patient with SDHA and EGLN1 variants

Eleftheria Kakargia[1], Athanasios Siolos[2], Athanasios Fountas[1], Ourania Psoma[2], Panagiota Christou[2], Artemis Papanikolaou[1], Constantine Stratakis[3], Labrini Papanastasiou[1], Athina Markou[1] & Stelios Tigas[2]
[1]Department of Endocrinology and Diabetes Center, Center of Excellence of Rare Endocrine Adrenal Disorders, 'Georgios Gennimatas' General Hospital of Athens, Athens, Greece; [2]Department of Endocrinology and Diabetes Center, Ioannina University Hospital, Ioannina, Greece; [3]ASTREA Health & Medical Genetics, Henry Dunant Hospital Athens; DIGENIA & EDIMO labs and Human Genetics & Precision Medicine, IMBB FORTH, Heraklion, Greece

Introduction
Takotsubo cardiomyopathy is a rare presentation of pheochromocytomas and paragangliomas (PPGLs) and it is associated with a higher degree of morbidity and mortality. In this report, we present a patient with PCC-induced Takotsubo cardiomyopathy with rare *SDHA* and *EGLN1* variants.
Case Presentation
A previously healthy 17-year-old woman with no cardiovascular risk factors was admitted to a cardiac intensive care unit due to dyspnea, chest pain and elevated blood pressure at 210/100 mmHg. In addition, the patient gave an 8-month history of paroxysmal hypertension, headache and diaphoresis. Serum troponin levels were elevated and ECG and heart ultrasound findings were indicative of Takotsubo cardiomyopathy with an ejection fraction of 20-25%. She was treated with a combination of bisoprolol, sacubitril/valsartan, empagliflozin, eplerenone, furosemide and doxazosine. An abdominal MRI revealed a 55 mm heterogenous left adrenal lesion with high T2 signal and no signal suppression on out-of-phase T1-weighted images. 24-h urine normetanephrine levels were elevated [1926 μg/24h (<669)] whereas 24h urine metanephrine levels were normal [67 μg (< 276)]. Whole-body MIBG scintigraphy revealed selective radiotracer uptake by the adrenal lesion. A diagnosis of pheochromocytoma was made and the patient underwent an uneventful laparoscopic left adrenalectomy 3 weeks later. Histology confirmed the diagnosis of pheochromocytoma with a PASS score of 8 and a Ki-67 of 3-4%. Genetic testing with whole exome sequencing identified the missense *SDHA* variant, c.1367C>T, resulting in replacement of serine by leukine at codon 456, p.Ser456Leu, of SDHA protein and the frameshift *EGLN1* variant, (c.1163_1166del).
Conclusion
Catecholamine-induced cardiomyopathy is an uncommon feature of pheochromocytoma. *SDHA*-related PPGLs, account for up to 2.8% of cases and are usually found in the head and neck region or the abdomen, with only 15% of them being pheochromocytomas. Although our patient's *SDHA* variant is considered of uncertain significance, it has been reported in a case of *SDH*-deficient GIST and received a cancer-like functional classification in a recent study using a novel human *SDHA*-knockout cell line model. Furthermore, our patient has a previously unreported variant of *EGLN1*, which is another susceptibility gene for PPGLs. Further studies are needed to determine whether these gene variants are pathogenic and whether they act synergistically for PPGL development.

Carbohydrate metabolism disorders in pheochromocytoma

Ahmed Boukhalfa[1], Sana Rafi[1], Sara Ijdda[1], Ghizlane El Mghari[1] & Nawal El Ansari[1]
[1]Cadi Ayad University, Mohamed VI University Hospital Center, Department of Endocrinology, Diabetes, Metabolic Diseases and Nutrition, Marrakesh, Morocco

Introduction
Pheochromocytomas (PCC) are neuroendocrine tumors that develop in the chromaffin cells of the adrenal medulla. They are responsible for hyperproduction of catecholamines. Among the abnormalities that can be observed in these tumors are disorders of carbohydrate metabolism (1).
MaterialS and Methods
Through a retrospective descriptive study of 48 patients diagnosed with PCC in our departement of Endocrinology, we describe the observed abnormalities of carbohydrate metabolism in this population.
Results
The average age of our patients was 40,9 years. The sex ratio was 0.45 with 15 men and 33 women. The average of BMI was 23,11 kg/m^2, 50% of our patients had high blood pression. Urinary methoxylate drifts were performed in 44 patients, 42 of whom had elevated levels. Abdominal CT was performed in 44 patients, while the remaining 4 patients benefited from abdominal MRI in the context of concomitant pregnancy. Thirty-three percent of our patients had

moderate fasting hyperglycemia, while diabetes was diagnosed in 29,16 % of cases who were put on non-insulin hypoglycemic agents and/or insulin, attached to the PCC and 6.25% of patients had type 2 diabetes already treated with insulin.
Discussion and Conclusion
Catecholamines exert their physiological effects via adrenergic receptors (α and β) for adrenaline and noradrenaline, and dopaminergic receptors (DA1, DA2) for dopamine. Catecholamine-induced hyperglycemia is mediated by alpha1 receptors. The consequences of their activation are increased lipolysis with the release of fatty acids constituting precursors of gluconeogenesis, glycogenolysis releasing glucose and inhibition of insulin secretion. On the other hand, activation of beta2 receptors has a hypoglycemic effect by stimulating insulin secretion, a little-known, rare but serious effect. In general, the alpha-adrenergic action predominates, hence the frequency of hyperglycemia during PCC (26%) (2). Carbohydrate abnormalities during PCC can be greatly improved after tumor resection (3), which is why it is important to detect them in order to manage them early and correctly.

Impact of Covid-19 pandemic on pheochromocytoma and paraganglioma incidence
Chanez Kalboussi[1], Bilel Ben Amor[1], Hamza Elfekih[2], Ines Bayar[1], Taieb Ach[2], Sana Abid[1], Ghada Saad[2], Héla Marmouch[1], Yosra Hasni[2], Hanene Sayadi[1] & Inès Khochteli[1]
[1]University hospital of Monastir, Endocrinology Department, Monastir, Tunisia; [2]University hospital of Sousse, Endocrinology Department, Sousse, Tunisia

Introduction
Pheochromocytoma and paraganglioma (PPGL) are rare neuroendocrine tumors, often diagnosed incidentally (1,2). The COVID-19 pandemic has led to significant changes in healthcare delivery, potentially influencing the detection of such conditions. The aim of this study was to evaluate the impact of COVID-19 on the incidence of pheochromocytoma (PHEO) and paraganglioma (PGL).
Materials and Methods
We conducted a bicentric retrospective study in the endocrinology departments of two Tunisian university hospitals (Monastir and Sousse, Tunisia). All cases of PHEO and PGL diagnosed between January 1991 and December 2023 were reviewed. Data were extracted from medical records and analyzed using SPSS version 21. Inclusion criteria involved patients with a confirmed diagnosis of PPGL.
Results
We have included 45 patients with PHEO, 8 with PGL and 1 patient who has both PHEO and PGL. Incidentally discovered PPGL on imaging accounted for 51.9% of our cases. The annual incidence of PHEO and PGL in both hospitals was 1.92 cases/year, with a noticeable increase starting in January 2020. Indeed, the annual incidence after 2020 was 5.25 cases/year and 38,8% of our patients were diagnosed between 2020 and 2023.
Discussion
Our study indicates a noticeable increase in the incidence of incidentally discovered PPGL starting in 2020, a trend that aligns with the disruptions caused by the COVID-19 pandemic. This shift is particularly relevant in the context of changing healthcare dynamics during the pandemic, including the increased use of computed tomographic scan of the thorax. Various studies have noted similar findings (3), highlighting how the pandemic may have influenced the detection of both common and rare conditions.
Conclusion
The COVID-19 pandemic has influenced the incidence and diagnostic pathways of PPGL, with an increasing number of incidental findings noted in imaging studies after 2020.

Glycemic disorders in pheochromocytoma and paraganglioma
Chanez Kalboussi[1], Bilel Ben Amor[1], Hamza Elfekih[2], Ines Bayar[1], Wiem Saafi[2], Sana Abid[1], Ghada Saad[2], Héla Marmouch[1], Yosra Hasni[2], Hanene Sayadi[1] & Inès Khochteli[1]
[1]University Hospital of Monastir, Endocrinology Department, Monastir, Tunisia; [2]University Hospital of Sousse, Endocrinology Department, Sousse, Tunisia

Introduction
Pheochromocytomas and paragangliomas (PPGL) are characterized by a wide spectrum of clinical and biological manifestations, primarily due to the excessive secretion of catecholamines. One of the common associated co-morbidities are glucose metabolism disorders, including both prediabetes and diabetes. The purpose of this study was to assess the prevalence of glycemic disorders observed in patients with PPGL.
Materials and Methods
We conducted a bicentric retrospective study in the endocrinology departments at two hospitals: Fattouma Bourguiba Hospital in Monastir and Farhat Hached Hospital in Sousse, Tunisia. This study included patients diagnosed with PPGL from January 1991 to December 2023.
Results
Out of the 54 patients included, 45 were diagnosed with PHEO, 8 with PGL, and 1 with both PHEO and PGL. We noticed a female predominance with sex ratio of 2.8. The median age of patients with PHEO and PGL was 46.4 and 49.2 years respectively. The mean BMI was 25 kg/m^2. A significant proportion of patients (75.9%) had hypertension, 37% had diabetes, while 25.9% had prediabetes.
Discussion
The glycemic disorders in patients with PPGL can be explained by multiples mechanisms. First, a defect in insulin secretion secondary to stimulation of α2 receptors, which inhibits insulin production (1,2) and second, insulin resistance through stimulation of α1 receptors, which activates lipolysis and gluconeogenesis (1,3). Elenkova *et al*. reported 30.4% for diabetes and 19.1% for prediabetes (4) and the Indian study by Khatiwada *et al*. described a higher rate of diabetes at 48.3% (3). We suggest that a comprehensive clinical examination, including glycemic screening, is crucial in the management of PPGL patients, especially considering the associated metabolic risks.
Conclusion
PPGL present a complex diagnostic and therapeutic challenge due to their highly variable clinical presentation and associated comorbidities, such as glycemic disorders and hypertension. Our study demonstrates a high prevalence of both prediabetes and diabetes in patients with PPGLs, underscoring the need for careful monitoring and management of glucose metabolism.

JOINT1109
A case of aldosterone synthase deficiency presenting with hyponatremia in a 17-year-old male
Jamala Mammadova[1,2]
[1]Lıv Bona Dea Hospital, Baku, Azerbaijan; [2]Lıv Bona Dea hospıtal, Baku

A 17-year-old male patient presented to our hospital with complaints of confusion and seizures. His medical history revealed that three years ago, he suffered a head injury resulting in a brain hemorrhage. He has been taking carbamazepine due to epilepsy. A physical examination showed that the patient's height was 146,5 cm (-4,7 SDS), and his weight was 48 kg (-3.02 SDS). His blood pressure and pulse rate at admission were 110/80 mmHg and 71 beats/min, respectively. There were no remarkable findings on chest and abdominal examinations. The findings of the neurological examination were unremarkable, except for muscle weakness. In the family history, the parents were consanguineous and one of his sisters was healthy. Initial laboratory testing was as follows: serum sodium 118 mEq/l, potassium 5.3 mEq/l serum osmolality 240 mOsm/kg, uric acid 1.5 mg/dl, urine osmolality 132 mOsm/kg and urine sodium 24 mEq/l. Other laboratory values of the patient are given in Table 1. The findings of an inappropriately concentrated urine (>100 mOsm/kg), low serum osmolality (<280 mOsm/ kg) and serum sodium (<135 mEq/l) were compatible with syndrome of inappropriate antidiuretic hormone secretion (SIADH). After fluid restriction to 1000 ml/m^2/day, serum sodium concentration increased up to 141 mEq/l. Since carbamazepine is known to cause SIADH, his treatment was switched to levetiracetam. Further studies were conducted to determine the cause of SIADH. Chest X-ray and magnetic resonance imaging of the brain were normal. When daily fluid intake became unrestricted, hyponatremia recurred. After exclusion of usual causes of SIADH, a nephrogenic origin of inappropriate antidiuresis was considered and the plasma renin activity (PRA), aldosterone level was checked. In the presence of hyponatremia (116 mEq/l) and high PRA (> 1000 ng/ml/h), the aldosterone level was undetectable (<0.01 ng/dl). Therefore, we switched our clinical diagnosis of SIADH to ASD. To correct hyponatremia, fludrocortisone treatment (0.2 mg/day) was started. The diagnosis of ASD was confirmed by genetic testing, which showed a homozygous mutation in *CYP11B2* gene, (c.1360>T; p.(Arg454Cys)).

Table 1. Laboratory values of cases

Parameters	Value	Reference ranges
Sodium (mEq/l)	118	135–145
Potassium (mEq/l)	5.3	3.5–5.5
Bicarbonate (mmol/l)	22	22–29
Osmolality (mOsm/kg H_2O)	240	275-295
Renin Activity (ng/ml/h)	>1000	0,4-15
Aldosterone (ng/dl)	<0,01	5-90
fT4 (ng/dl)	1.69	0.96-1.77
TSH (µIU/ml)	1.97	0.7-5.97
ACTH (pg/ml)	35,7	25-100
Cortisol (µg/dl)	15	8.5-23
Urine		
Osmolality (mOsm/kg H_2O)	132	50-1400[a]

Congenital adrenal hyperplasia: about 10 cases in burkina faso

Yempabou Sagna[1], Abraham Bagbila[1], Ella Saloukou[2], Carole Kyelem[1], Marceline Yameogo[1] & Macaire Ouedraogo[1]
[1]Nazi BONI University, Bobo-Dioulasso, Burkina Faso; [2]Regional Hospital of Koudougou, Koudougou, Burkina Faso

Background
Congenital adrenal hyperplasia (CAH) is a group of genetic disorders responsible for defects in adrenal steroidogenesis and resulting in diminished cortisol production. Very few newborns are examined by a paediatrician and screening of neonates with elevated 17-hydroxyprogesterone concentrations is not available in Burkina Faso. Until 2023, there was no pediatric endocrinologist in the country, which is also short of pediatric doctors. We aimed to describe the main characteristics of patients diagnosed with CAH in this country
Patients and Methods
Data were collected from a retrospective program register between 2018 and 2024 in the 2 main cities of Burkina Faso. Diagnostic criteria were the presence of clinically suspected signs with elevated serum 17-hydroxyprogesterone or DOC and/or 11-deoxycortisol concentrations.
Results
Total of 10 children and adolescents (including 9 classic forms) aged between 1 month and 18 years were diagnosed with CAH. The karyotype showed 8 46, XX patients and 2 46, XY patients. Although symptoms had been present since birth, the mean age of diagnosis was 8.5 years. The main symptoms of the 46, XX patients were atypical genitalia (8/8), oligomenorrhea/amenorrhea (4/8), and hirsutism (2/8). For the 46, XY patients there was a post-natal virilization (2/2). Two children were from the same family. Biological assays showed 21-hydroxylase deficiency in 9 patients and 11-hydroxylase deficiency in the 1 remaining patient who also had hypertension. Genetic analysis was performed on a single patient (male), showing a composite heterozygous mutation 668-13C>G. All patients were treated with chronic hydrocortisone therapy and 1 died. The child with 11-hydroxylase deficiency received also a mineralocorticoid receptor antagonist to treat hypertension. Genital surgery was performed in 4/8 46, XX patients.
Conclusion
CAH can result in mortality if left undiagnosed or insufficiently treated. Patients come late for consultation. This can be explained by a lack of knowledge of this pathology by medical staff, but also by the lack of paediatric endocrinologists.

Cell-cell communication shapes the impact of obesity-associated stressors on human vascular cells

Narjes Nasiri-Ansari[1], Virginie Dubourg[1], Michael Kopf[1], Sindy Rabe[1], Sigrid Mildenberger[1], Gerald Schwerdt[1], Barbara Schreier[1] & Michael Gekle[1]
[1]Medical Faculty of the Martin-Luther-University Halle-Wittenberg, Julius-Bernstein-Institute of Physiology, Halle(Saale), Germany

Background and Aim
Cardiovascular disease (CVD) is the leading cause of death in individuals with obesity, driven largely by endothelial (EC) and smooth muscle cell (SMC) dysfunction. Obesity-induced EGFR transactivation, mediated a.o. by elevated angiotensin-II (AngII) and norepinephrine (NE) levels is supposed to contribute to vascular dysfunction and remodeling. However, the role of EC-SMC interactions in obesity-related CVD remains unclear. This study investigates the impact of AngII and NE on human primary ECs and SMCs under conditions mimicking obesity (elevated FFA and glucose).
Methods
Human primary ECs and SMCs were cultured alone or as co-culture in opposite side of cell culture insert membrane. The effects of metabolic stimuli (MS) and hormonal stimuli (HS), alone or in combination, on gene expression (DEG) were assessed by RNA-sequencing followed by gene-ontology term and functional enrichment analysis. To evaluate their impact on cell function, key parameters such as cell apoptosis/necrosis, DNA-synthesis/proliferation, glucose consumption (dglucose), lactate production (dlactate), oxidant–antioxidant balance, ATP production, mitochondrial function as well as the secretory profiles of inflammatory molecules were analyzed under each condition.
Results
In monoculture, incubation of cells with each stimulus, alone or in combination, did not affect cell apoptosis, necrosis and GSSG/GSH-ratio while proliferation and proton leak was induced in HAoEC under MS. HAoSMC metabolism was altered by MS, evidenced by elevated ATP levels. dglucose and dlactate/dglucose-ratio were enhanced by either MS or all stimuli. Incubation of cells with either or both stimuli in the presence of AG1478/EGF revealed that MS-induced cell proliferation, dglucose, dlactate and ATP production seems to be EGFR dependent. In co-culture, proton leak and GSH content were induced in HAoECs by MS and HS respectively. Transcriptomic analysis revealed that under the effect of obesity-associated stressors, number of DEG in ECs was significantly higher in co-culture. IPA highlighted the involvement of DEGs in regulation of cell cycle and inflammation. This was not the case for SMC. Co-culture also led to a significant change of the extracellular inflammatory marker profile compared to monoculture, thereby exposing cells to a different micromilieu. A potential role of EGFR in co-culture is under investigation.
Conclusion
This study indicates that the transcriptome and functional profile of cells are profoundly influenced by the cell culture type, underscoring the critical role of cell interactions in cellular behavior. The effects of MS in different vascular cells are, at least partially, mediated by EGFR. In few cases, these effects are further altered by HS.

Adrenal incidentalomas and risk for cancer: a monocentric study in a tertiary greek center

Stavroula Asimakopoulou[1], Petros Papalexis[1], Vasiliki Siampanopoulou[1], Alexandros Lafioniatis[1], Varvava Chalmantzi[1], Georgia Tsirou[1], Amalia Anastasopoulou[1], Dimitrios Ziogas[1], Helen Gogas[1] & Anna Angelousi[1]
[1]Laikon General Hospital of Athens, National and Kapodistrian University of Athens, First Department of Internal Medicine, Athens, Greece

Objective
There is an increased interest in the incidence of malignancy among patients with endogenous Cushing's syndrome (CS). Although immunosuppression in patients with overt CS is a well-established knowledge favoring a cancerous state, the presence of a mild autonomous cortisol secretion (MACS) or a nonfunctional adrenal incidentaloma (NFAI) has not been studied adequately.
Design
This is a matched monocentric cohort analysis investigating the prevalence of an adrenal incidentaloma among oncological patients diagnosed either before the diagnosis of malignancy or at the staging of the malignancy before any therapeutic regimen. The medical files of a total of 370 patients followed at the Units of Oncology and Endocrinology of the First Department of Internal Medicine at Laikon General Hospital were analysed from 2016 to 2024.
Methods
Patients with adrenal metastatic lesions were excluded based on routine imaging criteria (MRI or CT), functional imaging (18FDG-PET) or biopsies. A complete hormonal profile was performed including the baseline plasma and urine measurements as well as hormonal functional tests. All measurements were performed before any oncological therapeutic regimen. Forty subjects with no active malignancy or history of cancer and no adrenal lesion were included as controls. All controls were age, sex, and body mass index-matched with the oncological patients.
Results
A total of 48 (12.9%) oncological patients with a median age of 66 (25-75%: 59-72) years old out of a total of 370 oncological patients (41,7% with melanoma, 18,8% with breast cancer and the remaining with renal, lung, colon, and bladder cancer) had a diagnosis of a benign adrenal tumor found either incidentally at staging or based on their medical history. The 56.3% of them presented a left unilateral adenoma whereas the 27.5% had bilateral lesions. The median size of the adrenal lesion was 16.5mm (25-75%: 11-28) and based on the endocrine functional tests (1 mg overnight dexamethasone secretion test), 66.7% had NFAI and 33.3% MACS. The 29% of these patients presented with diabetes mellitus, 25% with osteoporosis and 32.5% with hypertension compared with 23%, 17% and 23% respectively among controls. The mean time between diagnosis of cancer and AI diagnosis was 1.93 years.
Conclusion
Benign AI were diagnosed in 13% out of patients with a history of cancer. The vast majority included NFAI. However relevant comorbidities were more frequent in those patients compared to age and sex-matched controls. These findings underscore the need for further research to establish recommendations for cancer screening in patients with AI.

Aspects of diagnosing testosterone-producing tumours

Nóra Garam[1], Judit Tőke[1], Attila Doros[2], Jakab Zsuzsanna[1], Lilla Madaras[3], György Barta[4] & Nikolette Szücs[1]
[1]Semmelweis University, Department of Internal Medicine and Oncology, Budapest, Hungary; [2]Semmelweis University, Department of Neuroradiology, Medical Imaging Centre, Budapest, Hungary; [3]Semmelweis University, Semmelweis University Department of Pathology, Forensic and Insurance Medicine, Budapest, Hungary; [4]Heténvi Géza Hospital, Szolnok, Hungary

Introduction
Several endocrine disorders can lead to elevated testosterone levels in women. During the differential diagnosis, it is essential to consider conditions such as polycystic ovarian syndrome(PCOS), congenital adrenal hyperplasia(CAH), Cushing's syndrome, exogenous testosterone intake, or testosterone-producing tumours of the ovaries or adrenal glands. In addition to hormonal assessments, imaging methods can be useful for accurate diagnosis.
Case descriptions
A 29-year-old woman was diagnosed with non-classical 21-hidroxylase deficiency. Even with glucocorticoid supplementation, consistently elevated testosterone suggested the possibility of autonomous androgen production. CT of the adrenal glands revealed no abnormalities. Transvaginal ultrasound and pelvic MRI detected a 3 cm mixed-echogenic tumour in the left ovary. A left-sided adnexectomy was performed, and histological analysis confirmed Leydig-cell tumour. A 65-year-old woman was presented with hirsutism. Her testosterone were elevated, whith suppressed LH and FSH. A CT did not reveal any abnormalities in the adrenal gland, the pelvic MRI showed cysts in the right ovary, the left ovary could not be visualized. Exploratory laparoscopy was conducted, leading to a bilateral adnexectomy. The histopathology identified Leydig-cell tumour in the right ovary. A 50-year-old woman was examined because of virilism. Testosterone level was found to be 524ng/dl(ref:8-60ng/dl). Based on hormone levels Cushing-syndrome, PCOS and CAH was unlikely. CT of the adrenal glands suggested the possible presence of right-sided adenoma. Pelvic MRI and transvaginal ultrasound did not indicate tumour in the ovaries. To determine the source of the elevated testosterone, selective sampling of both the ovarian and adrenal veins was performed. The results revealed that the testosterone was produced by the right ovary. Consequently, an adnexectomy was performed, which identified Leydig-cell tumour in the right ovary. A 50-year-old woman presented with hirsutism and androgenic alopecia was diagnosed with hyperandrogenism. An abdominal ultrasound and CT did not describe any abnormalities. However, a transvaginal ultrasound failed to visualize the left ovary. On MRI, a heterogenous, contrast-enhancing tumour measuring 6.3x4.8x6.1 cm in the right ovary was seen. Subsequently, a bilateral adnexectomy was performed. Histology report identified the tumour as Sertoli-cell tumour.
Discussion
Determining the etiology of hyperandrogenism can be challenging. Collaboration with the radiologists and gynaecologists is essential to evaluate each case. The hormonal testing plays a crucial role in the differential diagnosis. However if there is a suspicion of a testosterone-producing tumour, abdominal and pelvic CT and MRI imaging, can provide valuable insights. Selective sampling of the adrenal and ovarian veins may also be helpful in such cases.

Primary adrenal lymphoma- 15years retrospective analysis from a tertiary care centre

Preeti Dabadghao[1], Subhash Yadav[2] & Bibhuti Bhusan Mohanta[1]
[1]Sanjay Gandhi Post Graduate Institute of Medical Sciences, Endocrinology, Lucknow, India; [2]Sanjay Gandhi Post Graduate Institute of Medical Sciences, Endocrinology, Lucknow UP, India

Introduction
Primary adrenal lymphoma (PAL) is a rare malignancy, accounting for $<1\%$ of extra-nodal lymphomas yet highly aggressive and invasive disease. Timely diagnosis is crucial for improved prognosis. We describe ten cases of PAL seen in our department who presented with diverse clinical presentations, posing challenges in both diagnosis and treatment.
Patients and Methods
Ten cases of PAL were confirmed by histopathology and immunohistochemistry from a retrospective cohort of 125 cases of primary adrenal insufficiency admitted in the Endocrinology ward over 15 years duration from 2010-2025. Data-analysis was performed using SPSS 27.
Results
The median age at presentation was 53 years (range: 22–70 years), 7 were males and had symptom duration of 1–4 months. Features of adrenal insufficiency like nausea, vomiting, hyperpigmentation weight loss, and loss of appetite were reported in 7 out of 10 cases and were confirmed in all 7. Fever and B symptoms were present in 8 out of 10 cases. Anemia was present in 9 out of 10 cases, while pancytopenia was observed in 1. Hyponatremia was noted in 8 out of 10 cases, and severe hypercalcemia occurred in 1 case. The mean LDH level was 1796 U/l (range: 703–3584 U/l) normal range (85-450). All patients had bilateral adrenal enlargement with lymphadenopathy in 8 out of 10 cases, hepatomegaly in 3, and splenomegaly in 2 out of 10 cases. The adrenal gland contour was oval in 5 out of 10 cases, irregular in 4 cases, and round in 1. All 10 cases were identified as B-cell non-Hodgkin lymphoma (NHL). Five patients received the R-CHOP regimen, and one received the R-CVP regimen. Chemotherapy was not initiated in four patients due to poor performance status. The median survival was 8 months (range: 4–30 months) in the chemotherapy group compared to 1 month (range: 1–4 months) in the non-chemotherapy group. Survival was 1–3 months in 3 cases, 3–6 months in 3 cases, 6–12 months in 1 case, and over 12 months in 1 case.
Conclusion
In India, tuberculosis and histoplasmosis are the leading causes of primary adrenal insufficiency with bilateral adrenal masses. PAL should be considered if

infectious causes are ruled out, as its treatment differs and carries a poor prognosis. PAL prognosis is generally unfavorable, with predictors of poor outcomes including older age, large tumor size, bilateral adrenal involvement, adrenal insufficiency at presentation, elevated LDH levels, and non-germinal B-cell lymphoma.

Nonsurgical management of pheochromocytoma in the very elderly – a case series and review of the literature

Regev Landau[1], Miriam Shtainsneider[1,2], Efrat Markus[1,2], Rutie Mamlok[1,2] & Shlomit Koren[1,2]
[1]Shamir Medical Center, Endocrinology and Diabetes, Zerifin, Israel; [2]Tel-Aviv University, Faculty of Medicine, Tel-Aviv, Israel

Introduction
Pheochromocytoma (PCC) is a rare tumor with potentially fatal complications, namely cardiovascular events and PCC spells. Few cases of PCC treated non-surgically in the elderly have been described.
Methods
we collected data regarding three PCC patients that did not undergo adrenalectomy for various reasons on an average follow up of 5.69 years.
Results
Patient 1 was 75 years old (YO) at diagnosis, he had a tumor diameter of 3.2 cm and refused surgery. He had a stroke 6.6 years after presentation and survived for 14.1 years. His first available 24-h urinary metanephrines and normetanephrines were 5.91 and 1.98 times upper normal limit (UNL) respectively. Blood pressure (BP) treatment was with doxazosin, losartan and bisoprolol. Patient 2 was 86 YO when he had an adrenal mass of 4.9*6.2*4.5 cm found on CT, he wasn't referred to workup at that time and workup was complete only 7.31 years later, at age 94 when the adrenal mass was 7.4*8.1*8.8 cm and 24-h urinary metanephrines, normetanephrines and methoxytyramine were 12.73, 15.51 and 1.42 times the UNL respectively. He had no cardiovascular events at this time and refused further workup. BP and heart rate (HR) were controlled with doxazosin and metoprolol. Ehocardiography showed an ejection fraction of 45% with diffuse reduction of systolic function and a grade 2 diastolic dysfunction. Patient 3 was 85 YO at diagnosis, with tumor dimensions of 4.5*5.5, she had a positive F-DOPA scan, refused urinary metanephrines collection or any other workup. On a follow up of 0.54 years BP was slightly elevated and was controlled with doxazosin, lercanidipine and bisoprolol. She remained alive with no cardiovascular events. Our average age at diagnosis was 82 years, and average follow up time was 5.69 years. During follow up one patient passed away after 14.1 years of follow up, the same patient experienced a stroke at 6.61 years and a syncope at 2.4 years. No other cardiovascular events were recorded in the other two patients. The average age at end of follow up was 88 years.
Conclusion
in this series of three elderly patients with PCC that did not have an adrenalectomy we found one occurrence of a stroke and one death in the same patient on an average follow up of 5.69 years. It thus seems that medical management may allow satisfactory disease control in select cases in which surgery is not possible or refused by very elderly patients.

The necessity for new criteria for overnight dexamethasone suppression test to diagnosis of cushing's syndrome

Han Na Jang[1]
[1]Kangbuk Samsung Hospital, Division of Endocrinology and Metabolism, Department of Internal Medicine, Seoul, South Korea

Introduction
The overnight 1 mg dexamethasone suppression test (ODST) is used to screen and diagnose Cushing's syndrome, suspected when plasma cortisol levels exceed 1.8 μg/dl after dexamethasone administration. However, factors such as stress, illness, obesity, pregnancy, oral contraceptives, alcohol abuse, depression, and medications affecting dexamethasone metabolism can lead to false-positive results, requiring careful interpretation. This study aims to propose new criteria for ODST cortisol levels in diagnosing Cushing's syndrome by confirming whether patients with positive ODST results were diagnosed with Cushing's syndrome through further testing.
Methods
This study was conducted on subjects who showed positive results from ODST for the evaluation of adrenal adenoma or adrenal hyperplasia and subsequently underwent the low dose dexamethasone suppression test (LDDST) between January 2021 and October 2024 at Kangbuk Samusng Hospital. Patients with CKD grade 3b (estimated glomerular filtration rate [eGFR] < 45 ml/min/1.73m^2), those on medications affecting dexamethasone metabolism, and those undergoing cancer treatment were excluded. Diagnosis of Cushing's syndrome required two or more positive results from the ODST, LDDST, or late-night serum cortisol test (> 7.5 μg/dl).
Results
A total of 154 patients with positive ODST results underwent the LDDST. The mean age of the subjects was 55.9 $\pm$ 14.2 years, 58 (37.7%) were male, and the median body mass index (BMI) was 24.7 [22.7, 27.3] kg/m^2. 73 (47.4%) had hypertension, 37 (24.0%) had diabetes, and 46 (29.9%) had dyslipidemia. The median eGFR was 101.1 ml/min/1.73m^2. The basal, ODST, LDDST, and late-night cortisol levels were 11.4, 3.5, 2.8, and 4.6 μg/dl, respectively. Among the patients, 42 were not diagnosed with Cushing's syndrome, while 112 were. There were no significant differences in age, BMI, sex, or comorbidities between those diagnosed and those not diagnosed with Cushing's syndrome. The eGFR was significantly lower in patients without Cushing's syndrome (97.0 [87.9, 104.6] ml/min/1.73m^2) compared to those with Cushing's syndrome (102.5 [94.3, 110.9] ml/min/1.73m^2) ($P = 0.039$). ODST, LDDST, and late-night cortisol levels were significantly lower in patients without Cushing's syndrome ($P < 0.001$). The ODST cortisol level for diagnosing Cushing's syndrome was 3.15 μg/dl (AUC 0.818).
Conclusion
Despite positive ODST results, many patients were not diagnosed with Cushing's syndrome. Considering the high prevalence of obesity and stress in modern society, further research is needed to establish new criteria for ODST cortisol levels in diagnosing Cushing's syndrome.

From venipuncture to self-sampling DBS: a shift in monitoring testosterone levels

Anouk Olthof[1,2], Jacquelien Hillebrand[1,2], Lysette van Deursen-Nagel[3], Anita Boelen[2,4,5], Andreas Meißner[3,5,6] & Annemieke C Heijboer[1,2,5]
[1]Endocrine Laboratory, Department of Laboratory Medicine, Amsterdam UMC, University of Amsterdam, Vrije Universiteit Amsterdam, Amsterdam, Netherlands; [2]Amsterdam Gastroenterology, Endocrinology & Metabolism, Amsterdam, Netherlands; [3]Department of Urology, Amsterdam UMC, location University of Amsterdam, Amsterdam, Netherlands; [4]Endocrine Laboratory, Department of Laboratory Medicine, Amsterdam UMC, University of Amsterdam, Amsterdam, Netherlands; [5]Amsterdam Reproduction and Development, Amsterdam, Netherlands; [6]Amsterdam Public Health, Amsterdam, Netherlands

Background
Dried Blood Spot (DBS) sampling offers the convenience of at-home blood sampling, making it an advantageous solution for patients requiring regular check-ups of their hormone levels, such as testosterone. It eliminates the need for venipunctures, which require additional or longer hospital visits, resulting in significant advantages for patients, physicians, laboratory staff and hospitals. DBS samples can be sent by regular mail to the laboratory for analysis, ensuring that results are available during outpatient clinic visits. The aim of this study is to evaluate the feasibility and reliability of using DBS samples for monitoring testosterone levels in patients receiving testosterone replacement therapy (trt).
Methods
A total of 59 males from the andrology outpatient clinic receiving trt (via deeply intramuscular injection of testosteroneundecanoate or dermal application of testosterone gel) were included in this study. Blood was collected parallel by venipuncture (reference value) and finger prick (DBS sample) performed by the patient self after reading the instruction material to guide them and additional instruction from the andrology consultant. Testosterone concentrations in both serum and DBS were quantified using a validated liquid chromatography-tandem mass spectrometry (LC-MS/MS) method. Pearson correlation coefficient was calculated.
Results
39 DBS samples were suitable for analysis, while the remaining 20 samples were unreliable due to contamination from testosterone gel (12), improper sampling

technique such as finger stamping, blood stacking, or collection of too small droplets (6) or analytical difficulties (large duplicate variation) (2). The correlation coefficient between testosterone concentrations in self-sampled DBS and serum was $r = 0.87$.

Conclusions

For patients receiving trt via deeply intramuscular testosteroneundecanoate injection, monitoring testosterone levels via DBS sampling at home is feasible, enhancing patient comfort and convenience. Patient education is needed to ensure proper collection of DBS samples, leading to high quality DBS and accurate testosterone quantification.

Targeted proteomics reveals novel biomarkers of disease activity and cardiometabolic risk in acromegaly

Kristin Godang[1], Maren Wessel[1,2,3], Yusuf Khan[3,4], Ansgar Heck[1], Jens Petter Berg[2,5], Jens Bollerslev[1] & Nicoleta Cristina Olarescu[1]
[1]Section of Specialized Endocrinology, Department of Endocrinology, Oslo University Hospital (OUS), Oslo, Norway; [2]Institute of Clinical Medicine, Faculty of Medicine, University of Oslo, Oslo, Norway; [3]Research Institute of Internal Medicine, OUS, Oslo, Norway; [4]Department of Cardiothoracic and Vascular Surgery, University Hospital of North Norway, Tromsø, Norway; [5]Department of Medical Biochemistry, OUS, Oslo, Norway

Objectives

Acromegaly is linked to metabolic complications such as diabetes and an elevated risk of cardiovascular disease, even though patients often exhibit a favorable body composition with reduced fat and increased muscle mass. This paradox highlights a gap in understanding the underlying metabolic consequences of disease activity [1]. Current diagnostic approach relies heavily on serum levels of growth hormone (GH) and insulin-like growth factor 1 (IGF-1), which are dynamically influenced by various factors, thereby highlighting the need for more precise biomarkers for disease activity monitoring. We hypothesized that dysfunctional adipose tissue drives increased cardiometabolic risk in acromegaly through adipocytokine release and subsequent systemic insulin resistance. Moreover, we aimed to identify potential biomarkers for disease activity and cardiometabolic risk.

Methods

Clinical and biochemical data, including glucose, HbA1c, GH and IGF-1 levels, and body composition measured by dual-energy X-ray absorptiometry (DXA), were recorded in a cohort of patients with acromegaly ($n = 32$) at diagnosis and after successful disease remission by transsphenoidal surgery (mean $\pm$ 1SD, 18.3 $\pm$ 5.8 months). Expression of 92 proteins was measured on Olink Target 96 Cardiovascular III, in first-time-thawed EDTA plasma samples at baseline and after surgery. Statistical analysis was conducted in R using R Studio, and SPSS.

Results

Mean age at diagnosis was 49.8 $\pm$ 14.1 years, and 18 (56 %) were men. At diagnosis, GH correlated negatively with all fat depots and plasma MMP-3, and positively with MEPE and COL1A1. The correlations were not preserved after treatment. Following treatment, GH, IGF-1, glucose, and HbA1c decreased significantly ($P < 0.05$). Plasma MMP-3, IGFBP-2, and EGFR increased, whereas COL1A1, MEPE, OPN, MMP-2, and CNTN1 significantly declined (adjusted P-value < 0.05). Table 1 presents the statistically significant correlations between changes in GH and IGF-1 and glucose, total body fat and proteins.

Table 1. Spearman correlation coefficients (R) between changes (%) in GH, IGF-1, glucose, total body fat and selected proteins (p-values < 0.05 for all).

% change	Glucose	Total Body Fat	MEPE	MMP-3	IGFBP-2	MMP-2	EGFR
GH	0.39	-0.42	-	-	-	0.44	-0.39
IGF-1	0.42	-	0.36	-0.52	-0.60	-	-

Conclusion

Our results reveal close association between several proteins related to metabolic and cardiovascular dysregulation and disease activity in acromegaly. These findings point to COL1A1 and IGFBP-2 as potential biomarkers to assess disease activity and cardiometabolic risk.

Vitamin D receptor mRNA expression in adrenal medulla and pheochromocytoma cells

Ewelina Rzepka[1], Anna Skalniak[2], Magdalena Ulatowska-Białas[3], Martyna Lech[3], Marta Opalińska[1], Aleksandra Gilis-Januszewska[1], Elwira Przybylik-Mazurek[1] & Alicja Hubalewska-Dydejczyk[1]
[1]Chair and Department of Endocrinology, Jagiellonian University Medical College, Cracow, Poland; [2]Center for the Development of Therapies for Civilization and Age-Related Diseases, Jagiellonian University Medical College, Cracow, Poland; [3]Department of Pathomorphology, Jagiellonian University Medical College, Cracow, Poland

Objective

The expression of vitamin D receptor (VDR) and the role of 1,25-dihydroxyvitamin D3 (1,25(OH)D3) in human adrenal medulla is not well investigated. Previous reports showed that 1,25(OH)D3 accumulates in the nuclei of adrenal medullary cells in mice and increases expression of tyrosine hydroxylase gene in cultured bovine adrenal medullary cells. No genomic data regarding VDR mRNA expression in human pheochromocytoma or normal adrenal medulla has been reported. The aim of this study was to elucidate the expression of VDR in healthy human adrenal medulla and human pheochromocytoma cells, and to investigate the potential association between VDR presence and the clinicopathological characteristics of pheochromocytoma.

Design and Methods

A total of 31 pheochromocytoma cases with available tissue samples from surgical resection, 4 samples of healthy adrenal cortex and 4 samples of unaltered adrenal medulla as control group were analysed. The expression of VDR at the mRNA level was assessed by digital PCR in all pheochromocytoma cases and the control group. For pheochromocytoma patients, clinical manifestation, hormonal status and histopathological results were retrospectively assessed.

Results

VDR mRNA expression in adrenal medulla and pheochromocytoma cells was compared to the expression in the control adrenal cortex, set at 1.0. The median VDR mRNA expression in pheochromocytoma specimens was the lowest when compared to unaltered adrenal medulla and adrenal cortex (median expression = 0.05; range: minimum = 0.0, maximum = 0.56). Unaltered adrenal medulla specimens demonstrated higher VDR expression than pheochromocytomas, but lower than that observed in the normal adrenal cortex (median = 0.49; range: minimum = 0.32, maximum = 0.58). No statistically significant correlations were observed between VDR mRNA expression levels in pheochromocytomas and most clinical parameters evaluated in this study. However, VDR expression in tumour tissues was negatively associated with somatostatin receptor 2 (SSTR2) expression, taking into account the confounding factors of sex and the interaction with elevated 3-methoxytyramine concentration.

Conclusions

In our study, we present, for the first time, the expression of the vitamin D receptor (VDR) in human adrenal medulla and pheochromocytoma tissue. VDR expression at the mRNA level was detected in unaltered adrenal cortex, adrenal medulla, and pheochromocytoma cells, with quantification achieved through digital PCR. The highest median expression was observed in the adrenal cortex, followed by an intermediate median expression in the adrenal medulla, and the lowest one in pheochromocytoma cells. No correlation between VDR mRNA expression levels and the primary clinical features of the disease was identified.

Long-term metabolic comorbidities in patients with adrenal incidentalomas - a single center experience

Antoan Stefan Sojat[1], Miomira Ivovic[1], Bogdan Dugic[2], Natalija Antic[1], Kristina Saravinovska[1], Svetlana Vujovic[1] & Ljiljana Marina[1]
[1]Clinic for Endocrinology, Diabetes and Metabolic Diseases, University Clinical Centre of Serbia, National Centre for Infertility and Endocrinology of Gender, Belgrade, Serbia; [2]The University of Belgrade, School of Electrical Engineering, Belgrade, Serbia

Introduction

Current guidelines for managing adrenal incidentalomas (AI) do not recommend long-term follow-up for patients with non-functioning adrenal incidentalomas (NAI) unless in case of significant changes in comorbidities potentially attributed to mild autonomous cortisol secretion (MACS).

Aim

This study aimed to assess the long-term development of cardiometabolic risk factors in patients with AI and evaluate the need for follow-up.

Methods
In this single-center prospective cohort study, 88 patients with AI (70 females [79.5%], 18 males [20.5%]) underwent clinical, biochemical, and imaging evaluations at baseline and final follow-up (median 55 months, IQR 47–80). Based on the result of 1 mg dexamethasone suppression test at baseline, patients were stratified into NAI (1 mg dexamethasone suppression test [1 mg DST] cortisol $\leq$50 nmol/l) or MACS (1 mg DST cortisol $>$50 nmol/l).
Results
At the final follow-up, patients with MACS demonstrated a significant increase in body mass index (BMI) (27.1 vs. 27.8 kg/m^2, $P = 0.03$), a higher incidence of bilateral tumors (51.2% vs. 34%, $P = 0.016$), increase in antihypertensive medication count ($P < 0.001$), and a nonsignificant trend toward higher dyslipidemia rates (66% vs. 41%, $P = 0.06$). In contrast, NAI patients exhibited a significant increase only in antihypertensive medication count ($P < 0.001$). In the univariate linear regression model, significant predictors for antihypertensive medication count in NAI were baseline BMI (B = 0.08, 95% CI [0.005–0.166], $P = 0.04$), follow-up duration (B = 0.01, 95% CI [0.004–0.026], $P = 0.01$), and baseline antihypertensive medication count (B = 0.85, 95% CI [0.548–1.146], $P < 0.001$). In multivariate regression, follow-up duration (B = 0.01, 95% CI [0.001–0.018], $P = 0.04$), and baseline antihypertensive medication count (B = 0.73, 95% CI [0.406–1.056], $P = 0.01$) remained significant. Notably, 19.1% (9/47) of NAI patients progressed to MACS during follow-up.
Conclusions
Although NAI patients did not exhibit significant cardiometabolic risk progression over a median follow-up of 4.6 years, nearly 20% developed MACS. These findings suggest that patients with NAI should undergo at least one reassessment for MACS within a 4-year period to guide clinical management.

Analysis of clinical characteristics and pharmacological treatment to achieve adequate plasma renin activity levels in primary hyperaldosteronism

Cristina Franco Borras[1,2], Theodora Michalopoulou Alevras[1,2], Ana Megia[1,2,3], Ariadna Prats Custal[1] & Maria Castell[1]
[1]Rovira i Virgili University, Tarragona, Spain, Departament of Endocrinology and Nutrition. Research Unit. University Hospital of Tarragona Joan XXIII-Institut dInvestigació Sanitària Pere Virgili (IISPV), Tarragona, Spain, Endocrinology and Nutrition, Tarragona, Spain; [2]Departament of Endocrinology and Nutrition. Research Unit. University Hospital of Tarragona Joan XXIII-Institut dInvestigació Sanitària Pere Virgili (IISPV), Tarragona, Spain, Endocrinology and Nutrition, Tarragona, Spain; [3]Grupo de investigación de Diabetes y Enfermedades Metabólicas Asociadas (CIBERDEM)-Instituto de Salud Carlos III, Madrid, Spain, Tarragona, Spain

Introduction
In primary hyperaldosteronism (PH), achieving a plasma renin activity (PRA) $\geq$ 1 ng/ml/h is associated with a lower cardiovascular risk. This study aims to analyze how many patients achieve this target and evaluate the number (nº) and type of medications used.
Materials and Methods
A retrospective observational study of a cohort of PH patients undergoing medical treatment for: lack of biochemical success after surgery; preference for medical treatment; or being unsuitable for surgery. Based on the PRA value at the last follow-up, patients were divided into two groups (21 patients with PRA $<$1 and 11 with PRA $\geq$1). Clinical and analytical data were collected, including the total nº and combinations of antihypertensive drugs used, focusing on the following combinations: mineralocorticoid receptor antagonists (MRAs) with ACE inhibitors (ACEIs) or angiotensin II receptor blockers (ARBs), and MRAs with hydrochlorothiazide (HCT), to determine their effectiveness in achieving the PRA target.
Results
During a mean follow-up of 45 months, only 33% of patients achieved the PRA target of $\geq$1. Clinical and analytical characteristics were similar in both groups, although the number of smokers tended to be higher in the PRA $<$1 group ($P = 0.06$). The number of antihypertensive medications (up to 7 drugs) used was similar in both groups ($P = 0.61$). In the PRA $<$1 group, the use of eplerenone was higher than that of spironolactone ($P = 0.038$). No significant differences were found regarding the combination of antihypertensive medications studied and PRA inhibition, although a trend toward significance was observed in patients treated with MRA and HCT ($P = 0.068$).
Conclusions
Achieving PRA levels $\geq$1 is difficult with medical treatment, and clinical and analytical characteristics do not help to identify which patients will achieve this target. Eplerenone is the least effective of the MRAs, and the combination of MRA and HCT may be a promising alternative.

3 cases with different clinical features due to adrenal insufficiency after adrenal hemorrhage in newborns

Gozde Tanis[1], Merve Hepokur[1], Asan Camas[1] & Hamdi Emeksiz[1]
[1]Istanbul Medeniyet University Medical Faculty, Pediatric Endocrinology Department, Istanbul, Türkiye

Introduction
Adrenal hemorrhage is a rare condition in the neonatal period (0.2%-0.55%) and rarely causes adrenal insufficiency. Here, we present 3 cases that developed adrenal insufficiency in the neonatal period due to different reasons and then had different clinical courses.
Case 1
The patient was admitted to the neonatal intensive care unit due to urinary tract infection(UTI). During the investigation of the etiology of UTI, an ultrasound scan was performed to observe adrenal hemorrhage measuring 33x24mm on the right and 40x22mm on the left in both adrenal gland locations. After the 250 mg ACTH stimulation test, peak cortisol was determined 12.6 mg/dl and 6 mg/m^2/day hydrocortisone treatment was started. The patient was born term and 3800gr, had no birth trauma. The patient continued to use hydrocortisone for 6 months. In the 7th month 1 mg ACTH stimulation test, the peak cortisol response was observed as 16.2 and the medication was stopped. He has been followed up without medication for 6 years.
Case 2
A male patient born term, 4000gr and 52 cm, had a 43x16x33mm hemorrhage area in the right adrenal gland and a 35x20x33mm hemorrhage area in the left adrenal gland during the abdominal USG performed due to traumatic birth. The patient's cortisol was 11 mg/dl and ACTH was 202, and due to insufficient cortisol response to the standard dose ACTH stimulation test, hydrocortisone treatment was started. Hydrocortisone treatment is being continued at 12 mg/m^2/day.
Case 3
A female patient who was examined for sepsis as a newborn had a 23x13mm hematoma on the right adrenal gland and a 18x15mm hematoma on the left. She was born at term, vaginally, and weighed 3800grams. There was no hypoglycemia in the patient, but blood sodium was measured as 132 mg/dl and potassium as 6 mg/dl. When a standard dose ACTH stimulation test was performed, peak cortisol levels were determined as 12.6 mg/dl. The patient was started on 54 mg/m^2/day hydrocortisone treatment. When she was 15 months old, the treatment was discontinued because peak cortisol was sufficient in a standard dose ACTH stimulation test.
Discussion
Adrenal hemorrhage may be caused by different clinical reasons and may progress with different clinics. Our study has shown that the clinical course of adrenal insufficiency secondary to adrenal hemorrhage may be very variable, and it is important that the clinical follow-up of these patients must be personalized and frequent.

Thematic analysis of quality of life in a community-based sample of adults living with congenital adrenal hyperplasia reveals a significant unmet medical need

Kathryn James[1], Parkin Nicola[2], Syed Ahmed[3], Sue Elford[4], Yasir Elhassan[5], Nils Krone[6], Sofia Llahana[7], Christine McKnight[8], Michael O'Reilly[9], Jeremy Tomlinson[10], Rhiannon Phillips[8] & Dafydd Rees[2]
[1]Cardiff and Vale University Health Board, Cardiff University, Cardiff, United Kingdom; [2]Cardiff University, Cardiff, United Kingdom; [3]University of Glasgow, Glasgow, United Kingdom; [4]Living with CAH Support Group, Tamworth, United Kingdom; [5]Queen Elizabeth University Hospital Birmingham, Birmingham, United Kingdom; [6]University of Sheffield, Sheffield, United Kingdom; [7]City St George's, University of London, London, United Kingdom; [8]Cardiff Metropolitan University, Cardiff, United

Kingdom; [9]RCSI Education & Research Centre, Beaumont Hospital, Dublin, Ireland; [10]University of Oxford, Oxford, United Kingdom

Introduction
Congenital adrenal hyperplasia (CAH) is a genetic disorder most commonly arising due to partial or total deficiency of the 21-hydroxylase enzyme, leading to decreased cortisol production and increased androgen secretion. The physical manifestations of CAH are well recognised but the effects on quality of life are unclear.
Aim
To explore the impact of CAH on quality of life.
Methods
In-depth, semi-structed interviews were undertaken virtually with a purposive sample of adults (>18 years) with CAH. Participants were recruited via the Living with CAH patient support group. Interviews were audio-recorded, transcribed verbatim and analysed inductively using reflexive thematic analysis. Ethical approval was obtained for the study.
Results
Twenty-one interviews were conducted with 4 men and 17 women living with CAH (median age = 41; age range: 20-62 years). Twenty had classical CAH and 1 had non-classical CAH. CAH was considered part of a participant's identity. The impact on quality of life was variable with significant effect at transitions of life (e.g. adolescence, family planning, menopause). The experiences of males and females were different, with females reporting greatest negative impact. Adrenal crises were physical effects noted by all participants. Females reported significant distress from precocious puberty, hirsutism and acne. Thirteen women had undergone genital surgery with a few participants reporting complications such as painful intercourse, urinary tract infections and incontinence. Medication side-effects (osteoporosis, diabetes, weight gain) were of particular concern to older participants but life-dependent need for steroid treatment outweighed the risks. Participants reported psychological symptoms including anxiety and depression. Female participants experienced childhood trauma from exhibiting genitalia during medical examinations and lack of agency in treatment decision, leading to mistrust of the medical profession. Complex family dynamics were also noted. Feelings of shame were often instilled in childhood with a reluctance to disclose the name of the condition to relatives and friends. Consequently, participants reported isolation and loneliness with difficulty forming friendships and intimate partner relationships. Maladaptive coping strategies including disordered eating, alcohol and substance misuse were also reported by a minority of individuals.
Discussion
CAH has a profound physical, psychological and psychosocial impact on individuals with loss of adjustment significant at transitions of life. Adopting a trauma-informed approach to care has the potential to improve patient health outcomes and quality of life. The study findings are limited to a self-selecting sample of predominantly females with CAH. Further work will explore the generalisability of the results to the wider CAH community.

Two different clinical presentations, one rare diagnosis: adrenocortical tumor

Selen Hürmüzlü Közler[1], Gizem Böke Koçer[1], Esra Koçyiğit[1], Sibel Tuğçe Aygün[1], Jeremy Huw Jones[2], Nazlı Gönç[3] & Filiz Mine Çizmecioğlu Jones[1]
[1]Kocaeli University Faculty of Medicine, Pediatric Endocrinology & Diabetes, Kocaeli, Türkiye; [2]Kocaeli University, Department of Academic Writing, Kocaeli, Türkiye; [3]Hacettepe University Faculty of Medicine, Pediatric Endocrinology & Diabetes, Ankara, Türkiye

Introduction
Adrenocortical tumors (ACTs) are rare in childhood, and most are functional, leading to endocrine symptoms. ACT should be considered in the differential diagnosis of children presenting with precocious puberty and/or Cushing syndrome. This report describes the diagnosis and treatment of two pediatric cases.
Case 1
A 3-year-old male patient with a history of left hemihypertrophy was referred due to the rapid (14-day) development of moon face and acanthosis nigricans(AN). On physical examination, weight:17 kg(0.5 SD), height:100 cm(-0.1 SD) with cushingoid face, AN on the neck and left hemihypertrophy. Laboratory investigations revealed hypercortisolism. A 40×38 mm heterogeneous mass in the left adrenal gland, with no invasion, poor fat content, and no calcifications reported on MRI. Following a multidisciplinary team discussion, the etiology of hypercortisolism was ACT, and the patient underwent left adrenalectomy. Histopathological examination confirmed a solid neoplasm with a Ki-67 index of 10%, without metastasis or invasion. During follow-up, the patient's physical examination was unremarkable, except for persistent left hemihypertrophy. Genetic analysis for Beckwith-Wiedemann syndrome yielded normal results, and further investigations are ongoing.
Case 2
A 2-year-old girl was referred to the oncology clinic due to an abdominal mass detected during examination for abdominal pain. MRI showed a heterogeneous 82×87×107 mm mass in the right adrenal gland, with hemorrhage, calcifications, and liver compression, reported as neuroblastoma. Tru-cut-biopsy revealed an ACT (Ki-67: 7-8%), and the mass was deemed inoperable due to compression of the IVC and portal vein. The patient developed hypertension after biopsy, managed with amlodipine. The case was referred to our clinic for further evaluation. History revealed genital hair development at 6 months, intermittent vaginal discharge, increased hair growth, and breast development over the past month. Family history included pancreatic and colon cancer. On examination: weight:10.6 kg (-0.92 SD), height:85 cm (-0.51 SD), BP 140/90 (>99th percentile), Tanner stage 3 breast/pubic hair, and distended abdomen with palpable liver (8 cm) with no clitoromegaly. Surgery was deemed unsuitable and chemotherapy was initiated per the multidisciplinary team's decision. Genetic analysis for *TP53* variant is ongoing.
Conclusion
Although rare, ACTs must be considered in the differential diagnosis ofchildren presenting with hormonal excess. Importantly, biopsy is contraindicated due to the risk of tumor cell dissemination, which worsens the prognosis. Thus, a multidisciplinary approach to ensure accurate diagnosis and optimal management is important. Early recognition is critical, as timely diagnosis and intervention can significantly impact prognosis.

JOINT1921

A case of glucocorticoid deficiency due to MC2R mutation

Renato Vaiasuso[1,2], Sara Barneschi[1,2], Giulia Del Medico[1,2], Lara Devilli[1,2], Emanuela Pignatone[1,2], Gaia Varriale[2], Stefano Stagi[1,2] & Franco Ricci[2]
[1]Department of Health Sciences, University of Florence, Florence, Italy; [2]Diabetology and Endocrinology Unit, Meyer Children's Hospital IRCCS, Florence, Italy

Background
A mutation in the adrenocorticotropic hormone (ACTH) receptor gene, also known as MC2R, causes familial glucocorticoid deficiency (FGD) type 1, a rare autosomal recessive disorder. This condition is characterized by resistance to ACTH action on the adrenal cortex, leading to isolated glucocorticoid deficiency with normal mineralocorticoid activity. It typically presents in infancy or early childhood with episodes of hypoglycemia, hyperpigmentation, recurrent infections, and convulsions, which can result in coma or death if left untreated. We report the case of a 2-year-old boy with isolated hypocortisolism due to MC2R mutation.
Clinical Case
Our patient was born at 39 weeks of gestation. His growth parameters at birth were within normal limits according to INeS Charts. From first day of life he presented recurrent severe hypoglycemic episodes, so he was held in neonatal intensive care unit. Neonatal physical examination revealed areas of hyperpigmentation on the limbs, trunk, and scrotum. Diagnostic investigations, including endocrinological and metabolic blood tests, showed elevated ACTH levels (>3000 ng/l), low cortisol, and normal 17-hydroxyprogesterone, ruling out congenital adrenal hyperplasia (CAH). Given the adrenal insufficiency, continuous intravenous hydrocortisone therapy was started to prevent adrenal crisis and later switched to an oral formulation after stabilization of blood glucose levels and improvement in laboratory tests. Subsequently, an abdominal ultrasound revealed bilateral adrenal hypoplasia. To further investigate the etiology of primary adrenal insufficiency, genetic testing was performed. Whole-exome sequencing identified the c.[634delA] variant in homozygosity in the MC2R gene, which was inherited from both parents and represents a rare cause of FGD. The patient was therefore referred to our endocrinology unit. During follow-up, oral hydrocortisone therapy was maintained at a dose of 10 mg/m^2/day, with regular progression in both height (-0.51 SDS) and weight (0.48 SDS), adequate height growth rate (4.41 SDS) and without any side effects.
Conclusions
Glucocorticoid deficiency is an endocrinological emergency and potentially life-threatening condition. Despite being the most common cause of primary adrenal insufficiency in pediatric patients, CAH is not the only condition that can lead to it. During the neonatal period, less common conditions should also be

investigated, such as familial glucocorticoid deficiency. Beyond the correct diagnostic approach, another challenge for the pediatrician is the appropriate therapeutic management of glucocorticoid deficiency, which involves adjusting the hydrocortisone dosage over time. This aims to avoid both excess and deficiency of cortisol, while keeping the patient asymptomatic with stable biochemical parameters, ensuring regular growth and enabling normal pubertal progression.

"Adrenal insufficiency with low 17-hydroxyprogresterone: lesson learned from a developing country"

Agustini Utari[1], Epifani Chandra[1], Dineke Westra[2], Antonius van Herwaarden[3] & Hedi Claahsen-van der Grinten[4]
[1]Universitas Diponegoro, Department of Pediatrics, Semarang, Indonesia; [2]Radboud University Medical Centre, Department of Laboratory Medicine, Nijmegen, Netherlands; [3]Radboud University Medical Center, Department of Human Genetics, Nijmegen, Netherlands; [4]Amalia Children's Hospital, Radboud University Medical Centre, Division of Pediatric Endocrinology, Department of Pediatrics, Nijemgen, Netherlands

Background
Congenital Adrenal Hyperplasia due to 21 hydroxylase deficiency (21 OHD) is the primary cause of adrenal insufficiency in Indonesia, as limited resources of hormonal and genetic laboratories can pose challenges in diagnosing rare adrenal conditions leading to missed diagnosis with high mortality. Here, we present two exceptionally rare cases of congenital adrenal insufficiency other than 21OHD.
Case presentation
Case 1: A-seven-years-old boy was admitted to the hospital due to recurrent seizures, vomiting, dehydration, and repeated severe hyponatremia without hyperkalemia. There was no consanguinity. The older sibling had a similar history and died due to seizures at the age of 4.5 yo. Physical examination showed normal neurology examination, hyperpigmentation, and dark spots on the tongue, normal penis and testicles. Laboratory examination revealed a low 17-Hydroxyprogesterone (17-OHP) level (the hallmark of 21OHD), low cortisol level, and hyponatremia. This patient was treated as an adrenal insufficiency patient with hydrocortisone and fludrocortisone, and the response to treatment was good. Exome sequencing showed a hemizygous pathogenic variant in NR0B1 ChrX(GRCh37):g.30327091dup NM_000475.5:c.391dup p.(Arg131fs) which is not reported in previous studies. Pathogenic variants of the NR0B1 gene had been described previously as causative for X-linked recessive congenital adrenal hypoplasia. Case 2: A-18-days-old female baby was admitted to the hospital because of recurrent hypoglycemia and hyperpigmentation, recurrent vomiting, and hyperpigmentation. There was no consanguinity; the older sister died at the age of 3 months with a similar condition. Physical examination showed skin hyperpigmentation, no clitoromegaly, no palpable testis, presence vagina and labia minora. Laboratory results showed low 17-OHP level, hyponatremia, hyperkalemia, hypoglycemia, and a 46,XY karyotype. This patient was treated as an adrenal insufficiency patient with hydrocortisone and fludrocortisone. Exome sequencing showed a homozygous variant in the Steroidogenic Acute Regulatory Protein (StAR) gene as the causative for autosomal recessive lipoid adrenal hyperplasia, and this is the first reported case in Indonesia.
Conclusions
Adrenal insufficiency often presents with aspecific features leading to delayed or missed diagnosis. Low 17-OHP levels should prompt clinicians to consider alternative etiologies beyond 21-OHD,

How to discover non-functioning adrenal cortical adenomas

Yesmine Elloumi[1], Mouna Elleuch[1], Yasmine Abdelkafi[1], Nada Hassairi[1], Kouloud Boujelben[1], Hadjkacem Faten[1], Nadia Charfi[1], Mouna Mnif[1], Mohamed Abid[1], Dhoha Ben Salah[1] & Nabila Rekik Majdoub[1]
[1]Hedi Chaker University Hospital, Endocrinology Department, Sfax, Tunisia

Background
Non-functioning adrenal cortical adenomas (NFAA) represent 70-90% of non-functioning adrenal incidentalomas. Despite being non-secretory, these tumors may exhibit minimal, inapparent, yet prolonged cortisol secretion, which can predispose individuals to components of the metabolic syndrome. This underscores the importance of screening for NFAA and the need for continuous monitoring to ensure optimal management and early detection of potential metabolic complications.
Methods
The study was retrospective and included patients followed for non-functioning adrenal cortical adenomas associated with metabolic disorders. These patients were enrolled from the Endocrinology-Diabetology Department of Hedi-Chaker University Hospital in Sfax.
Results
Our cohort consisted of 31 patients with non-functioning adrenal cortical adenomas, aged between 34 and 80 years. A female predominance was observed in 60% of cases. The adrenal adenomas were diagnosed incidentally in 90.6% of patients, with a hypertensive peak in 6%, and refractory hypertension as the reason for diagnosis in 3%. Features such as truncal obesity, with or without hypertension, facial erythema, rapid weight gain, melanoderma, and hypokalemia were not identified as presenting symptoms. Abdominal ultrasound was performed for an unrelated indication and incidentally led to the discovery of an adrenal incidentaloma in 58% of the sample.
Conclusion
Early detection of NFAA through screening and continuous follow-up is essential for optimizing patient management and preventing long-term complications.

A rare case of iatrogenic cushing's syndrome

Susana Mallea-Gil[1], Maria Marta Aparicio[1], Yamila Sanchez[1], Cindy Lopez[1], Viviana Flores Rios[1], Cindhy Castro Basurto[1] & Carolina Ballarino[1]
[1]Hospital Militar Central, Endocrinology, Buenos Aires, Argentina

The complex pharmacological interaction between ritonavir, a protease inhibitor frequently used in HIV infection that acts through the inhibition of the cytochrome P450, and fluticasone produced a significant increase in the systemic concentrations of the latter, consequently generating iatrogenic Cushing's syndrome.
Clinical case
In 2022 a 42-year-old male with a history of chronic persistent asthma and HIV on ritonavir treatment was referred to by Pulmonology for presenting weight gain with truncal obesity, severe skin pain predominantly in recent and acute reddish stretch marks, edema in the lower limbs, asthenia and severe low back pain.
Personal history
In 2018 the patient was diagnosed with HIV, starting treatment with darunavir/ritonavir 800/160 mg and dolutegravir 50 mg/day evolving to undetectable viral load; he had grade II obesity and severe and persistent asthma. In July 2022 he presented worsening asthma and was treated with meprednisone 40 mg for 7 days, budesonide/formoterol 100 mg 2 puffs twice a day, montelukast 1 tablet/day at night, salmeterol/fluticasone 500/500 (Seretide diskus) 3 times a day and tiotropium 18 mg/day. The physical examination showed arterial hypertension (160/100 mmHg), heart rate: 100/bpm, rounded face, fatty hump, fat in the supraclavicular spaces, bilateral rhonchi, severe abdominal obesity, painful wide dark red striae. Although the findings were suggestive of Cushing's syndrome, the discontinuation of inhaled fluticasone was complicated due to the severity of the respiratory condition. Diagnostic studies confirmed suppression of the adrenal axis, MRI showed lumbodorsal vertebral compression fractures: T7-T10 and L4 and evidence of osteoporosis in the bone mineral density. After stabilizing the asthmatic condition, the dose of corticosteroids was reduced: salmeterol/fluticasone 25/250 mg 1 puff twice a day, budesonide was discontinued and hydrocortisone 10 mg/day was indicated. The antiretroviral medication had to be changed for Dolutegravir/ Tenofovir/ Lamivudine; the patient improved Cushing syndrome symptoms; zoledronic acid was prescribed for the secondary osteoporosis.
Conclusions
Cushing syndrome triggered by inhaled corticosteroids is very rare, that is why we started to investigate the possible interaction between fluticasone and HIV medication. We found that ritonavir was the drug which produced a severe increase of fluticasone half-life causing a dramatic syndrome. This case highlights the need for effective communication between health professionals, multidisciplinary management, and knowledge of drug interactions in unique clinical situations.

A case of concurrent RET and FH GENE mutations in a patient with metastatic pheochromocytoma

Vasiliki Siampanopoulou[1], Florentia Fostira[2], Petros Papalexis[1], Alexandros-Aristeidis Lafioniatis[1], Georgia Tsirou[1], Varvara Chalmatzi[1], Constantine Stratakis[3] & Anna Angelousi[1]
[1]Endocrinology Unit, First Internal Medicine Department, Laiko General Hospital of Athens, National and Kapodistrian University of Athens, Athens, Greece; [2]Human Molecular Genetics Laboratory INRASTES (Institute of Nuclear and Radiological Sciences and Technology, Energy and Safety), National Centre for Scientific Research Demokritos, Athens, Greece; [3]Human Genetics & Precision Medicine, DIGENIA & EDIMO, Institute of Molecular Biology and Biotechnology of the Foundation for Research and Technology Hellas (IMMB-FORTH), Heraklion, Greece

Introduction
Pheochromocytomas are rare tumours arising from the adrenal medulla. Numerous genetic defects have been identified either as a part of inherited syndromes or in sporadic forms.
Objective
We present the case of a 64-year-old female patient diagnosed with bilateral pheochromocytomas in 2009 treated surgically with bilateral adrenalectomy (R0, ki67 < 1%). She presented 14 years later with hypertension and important weight loss. Imaging showed multiple lesions in the retroperitoneal area, pulmonary and liver metastasis. Hormonal workup revealed plasma metanephrines and normetanephrines > 400 times the upper normal limit. Fine needle biopsy (FNB) of the hepatic lesion was compatible with metastatic pheochromocytoma (ki67 < 2%.)
Methods
Germline testing was pursued through a 67-cancer gene panel following genetic counselling.
Results
Genetic testing revealed a *RET* pathogenic variant, i.e.c.2370G > T p.(Leu790Phe) which is strong predisposing factor for pheochromocytoma diagnosis. A concurrently present variant in the fumarate hydratase (*FH*) gene was also identified; our patient was heterozygous for the c.1127A > C p.(Gin376Pro) (cluster 1b), 1127A > C, p.(Gin376Pro) which is classified as pathogenic and is associated with hereditary leiomyomatosis and renal clear cell carcinoma (HLRCC). Further familial genetic testing is expected to provide crucial information about the penetrance of the aforementioned predisposing variants.
Conclusions
Genetic analysis plays a critical role in the diagnosis and management of patients with pheochromocytomas. We presented an individual who had not just one but two clinically important germline variants, accounting perhaps for the aggressiveness of her tumour. The presence of clinically relevant variants may contribute to define not only genotype-phenotype correlations but are also important for cascade testing of asymptomatic individuals within the family.

Two decades of ectopic ACTH cushing syndrome: retrospective analysis from a tertiary care centre in north India

Jayakrishnan C[1], Subhash Yadav[1], Preeti Dabadghao[1] & Anand Kumar[1]
[1]Sanjay Gandhi Postgraduate Institute of Medical Sciences, Endocrinology, Lucknow, India

Introduction
Ectopic ACTH Cushing syndrome (EAS) is a rare yet significant cause of endogenous hypercortisolism. Differentiating EAS from pituitary Cushing syndrome (CD) poses a diagnostic challenge due to overlapping clinical and biochemical features. While inferior petrosal sinus sampling (BIPSS) is the gold standard and newer nuclear imaging modalities hold promise, these are not widely available. This study presents 2 decades of experience with EAS from a tertiary care center in India; comparing it's clinical, biochemical and radiological characteristics with those of CD. Additionally, it evaluates the diagnostic utility of the overnight high-dose dexamethasone suppression test (ONHDST) in this population.
Methods
This retrospective study analyzed 113 adults (30% male, age 18-72 years) diagnosed with ACTH-dependent Cushing syndrome (CS) (plasma ACTH > 20.0 pg/ml). The diagnosis of EAS was made by histologic confirmation of tumor on histopathology, finding an ectopic tumor on radiology/imaging, or a central: peripheral gradient of < 2 on BIPSS. Parameters differentiating EAS and CD were analyzed, and the diagnostic performance of ONHDST was evaluated.
Results
Among 113 patients with ACTH-dependent CS, 27(24%) had EAS while 86(76%) had CD. The most common source of EAS was the lung in 14(52%) patients [10 pathologically confirmed pulmonary neuroendocrine tumors (NET), 4 did not undergo surgery]. 4 patients had thymic NET, 2 had medullary thyroid carcinoma, 1 had a gall bladder NET and 6 had occult EAS. Multivariable logistic regression identified male gender, hypokalemia, and < 50% suppression on ONHDST as significant predictors of EAS. In a receiver-operating characteristic (ROC) curve analysis, < 50% suppression following ONHDST had 77% sensitivity, 62% specificity, 40% positive predictive value (PPV) and 89% negative predictive value (NPV) in diagnosing EAS vs CD (AUC 0.70; 95% CI 0.59-0.81; $P = 0.002$). The major diagnostic dilemma usually occurs when the MRI is normal or shows a small microadenoma. In this situation the ONHDST using the same cut-off performed better (sensitivity 77%, specificity 71%, PPV 54% and NPV 87%) (AUC 0.77; 95% CI 0.66-0.88; $P = 0.00009$). Among 10 patients with histopathologically confirmed pulmonary NET, 9 were in remission at last contact, while one patient was lost to follow-up. Other forms of EAS ($n = 17$) had poorer outcomes: 9 lost to follow-up, 7 died, and 1 in remission after bilateral adrenalectomy.
Conclusion
EAS accounted for 24% of ACTH-dependent CS in our institution and was mostly due to pulmonary NETs, which had good prognosis. The ONHDST is a valuable test in differentiating CD from EAS, especially in resource limited settings.

Assessment of atherosclerotic cardiovascular disease (ASCVD) risk using ASCVD risk estimator plus in indian patients with type 2 diabetes – a subgroup analysis from real-world, retrospective study

Pranav Sheth[1], Ajit Mullasari[2], Prachi Ahire[3], Chintan Khandhedia[1], Neeraj Markandeywar[1], Amey Mane[1] & Suyog Mehta[1]
[1]Sun Pharma Laboratories Ltd, Mumbai, India; [2]The Madras Medical Mission Hospital, Chennai, India; [3]Sun Pharmaceutical Industries Ltd, Mumbai, India

Background
T2D is associated with increased cardiovascular (CV) morbidity and mortality. ASCVD risk assessment can help to identify individuals with higher risk and optimizing treatment. This subgroup analysis of a retrospective, observational, multicentre, electronic medical record (EMR) based study (HEART STRONG STUDY) aimed to assess ASCVD risk in patients with T2D.
Methods
Aggregated and anonymised EMRs of patients aged 20-79 years, with total cholesterol (TC) 130-320 mg/dl, HDL 20-100 mg/dl and data available on T2D and smoking status and hypertension treatment were used to calculate ASCVD Risk Scores by American College of Cardiology Risk Estimator+. EMRs of patients with current or history of ASCVD were excluded. Primary endpoint was mean 10-year ASCVD risk. Here we present subgroup analysis of patients with T2D.
Results
Of total patients on EMR from 2017-2023, 4114 patients met eligibility criteria of which 3423 had T2D. Mean age was 55.8 years, BMI 26.89 kg/m^2 and 80% were males. Mean 10-year ASCVD risk score ($n = 2777$) was 17.8% vs 16.6% in overall study population. Risk was high, intermediate, borderline and low in 35.9 vs 32.6%, 34.9 vs 34.1%, 11.2 vs 11.9%, and 18 vs 21.3% in T2D vs overall study population. Mean Lifetime risk ($n = 2115$) was 54.6% and mean Optimal risk ($n = 3112$) was 5.4%. Mean values of TC, LDL-C, HDL, VLDL, TG were 182.5 ($n = 3423$), 103.7 ($n = 3331$), 42.6 ($n = 3423$), 28.4 ($n = 2143$), and 180.1 ($n = 3242$) mg/dl respectively. Mean HbA1c was 9% ($n = 2836$), FBG was 168 mg/dl ($n = 2868$), PPBG was 248.65 mg/dl ($n = 2703$). Metformin (91%), Sulphonylurea (59%), DPP4i (53%), SGLT2i (19%) were most frequently prescribed antidiabetic drugs. Patient receiving > 4, 4, 3, 2, 1 antidiabetic drugs were 18.9, 22.5, 24.0, 24.4, 9.9% respectively. Lipid lowering agents were prescribed to 56% patients.
Conclusion
In this T2D subgroup, almost every third patient had either high or intermediate ASCVD risk. Diabetes was poorly controlled despite multiple drugs which is likely to lead to poor CV outcomes. About half patients received lipid lowering agents and 19% received SGLT2i despite guideline recommendations. Adherence to guidelines and aggressive T2D treatment is urgently needed to reduce CV disease burden in Indian patients.

JOINT1368

Treatment of MACS with low doses of metyrapone - a preliminary report

Agata Tuszyńska-Meissner[1], Karolina Madej-Urbanek[2] & Lucyna Papierska[1]
[1]Centre for Postgraduate Medical Education, Endocrinology, Warsaw, Poland; [2]Bielański Hospital, Endocrinology, Warsaw, Poland

The justification of the elective surgery in a patient with mild autonomous cortisol secretion (MACS) is debatable, as adrenalectomy does not result in clinical improvement in every patient, especially in cases without lateralization of hormone secretion. So why not try to treat these patients pharmacologically, avoiding irreversible surgery? We would like to present the preliminary findings of the study we are conducting in Poland, in the first 9 MACS patients out of 50 planned as per protocol, treated with low-dose metyrapone. 6 patients have completed 6-month treatment, 3 others are so far at 3 months, and 5 more have been enrolled to date. Presented group consists of 8 women and 1 man, mean age 63.44 $\pm$ 7.41 years. 5 out of 9 presented bilateral adrenal lesions. Hypertension has been diagnosed in 8 subjects, hyperlipidaemia in all 9, 8 were overweight or obese, 4 had impaired glucose tolerance, and 5 presented osteopenia or osteoporosis. 500 mg of metyrapone (two caps of Metopirone® 250 mg) have been administered once daily at circa 7pm with a light meal. The drug was well tolerated by all patients. The following tests have been performed prior to treatment and at 3 and/or 6 months: - metabolic profile including HbA1C and oral glucose tolerance test (OGTT) measuring both glucose and insulin concentrations in patients without diabetes; morning and midnight serum cortisol, ACTH plasma concentration and 24-h urinary free cortisol (UFC), body composition and bone mineral density assessment. During treatment with metyrapone, we observed a reduction in morning and midnight serum cortisol levels, as well as in 24-h urinary cortisol excretion. No disinhibition of ACTH secretion was noted. After 3 months of treatment already, the effect of metyrapone upon blood pressure made possible in almost half of the patients (4/9) discontinuation of one of the anti-hypertensive drugs they were taking. In patients who completed the full 6-month course of treatment, we found considerable decrease in body weight (2/6), body fat (3/6), waist circumference (6/6), insulin (2/6) and uric acid (5/6) levels. Further patients are being enrolled in the study. The final statistical analysis is planned upon completion of the study on a set of 50 patients. Preliminary observations are encouraging with regard to the anticipated effects of the proposed treatment in MACS patients. As part of this presentation, we prepared a case report on our first MACS patient who completed the study.

The role of a multidisciplinary team in the management of phaeochromocytomas

Milena Yoveva[1] & Gideon Mlawa[1]
[1]Barking, Havering and Redbridge University Hospitals NHS Trust, Acute Medicine, Romford, United Kingdom

Introduction
Phaeochromocytomas, Paragangliomas, Glomus jugulare are rare neuroendocrine tumours arising from chromaffin cells of the adrenal medulla or extra-adrenal paraganglia. Most of them produce catecholamines. They cause variable symptoms like headache, hyperhidrosis, tachycardia, and hypertension.
Case
A thirty seven year old window cleaner, was referred to Cardiology with a six months history of worsening random dizziness, impacting on his work. He reported one to five minutes episodes of feeling faint, chest tightness, breathlessness, closing of his throat, tingling sensation of the face, grey face and hands. Symptoms occurred up-to five times per day. He has a ten year history of random palpitations, dizziness and non-cardiac chest pain, which was evaluated by Cardiology. Six months previously, he was commenced on a diet for hypercholesterolemia. He takes no medications or supplements. He binge drinks, smokes nicotine, uses cocaine once or twice per week and used cannabis previously. No family history of note, except father dying at age of forty six from a heart attack. Clinic blood pressure was one hundred and thirty one over ninety three mmHg. He had two symptomatic episodes of his blood pressure raising to two hundred and forty one over one hundred and seventeen mmHg for two and then three minutes. His physical examination was unremarkable. ECG and Holter were normal. Echocardiogram revealed mild concentric LVH, preserved LVEF. Renal function, electrolytes, cortisol, TSH, CK, aldosterone/renin ratio were normal. Urine metanephrines were raised. Doxazosin initiated. He underwent adrenal MRI revealing a large left adrenal tumour suggestive of phaeochromocytoma. Contrast CT adrenal, abdomen, NM MIBG whole body were consistent with beta-adrenergic receptor positive tumour tissue of neural crest in origin in the left adrenal gland, most probably due to a solitary phaeochromocytoma. He was referred to Endocrine MDT and admitted for a laparoscopic left adrenalectomy. The histology result was consistent with benign pathology and a follow-up was arranged for a repeat metanephrine +/- MIBG or MRI if positive metanephrines.
Discussion
Thorough evaluation led to treating this patient's symptoms and preventing cardiovascular, respiratory, metabolic or neurological complications including death.
Conclusion
Phaeochromocytomas, Paragangliomas, Glomus jugulare tumours cause less than zero point one percent of the hypertension cases. It is extremely important to exclude these conditions as a cause for hypertension in male and female patients in their third and forth decade because of a high risk of death. The post-mortem diagnosis is as high as fifty percent. Managing phaeochromocytomas require multidisciplinary approach.

JOINT2585

Pheochromocytoma and pregnancy: diagnostic challenges and multi-disciplinary management

Oussama Jaddi[1], Sana Rafi[1], Sara Ijdda[1], Ghizlane El Mghari[1] & Nawal El Ansari[1]
[1]Mohammed VI University Hospital of Marrakesh, Department of Endocrinology, Diabetes, Metabolic Diseases and Nutrition, Marrakesh, Morocco

Introduction
Pheochromocytomas are rare neuroendocrine tumors, typically located in the adrenal medulla, but they can also affect sympathetic paraganglia, where they are referred to as paragangliomas. Rare but serious during pregnancy, pheochromocytoma poses a high risk of maternal and fetal mortality, highlighting the importance of early diagnosis and treatment to improve prognosis.
Observation
A 31-year-old patient was admitted for severe preeclampsia at 31 weeks of gestation, with a history of untreated hypertension prior to pregnancy. Given the suspicion of secondary hypertension and the presence of the Menard triad, an abdominal MRI was requested, which revealed a left adrenal mass measuring 5.8 $\times$ 4.7 $\times$ 7.6 cm, with a cystic fleshy component in the center (necrosis?), associated with centimeter-sized juxta-lesional lymphadenopathy, suggestive of pheochromocytoma; however, an adrenal corticoid tumor could not be ruled out, necessitating confrontation with clinical, biological, and histological data.
Methoxy derivatives
Normetanephrine 18.45 µmol/24h (0.40-2.10 µmol/24h) Metanephrine 0.17 µmol/24h (0.20-1.00 µmol/24h). After a multidisciplinary team meeting: Decision for fetal extraction via cesarean section followed by left adrenalectomy 10 days later. The newborn died on day 3 due to respiratory distress.
Discussion
The symptoms of pheochromocytoma during pregnancy are often nonspecific and can mimic common conditions such as preeclampsia or gestational hypertension. The biological diagnosis relies on measuring plasma or urinary metanephrines, which remain reliable during pregnancy (Gruber *et al*., 2022). A significant elevation of these markers confirms the diagnosis. MRI imaging without gadolinium is the preferred examination to locate the tumor during pregnancy, as it is non-radiating and very sensitive. Initial management involves medical treatment aimed at stabilizing blood pressure and preventing hypertensive crises. Alpha-blockers, such as phenoxybenzamine or doxazosin, are used to block the effects of catecholamines. Surgical excision of the tumor is the curative treatment for pheochromocytoma. The timing of the intervention depends on the stage of pregnancy: Before 24 weeks of amenorrhea, laparoscopic surgery is recommended after medical stabilization. After 24 weeks, surgery is generally deferred until after delivery, except in life-threatening situations.
Conclusion
Pheochromocytoma during pregnancy is a rare but potentially fatal condition. Its diagnosis requires heightened vigilance in the face of atypical hypertension or paroxysmal symptoms. Management relies on rigorous medical stabilization, followed by surgical excision at the appropriate time.

Incidentaloma: pathological and biochemical analysis management in the disorders of the adrenal medulla in albania popullation

Brunilda Mezani[1]
[1]1Department of Biology, University Tirana Albania, 2Department of Medical Laboratory Sciences and Imaging, Western Balkans University Tirana, Albania 3Pathologist in the American Hospital of Tirana. 4Head of pathology department of American Hospital. 5Vice president of the Albanian Society of Pathology. 6Intermedica Clinic, Tirana Albania, Albania, Albania

Background & Aim
The adrenal incidentaloma is an adrenal tumor discovered by an imaging test that is being done for a control by that is not related to adrenal disease. Pheochromocytoma is a rare tumor that develops in the adrenal medulla, the inner part of the adrenal glands. This tumor leads to the excessive release of catecholamines, resulting in symptoms such as rapid heart rate, high blood pressure, anxiety, intense headaches, excessive sweating, and unintentional weight loss.
Methodology
This study studied Incidentaloma patient with the pheochromocytoma. Levels of catecholamines and their byproducts in the blood and urine are measured. The analysis includes measuring plasma-free metanephrines or fractionated metanephrines in urine. Additional tests, such as measuring total urinary metanephrines, plasma or urinary catecholamines, or urinary vanillylmandelic acid (VMA), will be used to confirm the presence of the tumor.
Results
The study was conducted on patients aged 15-98 years old. In this study, the pathological pathologies and imaging images of the patients are going to be analyzed. We detect elevated levels of catecholamines or their byproducts in the blood and urine of patients with pheochromocytoma. The most accurate tests include measuring plasma-free metanephrines or fractionated metanephrines in urine. Additional tests, such as measuring total urinary metanephrines, plasma or urinary catecholamines, or urinary vanillylmandelic acid (VMA), will be used in future steps to confirm the presence of the tumor.
Conclusion & Future Research
This study highlights the diagnostic value of plasma-free metanephrines and fractionated urinary metanephrines as the most accurate tests for detecting the tumor. Elevated levels of catecholamines and their byproducts provide critical evidence for diagnosis, while additional confirmatory tests, including urinary vanillylmandelic acid and total catecholamine measurements, can strengthen diagnostic accuracy. Early and precise diagnosis is essential to prevent life-threatening complications such as hypertensive crises, arrhythmias, or stroke. Future research should focus on refining diagnostic algorithms, and incorporating novel biomarkers.

Stratification of total cardiovascular risk in young patients with type 1 diabetes mellitus

Alla Shepelkevich[1], Diana Baalbaki[1], Yuliya Dydyshka[1] & Alena Yurenia[2]
[1]Belarusian State Medical University, Minsk, Belarus; [2]Minsk-city clinical endocrinology center, Minsk, Belarus

Background
Cardiovascular disease (CVD) is a common macrovascular complication of type 1 diabetes (T1D) which still remains the leading cause of death even in well-controlled T1D. Over the last decades young patients with T1D have not shared in the overall reduction of cardiovascular morbidity and mortality but instead according to data from recent epidemiological studies showed a striking increase. Therefore, to improve the prognosis of young patients with T1D targeted primary prevention of CVD is crucial e.g., total cardiovascular risk assessment.
Objectives
Assessment and stratification of total CV risk in young patients with T1D living in Minsk.
Methods
The study was based on a retrospective review of young patients with T1D without previous CVD attending the outpatient clinic "Minsk City Clinical Endocrinological Center". The stratification of CV risk was performed using the Steno T1 Risk Engine (ST1RE). Control group included patients without T1D, for CV risk stratification Framingham risk score was used.
Results
Eighty-eight patients were enrolled (43F, 45M), median age 36 years [IQR 28-41] with onset of T1D 16 [11-25]. Of these, 20,5% (18 patients) had an early onset of T1D 6,5 [5-8,5]. Glycemic control of our young patients with T1D was suboptimal HbA1c – 7,65% [6,7-8,65]. Using the ST1RE algorithm: 23,9% (21 patients) were at high CV risk, 76,1% (67 patients) had moderate and none had low risk. In the control group ($n = 88$): 95% of patients had low CV risk, 5% had moderate CV risk. The frequency of occurrence of moderate risk was statistically higher in patients with T1D when compared to the control group (76,1% vs 5%, $p < 0.01$).
Conclusions
Our study suggests that further preventive interventions based on accurate CVD risk prediction algorithm is required for primary prevention of CVD in young patients with T1D.

Penchev", Sofia, Bulgaria; [7]Faculty of Medicine, Medical University-Plovdiv, Plovdiv, Bulgaria

Background
The prevalence of asymptomatic pituitary adenomas varies between 10% and 22%, while clinically relevant pituitary adenomas occur in 1 of 1000 individuals (1). The prevalence of pituitary lesions in patients with congenital adrenal hyperplasia (CAH) is unknown. Therefore, the study aims to present pituitary findings in CAH patients from a single Expert Center for Rare Endocrine Diseases.
Methods
The present retrospective study includes all patients (18-57 years old) with CAH who have been followed-up in the last 15 years. Imaging studies have reported the prevalence and characteristics of the established pituitary formations.
Results
The data of 72 CAH patients (60 women and 12 men) were studied. Ten pituitary lesions (13.9 %) were found, including one Rathke cyst (1.4%), three prolactinomas (4.2%), and six nonfunctioning adenomas (8.3%) in 8 CAH women and 2 CAH men. Additionally, three female cases of "empty sella" were revealed by imaging studies (4.2%). The main indications for MRI in CAH patients were headache, mildly or moderately increased prolactin levels, and increased ACTH levels with suspicion of reactive adenomas. All pituitary adenomas were microadenomas varying between 3 and 7.8 mm. Most pituitary microadenomas (66.7 % [6/9]) were found in women with a late CAH form. No age (27.5 vs. 28 years, $P = 0.530$) or ACTH differences (16.61 vs. 15.05 pmol/l, $P = 0.491$) were found between patients with pituitary lesions and other CAH patients;
Conclusions
Pituitary microadenomas are commonly found in female patients with a late CAH form. Further studies are needed to evaluate the prevalence of different pituitary lesions and their evolution in CAH individuals.
Keywords
CAH, pituitary adenoma, prolactinoma.

Multiple recurrent cerebral and coronary vasospasms as an unusual initial presentation of pheochromocytoma: a case report and literature review

Florence Perreault[1], Frédéric Mercier[2], Jessica Moramarco[3], Nathalie Routhier[4], Mathieu Latour[5] & Isabelle Bourdeau[1]
[1]Division of Endocrinology, Department of Medicine and Research Center, Centre Hospitalier de l'Université de Montréal (CHUM), Montreal, Canada; [2]Division of Surgical Oncology, Department of Surgery and Research Center, Centre Hospitalier de l'Université de Montréal (CHUM), Montreal, Canada; [3]Division of Endocrinology, Department of Medicine, Hôpital du Sacré-Coeur de Montréal, Montreal, Canada; [4]Division of Internal Medicine, Department of Medicine, Hôpital du Sacré-Coeur de Montréal, Montreal, Canada; [5]Division of Pathology, Department of Medical Biology, Centre Hospitalier de l'Université de Montréal (CHUM), Montreal, Canada

Introduction
Pheochromocytomas (PHEOs) are rare tumors arising from chromaffin cells and secreting catecholamines. Arterial vasospasm is an organ and life-threatening condition. We present a rare case of recurrent coronary and cerebral vasospasms as an initial presentation of PHEO.
Case presentation
A 65 y-o female, known for type 2 diabetes, first presented for thunderclap headache that lasted 4 minutes. Cerebral CT-scan was normal. Two weeks later, she returned with recurrent symptoms plus retrosternal pain. Cerebral angio-CT scan demonstrated arterial vasospasms. She was diagnosed with reversible cerebral vasospastic syndrome (RCVS) plus vasospastic angina and started on calcium channel blockers (CCB). Three months later, she returned with retrosternal pain and non-ST-segment elevation myocardial infarction (high-sensibility troponins 279 ng/l, N 0-34), but normal coronary angiography and transthoracic cardiac ultrasound. In the following months, she experienced multiple paroxysmic episodes of headache and retrosternal pain, with palpitations and diaphoresis, but normal blood pressure. After multiple visits to the emergency room, PHEO was diagnosed with elevated plasma metanephrines (2.52 nmol/l, $n < 0.48$) and normetanephrines (4.46 nmol/l, $n < 1.20$), as well as 24h urinary catecholamines (noradrenaline: 832 nmol/d, $n < 472$; adrenaline: 402 nmol/d, $n < 108$; normetanephrines: 1524 nmol/d, $n < 235$; metanephrines: 1298 nmol/l, $n < 269$). Adrenal MRI showed a 4.7 × 4.8 cm right adrenal mass, with DOTATATE-PET CT SUVmax of 14. Alpha-blocker was started. Peri-operative management included CCB maintenance and crystalloids administration. The patient underwent right laparoscopic adrenalectomy without significant hemodynamic instability. Pathology confirmed a PHEO, with PASS score of 4 and Ki-67 of 1.63%. All medication was stopped afterwards. Four months later, the patient is in clinical and biochemical remission.
Genetic analysis
Multigene panel of 19 PHEO susceptibility genes performed on leucocyte DNA (INVITEA) identified a rare missense variant of uncertain significance in the gene *TMEM127* (c.427G>A (p.Val143Ile), gnomAD exomes allele frequency: 2.531160e-05).
Discussion
PHEO diagnosis is often overlooked in this context. In our cohort of 465 patients with PHEO and paragangliomas, no other patient was diagnosed with arterial vasospasm. However, coronary and cerebral vasospasms were individually previously described as very rare complications of PHEOs in four and ten patients respectively, but never simultaneously. Some authors suggest that PHEO should be excluded in RCVS, but we did not find such recommendation for coronary vasospasm.
Conclusions
To our knowledge, this is the first case of a patient with PHEO presenting with both multiple recurrent coronary and cerebral vasospasms. This atypical presentation should be known of medical teams to avoid potential delay in PHEO diagnosis.

A Chinese case of familial progressive hyperpigmentation and hypopigmentation misdiagnosed as primary adrenal insufficiency

Miao Qin[1], Di Wu[1] & Min Liu[1]
[1]Beijing Children's Hospital, Department of Endocrinology, Genetics and Metabolism, Beijing, China

Objective
We report the clinical characteristics, diagnosis, and genetic analysis of a case of familial progressive hyperpigmentation and hypopigmentation (FHPP).
Methods
The clinical information of a 2-year-old girl with "hyperpigmentation since birth" was retrospectively reported. Whole exome sequencing analysis was performed on DNA extracted from peripheral blood and skin tissue. Candidate variant was verified by Sanger sequencing of her parents.
Results
A Chinese girl with uniform hyperpigmentation was noted since birth. She was born to healthy nonconsanguineous parents, following an uneventful pregnancy. At 2-month-old, blood tests revealed potassium levels of 6.06 mmol/l, sodium levels of 134.6 mmol/l, ACTH levels of 73.85 pg/ml, cortisol levels of 17.78 ug/dl, 17α-hydroxyprogesterone <0.2 ng/ml, and progesterone <0.05 ng/ml. Adrenal ultrasound and CT scans showed normal and the chromosome karyotyping showed 46, XX. She was initially diagnosed with primary adrenal insufficiency and started on hydrocortisone replacement therapy at a dose of 40 mg/m^2.d. Subsequently regular follow-up showed normal electrolyte levels, with ACTH level fluctuating between 1.5-12.4 pg/ml. The hydrocortisone dose was gradually reduced to 1.5 mg/day (2.6 mg/m^2.d). The child did not experience any salt-losing crises, but the hyperpigmentation gradually progressed. At 2-year-old, she was re-evaluated in our endocrinology department. Physical examination revealed a height of 90 cm (P25-50), weight of 12 kg (P25). Her trunk showed general hyperpigmentation, especially in the areolas and skin folds, with some superimposed irregular café –au–lait spots. Hypopigmented macules were also seen on the trunk. The level of ACTH, electrolyte and blood gas analysis were rechecked and showed normal after discontinuing hydrocortisone. The ACTH stimulation test indicated normal adrenal cortical function, then hydrocortisone treatment was continuous discontinued. Whole exome sequencing of peripheral blood and skin tissue revealed a heterozygous c.100A>C (p.Thr34Pro) variant of the KITLG gene, which was not present in her unaffected parents. The latest follow-up, conducted 1.5 years after discontinuing hydrocortisone (when she was 4-year-old), showed no salt loss crises. Her height and weight were both at average levels, and the hyperpigmentation became more noticeable with age.
Conclusion
Hyperpigmentation is a characteristic of many clinical diseases and can be challenging to diagnose. For infants with progressive skin pigmentation and hypopigmentation spots, FPHH caused by KITLG gene heterozygous variants should be considered.

Evaluation of cardiovascular complications of primary hyperparathyroidism

Nisrine Ezzouhri[1], Nassim Essabah Haraj[1], Siham El Aziz[1] & Asma Chadli[1]
[1]Faculty of Medicine and Pharmacy– Université Hassan II, Endocrinology and Metabolic Diseases Department, Casablanca, Morocco

Introduction
Primary hyperparathyroidism is a common condition associated with various complications, particularly cardiovascular ones. These complications are not widely studied, and further research is needed to better determine their prevalence. The objective of this study is to assess the cardiovascular impact of primary hyperparathyroidism in our series.
Objective
The aim of our study was to assess cardiovascular complications in patients with primary hyperparathyroidism.
Materials and Methods
A retrospective descriptive study including 40 patients followed for primary hyperparathyroidism over a 6-year period from 2018 to 2024.
Results
The mean age was 50 ± 10 years, with a male-to-female ratio of 0.05, and 95% of the patients were women. The evaluation of cardiovascular impact in primary hyperparathyroidism revealed electrocardiographic signs of hypercalcemia in 12.5% of patients, as well as newly diagnosed hypertension with a normal echocardiography, without valvular or myocardial calcifications, in 22.5% of patients. Notably, no cases of pulmonary embolism or peripheral venous thrombosis were observed in our study population.
Conclusion
Primary hyperparathyroidism is known for its cardiovascular complications, which are linked both to the direct effects of parathyroid hormone (PTH) as a hormone with cardiovascular properties and to the impact of hypercalcemia. Consequently, PHPT contributes to the worsening of cardiovascular risk factors or their de novo occurrence, highlighting the importance of early screening and appropriate management.

Clinical and paraclinical monitoring of pediatric patients with congenital adrenal hyperplasia: challenges and outcomes

Bogdan Pascu[1] & Andreea Creanga[2]
[1]INSMC Alessandrescu Rusescu, Pediatric Endocrinology, Bucharest, Romania; [2]INSMC Alessandrescu Rusescu, Bucharest, Romania

Introduction

Congenital adrenal hyperplasia (CAH) is an autosomal recessive disorder caused by mutations in the CYP21A2 gene, leading to 21-hydroxylase deficiency, the most common form of CAH. Classic CAH presents as either virilizing or salt-wasting forms. This study evaluates the clinical and paraclinical evolution of 11 pediatric patients with classical CAH, focusing on treatment response and management challenges.

Methods

A retrospective analysis was conducted on clinical, paraclinical, and genetic data from 11 children diagnosed with CAH, aged between 1 month and 12 years. Parameters such as growth, bone age, androgen axis control (17-hydroxyprogesterone [17-OHP], testosterone, androstenedione, dehydroepiandrosterone sulfate [DHEA-S]), renin levels, and blood pressure were analyzed. All patients were treated with hydrocortisone and fludrocortisone, with doses adjusted based on weight and body surface area.

Results

1. Genetic Profile: The most frequent mutations identified were I2 splice, P30L, and Del 8bp E3. Rare combinations of severe mutations were observed, associated with virilizing and salt-wasting forms.
2. Growth: Most patients exhibited accelerated bone age compared to chronological age, necessitating regular adjustments of hydrocortisone doses to prevent early puberty.
3. Complications: Three patients developed obesity (BMI >95th percentile). Two patients presented with Grade I hypertension, likely due to fludrocortisone overtreatment, which was managed by dose adjustment. Four patients had genital ambiguity, with surgical interventions (e.g., feminizing genitoplasty) planned or performed.
4. Paraclinical Response: Most patients had 17-OHP and renin levels outside the target therapeutic range (17-OHP >10 ng/mL, renin >30 pg/ml), requiring treatment optimization. Elevated androstenedione levels correlated with signs of virilization.

Discussion

The results underscore the challenges in managing CAH in pediatric patients, including the high prevalence of metabolic complications, the need for continuous treatment adjustments, and the importance of multidisciplinary monitoring. Androgen axis control in our cohort was moderate, consistent with findings in the literature. These findings highlight the need for dose adjustment guidelines based on body surface area and growth rates.

Conclusions

Individualized monitoring is essential to optimize CAH treatment and prevent long-term complications. This study advocates for stricter dosing protocols and closer collaboration among endocrinology, genetics, and pediatric surgery teams.

Effects of cushing's Syndrome remission on glycemic control: does remission always lead to improvement

Baltagi Myriam[1], Ibtissem Ben Nacef[1], Sawsen Essayeh[1], Rihab Laamouri[1], Sabrine Mekni[1], Khiari Karima[1] & Rojbi Imen[1]
[1]Hospital of Charles Nicolle, Tunis, Tunisia

Introduction

The remission of Cushing's syndrome (CS) is known to improve glycemic control, but the extent and statistical significance of these improvements remain poorly documented. This study aims to quantitatively assess the effect of CS remission on glycemic parameters.

Methods

A cohort of **22 patients with CS** was followed from diagnosis to remission. The primary glycemic parameters analyzed were **fasting blood glucose (FBG) and glycated hemoglobin (HbA1c)**, measured before and after treatment. A **paired t-test** was used to compare pre- and post-remission values. Additional analyses were performed based on **baseline glycemic status and the type of treatment received** before remission.

Results

The analysis demonstrated a significant improvement in glycemic control following CS remission. On average, **fasting blood glucose decreased by 23% ($P = 0.001$), and HbA1c dropped by 0.9% ($P = 0.008$)**. Among **diabetic patients ($n = 10$)**, fasting blood glucose decreased from **142.6 ± 18.4 mg/dl to 109.2 ± 14.7 mg/dl ($P = 0.001$)**, while HbA1c declined from **7.8 ± 1.1% to 6.9 ± 0.9% ($P = 0.005$)**. Notably, **50% of these patients achieved normoglycemia post-remission**, whereas the remaining half continued to exhibit impaired glucose metabolism. In contrast, **non-diabetic patients ($n = 12$)** also experienced significant reductions in glycemic markers. Their fasting blood glucose decreased from **98.7 ± 10.3 mg/dl to 89.4 ± 7.8 mg/dl ($P = 0.02$)**. Patients who required **insulin therapy before remission ($n = 6$, 27.3%)** exhibited variable responses post-remission. While **four patients (66.7%) continued to require pharmacological treatment**, those initially managed with oral antidiabetic drugs or lifestyle modifications were more likely to achieve complete glucose normalization. Furthermore, an analysis of **baseline cortisol levels** revealed a significant correlation with post-remission glycemic outcomes. Patients with persistent hyperglycemia had significantly **higher baseline cortisol levels (562.3 ± 91.4 nmol/l vs. 398.1 ± 76.2 nmol/l, $P = 0.02$)** compared to those who achieved normoglycemia.

Discussion

This statistical analysis confirms that **CS remission leads to significant improvements in glycemic control**, particularly in diabetic patients. However, the degree of improvement appears to be influenced by **baseline cortisol levels and disease duration**, highlighting the impact of prolonged hypercortisolism on **insulin resistance and pancreatic beta-cell dysfunction**. Despite overall improvements, some patients **remain hyperglycemic post-remission**, emphasizing the need for ongoing metabolic follow-up.

Conclusion

Our findings demonstrate that **Cushing's syndrome remission significantly improves glycemic parameters**, particularly in diabetic patients. However, **persistent hyperglycemia post-remission is associated with higher baseline cortisol levels and pre-existing insulin dependence**, suggesting a potential irreversible impact on pancreatic function. **Long-term monitoring remains essential to optimize metabolic outcomes in these patients.**

Infant with pubarche and suppressed serum cortisol. what is the diagnosis?

Eirini Dikaiakou[1], Ioanna Kosteria[1], Katerina Papadopoulou[1], Chrysa Athousaki[1], Maria Soile[2], Nikoleta Mastrantonaki[2], Anastasia Konidari[2] & Elpis Vlachopapadopoulou[1]
[1]Children's Hospital "P.& A. Kyriakou", Deptartment of Endocrinology-Growth and Development, Athens, Greece; [2]Children's Hospital "P.& A. Kyriakou", Deptarment of B Pediatric clinic, Athens, Greece

Introduction

Pubarche is a rare encounter during infancy that needs to be thoroughly investigated. Etiology ranges from normal variant to adrenal tumors.

Methods

An 8-month-old girl with pubarche was referred by her pediatrician after initial evaluation that revealed suppressed levels of cortisol and adrenal androgens. Parents noticed pubic hair onset about one week before referral. Her past medical history was remarkable for recurrent respiratory infections during the previous trimester and bronchiolitis for which she was treated with inhaled corticosteroids in high doses (250 micrograms of fluticasone propionate twice daily), with short intervals without treatment. The review of the growth chart revealed impaired growth velocity from the age of 6 months, as the infant's length deviated from the 50th to the 10th percentile, while her weight followed the 50th percentile. On physical examination her length was 66 cm (10th %ile), her body weight (BW) 8.35 kg (50th %ile), Tanner stage: Axillary I, pubic hair II, breast II. Facial plethora was appreciated, while clitoral size was normal.

Results

Diagnostic work-up confirmed suppressed cortisol, adrenal androgens and inappropriately low ACTH (serum Cortisol 0.36μg/dl, ACTH 11.52pg/ml, DHEA-S 0.003μg/dl, 17-OH PRG 0.95ng/ml, FSH 3.88mIU/ml, LH<0.3mIU /ml, prolactin 473mIU/ml, estradiol 9.9 pg/ml). Tumor markers (βHCG, aFP) were negative. Abdominal sonogram was normal. The diagnosis of iatrogenic Cushing syndrome was established, based on the above medical history, physical examination and laboratory results. Inhaled corticosteroids were discontinued and hydrocortisone was administered at a replacement dose until the adrenal axis recovered. During follow up, two months later, her height velocity accelerated and laboratory results were normalized (serum Cortisol 11.3 μg/dl, ACTH 52.5pg/ml, DHEA-S 5.1μg/dl, 17-OH PRG 1.2ng/ml, FSH 4.92mIU/ml, LH< 0.2mIU/ml, estradiol<6pg/ml). Hydrocortisone was discontinued. At the age of 12 months, the infant had complete regression of pubic hair and normal growth,

(length 76 cm, 75th %ile, BW 10.8 kg, 50th-75th %ile), while premature thelarche persisted.
Conclusions
Inhaled steroids are commonly used in treatment of asthma and respiratory pediatric infections. They are considered safer compared to systemic steroids, however iatrogenic Cushing syndrome can be caused by high-dose inhaled regimens. That's why children on steroid treatment should be followed up closely to prevent iatrogenic Cushing syndrome. The differential diagnosis of the syndrome includes malignant tumors, adenoma, and nodular hyperplasia of the adrenal glands, which are very rare in infants.

Hypovitaminosis D and its association with the incidence and severity of major adverse cardiovascular events

Carlos Hernan Cacalderon[1], Dinael GarcÍa Sissa[1], Oscar Iván Osivci[1] & Luis Ichavez[1]
[1]Hospital Santa Clara, Bogota, Colombia

Background
traditionally associated with bone metabolism, hypovitaminosis D has emerged as a potential cardiovascular risk factor. Although it is a global issue, few studies in Colombia have evaluated its local impact. This study addresses that gap by examining its role as a potentially modifiable cardiovascular risk factor.
Objective
to determine the association between hypovitaminosis D and the development of major adverse cardiovascular events (MACE), as well as the relationship between the severity of hypovitaminosis D and mortality associated with these events in a Colombian population.
Methods
we conducted a retrospective cohort study with 254 patients aged $\geq$50 years treated between January 2021 and April 2022. Patients were categorized as having insufficient ($<$30 ng/mL) or sufficient ($\geq$30 ng/mL) vitamin D levels. Demographic, clinical, and paraclinical variables were analyzed alongside MACE occurrence using descriptive statistics and logistic regression models.
Results
fifty percent of patients had vitamin D insufficiency, and 10.2% had severe deficiency ($<$15 ng/mL), predominantly in women $>$65 years. Patients with hypovitaminosis D showed a higher incidence of MACE and a 57.1% mortality rate compared to 0% in the sufficient group. In multivariate analysis, chronic kidney disease was the main risk factor for MACE (OR: 6.84; 95% CI: 1.14–40.9), and vitamin D levels $<$15 ng/mL were associated with increased cardiovascular risk (OR: 4.1; 95% CI: 0.99–17.02).
Conclusion
hypovitaminosis D increases the risk of MACE and mortality, particularly in patients with chronic kidney disease.

Significant metabolic syndrome improvement in a patient with adrenal Cushing's syndrome treated preoperatively with osilodrostat

Vasiliki Daraki[1], Evangelia Pissadaki[1], Eleni-Konstantina Syntzanaki[1], Irini Lambiri[2], Vasiliki Venetsanaki[1], Panagiotis- Nikolaos Tsakalomatis[1], Fotis Mermigkas[1], Rodanthi Vamvoukaki[1], Grigoria Betsi[1], Maria Sfakiotaki[1], Chrysanthi Aggeli[3], George Zografos[3] & Paraskevi Xekouki[1]
[1]University General Hospital of Heraklion, Department of Endocrinology Diabetes and Metabolic Diseases, Crete, Greece; [2]University General Hospital of Heraklion, Department of Thoracic Medicine, Crete, Greece; [3]Athens General Hospital, 1st Department of Surgery, Athens, Greece

Background
Cushing syndrome (CS) is associated with high morbidity and mortality, due to its metabolic consequences. The treatment of choice is surgical resection of the causative tumor. Data on the preoperative use of osilodrostat, an inhibitor of 11β-hydroxylase, in patients with adrenal CS (ACS) are scarce. We present a rare case of ACS treated preoperatively with osilodrostat with significant metabolic syndrome improvement.
Case presentation
A 47-year-old woman, with a previous history of cervical cancer, presented to the outpatient clinic with a 3,6 cm left adrenal mass discovered incidentally, 4 years prior to presentation. She suffered from poorly-controlled diabetes mellitus (DM) (HbA1c 9,5%), dyslipidemia, chronic obstructive pulmonary disease (COPD) and significant weight gain (25 kgr, BMI 46) over the last 8 years. Clinical examination revealed facial plethora, posterior cervicothoracic fat pad and severe truncal obesity. Laboratory tests were indicative of adrenal Cushing syndrome (morning serum cortisol 20,7 μg/dl after low dose oral dexamethasone suppression, adrenocorticotropin (ACTH)5,32 pg/ml and urinary free cortisol 384 μg/24hr (normal values 20,9-292 μg/24hr). Adrenalectomy was postponed twice due to her severe obesity and poorly-controlled DM and COPD. The patient was lost to follow-up. She returned a year later with deterioration of her clinical symptoms. Her urinary free cortisol levels were further increased ($>$1000 μg/24hr). Treatment with osilodrostat was decided at a dose of 4 mg daily. However, a week later she presented with symptoms suggestive of adrenal insufficiency (nausea, fatigue and low blood pressure). Osilodrostat was reduced to 1 mg daily, while oral hydrocortisone 20 mg daily was added with symptom resolution. Two weeks later, hydrocortisone was stopped and osilodrostat was continued with a slow titration initially to 2 mg for 6 months and subsequently to 3 mg. Ten months after her 1st osilodrostat dose, the patient achieved a significant weight loss (20 kg, BMI:38), while her DM and dyslipidemia were well controlled (HbA1c 6,1%) without treatment modification. Her last urinary free cortisol measurement was within normal range (147 μg/24hr). She has been scheduled for adrenalectomy next month.
Discussion
Treatment of ACS with osilodrostat, has been rarely reported in the literature. In our patient, a 10-month treatment with low osilodrostat dose resulted in significantly reduced cortisol levels concomitantly with important weight loss and improvement of all metabolic parameters prior to curative adrenalectomy. Further studies are warranted to evaluate preoperatively osilodrostat use on surgery-related morbidities and outcomes in such patients.

Mild autonomous cortisol secretion (MACS): data from a romanian tertiary centre

Vlad Radulescu[1], Bratu Gratiela[1], Anastasia Patricia Stanescu-Smocot[1,2], Monica Livia Gheorghiu[1,2], Anda Dumitrascu[1] & Corin Badiu[1,2]
[1]National Institute of Endocrinology "C.I Parhon", Bucharest, Romania; [2]"Carol Davila" University of Medicine and Pharmacy, Bucharest, Romania

Introduction
Mild autonomous cortisol secretion (MACS) is diagnosed, based on an abnormal overnight 1 mg dexamethasone suppression test, in 20-50% of patients with adrenal adenomas without signs of Cushing syndrome. MACS is associated with cardiovascular morbidity, fragility fractures, decreased quality of life and increased mortality. Management of MACS should be individualized based on patient characteristics and include adrenalectomy or conservative follow-up with treatment of associated comorbidities.
Aim
To retrospectively compare the comorbidities and the management between a cohort of cases with MACS and non-functional adenomas (NFA) admitted at least yearly in a tertiary institution, between 2019-2023.
Patients and Methods
229 patients (170 women, 59 men) were evaluated for adrenal lesions. 135 patients were included in the study after exclusion of other adrenal functional lesions. Adrenal function was assessed by basal and dynamic cortisol (suppression tests) and ACTH, testosterone, DHEA-S, aldosterone and renin, urinary and plasma metanephrines and normetanephrines.
Results
In the MACS group 34 patients were included with a ratio of almost 1:3 for the non-functional adenoma group (n = 101 patients). 11 patients (7 left nodules + 4 right nodules) in the MACS group underwent surgery vs 4 patients in the NFA group. The criteria for surgery were the radiological features [Hounsfield units, biggest nodule or the easiest surgical approach (if bilateral)]. There were 2 cases of post-operatory transient adrenal insufficiency (evaluated with 1 ug short Synacthene testing), 1 case of residual cortisol secretion after surgery (surveillance decided). The mean follow-up duration was 4.8 years ($\pm$3.06). All the other patients had normal hormonal work-up after surgery. When discussing comorbidities: the MACS group had a higher rate of dyslipidemia of 85.3% vs 67.3% in the NFA group (P = 0.049), a higher prevalence of hypertension: 82.4% vs 59.4% in the NFA group (P = 0.021) and a higher prevalence of diabetes mellitus: 32.4% vs 13.9% (P = 0.022). Interestingly, the MACS group showed greater dimensions of the adrenal lesions than the NFA group in transverse and antero-posterior computed tomography measurements ($p<0.023$).

Conclusion
The detailed continuous clinical and biochemical follow-up every 6-12 months of patients with MACS is necessarily for proper and individualized management, especially for evaluating and modifying the treatment of comorbidities.

ESPE caucasus&central asia school (C&CAS) sharing knowledge for saving patients' lives:organizing newborn-screening and pediatric endocrinology care for patients with adrenal insufficiency in armenia

Lusine Navasardyan[1,2], Elena Aghajanova[1], Irina Muradyan[1], Shogher Grigoryan[1], Sona Samvelyan[3] & Elena Lundberg[4]
[1]Yerevan State Medical University, Yerevan, Armenia; [2]Arabkir Medical Center, Yerevan, Armenia; [3]Wigmore Women's and Children's Hospital, Yerevan, Armenia; [4]Institute of Clinical Sciences, Pediatrics, Umea, Sweden

Introduction
Congenital adrenal hyperplasia (CAH) is an autosomal recessive disorder associated with congenital errors of steroid biosynthesis in the adrenal glands. A delayed diagnosis is associated with an increased risk of neonatal morbidity/mortality, whereas early diagnosis reduces mortality rates. Newborn screening of CAH is a cost-effective method to identify affected neonates early. Treatment is lifelong, and access to necessary medication, which is affordable and lifesaving, is unfortunately still low in Armenia. The ESPE C&CA School took place in Yerevan in 2023. During this event teachers shared knowledge and experience regarding CAH. Armenian doctors received support from the ESPE in developing and implementing a strategic plan to address unmet needs in the area of CAH, which was a great opportunity for a country with limited resources.
Aim
To initiate research into CAH, implement standardized systematic education for both patients and families with CAH and healthcare providers, to continue the evaluation and monitoring of the implemented program.
Methods
Identifying the pediatric population with CAH, creating and organizing standard educational program for healthcare staff, implementing of educational programming for parents and families and translating and distributing the CAH emergency cards and providing access to the online version at the www.a-drenals.eu, starting the CAH newborn screening in the Capital of Armenia and regions.
Results
A newborn-screening program was started from 11 April 2024 including the capital city of Armenia. 16 168 newborns were screened, 4 cases of CAH from which were conformed. It is planned to involve into the newborn-screening program all the Armenian regions starting from April 2025. Two medical centers are involved in the process: in one center the screening is done, and these data is referred to the pediatric endocrinology center where the next investigations, management and follow-up are done. One of the challenges we meet is the lack of Synacten, less availability of hydrocortisone, as well as some financial issues. The European CAH emergency cards have been already translated into Armenian. An individual treatment plan has been created and adapted to local practices.
Conclusion
A newborn-screening for the all Armenian regions and the educational approach for pediatric endocrinologists will significantly improve the quality of CAH patient revelation and care. This approach ensures that patients and their families receive consistent and high-quality medical care and education. Now we can "speak the language" of European Pediatric Endocrinologists! More long-term follow up is needed to endure sustained benefits for CAH patients in Armenia.

Primary adrenal insufficiency secondary to bilateral adrenal metastases: can extreme hyponatremia be compatible with life?

Leandro Augusto Silva[1], Ana Rita Elvas[1], Andreia Martins Fernandes[1], Joana Couto[1], Raquel G. Martins[1], Teresa Martins[1], Jacinta Santos[1], Andreia Matos[2] & Fernando Rodrigues[1]
[1]Portuguese Institute of Oncology of Coimbra Francisco Gentil, Coimbra, Portugal; [2]Local Health Unit of Coimbra, Coimbra, Portugal

Introduction
Severe hyponatremia is associated with high mortality, with severity linked to its etiology and the speed of onset. Primary adrenal insufficiency should be considered, bearing in mind that, although rare, bilateral adrenal metastases can be a potential cause.
Clinical case
A 53-year-old male was admitted at emergency room with confusion and diarrhea. His medical history included plurimetastatic lung adenocarcinoma. On examination, he presented with hemodynamic instability and hyperpigmentation of the skin and mucosae. Blood gas analysis revealed metabolic acidosis compensated by respiratory alkalosis and unmeasurable sodium level. Analytical workup showed $Na^+ < 100$ mmol/l (RR 136-146), K^+ 5.5 mmol/l (3.5-5.1), serum osmolality 214 mOsm/Kg (260-302), ACTH 615 pg/ml (9-52), urinary Na^+ 43 mmol/l and urinary osmolality 423 mOsm/Kg (300-900). Based on clinical presentation, medical history and laboratory findings, a diagnosis of symptomatic hypovolemic hypoosmolar hyponatremia secondary to primary adrenal insufficiency due to bilateral adrenal metastases was made. The patient started treatment with intravenous hydrocortisone and fluid therapy, leading to clinical improvement and was subsequently admitted for continued care. One year after this acute event, the patient remains stable under clinical follow-up in Endocrinology and Medical Oncology, on hydrocortisone (20 mg) and fludrocortisone (0.1 mg) treatment, with stable neoplastic disease under systemic palliative therapy.
Conclusions
Extreme hyponatremia (< 100 mmol/l) is rare and potentially fatal. In oncology patients, it requires clinical suspicion due to nonspecific symptoms often attributed to progressive neoplastic disease or antineoplastic therapy. Its etiology must be determined along with ensuring a safe correction. Severe hyponatremia caused by primary adrenal insufficiency is extremely rare in the literature. Although adrenal metastases are not uncommon in oncology patients, the prevalence of resulting primary adrenal insufficiency is notably low. The prognosis for these patients is generally very poor. However, as this case illustrates, advancements in oncological treatments have significantly improved outcomes.

Evaluation of bilateral adrenal incidentaloma at an endocrine department in Tunisia

Wided Debbabi[1], Samah Allous[2], Hajer Marzouk[3], Mouna Elfarouki[2] & Issam Kharrat[1]
[1]Ibn Aljazzar University Hospital, Faculté de Médecine de Sousse, Endocrinology Departement, Kairouan, Tunisia; [2]Ibn Aljazzar Hospital, Kairouan, Tunisia; [3]Ibn Aljazzar Hospital, Faculté de Médecine de Sousse, Kairouan, Tunisia

Introduction
Bilateral incidental adrenal incidentaloma represent 10–23% of all incidental adrenal nodules. The general approach to these nodules follows the same premise as for unilateral incidental adrenal nodules however there are features unique to bilateral nodules including the differential diagnosis, the diagnostic approach as well as the management. The aim of our study is to describe the clinical and biological profile of bilateral AIs.
Methods
This was a retrospective, descriptive study carried out in an Endocrinology department, on records of patients in whom a bilateral AI has been discovered. The following parameters were identified: Clinical and biological presentation, etiological profile, diagnosis and therapeutic means.
Results
A total of 29 records were studied, 18 women and 11 men with a mean age of 57,2 years [26-80 years]. Of these patients, 10 were hypertensive, 8 were diabetic and 5 six had dyslipidemia. Metabolic syndrome was present in 11 patients and 4 patients had history of extra-adrenal neoplasma. Adrenal CT scans were performed in 26 patients and MRI in tox others. AIs in Size was greater than 4 cm in 2 cases. Adrenal insufficiency was found in 6 patients with bilateral AIs. Hormonal exploration revealed a secreting mass in 7 cases concluding to MACS in 5 patients and primary hyperaldosteronism in tow cases. in a single case, the presence of large bilateral masses was associated with 11 beta hydroxylase deficiency in a 27-year-old patient in whom the diagnosis has been confirmed genetically. Myelolipomas were diagnosed in two cases and a bilateral acute adrenal hemmoragia during covid 19 infection in another case. hydrocortisone has been prescribed in patients with adrenal insufficiency as a replacement therapy and as a suppressant treatment in patients with congenital adrenal hyperplasia. Aldactone treatment has been prescribed for the case of primary

hyperaldosteronism. Therapeutic monitoring or abstention have been decided in other patients
Conclusion
Hormonal exploration and radiologic imaging generally makes it possible to link AIs to its etiology and to establish the therapeutic strategies adapted for each patients. investigation of adrenal insufficiency is the rule in order to avoid acute decompensation.

An adolescent-onset case of X-linked adrenoleukodystrophy with diagnostic challenges

Zulal Ozdemir Uslu[1], Nur Berna Celik Ertas[1], Yagmur Unsal[1], Hande Nur Şengil[1], E. Nazlı Gönç[1] & Alev Ozon[1]
[1]Hacettepe University, Department of Pediatrics, Division of Pediatric Endocrinology, Ankara, Türkiye

Introduction
X-linked adrenoleukodystrophy (X-ALD) is a rare peroxisomal disorder caused by mutations in the ABCD1 gene, leading to impaired beta-oxidation of very-long-chain fatty acids (VLCFAs) and their accumulation in the brain, spinal cord, gonads, and adrenal glands. It should always be considered in the etiology of primary adrenal insufficiency in males. Here, we present a case of X-ALD with diagnostic challenges.
Case
A 17-year-old male presented with fatigue, exhaustion, diarrhea after an active day, followed by confusion and syncope the next morning. He was evaluated at a center in Rome, Italy, where hypoglycemia, hyponatremia, metabolic acidosis, and hypocalcemia were detected. Low serum cortisol and markedly elevated ACTH levels suggested primary adrenal insufficiency, hypocalcemia was considered to be due to hypoparathyroidism, which led to a diagnosis of autoimmune polyglandular syndrome. Intravenous hydrocortisone infusion, oral fludrocortisone, calcium, and calcitriol was initiated. The patient was subsequently transferred to our hospital via air ambulance. In the history the patient reported fatigue, difficulty during physical exertion or severe illnesses, and significant skin darkening over the course of 2 years. Parents were first-degree cousins. On physical examination, height, weight SDS were normal. There was hyperpigmentation on extensor surfaces. Puberty was consistent with Tanner stage 5. Autoimmune markers for celiac disease and thyroid autoantibodies were negative. The treatment initiated in Italy was continued. Over the course of his treatment serum phosphate levels were within normal limits, suggesting that hypocalcemia might be linked to critical illness rather than hypoparathyroidism, and original diagnosis was reconsidered. Etiological evaluation for primary adrenal insufficiency revealed elevated plasma VLCFA levels. Calcitriol was discontinued, and hypocalcemia did not recur. Genetic analysis (hemizygous *ABCD1* c.1876G>A (p.Ala626Thr mutation) proved a diagnosis of X-ALD. There were no cognitive abnormalities, behavior changes, handwriting issues, or neurological symptoms. MRI findings of the brain and spinal cord were unremarkable. During the last follow-up, mild sensory loss was noted on physical.
Conclusion
Clinical course of hypocalcemia in critical illness may lead to a misdiagnosis of hypoparathyroidism. Reassessment is important during follow-up.
Key Words
Critical illness hypoparathyroidism, primary adrenal insufficiency, primary hypothyroidism, X-linked adrenoleukodystrophy

Pheochromocytomas and paragangliomas: clinical presentation, management, and outcomes in a tunisian cohort

Emna Mraihi[1], Dorra Dorraelguiche[1], Bchir Najla[1], Arige Abid[1], Annam Benchhida[1], Zouaoui Chadia[1] & Haroun Ouertani[1]
[1]University Military Hospital Tunis, Tunis, Tunisia

Introduction
Pheochromocytomas and paragangliomas are rare neuroendocrine tumors that develop from chromaffin cells located in the adrenal medulla and neural ganglia. The incidence of these tumors ranges from 0.04 to 0.95 per 100,000 individuals annually, with an increase in diagnoses attributed to advancements in imaging technologies. Both the clinical presentation and management of these tumors are highly variable, posing challenges in early detection, biochemical assessment, and treatment.
Subjects and methods
This retrospective descriptive study was conducted on 17 patients diagnosed with pheochromocytomas or paragangliomas at the Endocrinology and Diabetology Department of Tunis Military Hospital from 2013 to 2024. The study analyzed various parameters, including demographic features, clinical findings, biological aspects, radiological assessments, and post-operative follow-up.
Results
The study involved 17 patients, consisting of 10 females (58.8%) and 7 males (41.2%). The median age at diagnosis was 49 years, ranging from 33 to 62 years. The main circumstances leading to the diagnosis included paroxysmal symptoms in 41.2% of patients and incidental findings in 58.8%. Sixteen patients had pheochromocytomas (94.1%) while one had a paraganglioma (5.9%). Hypertension was prevalent among participants; 64.7% experienced permanent hypertension, while 23.5% had resistant hypertension. Other common symptoms included headaches (76.5%), sweating (76.5%), palpitations (70.6%), and abdominal pain (29.4%). Biologically, normetanephrine secretion was predominant in 50% of cases, while 33.3% of patients exhibited exclusive metanephrine secretion. Functional imaging revealed single hyperfixation in 88.9% of cases. The median tumor size was 52.5 mm, ranging from 46.25 mm to 65.25 mm, and the median absolute washout was 35%, ranging from 23% to 49.45%. Additionally, no patient presented with metastatic tumors. Surgical treatments were performed through laparotomy in 82.4% of cases and laparoscopy in 17.6%. Postoperatively, blood pressure normalized in 44.4% of patients, while 33.3% experienced recurrent hypertension. Metabolically, diabetes worsened in 28.6% of patients. Three months later, 14 participants had normalization of methoxylated derivatives, while the remaining were lost to follow-up. Our findings align with the existing literature on demographic trends, clinical presentations, and biochemical profiles. There is variability in the management of hypertension, surgical techniques, and metabolic outcomes.
Conclusion
Pheochromocytomas and paragangliomas have diverse clinical and biochemical profiles, complicating their diagnosis and treatment. While surgery is the main treatment of these tumors, outcomes can vary, particularly for hypertension and diabetes. Long-term follow-up is crucial to monitor recurrence and manage metabolic complications.

Prevalence, clinical and laboratory features of pheochromocytoma in minsk residents: analysis of data for 2023

Ekaterina Shepelkevich[1], Yuliya Dydyshka[1], Shepelkevich Alla[1] & Elena Yurenya[2]
[1]Belarusian State Medical University, Minsk, Belarus; [2]Minsk city edocrinological center, Minsk, Belarus

Introduction
According to official statistics, the prevalence rate of the pheochromocytoma (PHC) at the beginning of 2022 in the Republic of Belarus was 0.74 per 100 thousand population, which may indicate insufficient timely diagnosis of this disease. **The aim was** to assess the prevalence and clinical and laboratory features of PHC in residents of the city of Minsk, referred to confirm this diagnosis at the Minsk City Clinical Endocrinology Center.
Materials and methods
A one-time retrospective study was performed, which included 50 patients, residents of the city of Minsk (12 men and 38 women; 1: 3.2), referred for additional diagnostics of PHC during 2023.
Results and their discussion
In total, data from 59 patients with clinical manifestations of secondary arterial hypertension and/or adrenal formations were analyzed. The average age of patients was 69(56-74) years. Adrenal masses were detected in 78%($n = 39$), arterial hypertension was confirmed in 88%($n = 44$). Comorbid conditions include thyroid pathology (60%, $n = 30$), parathyroid glands (2%, $n = 1$), diabetes mellitus (12%, $n = 6$), psychoemotional disorders (panic attacks in4%, $n=2$). The results of laboratory diagnostics showed the level of free metanephrine in blood plasma - 60.83(19.29-103.1) pg/ml, an increase in the indicator is typical for 28%($n = 14$), an increase in the upper limit of the reference by 3 or more times - 4%($n = 2$). The concentration of normetanephrine was 189.45(59.5-275.7) pg/ml, above the reference interval in 48%($n = 24$), an increase by 3 or more times - 4%($n = 2$). Taking into account the clinical, anamnestic and laboratory-instrumental data, a subgroup of patients with confirmed diagnosis of PHC was formed, including 5 people, which is 10%. Average age was 70 (60-71) years, the ratio of men ($n = 3$)

to women ($n = 2$) was 1.5:1, adrenal masses were detected in 60% ($n = 3$), with a native density of more than 10 UHin 40% ($n = 2$), and a size of more than 4 cm in 40% ($n = 2$). A history of surgical treatment of adrenal masses was reported in 20% ($n = 1$). Antihypertensive therapy is received by 60% ($n = 3$), two drugs – 40%($n = 2$), three drugs, including digoxin – 20%($n = 1$). The median metanephrine was 135.1 (15.6-299.8)pg/ml, increased in 60%($n = 3$), more than 3 times–40%($n = 2$), normetanephrine - 570.1(417.8-2219)pg/ml, increased in all patients, more than 3 times–60%($n = 3$), aldosterone – 132.4(94.21-172.45)pg/ml, renin – 0.15(0.09-0.49)μIU/ml.
Conclusions
Confirmation of PHC was noted in 10% of patients, which confirms the clinical significance of the study of free plasma metanephrines and substantiates the importance of this study in patients with adrenal tumors and the presence of arterial hypertension.

21-hydroxilase autoantibodies positivity in Bulgarian patients with addison's disease and premature ovarian failure

Aylin Feyzullova[1], Ralitsa Robeva[1,2], Georgi Kirilov[2,3], Atanaska Elenkova[1,2] & Sabina Zacharieva[2,3]
[1]Department of Endocrinology, Faculty of Medicine, Medical University-Sofia, USHATE "Acad. Iv. Penchev", Sofia, Bulgaria; [2]Expert Center for Rare Endocrine Diseases - USHATE "Acad. Iv. Penchev", Sofia, Bulgaria; [3]USHATE "Acad. Iv. Penchev", Sofia, Bulgaria

Background
Autoimmunity plays a fundamental role in the development of Addison's disease (AD), and the presence of 21-hydroxylase autoantibodies (21OH-Abs) has been widely used as a highly specific diagnostic marker for proper diagnosis, considering that up to 90% of AD patients remain positive for 21OH-Abs up to 30 years post-diagnosis of AD (1). Moreover, 21OH-Abs could predict autoimmune adrenalitis in patients with premature ovarian failure (POI) making their measurement a recommended diagnostic tool (2). Therefore, the present study aims to establish the prevalence of 21OH-Abs positivity in Bulgarian patients with AD and POI.
Methods
A total of 43 AD (35 women and eight men [18-75 years]), 15 female non-genetic POI patients [18-39 years], and a control group of 31 healthy individuals (23 women and eight men [25-73 years]) were included in the study. 21OH-Abs were measured by ELISA (ElisaRSR™ 21-OH Ab) in all participants.
Results
21OH-Abs were positive in 72.1% [31] of AD patients (50% [4] of AD men and 77.1% [27] of AD women, $P = 0.227$), while no one of the POI patients or healthy controls showed positive results. Six (17.1%) of the AD women had also POI with four of them (66.7%) being 21OH-Abs positive. Negative for 21OH-Abs AD patients were slightly older than positive AD patients (55.5 vs. 50 years, $P = 0.063$) , However, no significant association between 21OH-Abs positivity and the disease duration was observed.
Conclusions
21OH-Abs were highly positive in AD patients, proving the autoimmune etiology of the disease. Nevertheless, nearly 30 percent of patients were antibody-negative, suggesting decreased antibody production associated with aging or different underlying AD causes that need to be explored. In Bulgarian POI patients, 21OH-Abs positivity appears to be uncommon.

Reversion of impaired glucose tolerance and diabetes in patient with primary hyperaldosteronism –case report

Ana Matijaca[1], Mirna Hrabar[1] & Srećko Marušić[1]
[1]Clinical Hospital Dubrava, Zagreb, Croatia

A 65-year-old patient was referred to an endocrinologist due to hypokalemia and arterial hypertension. He had been taking medication for arterial hypertension for more than 30 years and had normal values with amlodipine and perindopril. Hypokalemia was constant in laboratory findings over the years, with potassium levels usually 3.0–3.9 mmol/l. He also had episodes of supraventricular tachycardia a few months ago. Laboratory findings two years ago showed impaired glucose tolerance with FGP 6.7 mmol/l and HbA1c 6.4% then. These findings were checked and now showed that the patient had overt diabetes mellitus with HbA1c 7.1%. Aldosterone level was measured and came convincingly high with suppressed renin angiotensin plasma activity (0.1 ug/l/h) and aldosterone 2131 pmol/l and 1978 pmol/l, respectively, so a confirming test was not needed. Further, an abdominal CT scan was done and showed an adenoma in the right suprarenal gland. The patient refused adrenal vein sampling since he was not interested in surgical treatment, so spironolactone 50 mg was initiated. The patient was not obese, with an ITM of 24 kg/m^2 and no changes in body weight during the years. Also, there was no family history of diabetes. Since the initiation of spironolactone treatment, hypokalemia withdrew, and the patient noticed normal glucose levels during SMBG with FBG constantly below 7 mmol/l and postprandial BG below 8 mmol/l. After six months, he had definite remission of diabetes with HbA1c 5.7% without any medication. It is known that primary hyperaldosteronism leads to many cardiovascular consequences, but it can be seen in a broad range of phenotypes. It is important to remember that primary hyperaldosteronism is one of the possible endocrine causes of glucose metabolism impairment, which was the case with the patient we presented. Also, although the use of MRA as spirinolactone is connected with development of glucose metabolism impairment the opposite happened in this case.

Uncharted territory: a novel SDHC mutation in a young patient with paraganglioma

Vasiliki Siampanopoulou[1], Emmanouela Linardaki[2], Petros Papalexis[1], Alexandros-Aristeidis Lafioniatis[1], Georgia Tsirou[1], Varvara Chalmatzi[1], Constantine Stratakis[2] & Anna Angelousi[1]
[1]Endocrinology Unit, First Internal Medicine Department, Laiko General Hospital of Athens, National and Kapodistrian University of Athens, Athens, Greece; [2]Human Genetics & Precision Medicine, DIGENIA & EDIMO, Institute of Molecular Biology and Biotechnology of the Foundation for Research and Technology Hellas (IMMB-FORTH), Heraklion, Greece

Introduction
Paragangliomas are rare neuroendocrine tumours of the sympathetic or parasympathetic ganglia that have a strong genetic predisposition. Mutations of the succinate dehydrogenase (SDHx) genes are most commonly involved and transmitted in an autosomal dominant manner.
Objective
We present the case of a 23-year-old female patient who was referred to our department for hoarseness and a palpable mass in the neck. Magnetic resonance imaging (MRI) revealed a 37x17x36 mm lesion involving the right carotid space, while the 68-Gallium-DOTATATE scan that followed unveiled a strong enhancement of the described mass (SUVmax = 18, SUVliver = 7). Urine and plasma metanephrines/normetanephrines levels were negative for catecholamine excess. The lesion was removed surgically, and the histology report confirmed the presence of a right carotid body paraganglioma.
Methods
Germline testing was pursued through a 50-cancer gene panel following genetic counselling.
Results
Genetic testing revealed a SDHC likely pathogenic variant (c.2T > G p.Met1?)in a heterozygous state, causing a substitution in exon 1 of the SDHC gene, which disrupts the initiation (start) site of the coding for the SDHC RNA that probably leads to not expressing the corresponding protein from the mutant allele, consistent with SDHC haploinsufficiency. This specific variation (chr1:161284197) has not been referred before in the gnomAD database, however, five other variants in the same coding area are listed in the CliVar database as pathogenic and related to paragangliomas. This patient was also a carrier of an SPG11 gene mutation (c.1471-1472delCT) which is associated with hereditary spastic paraplegia (HSP) in the homozygous states. Currently, no direct link has been found between these two gene mutations, as the first involves disruption of central to mitochondrial energy metabolism and the latter disorders in axonal maintenance and endosomal-lysosomal transport of neurons. The genetic analysis of the parents is pending.

Conclusion
Genetic analysis plays a vital role in the diagnosis and management of patients with paragangliomas. Clinically relevant variants can not only help establish genotype-phenotype correlations but also may identify asymptomatic family members.

Cyclical cushing's syndrome secondary to ectopic ACTH-secreting neuroendocrine tumor: a diagnostic and therapeutic challenge

Carolina Peixe[1,2], Catarina Isabel Lopes[1], José Vicente Rocha[1,2], Mariana de Griné Severino[1], Mariana Lopes-Pinto[1], Marta Vaz Lopes[1], Miguel António Duarte[1], Ana Gomes[1,2], Ana Paula Barbosa[1,2], Maria Inês Alexandre[1,2] & Ema Lacerda Nobre[1,2]
[1]Hospital de Santa Maria, ULS Santa Maria, Endocrinologia e Nutrição, Lisboa, Portugal; [2]Faculdade de Medicina da Universidade de Lisboa, Lisboa, Portugal

Introduction
Cyclical Cushing's Syndrome (CCS) involves alternating episodes of hypercortisolism and eucortisolism, with an annual incidence of 0.2-5.0 cases per million. Ectopic ACTH secretion accounts for 26% of CCS cases. Diagnosing and treating CCS is challenging due to its episodic nature. We present a case of CCS caused by ectopic ACTH secretion from a neuroendocrine tumor (NET).
Case Report
A 45-year-old male was diagnosed with a NET at age 39, following a transthoracic biopsy of a 127x96mm anterior mediastinal mass, incidentally, found on a CT scan. Retrospectively, the patient reported symptoms including edema, fatigue and myopathy. New-onset hypertension and hypokalemia raised suspicion for Cushing's syndrome (CS). Laboratory tests confirmed ACTH-dependent CS, with urinary cortisol of 3510µg/24h (167–827) and ACTH of 246pg/ml (7–63). Elevated chromogranin A (1875ng/mL, <102), calcium (11.3 mg/dl, 8.6–10.2), and PTH (96.9pg/ml, <72) were also noted, with normal remaining pituitary function. The concurrent diagnosis of primary hyperparathyroidism prompted genetic testing, which ruled out multiple endocrine neoplasia type 1 (MEN-1). Resection of the mediastinal mass confirmed a NET G2 (Ki-67 of 10%) with ACTH-positive immunoreactivity, validating ectopic CS. Despite surgery, persistent local disease required treatment with somatostatin analogues, chemotherapy, and radiotherapy, though tumor progression continued. The patient also started bisphosphonate therapy for hyperparathyroidism. Postoperatively, transient reduction of hypercortisolism was observed (cortisol 215µg/24h, ACTH 40.3pg/ml). Over the following years, the patient experienced three episodes of severe hypercortisolism (peak urinary cortisol of 7365µg/24h, ACTH 154pg/ml), linked to the initiation of NET-targeted treatments (radiotherapy, chemotherapy). Management include metyrapone (up to 1600 mg/day), antihypertensives, and antidiabetics. These phases alternated with periods of eucortisolism that required no treatment. In september 2023, bilateral adrenalectomy was performed to address cyclical hypercortisolism. Postoperatively, the patient started glucocorticoid and mineralocorticoid replacement therapy, with no further treatment needed for cortisol-related comorbidities.
Conclusion
This case highlights the complexity of managing CCS, particularly due to ectopic ACTH from a NET. Bilateral adrenalectomy, though a last-resort option, resolved hypercortisolism and related comorbidities, improving quality of life. However, further management of the NET remained essential, highlighting the need for individualized therapeutic strategies in complex CCS cases.

Incidental adrenal mass leading to diagnosis of a rare composite pheochromocytoma

Bruna Pimentel[1], Catarina Gama[1], Margarida Oliveira[1], Carolina Monteiro Antunes[1], Paula Sprovera[1], Rita Roque[2], Clara Cunha[1] & Catarina Saraiva[1]
[1]Unidade Local de Saúde Lisboa Ocidental, Endocrinology, Lisbon, Portugal; [2]Unidade Local de Saúde de Lisboa Ocidental, General Surgery, Lisbon, Portugal

Introduction
Composite pheochromocytoma (CP) is an exceptionally rare tumor (3% of the cases of pheochromocytomas) derived from neural crest cells. It is characterized by the coexistence of a chromaffin cell tumor and another tumor of neuronal origin, most commonly a ganglioneuroma, which arises from autonomic ganglion cells of the nervous system. The majority of diagnoses occur between the third and fifth decades.
Case Report
A 53-year-old woman, medicated with a combined oral contraceptive, presented with an incidental left adrenal mass identified on abdominal magnetic resonance imaging (MRI) performed for study of Hepatic focal nodular hyperplasia. Her family history was positive for melanoma (mother) and prostate cancer (father). The patient was referred to the endocrinology department for further investigation. She reported episodic palpitations and excessive sweating. Arterial hypertension was not observed. MRI demonstrated an expansive lesion at the left adrenal limb junction, measuring 28x24 mm, with necrotic areas and solid components, displaying T2 hyperintensity displayed, T1 hypointensity and progressive contrast uptake, particularly avid at the periphery during the arterial phase, suggestive of pheochromocytoma. Biochemical evaluation revealed elevated plasma metanephrines (163 pg/ml normal <90 pg/ml), elevated urinary total metanephrines (1154 µg/day; normal <320), including urinary metanephrines (646 µg/day; normal <320), urinary normetanephrines (392 µg/day; normal <390) and normal chromogranin (2.6 ng/mL, normal <100ng/mL). Staging with 123I-MIBG scintigraphy showed intense radiopharmaceutical uptake at the lesion site, with no evidence of distant lesions. The patient underwent laparoscopic left adrenalectomy with perioperative alpha-blockade (doxazosin), without complications. Histopathological analysis revealed a composite pheochromocytoma with ganglioneuroma, with complete surgical excision. Genetic testing did not identify any mutations associated with pheochromocytoma-related syndromes. The patient showed improvement in symptoms, with normalization of metanephrines 4 weeks after surgery.
Discussion/conclusion
CPs are rare entities requiring multidisciplinary management. Adrenalectomy is the gold standard treatment. There are cases of CPs with a malignant neurogenic component, however, CPs with ganglioneuroma component usually have an indolent behavior. Careful histopathological examination is essential. Genetic testing may provide insights into potential hereditary syndromes linked to composite adrenal tumors.

JOINT2902

ACTH-independent cushing's disease due to macronodular hyperplasia with a late diagnosis of klinefelter's syndrome

Ioana Madalina Balan-Cristian[1], Andreea Manea[1], Simona Georgeta Jercalau[1], Anda Dumitrascu[1], Elena Braha[1], Oana Stanciulea[2] & Corin Badiu[1]
[1]"C.I. Parhon" National Institute of Endocrinology, Endocrinology 4, Bucharest, Romania; [2]Fundeni Clinical Institute, General Surgery, Bucharest, Romania

Klinefelter's syndrome is the most common genetic form of male hypogonadism. However, the overt phenotype does not become apparent until after puberty. During childhood and even early puberty, pituitary-gonadal function is relatively normal in 47XXY subjects. Clinical manifestations of androgens deficiency may vary and it's related to the degree of decreased testosterone production and androgens alterations. Thus there are patients with no secondary sexual development; others cannot be distinguished from healthy individuals. Even though many of the undiagnosed causes are due to failure to recognize Klinefelter syndrome, the majority of missed diagnoses are due to minimally abnormal phenotype of Klinefelter syndrome.
Case Report
A 65-year-old male was diagnosed in May 2023 with multinodular goiter and bilateral macronodular adrenal hyperplasia based on CT findings, later on confirmed with ACTH-independent Cushing's syndrome (basal cortisol = 16.10 ug/dl, ACTH = 1.50 pg/ml, cortisol after 2x2DXM = 18.18 ug/dl), with secondary diabetes mellitus HbA1c = 6.9% and hypertension. At that time primary hypogonadism was diagnosed: testosterone = 1.08 ng/ml, FSH = 31.54 mIU/ml, LH = 25.26 mIU/ml. He underwent laparoscopic left adrenalectomy on November 2023 with significant clinical improvement, normalization of blood pressure and remission of diabetes (Hba1c = 5.7%). Although post-operatively patient had an apparent normalization of adrenocortical function, he presented adrenocortical insufficiency (ACTH = 4 pg/ml, cortisol 8AM = 4.87ug/dl) requiring initiation of low-dose hydrocortisone replacement therapy. He was also found with primary hypogonadism, (testosterone = 1.05 ng/ml, FSH = 36.81mUI/ml, LH = 40.27mUI/ml). He reported a history of surgical single testis, but had never undergone further investigation for gonadal dysfunction. Karyotyping was performed given the biochemical findings and clinical

suspicion, confirmed the result-47XXY, diagnostic of Klinefelter syndrome. The patient's long undiagnosed hypogonadism together with Cushing's syndrome had likely contributed to his osteoporosis (DXA L_1-L_4T score = -4.0 DS). Management was done by administration of ibandronate and transdermic testosterone.
Conclusions
This case illustrates the complications that can arise from the association between Cushing's disease and delayed diagnosis of hypogonadism. One reason for the delayed diagnosis of Klinefelter's syndrome was that hypogonadism, is a feature common to both Klinefelter's and Cushing's syndrome, which masked it's recognition. The overlapping metabolic and hormonal clutter in Cushing's syndrome can hide clinical presentation of Klinefelter's syndrome, leading to delayed recognition and treatment of osteoporosis, but in the absence of fractures, most likely to have a positive outcome and improvement in bone mineral density. Rapid approach of Klinefelter in older patients may improve long-term results by addressing associated metabolic, cardiovascular and bone complications.

Age-related differences and machine learning- based insights in patients with non-functioning adrenal adenomas

Ana-Silvia Corlan[1], Costi Flavia[2] & Darian Onchis[3]
[1]University of Medicine and Pharmacy Timisoara, Romania, Internal Medicine, Endocrinology, Timisoara, Romania; [2]West University of Timisoara, Computer Science, Timisoara, Romania; [3]West University of Timisoara, Machine Learning, Timisoara, Romania

Background
Non-functioning adrenal adenomas (NFAs) are considered benign incidental findings, yet their potential metabolic impact remains uncertain. Emerging evidence suggests that NFAs may be associated with metabolic disturbances and an increased prevalence of comorbidities, such as hypertension, type 2 diabetes, depression, osteoporosis and hepatic steatosis. It remains unclear whether these clinical and biological alterations are age-dependent or if obesity acts as a mediator in this association.
Methods
We analyzed a cohort of 150 patients with NFAs, stratified into 2 age groups(below50 and over 50 years). This cutoff was chosen based on physiological transitions associated with aging, including a higher prevalence of insulin resistance, altered immune function and increased cardiometabolic risk. Each of these subgroups is further divided based on the presence or absence of obesity. Clinical analyzed features are: arterial hypertension, osteopenia/osteoporosis, clinical depression, hepatic steatosis, type 2 diabetes. Biological parameters included total, LDL and HDL-cholesterol, serum triglycerides, fasting serum glucose, serum uric acid, serum phosphate, lymphocyte, eosinophil and basophil percentage and C-reactive protein levels. Machine learning (ML) techniques, including Permutation Feature Importance and attention mechanisms, were applied to identify the most relevant predictors of metabolic alterations and evaluate whether obesity mediates these associations. To enhance the accuracy and interpretability of our results, we applied the Permutation Feature Importance method which evaluates the relevance of each feature by measuring its impact on model performance when its values are randomly permuted.
Results
This study aimed to:assess differences in clinical, metabolic, and biochemical features between younger and older patients with NFAs, evaluate the prevalence of associated comorbidities and apply ML techniques to identify key metabolic risk patterns. Additionally, we investigated whether obesity mediates the relationship between NFAs and metabolic alterations, providing new insights into the potential interplay between NFAs, metabolic dysfunction and systemic disease. We selected the Permutation Feature Importance method due to its ability to provide a direct and intuitive measure of feature importance without requiring access to the model's internal structure. Additionally, we utilized an attention mechanism to assess the importance of these features in predicting metabolic risk. This approach led to a significant increase in model accuracy- approximately 17% higher compared to traditional ML models-demonstrating the benefits of explainability and attention mechanisms in optimizing predictive algorithms.
Conclusion
Our findings suggest that while obesity is common in patients with NFAs, it does not fully explain the observed metabolic alterations. Instead, obesity may act as an aggravating factor, amplifying the metabolic impact of NFAs. Future studies should explore the potential role of insulin resistance and chronic inflammation in the NFA-obesity-metabolism axis.

Exploring the role of bilateral adrenalectomy in pediatric cushing's syndrome: case series and literature review

Lama Aljumaah[1], Sarah Alharthi[2], Afaf Alsughair[3] & Raghad Alhuthail[3]
[1]Alfaisal University, Riyadh, Saudi Arabia; [2]AlFaisal University, Riyadh, Saudi Arabia; [3]King Faisal Specialist Hospital and Research Center, Riyadh, Saudi Arabia

Introduction
Cushing Syndrome (CS) is an endocrine disorder caused by prolonged exposure to elevated cortisol. Distinctive clinical features of the disease termed "cushingoid features" include facial plethora, obesity, and growth failure in children. In pediatric patients, diagnosis and treatment is scarcely documented, particularly for ACTH-independent forms where bilateral adrenalectomy (BLA) is currently the only available curative treatment.
Objectives
To present two cases of neonatal ACTH-independent Cushing Syndrome managed with BLA. These cases are analyzed for surgical outcomes and pre- and post-operative cortisol trends, in aims to reach a conclusion for management of CS in pediatric patients aged 0-14. Additionally, this review examines existing literature on BLA in pediatric ACTH-independent CS to provide a comprehensive understanding of its efficacy and safety.
Methods
This case series details clinical presentation, laboratory findings, imaging results, and surgical management of two pediatric patients with ACTH-independent CS. A review of literature on pediatric BLA was conducted to contextualize these findings within broader clinical practice.
Results
A total of 7 cases of pediatric CS treated with BLA were analyzed, including 2 from our center and 5 previously reported in the literature. Of these cases, 6 (85.7%) favored BLA after reporting resolution of symptoms. 5 cases (57%) described a decrease in cortisol levels, and 1 case (14%) succumbed to chronic sequelae of CS.
Conclusion
These cases support the role of BLA as a viable treatment for pediatric ACTH-independent CS to target refractory disease activity. While BLA effectively normalizes cortisol and improves clinical symptoms, postoperative management of potential complications and lifelong glucocorticoid replacement therapy remains essential. Our review highlights the need for further research on pediatric BLA outcomes to enhance decision-making and optimize care for pediatric patients with CS.

Aldosteronproducing adrenal oncocytoma

Irida Kecaj[1], Ergita Nelaj[1], Ilir Gjermeni[2], Denis Godaj[2], Ina Refatllari[2] & Kei Xhixhabesi[2]
[1]University Hospital Center "Mother Teresa", Internal Medicine, Tirana, Albania; [2]University Hospital Center "Mother Teresa", Tirana, Albania

Introduction.
The usual location of oncocytic cell tumors is in kidney, salivary gland, thyroid gland, parathyroid, and pituitary gland, although they have also been reported in other locations. Adrenal oncocytomas (AO) are extremely rare, mostly benign and non-functional, however they can be hormonally overproduced and potentially malignant. We present a case of resistant hypertension resulting from aldosterone-producing AO.
Case presentation
A 63-year-old male hospitalized in the emergency department for hypertensive encephalopathy, with high blood pressure levels resistant to medication. The patient was known to be hypertensive for 15 years with current antihypertensive therapy of Olmesartan plus 40/12.5 mg daily, Lercanicipine 20 mg daily and Moxonidine 1 mg daily. Routine laboratory examinations showed K + 3.2 mmol/l and other laboratory parameters within the norm. Echocardiography showed severe concentric hypertrophy of the left ventricle with other echographic indices within the norm. According to the criteria of the European Society of Endocrinology for the exploration of secondary hypertension (Resistant HTN with unexplained hypokalemia and severe concentric hypertrophy of the left ventricle) plasma renin activity, aldosterone and their ratio were measured, which

resulted in compatibility for primary hyperaldosteronism. Adrenal CT identified a solid mass in the left adrenal gland which was 15 × 10 mm in size, consistent with adenoma. The patient underwent surgical intervention of the adrenal mass, which was followed by stabilization of blood pressure values. The histopathologic study showed cortical adenomas with oncocytic cells.
Discussion
About 1.8% of adrenal tumors are oncocytic tumors, which are discovered incidentally and present as benign, nonfunctioning tumors. According to recent data, about 20% of adrenal oncocytomas are malignant and 30% of them are functional, causing symptoms related to hormonal overproduction. Histological diagnosis differentiates these tumors from adrenal adenomas.

Adult onset of X-linked adrenoleukodystrophy: insights from a unique case

Ana Milea Gheorghe[1,2] & Carmen Emanuela Georgescu[1,2]
[1]Clinical County Emergency Hospital Cluj-Napoca, Department of Endocrinology, Cluj-Napoca, Romania; [2]Iuliu Hatieganu University of Medicine and Pharmacy, Department of Endocrinology, Cluj-Napoca, Romania

Introduction
Adrenoleukodystrophy (ALD) is a rare X-linked disorder caused by mutations in the *ABCD1* gene, leading to an abnormal metabolism of very long-chain fatty acids (VLCFAs). As a result, VLCFAs accumulate in the adrenal cortex, testes, white matter of the brain and spinal cord.
Case presentation
A 27-year-old male, with a history of alopecia areata, presented to the emergency department complaining of abdominal cramps, nausea, and vomiting that started approximately one week prior to presentation, along with increased cravings for salty foods, daytime sleepiness, and dizziness over the past six months. He had also recently sustained a severe ankle sprain resulting in a calcaneus fracture and an avulsion fracture of the lateral malleolus tip, requiring immobilization in a cast. The physical examination revealed hyperpigmentation of the skin on the mammary areolas and scrotum, low blood pressure (100/70 mmHg) and tachycardia (110 bpm). Laboratory evaluation showed hyponatremia and hyperkalemia. Adrenal crisis was suspected and treatment with Hydrocortisone hemisuccinate and isotonic saline solution were initiated, with a favorable outcome. The diagnosis of primary adrenal insufficiency (PAI) was established based on hormonal test results showing low cortisol levels (4.1 µg/dl) and elevated ACTH levels (1906 pg/ml). The patient was discharged on Hydrocortisone (20 mg/ day) and Fludrocortisone (0.1 mg/ day) therapy. Despite adequate physical therapy for the ankle sprain, the patient experienced progressive walking difficulties, weakness, and pain in the legs, prompting a neurology referral. He was diagnosed with spastic paraparesis, ataxia, and bipyramidal syndrome. Given the combination of neurological symptoms and PAI, adrenoleukodystrophy was suspected. Evaluation of VLCFAs revealed elevated levels of hexacosanoic acid (1.15 mg/l), along with increased C24/C22 (2) and C26/C22 (0.07) ratios. Genetic testing identified a hemizygous missense variant in the *ABCD1* gene, c.1833G>C, p.(Gln611His), classified as likely pathogenic, which was inherited from the patient's mother who is heterozygous for the same mutation.
Conclusions
ALD is a disorder with variable clinical manifestations, usually including signs and symptoms of PAI and progressive neurological dysfunction. To the best of our knowledge the mutation found in our patient has not been described in the literature, although another missense variant in the same codon, p.(Gln611Arg), was reported in individuals with *ABCD1*-related phenotypes, emphasizing the importance of the affected amino acid. Adrenergic crises simulating severe cardiac pathology

Maria Jose Vallejo Herrera[1] & Veronica Vallejo Herrera[2]
[1]Endocrinology and Nutrition. Málaga Regional University Hospital., MALAGA, Spain; [2]Radiodiagnosis. Málaga Regional University Hospital., MALAGA, Spain

Introduction
Pheochromocytomas can present serious cardiac complications that simulate acute pulmonary edema, arrhythmias, myocarditis, acute coronary syndrome, dilated/hypertrophic cardiomyopathy and takotsubo syndrome. They can also cause neurological complications (PRESS syndrome). The management of adrenergic crises is complicated: intravenous antihypertensives, alpha-antagonists and beta-blockers and in unstable patients, vasopressors.
Objectives
To identify rare cases of pheochromocytoma with severe cardiac pathology diagnosed in our hospital.
Material and Methods
We collected 2 cases of adrenergic crises induced by pheochromocytoma seen in the emergency room, one with a fatal outcome and a postmortem autopsy diagnosis and the other with a satisfactory evolution after adequate diagnosis and treatment.
Results
1) 53-year-old woman admitted for respiratory distress, chest pain, seizure episode and sudden decrease in level of consciousness. Hypotension, tachycardia and tachypnea. D-dimer 46335, Troponin I 2922.30 and metabolic acidosis. ECG: ST depression on the lower face. Chest X-ray: acute pulmonary edema. Urgent coronary angiography: normal coronary arteries and pattern compatible with stress cardiomyopathy/myocarditis. Echocardiogram: non-dilated LV, mild-moderately depressed systolic function, marked hypokinesia of the basal septum (Takotsubo). Chest CT angiography: cardiac failure, renal infarcts and 46 mm left adrenal mass (adrenal hemorrhage/-pheochromocytoma). Hormonal study: Elevated metanephrines.
   - Evolution: High doses of norepinephrine and dobutamine are required to maintain blood pressure with severe systolic dysfunction, so levosimendan is started. Pulmonary edema and cardiac function improve, but neurological evolution is poor (head CT - ischemic lesions/vasogenic edema), resulting in death.
   - Autopsy: myointimal hyperplasia of coronary arteries. Generalized alveolar edema. Bilateral adrenal hemorrhage, with pheochromocytoma in the left adrenal gland. Heart: changes in the heart muscle typical of infarction, with cardiomyopathy and myointimal hyperplasia of coronary vessels, which could lead to arrhythmogenic changes.
2) 60-year-old male admitted for cardiorespiratory arrest. General malaise, tachycardia, profuse sweating. metabolic acidosis, troponin I 40. ECG: sinus tachycardia and peaked T waves. Chest CT: rules out PE, bilateral pleural effusion and heart failure, left adrenal mass 6 cm. Urgent catheterization: normal coronary arteries. Severely dilated left ventricle (dilated cardiomyopathy), severe hypokinesia (LVEF 15%). Hormonal analysis (urine 24h): elevated metanephrines. Scintigraphy: left adrenal pathological deposit compatible with pheochromocytoma. Cardiac MRI: Non-ischemic dilated cardiomyopathy with severe biventricular systolic dysfunction. Evolution: need for vasoactive drugs with arterial hypertension, alpha and beta blockade is started. After completing the study, surgical resection showed improvement in ventricular function.

Conclusions
Pheochromocytoma may resemble acute coronary syndrome/cardiogenic shock with high mortality, and should be suspected in patients with normal catheterization.

JOINT2107

Preparation for adrenal cortical carcinoma surgery with injectable fluconazole, a second successful experience (case report)

Mohamed Samir Merad[1]
[1]Oran 1 Ahmed Ben Bella Medical University, Endocrinology and Diabetology Departement -Larribere Clinic – University Hospital Dr Benzerdjeb, Oran, Algeria

Background
The malignant adrenocortical carcinoma is an aggressive tumor of the adrenal cortex, with an incidence of between 1 and 2 cases per million population and a peak between the ages of 40 and 50. Rapid management of hypercorticism is essential to prepare for surgical intervention. As Ketoconazole is not available, Fluconazole, another azole antifungal, is a suitable alternative that has been successfully used in our department for another patient with paraneoplastic Cushing's syndrome, with no adverse effects.
Case presentation
The patient was 31 years old and presented with hypertension complicated by heart failure and a clinical Cushing's syndrome consisting of truncal obesity, buffalo neck, and purple stretch marks; the hormonal work-up confirmed

endogenous hypercorticism. A CT angio scan identified a large left adrenal mass measuring 205 × 191 × 156 mm, with infiltration of the perilesional fat. Further staging via thoraco-abdomino-pelvic CT revealed the presence of pulmonary metastases. Following the successful emergency surgery on injectable Fluconazole for a patient with paraneoplastic Cushing's syndrome, we opted for fluconazole 400 mg injectable daily, with 24-h urinary free cortisol (UFC) monitoring and liver function tests every 48 hs. After 12 days of treatment, the patient's UFC levels decreased from 632.5 nmol/24 h to 60 nmol/24 h without any signs of liver damage. Following adrenalectomy, the patient experienced a postoperative adrenal insufficiency with a postoperative UFC of 16.73 nmol/24 h at 7 days after surgery.
Conclusion
This is the second case in our department of successful management of hypercorticism by injectable fluconazole in preparation for surgery. These findings suggest that Fluconazole is a safe and effective alternative to ketoconazole. Further studies involving larger patient populations are needed to fully evaluate its potential as a synthetic anti-cortisolic agent.

Diagnosis of pheochromocytoma in a patient with recurrent reverse takotsubo cardiomyopathy

Foteini Thanasoula[1], Foteini Petrea[1], Marina Mitropoulou[1], Ioannis Petropoulos[2], Anna Dimoula[2], Evangelos Repasos[2] & Vasiliki Vasileiou[1]
[1]Alexandra General Hospital, Endocrinology Department and Diabetological Centre, Athens, Greece; [2]Alexandra Hospital of Athens, Department of Clinical Therapeutics, Athens, Greece

Background
Pheochromocytomas (PHEO) are rare neuroendocrine tumors that secrete excess catecholamines, leading to severe cardiovascular complications. While their typical symptoms include episodes of hypertension and tachycardia, their association with Takotsubo syndrome (TTS) is less commonly recognized, especially with reverse TTS, which is an even more rare clinical presentation of PHEO. TTS often resolves with supportive care, however when related to catecholamine excess from pheochromocytomas, can lead to recurrent episodes and long-term cardiovascular risks.
Objectives
This case report aims to increase awareness among clinicians regarding the causal association between Takotsubo cardiomyopathy and catecholamine secreting pheochromocytoma.
Case Presentation
A 40-year-old female patient with a history of reverse Takotsubo cardiomyopathy two years ago, currently on ongoing antihypertensive treatment, was admitted to the emergency department due to palpitations, chest pain, headache, and vomiting. Clinical evaluation revealed a hypertensive crisis (B*P* = 220/110 mmHg), sinus tachycardia (HR = 120 bpm) and ischemic changes on the ECG. Biochemical tests revealed elevated troponin levels, severe hyperglycemia and increased lactate in the blood gases without acidosis. Echocardiography showed hypokinesia of the left ventricle, leading to urgent coronary angiography, which was normal. The patient was admitted to the ICU and treated with a non-selective beta-blocker (labetalol) and intravenous nitrate, leading to significant improvement in the left ventricular echocardiographic findings, suggesting a possible reverse Takotsubo syndrome. Due to the clinical picture, the patient's young age and medical history, pheochromocytoma was suspected.
Results
A computed tomography (CT) scan revealed a nodular mass in the left adrenal gland (3.1 x 2.7 cm) with heterogeneous contrast uptake. Hormonal screening confirmed elevated plasma catecholamines levels: metanephrine: 330 ng/l (normal <88), free normetanephrine: 1030 ng/l (normal <115), and free 3-methoxytyramine: 37 ng/l (normal <17.4). Staging with whole-body CT and Tecrotyde scan did not show secondary lesions or paragangiomas. The patient was prepared with alpha-blocker (doxasocin) for 15 days and underwent laparoscopic left adrenalectomy. Histopathological diagnosis confirmed pheochromocytoma (size =3 cm, PASS score= 1, Ki67 <1%, PT1NxMx). Genetic testing was negative. Postoperatively, hormonal screening was negative and imaging showed no recurrence. The patient remains asymptomatic without anthihypertensive medication.
Conclusion
The association between pheochromocytomas and Takotsubo syndrome underscores the importance of recognizing catecholamine-induced myocardial dysfunction in patients with acute chest pain and ECG abnormalities. Clinicians should suspect pheochromocytoma in unexplained TTS cases as early diagnosis and treatment are essential to prevent long-term cardiac damage. Further research is needed for optimal management of this potentially life-threatening complication.

The combination of afternoon and midnight salivary cortisol improves the diagnosis of cushing's syndrome

Luana Lionetto[1], Maria Elena Aloini[2], Donatella De Bernardini[1], Giuseppe Costanzi[1], Roberta Maggio[2], Guido Roberto[2], Francesca Ricci[2], Irene Biondo[2], Pina Lardo[2], Gerardo Salerno[2], Maurizio Simmaco[2] & Antonio Stigliano[2]
[1]Sant'Andrea University Hospital, Rome, Italy; [2]Sapienza University of Rome, Rome, Italy

The diagnosis of Cushing's syndrome is based on the inhibition test with 1 mg dexamethasone (1 mg DST), 24-h urine free cortisol, and serum and salivary cortisol measurements at midnight. Nevertheless, the diagnosis is challenging and often fraught with many pitfalls depending on several factors, such as taking drugs that interfere with the hypothalamic-pituitary-adrenal axis (HPA axis), the presence of molecules active on CYP3A4 enzyme and many other factors such as age, sex, and body mass index. In addition, some diseases such as renal and liver failure, or psychiatric disorders, reduce the diagnostic power of the tests commonly used in the diagnosis of hypercortisolism. We propose a new diagnostic strategy, simple to perform, easy to reproduce and with a high diagnostic performance. It consists of measurements of salivary cortisol by LC-MS/MS method, at three different times of the day: the first in the morning (0800 h), the second around 1400 h and the third between 2300 h and 2400 h. The reproducibility and specificity of the test identify patients with hypercortisolism in 95% of cases at midnight. Interestingly, when considering two specific points on the salivary cortisol curve, the success rate rises to 100%. Furthermore, the method allows diagnosis even in patients who cannot perform the commonly used diagnostic tests.

Adrenal tuberculosis has not revealed all its secrets:an unusual case

Hamza El Jadi [1] & Oumaima Mendari[1]
[1]Oued Eddahab Military Hospital, Agadir, Morocco

Introduction
Adrenal tuberculosis is rare, accounting for between 3% and 9% of the etiologies of adrenal insufficiency (AI). It is responsible of acute or chronic adrenal insufficiency. Our case illustrates an unusual presentation of adrenal tuberculosis whose ultimate aim is to make our medical community aware of the various aspects of this widespread condition in the Moroccan context.
Case
A 43-year-old patient with a history of chronic smoking and cured hepatitis B presented with diffuse abdominal pain. presented with diffuse abdominal pain with no other associated digestive signs. Questioning revealed weight loss of 8 kg in 2 months, associated with progressive melanoderma. Abdominal computed tomography revealed a necrotic pseudo adrenal mass measuring approximately 63x35x75 mm. Chronic adrenal insufficiency was based on a low cortisol level of 5.2ng/dl. The patient was started on hydrocortisone replacement therapy and referred for surgery due to the "suspicious" nature of the adrenal mass. The patient was referred to us from the pre-anaesthesia consultation for preoperative endocrinological evaluation. The clinico-biological data were in favour of a peripheral AI. The etiological investigation, notably the Quantiferon test, was very positive at 10 UI/ml. X-ray was normal. The diagnosis of adrenal tuberculosis was in consultation with the pneumo-phtisiologists, was based on a combination of radiological (appearance suggestive of a bacillary cause), clinical (signs of tuberculosis of tuberculosis impregnation) and biological (very positive quantiferon). The patient was put hormone replacement therapy with hydrocortisone, combined with antituberculosis antituberculosis treatment.
Discussion
The adrenal localization of tuberculosis occurs via the hematogenous route from the CT scan and biopsy play a vital role in the diagnosis. Adrenal tuberculosis, a rare cause of AI in the literature, is discovered late in the course of infection, with pathognomonic signs are adrenal calcifications, testifying to the chronicity of the

condition. Anti-tuberculosis treatment can lead to partial recovery of steroidogenesis. Our patient's clinical course looks very satisfactory, pending sufficient time for radiological control.

Our case

- Reports an AI during the active, progressive phase of adrenal tuberculosis, in contrast to cases often reported in the chronic phase.
- Unusual tumor-like radiological findings, which may lead to surgical intervention.
- Underlines the importance of multidisciplinary care and the need to respect the sphere of specialized skills.

JOINT1355

Post operative hypoaldosteronism after unilateral adrenalectomy. a case report and review of the literature

Abigail L'Amie[1,2,3] & Joey Yeoh[2]

[1]Auckland City Hospital, Te Whatu Ora Te Toka Tumai, Endocrinology and Diabetes, Auckland, New Zealand; [2]Middlemore Hospital, Te Whatu Ora Counties Manukau, Endocrinology and Diabetes, Auckland, New Zealand; [3]Auckland City Hospital, Women's Health, Auckland, New Zealand

Primary Aldosteronism (PA) is the most common cause of secondary hypertension and is associated with long term morbidity and organ dysfunction including chronic kidney disease (CKD). Optimal management for unilateral PA is adrenalectomy however development of post-operative hypoaldosteronism with resultant hyperkalaemia is increasingly being recognised as a complication. We present a patient with delayed diagnosis PA, established CKD and recovery complicated by hypoaldosteronism. We review the literature regarding the risk factors for and management of post-operative hypoaldosteronism, and present local data on post-operative hyperkalaemia rates. We describe a 60-year-old man who underwent unilateral adrenalectomy after 10 years of refractory hypertension. At time of surgery, he had established stage G3aA2 CKD, type 2 diabetes mellitus and ischaemic heart disease. Two weeks after surgery, the patient was admitted to hospital with severe hyperkalaemia, that was initially resistant to standard treatment measures. His hyperkalaemia resolved after initiation of Fludrocortisone and Sodium Bicarbonate. Post operative hyperkalaemia has been described in between 3-48% of patients undergoing unilateral adrenalectomy and attributed to transient, but sometimes prolonged, hypoaldosteronism. Most cases of hyperkalaemia are reported to occur within one to three weeks of surgery, however reports of up to 6 months post operatively have been described. This is likely a consequence of prolonged renal exposure to aldosterone excess, resulting in chronic suppression of renin with subsequent atrophy and suppression of the contralateral zona glomerulosa cells. In our hospital, between 2010 - 2020, 23 patients underwent unilateral adrenalectomy. Eight patients (34.8%) experienced transient hyperkalaemia; however, no cases of prolonged hyperkalaemia were recorded. Only 39.1% of patients had potassium levels monitored beyond 28 days, and 21.7% has levels monitored for less than 14 days. Hyperkalaemia can be severe and associated with life threatening cardiac arrhythmias. Despite this, there are not clear consensus guidelines on strategies to predict, prevent or monitor for this. Suggested risk factors include age >50 years, duration of hypertension >10 years, established CKD, adrenal adenoma >2 cm and male gender. As patients with established complications of hypertension may be both more at risk of complications, and less likely to derive benefit from surgery, this case highlights some considerations and complexities of patient selection for surgical management of PA. This case provides strength to recommendations to recognise and treat PA early, and to develop robust protocols for post-operative electrolyte surveillance, treatment and management of anti-hypertensives in the peri-operative setting.

Congenital adrenal hyperplasia and addison's disease: coincidence or consequence?

Yara Emara[1], Svenja Leibnitz[1], Anna Lauber[2], Richard Auchus[3], Christoph Berger[4], Claudia Cavelti-Weder[5] & Bettina Winzeler[5]

[1]University Hospital Basel, Department of Endocrinology, Diabetology and Metabolism, Basel, Switzerland; [2]Hospital of Fribourg, Department of Paediatrics, Fribourg, Switzerland; [3]University of Michigan, Departments of Pharmacology and Internal Medicine, Ann Arbor, United States; [4]University of Basel, Translational Immunology, Basel, Switzerland; [5]University Hospital Zurich, Department of Endocrinology, Diabetology and Clinical Nutrition, Zurich, Switzerland

Case description

In 2014, a 25-year-old patient was referred with unfulfilled desire to conceive, oligomenorrhoea, pronounced hirsutism since age 17, and clitoromegaly. A transvaginal ultrasound revealed bilateral ovarian lesions (left 4x2x1.5 cm; right 2x2 cm) later confirmed through MRI, as well as enlarged adrenal glands. Diastolic blood pressure was elevated and laboratory testing showed normal electrolytes and low cortisol (82 nmol/l[80-638]), however the patient had no signs of hypocortisolism. Further evaluation showed: testosterone 12.1 nmol/l[0.3-1.7], DHEA-sulfate 3.99 µmol/l[1.7-9.7], androstendione° >35.0 nmol/l[2.0-9.0], aldosterone 47 pmol/l[32-654], renin 0.6 ng/l[1.7-23.9], 17-OH-progesterone (stimulated) 19.4 nmol/l[<43], 11-desoxycortisol° >180 nmol/l[<12], ACTH 2008.0 pg/ml[<46.0]. We diagnosed congenital adrenal hyperplasia (CAH) with 11-β-hydroxylase deficiency and ovarian adrenal rest tumors (OARTs). Whole exome sequencing did not reveal a pathogenic variant. Due to active mineralocorticoid and glucocorticoid precursors, no substitution was required. Treatment with glucocorticoids was initiated to control androgen excess and restore menstruation. Subsequently she became pregnant spontaneously in 2017. After delivery, glucocorticoids were discontinued; nevertheless she became pregnant a second time and now has two healthy sons. In 2021, the patient presented with severe fatigue and low blood pressure of 92/61 mmHg (heart rate 69/min). Androgens were almost unmeasurable and cortisol very low: cortisol 20 nmol/l, ACTH 1107.0 ng/l, DHEA-sulfate 0.14 µmol/l, androstendione° <1.05 nmol/l, 17-OH-progesterone 1.6 nmol/l, 11-desoxycortisol° 10.2 nmol/l, sodium 140 mmol/l, potassium 3.9 mmol/l. She was diagnosed with an Addisonian crisis and substituted with hydrocortisone. 21-hydroxylase antibodies were positive (1.2 U/ml[<0.4]), suggesting autoimmune Addison's disease, however further autoimmunological testing (ANA, IgG, IgM, IgA, complement CH50, C3/C4, B-cell and T-cell-subpopulations) was negative. In 2022, aged 32 years, the patient presented with premature ovarian failure (cessation of menstruation, hot flashes, estradiol 26.5 pmol/l[114-1959], LH 48.1 IU/l[<95.6], FSH 21.8 IU/l[1.7-21.5]) and hormone replacement was started. Surprisingly, the OARTs regressed and had not been detectable in imaging since 2019.

Discussion

This case raises the question of whether the concurrence of CAH, Addison's disease, and premature ovarian failure in this patient is coincidental or indicative of a potential underlying connection. A case report (Sigrid Aslaksen *et al*., 2019) documented a patient with CAH with mutation in 3β-hydroxysteroid dehydrogenase and subsequent Addison's disease and premature ovarian failure. We hypothesize that prolonged ACTH stimulation could have led to progressive depletion or dysfunction of ACTH-dependent tissue. This is supported by the finding that the mineralocorticoid steroid synthesis, regulated by the Renin-Angiotensin-Aldosterone system rather than ACTH, remained intact.

JOINT3461

How early should screening be performed in patients with congenital adrenal hyperplasia?

Serpil Albayrak[1], Mehmet Keskin[2] & Murat Karaoglan[2]

[1]Cengiz Gökçek Children and Maternity Hospital, Gaziantep, Türkiye; [2]Gaziantep University Pediatric Endocrine Clinic, Gaziantep, Türkiye

Introduction

Testicular adrenal rest tumor (TART) is a rare type of benign tumor of the testis. However, TARTs have been described in rarer forms of congenital adrenal hyperplasia(CAH) such as CYP11B1, 3β-hydroxysteroid dehydrogenase type 2 deficiency (3βHSD2D) as it occurs in 21-hydroxylase deficiencydeficiency, although no clear association between hormonal control of all cells and the development of TART has been shown. TART may be missed on physical examination when it is deeply located and less than 2 cm in size. Ultrasound as a first-line examination method provides important information for the recognition of TART. Accurate and timely recognition of TART in cases of infertility or progression and deterioration is important, especially in the absence of adequate and continuous hormonal control.

Methods

Pediatric patients who were followed up in pediatric endocrine outpatient clinic between 2022 and 2024 with the diagnosis of adrenal insufficiency and screened for TART with routine testicular ultrasonography were included in the study. We included10 cases of TART with CAH (7 cases of 21-hydroxylase deficiency, 2 cases of 11β-hydroxylase deficiency, 1 case of 3βHSD2D-related TART).

Virilization and under-masculinization were assessed using Prader staging and pubertal development sttaged according to the system of Tanner. Steroids higher than the target range supported by high ACTH levels during follow-up were classified as poor control.
Results
The age of the patients was 13.07 ± 3.68 years. 3 patients (30%) were well controlled. All patients had advanced bone age and 1 patient was receiving GnRH analog therapy due to precocious puberty. The youngest affected patient was 5 years old. 2 (20%) patients were of Syriac nationality and had no regular follow-up with poor control.2 patients were interpreted as REST in the first USG and were diagnosed as Leyding cell tumor (LCT) with biopsies performed due to clinical progression. One of the two patients had no genetic diagnosis but was considered to have 21-hydroxylase deficiency based on laboratory and clinical findings.
Conclusion
Early diagnosis and treatment of TART is important for the preservation of gonadal function in children with CAD. Timely detection of the disease is important to prevent irreversible gonadal dysfunction and infertility. Abnormal serum ACTH levels are not seen in some cases and are also seen in patients younger than 6 years of age, so we recommend screening with early US scanning. Rarely, it can be caused by LCT and should be kept in mind in this respect.

Non-arteritic anterior ischemic optic neuropathy and addison's disease

Shyam Seshadri[1], Jaiminkumar Patel[1], Murtaza Rashid[1] & Michael Kouroupis[2]
[1]Queen Elizabeth Hospital Foundation NHS Trust, Department of Diabetes and Endocrinology, Kings Lynn, United Kingdom; [2]Queen Elizabeth Hospital Foundation NHS Trust, Department of Ophthalmology, Kings Lynn, United Kingdom

Nonarteritic anterior ischemic optic neuropathy (NAION) is the most common cause of acute optic neuropathy in adults presenting as sudden, painless vision loss due to ischemia of the optic nerve head. Risk factors that have been strongly associated with NAION include hypertension, hypercholesterolemia, diabetes mellitus, cardio- and cerebrovascular disease, and obstructive sleep apnoea. Addison's disease which is a rare autoimmune condition leading to adrenal insufficiency, is not commonly linked to NAION. However, chronic hypotension and vascular dysregulation in Addison's disease may contribute to ischemic complications, including NAION.
Case Presentation
We report on a 46-year-old female with known Addison's disease who presented with acute, painless blurry vision in the right eye upon waking up. On examination at eye casualty, visual acuity was 6/18 in the right eye and 6/6 in the left eye. Fundoscopy revealed optic disc swelling. Inflammatory markers were within the normal range with a very low GCA probability score and given the young age, Giant cell arteritis was considered highly unlikely. MRI of the brain showed white matter foci in keeping with small vessel disease and empty Sella syndrome. The neurologist reviewed her, and multiple sclerosis was excluded. She had a long-standing history of Addison's disease and autoimmune hypothyroidism. She was being treated with fludrocortisone and prednisolone and had previously experienced subjective hypotensive episodes. Lying and standing blood pressure checks in the clinic did not document postural hypotension. Adherence to corticosteroid and mineralocorticoid replacement therapy was monitored with serum prednisolone levels within the therapeutic range and plasma renin activity levels indicating sufficient fludrocortisone dosing. 24-h ambulatory blood pressure monitoring was arranged which could have detected nocturnal hypotension, however, our patient was unable to attend this. Chronic hypotension secondary to adrenal insufficiency was suspected as the precipitating factor for optic nerve head ischemia during presumed nocturnal hypotensive episodes, however, we could not conclude this due to lack of evidence of documented nocturnal hypotension. The patient did report subjective symptoms of dizzy spells, especially at night though with no other associated symptoms. Other vascular risk factors were absent, however, suggesting Addison's disease as a possible cause.
Conclusion
This case highlights a rare but significant association between Addison's disease and NAION. Clinicians should consider adrenal insufficiency in atypical presentations of NAION, particularly in younger patients or those without traditional vascular risk factors. Early recognition of Addison's disease and appropriate hormonal therapy may reduce the risk of ischemic events, including NAION.

JOINT2546

Skin lightening cream causing hypoadrenalism

Furhana Hussein[1], Aylin Can[1], Lina Eltayieb[1], Gideon Mlawa[1] & Bashir Mahamud[1]
[1]Barking, Havering, and Redbridge University Hospitals NHS Trust, Romford, United Kingdom, London, United Kingdom

Introduction
Skin lightening creams contain steroids and are easily accessible from over the internet and shops which are not regulated. Topical corticosteroids have important anti-inflammatory and immunosuppressive activity and are often prescribed for the treatment of dermatological disorders such as eczema and psoriasis. Adrenal insufficiency has been known to be a side effect for using topical steroid creams for long period of time and are therefore prescribed and monitored by the dermatologist.
Case Presentation
35-year-old female presented with 1-year history of lethargy, fatigue and muscle cramps which had got worse in the last one week. No infective signs. She was haemodynamically stable and apyrexic. She has a past medical history of depression and anxiety and was taking mirtazapine medication. Her menstrual cycle is regular and has two children. Her 9am Cortisol was found to be 7 nmmol/l and the pH, lactate and glucose was within normal range. She denied taking oral or inhaled steroids but on further questioning it was found she has been taking a skin lightening cream call 'Fashion fair cream' which contains clobetasol propionate. She had been using this cream all over her body for many years. On examination her skin had different pigmentation, thinner with more prominent veins. She had multiple striae on her arms, thighs and abdomen. She also looked cushingoid with moon face, central obesity, buffalo hump of neck, and striae all over the body significantly on the abdomen. Short synacthen test showed cortisol levels of 8nmol/l(0mins), 106 nmol/l(30mins) and 73 nmol/l(60mins). She was reviewed in the endocrine clinic where she was advised to stop her topical cream and started on hydrocortisone 10 mg/5 mg/5 mg with aim to wean down slowly
Conclusion
Many skin lightening creams contain steroids which patients may not be aware of. Long-term use of topical steroid cream can cause side effects and most importantly secondary adrenal insufficiency. Although commonly prescribed for dermatological conditions such as eczema and psoriasis they are monitored closely. However, skin lightening creams are not monitored and are easily available without prescription or monitoring from shops and online. This could lead to adrenal insufficiency if used for longer period of times. It is important to take a full history to check if patients are taking topical cream, eye drops, etc that may contain steroids. It is also important to have an MDT approach with the dermatologist and endocrinologist to help wean patient off the steroids and treat appropriately.

JOINT1638

Thyroid hormone resistance syndrome de novo in a patient with THR mutation c.749T > C. a case report

Enrique Castro-Martínez[1], Miguel Angel Ruiz-Ginés[2], Carles De Diego-Boguña[3], Ana Castro-Luna[1], Maria Ruiz de Ancos[1], Rocio Revuelta-Sánchez Vera[1] & Belén Martínez-Mulero[1]
[1]Hospital Universitario de Toledo, Endocrinology, Toledo, Spain; [2]Hospital Universitario de Toledo, Pathology and Laboratory Medicine, Toledo, Spain; [3]Hospital Universitario de Toledo, Genetic, Toledo, Spain

Background
Thyroid function test discrepancies often cause diagnostic delays and sometimes lead to unnecessary treatments. Thyroid hormone resistance syndrome is rare (1/40,000 births), affecting both sexes equally, with autosomal dominant inheritance. Diagnosis relies on excluding other causes of hyperthyroxinemia and genetic analysis of the thyroid hormone receptor (THR) beta subunit. Clinical symptoms are usually minimal. The primary differential diagnosis is with TSH-producing tumors and analytical laboratory system discrepancies.
Methods
A 22-year-old woman presented with discordant thyroid function tests since 2023, showing elevated or normal TSH and elevated free T4 and free T3 levels. No family history of thyroid dysfunction. Diagnosed with polycystic ovary syndrome, grade 1 obesity, and mild hyperprolactinemia. Previous tests from another hospital and ours (with a different system) revealed subclinical hypothyroidism with normal free T4 levels (2022 and earlier). No clear symptoms of hyperthyroidism or hypothyroidism. Treated with progesterone only and no supplements. Physical examination

showed no goiter, tachycardia, or ophthalmopathy. Anti-thyroid antibodies (anti-peroxidase and anti-thyroglobulin) were positive, TSI negative. Free alpha subunit and SHBG levels were normal. Pituitary MRI was normal. Thyroid ultrasound showed no nodules. Blood samples on other platforms (Vitros ECiQ and Architect i2000SR) showed similar results to our hospital (Cobas e801 Roche). Other studies were negative, including antibodies (antinuclear, heterophile, anti-thyroxine), rheumatoid factor, and no macro TSH or macro free T4. Genetic study for familial dysalbuminemic hyperthyroxinemia was negative. Serum selenium levels were normal. T3 suppression test (100 mg for 8 days) showed TSH 0.094 mIU/ml on day 8 (normal response). Octreotide LAR test (20 mg/28 days) showed no TSH decrease after one month. Genetic study for thyroid hormone resistance syndrome identified missense variant of the THRB gene c.749T>C (p.Ile250Thr) variant associated with OMIM #188570, autosomal dominant inheritance from her mother, with her two siblings also affected.
Conclusions
A previously normal phenotype did not raise suspicion for thyroid hormone resistance syndrome. Routine tests (TSH only) can overlook family history of thyroid discordant study. Genetic testing was key to diagnosis in this case. It is relevant that this case involves a woman of childbearing age, due to the therapeutic considerations for a future pregnancy.

Ectopic ACTH syndrome in a patient with pheochromocytoma

Gökhan Rıza Baykal[1], Gokcen Nailer Ertuna[1], Neslihan Çuhacı Seyrek[2], Asım Özayar[3], Cevdet Aydin[2], Oya Topaloglu[2], Reyhan Ersoy[2] & Bekir Cakir[2]
[1]Ankara Bilkent City Hospital, Department of Endocrinology and Metabolism, Ankara, Türkiye; [2]Ankara Yıldırım Beyazıt University Faculty of Medicine, Ankara Bilkent City Hospital, Department of Endocrinology and Metabolism, Ankara, Türkiye; [3]Ankara Yıldırım Beyazıt University, Faculty of Medicine, Ankara Bilkent City Hospital, Department of Urology, Ankara, Türkiye

Introduction
Pheochromocytoma is a rare catecholamine-secreting tumor that arises from chromaffin cells in the adrenal medulla. Pheochromocytomas may rarely secrete adrenocorticotropic hormone (ACTH) or CRH (corticotropin-releasing hormone) and calcitonin in addition to catecholamines. Ectopic ACTH syndrome due to pheochromocytoma is a very rare disorder. These patients carry a significant risk of severe complications if not diagnosed and managed appropriately.
Case
A 53-year-old male was referred to our clinic with muscle weakness, weight loss, high blood pressure, headache, palpitations, and flushing. The patient had developed diabetes in the last month and was taking oral antidiabetic medication. The patient was normokalemic in her first evaluation and in her hormonal evaluation. The patient's hormone levels showed that ACTH was 19.8 pg/ml, cortisol was 15.4 µg/dl, DHEA-SO4 was 89.51 µg/dl (34.5-568.9), 24-h urine cortisol was 46.69 µg (10-100), 1 mg dexamethasone suppression test was 11.1, 24-h urine metanephrine was 2719 µg, normetanephrine was 2693 µg, plasma metanephrine was 303 pg/ml, and normetanephrine was 935 pg/ml. The CT imaging of the patient's abdomen revealed a 35x30 mm thick-walled, low-density, heterogeneous lesion in the right adrenal gland. During follow-up, the patient rapidly became hypokalemic, potassium replacement was administered, and spironolactone was started. Plasma cortisol level increased to 110 µg, ACTH level to 452 pg/ml and 24-h urine cortisol level increased to 3755 µg. We started the patient on 400 mg of fluconazole intravenously. During follow-up, the patient benefited somewhat from the treatment. The treatment brought the patient's blood pressure and blood sugar under control. The patient was operated after appropriate surgical preparation. After the removal of a right adrenal pheochromocytoma, the patient's elevated levels of serum and urine corticosteroids, plasma ACTH, plasma catecholamines, and urinary catecholamine metabolites decreased. Pathological examination revealed diffuse positive staining with ACTH in the pheochromocytoma area. The patient became normotensive after the operation. The patient, who was receiving basal-bolus insulin therapy, continued his diabetes treatment with oral antidiabetic.
Conclusion
Ectopic ACTH syndrome is very rare in patients with pheochromocytoma. These patients have a relatively rapid course, marked hypokalemia, diabetes mellitus or significant hypertension. The management of these patients is difficult, and there may be difficulties in obtaining therapeutic agents. Proper preoperative recognition and management can result in total cure.

JOINT3800

Acute hypoglycemia after surgery – a clue for the diagnosis of adrenal insufficiency

Jelena Andric[1], Mirna Hrabar[2] & Jelena Jaksic[3]
[1]University Hospital Dubrava, University of Zagreb, Faculty of Kinesiology, Zagreb, Croatia; [2]University Hospital Dubrava, Zagreb, Croatia; [3]University of Zagreb, School of Medicine, Zagreb, Croatia

Introduction
Adrenal insufficiency (AI) is a rare but potentially life-threatening condition that often remains undiagnosed until an acute illness or other major physiologic stress, such as surgery, occurs. Cortisol deficiency leads to unopposed insulin action, resulting in increased peripheral glucose uptake and decreased hepatic glucose output, leading to hypoglycemia. This case report describes a patient who developed severe hypoglycemia after cholecystectomy, which eventually led to the diagnosis of AI.
Case presentation
A 42-year-old female patient with no known comorbidities underwent elective laparoscopic cholecystectomy for symptomatic gallstone disease. Preoperative assessment, including fasting glucose and routine laboratory tests, was unremarkable. The surgical procedure was uneventful, and no intraoperative complications were noted. However, on the first postoperative day, she developed severe hypoglycemia with a documented blood glucose level of 1.6 mmol/l (28.8 mg/dl), accompanied by neuroglycopenic symptoms. She was immediately treated with 10% intravenous glucose, which led to a rapid improvement in symptoms. After this episode, the patient remained hemodynamically stable and experienced no further hypoglycemic events during her hospitalization. Because the initial hypoglycemic episode was unexplained and neither exogenous insulin, an oral hypoglycemic agent, nor an anesthetic known to induce hypoglycemia was used, an endocrinological consultation was requested. At discharge, she was provided with a continuous glucose monitor (CGM) and a glucometer to detect possible recurrent hypoglycemic episodes. At her first endocrinological follow-up with CGM, early morning hypoglycemic episodes were noticed. Morning cortisol levels (measured at 8:00 am) were low (160 nmol/l), with an inadequate rise in cortisol levels during the Synacthen stimulation test. In addition, elevated ACTH levels of 64 pmol/l and positive anti-21-hydroxylase antibodies confirmed an autoimmune cause of primary adrenal insufficiency. Screening for other autoimmune diseases, including celiac disease, autoimmune thyroiditis, primary ovarian insufficiency and pernicious anemia, was negative. The patient was started on hydrocortisone replacement therapy, with dose adjustments for physiologic stress such as infection, surgery, or trauma. A review of previous medical records revealed multiple emergency room visits for nausea, vomiting, hyponatremia, and renal acute insufficiency, suggesting preexisting adrenal dysfunction in acute illness.
Conclusion
While transient hypoglycemia due to fasting or anesthetics may occur in the postoperative period, severe hypoglycemic episodes should prompt further endocrinologic evaluation. Recognizing adrenal insufficiency as a potential underlying cause is crucial, as timely diagnosis and appropriate glucocorticoid replacement therapy can prevent life-threatening complications and improve the patient's prognosis.

Composite adenomatoid tumor with myelolipoma of adrenal gland: case report

Hemmat El Haddad[1], Abdrabou Mashh[1,2], Ahmed Fayed[1,2], Amal Haridy[1,2], Randa Salam[1], Mohamed Magdy[1], Mohamed Gomaa[1,2] & Sobhi Eid[1,2]
[1]Cairo University, Cairo, Egypt; [2]Cairo University, Cairo, Egypt

Introduction
Adenomatoid tumor and myelolipoma are benign, hormonally inactive neoplasms of mesothelial origin, usually occurring in the male and female genital tracts. Rare extragenital adenomatoid tumors have been identified in the adrenal glands, heart, mesentery, pleura, and lymph nodes. That are often incidental findings in the adrenal glands. Myelolipoma is more common than adenomatoid tumor in this location but both are rare, yet the pathogenesis of both remains unclear
Case report
A 32 years old female gives a history of dragging left loin pain occurring in attacks for 2 years Examination revealed: Bp: 140/95, pulse: 84/Minute, Weight: 83 kgs Examination was normal apart from Left suprapubic anterior abdominal swelling about 2 to 3 cms with minimal tenderness Triphasic CT showed: A well circumscribed oval shaped right side hepatorenal pouch hypodense cystic lesion is seen insepraple from right adrenal gland is noted measuring 5.1*2.6 cms & indenting the liver surface. Mild hepatomegaly. A fairly defined isodense lesion is noted at the

left semilunar is being inseparable from left lateral aspect of the left rectus muscle measuring 2.3*2.2 cms.A left adnexal cyst is noted measuring 4.8*4.8 cms. MRI of the abdomen for further evaluation of the adrenal mass showed: Right adrenal multiloculated cystic lesion is seen measuring 2.5*4.5*5 cms, eliciting high T2 & low T1 signal with marginal septal postcontast enhacement yet no diffusion restriction. She was referred for the investigation of incidental adrenal mass. Serum cortisol and adrenaline metabolites were normal
Results of serum Cortisol am: 16.7 (5-25 mg/dl), ACTH am: 21.4(10-60 pg/dl) Cortisol pm: 5.2(3-10 mg/dl), Plasma renin: 12.68 (0.7-3.3 pg/dl), Aldosterone: <3.7 (<15 ng/dl)Plasma metanephrin: less than 14.9 (0.5 pg/dl), Plasma normetanephrin: 82 (<0.9 pg/dl)Urine metanephrin: 52(24-96 mg/24 hs), Urine normetanephrin: 88(75-375 mg/24 hs)The patient underwent surgery and removed both the adrenal swelling and the anterior abdominal wall swelling. The postsurgical recovery was uneventful. Microscopic examination revealed Right adrenal mass: adenomatoid tumor associated with myelolipoma. Free resection margins. Anterior abdominal swelling: endometriosis. No malignancy.
Conclusion
We report a rare case of primary Adenomatoid Tumor and Myelolipoma of Adrenal Gland treated with complete surgical resection of the tumor. A meticulous assessment of histological features pose a diagnostic challenge will aid in an accurate and effective diagnosis.. The differential diagnosis includes adrenocortical carcinoma and metastatic carcinoma, especially signet ring cell carcinoma.

JOINT2965

Neurofibromatosis type 1 with pheochromocytoma with high potential for progression (clinical case)

Maria Kats[1], Anna Lugovskaya[1], Valentina Shikina[1] & Irena Ilovayskaya[1]
[1]Moscow Regional Research and Clinical Institute ("MONIKI"), Moscow, Russian Federation

Neurofibromatosis type 1 (NF1) is one of the most common genodermatoses, and it can be associated with pheochromocytoma (PCC) in up to 14,6% of patients. PCC linked to *NF1* gene mutation belongs to the 2nd molecular cluster of genetic alterations that usually has low risk of tumor progression and metastasis. We present a clinical case of PCC in a female patient with NF1 and high potential for progression. Female patient P., 72 years old, has a medical history of multiple neurofibromas and skin spots since childhood, but no one paid attention to these signs. Over the last year, she noted episodes of rapid heartbeat and high blood pressure (BP) up to 190/90mmHg at the first time, so antihypertensive therapy was prescribed. Upon physical examination, BMI-18.9 kg/m^2, BP 124/78 mmHg, heart rate 68 bpm. She had multiple neurofibromas ranging in size from a few mm to 2 cm, "freckling" of the skin and multiple Lisch nodules on the iris of the eyes, which provided diagnosis of NF1. The tests showed an increase in metanephrines to 649 mg/day(18-277), normetanephrines to 3248 mg/day(42-423), testosterone to 8,16nmol/l (0,46-1,18). CT-scans demonstrated a formation of the right adrenal gland, 83x68x69mm with native illumination +38HU and areas of necrosis. After adrenalectomy histological and immunohistochemical examinations of the tumor verified PCC with a high potential for progression (average proliferation index Ki67 16.5%, PASS 9 points, GAPP 5 points). Six weeks after surgery, there was no any episodes of high BP, but there was a slightly elevated level of normetanephrines to 119 mg/day (5-77), after another 4,5 months to 363 mg/day. Testosterone levels also remained elevated up to 11,04nmol/l. This case demonstrates the lack of attention of doctors to NF1 diagnosis. Despite such a vivid clinical signs, the diagnosis was established during hospitalization at the age of 72. The development of arterial hypertension at this age may well be natural, which in turn can complicate the diagnosis of PCC. Despite the fact that *NF1*-associated PCC could have a low progression potential, in our clinical case high risk of malignance was detected. An increasing testosterone level is not characteristic of PCC, so the search for the source of hyperandrogenemia is needed. The patient is currently undergoing additional examination to exclude residual PCC tissue and a possible androgen-producing tumor.

Carotid paraganglioma: About 4 cases

Rachida Bouattay[1], Linda Misbah[1], May Ferjani[1], Khaled Harrathi[1] & Jamel Koubaa[1]
[1]ENT and Head and Neck Department, University Hospital of Fattouma Bourguiba, Monastir, Tunisia

Introduction
Carotid paragangliomas are the most common cervicocephalic paragangliomas. They are neuroendocrine tumors developed from small neuroectodermal structures derived from the neural crest. Their non-secreting nature makes their diagnosis difficult. Imaging allows their characterization and provides a precise lesion assessment.
Aim
The aim of this work is to study the clinical and paraclinical particularities and the therapeutic management of carotid paragangliomas.
Material and methods
A retrospective study collecting 4 cases of patients with carotid paraganglioma.
Results
These are 4 patients (2 men and 2 women) with a mean age of 50 years, who presented with chronic latero-cervical swelling. Ultrasound was performed in 4 cases showing a hypervascularized hypoechoic mass. CT scan performed in 3 cases showed an intensely enhancing isodense mass widening the carotid bifurcation. MRI performed in 3 cases showed a typical paraganglioma appearance with flow void spots. The paraganglioma was bilateral in one case, for which radiotherapy was indicated. The other 3 cases were operated on without incident with a favorable subsequent evolution.
Conclusion
Carotid paragangliomas are rare neuroendocrine tumors, most often benign and non-secreting, with a slow progression (5-7 years) and a growth rate of approximately 5 cm/year and of genetic origin in 10% of cases. The reference examination remains the CT angiography. Management is multidisciplinary, only surgical treatment is curative. When it is not possible, radiotherapy to reduce tumor progression may be an alternative to treatment.

A rare case of codeine-induced secondary adrenal insufficiency with hyponatremia worsened by hydrochlorothiazide: a case report and review of literature

Marjeta Kermaj[1], Ilia Cepa[1] & Agron Ylli[1]
[1]U.H.C "Mother Tereza", U.M.T, Endocrinology, Tirana, Albania

Introduction
Adrenal insufficiency can result from a variety of causes, including primary adrenal disorders, secondary causes such as adrenocorticotropic hormone (ACTH) deficiency, or suppression of the Hypothalamic-Pituitary-Adrenal (HPA) axis by medications. Long-term use of codeine is a recognized but underdiagnosed cause of opioid-induced adrenal insufficiency (OIAI), resulting from HPA axis suppression. It is important to note that Hydrochlorothiazide, a thiazide diuretic, is well-documented to cause hyponatremia. We present a case of a 67-year-old woman with codeine-induced secondary adrenal insufficiency and moderate hyponatremia exacerbated by Hydrochlorothiazide, highlighting the diagnostic and therapeutic challenges in managing such a complex condition.
Case report
A 69-year-old female, with a history of hypertension and osteoporosis, presented in June 2024 to the emergency department with hypotension, hyponatremia, and normal kalemia. She had been undergoing long-term treatment with codeine and paracetamol for bone pain. Upon arrival, she showed signs of hypotension. Her laboratory findings revealed moderate hyponatremia, along with low cortisol and ACTH levels confirming secondary adrenal insufficiency (SAI). Kidney function and complete blood count were within normal ranges. Hydrocortisone therapy was initiated, leading to an improvement in cortisol levels. Head CT, abdominal and thyroid ultrasound were normal, excluding other causes of situation. She was prescribed hydrocortisone (20 mg morning, 5 mg at noon, 5 mg evening), fludrocortisones 0.1 mg in addition to the previous treatment with antihypertensive (Irbesartan, Hydrochlorothiazide, Amlodipine, Metoprolol). After two weeks, her sodium levels improved to normal, while potassium remained stable. She discharged in a stable situation but six months later, the patient presented again to the emergency department with a hypertensive crisis (200/110 mmHg), hyponatremia and a 12 kg weight gain. The cortisol and ACTH levels were low. After workup it was concluded as
Final Diagnosis
Secondary adrenal insufficiency due to long -term codeine use, with hyponatremia exacerbated by hydrochlorothiazide. The synacten stimulation test resulted positive. After that, it was stopped Fludrocortisones and Hydrochlorothiazide and decreased gradually the dose of Hydrocortisone and Codeine (with monitoring by the toxicologist to prevent withdrawal syndrome). Follow-up tests confirmed stable electrolytes and cortisol levels.
Conclusion
This case highlights the critical importance of accurate diagnosis and tailored treatment in patients with secondary adrenal insufficiency induced by medication. It underscores the need for awareness of the potential for opioid-induced adrenal insufficiency and the exacerbating effects of thiazide diuretics, necessitating careful management and timely intervention to prevent complications.

JOINT2052

Unmasking the genetics: decoding the paternal code in pheochromocytomas

Yi Shan Der[1] & Brett Sillars[1]
[1]Sunshine Coast University Hospital, Endocrinology, Sunshine Coast, Australia

Introduction
Pheochromocytomas and paragangliomas (PPGLs) have the highest heritability among endocrine tumors, with approximately 40% of patients carrying a germline mutation in one of about 20 related genes. Succinate dehydrogenase (SDH) complex gene mutations are a well-known cause of hereditary PPGLs. Interestingly, unlike other SDH subunit gene mutations, germline SDHD mutations exhibit a 'parent-of-origin' effect. Tumors typically develop only when the mutated allele is inherited paternally, consistent with maternal imprinting. However, rare cases of maternally inherited SDHD pathogenic variants causing disease have been reported, including our case.
Case Report
A 22-year-old man presented with a two-week history of right iliac fossa pain, which resolved spontaneously. He denied headaches or palpitations but reported generalized sweating. Hypertension was noted on examination. CT revealed an incidental finding of a 5.5 cm left adrenal mass. Notably, he had a strong family history of SDHD mutation, with all affected family members on the maternal side, primarily presenting with head and neck paragangliomas. Plasma metanephrines showed an elevated normetanephrine level of 5690 pmol/l (reference range <560 pmol/l), with normal metanephrine and 3-MT levels. A DOTATATE PET scan revealed an intensely avid left adrenal mass with no suspicious findings elsewhere, particularly in the head and neck region. He subsequently underwent a laparoscopic left adrenalectomy, and histology confirmed a 46 mm PPGL with clear margins, a GAPP score of 2 and negative SDHB staining. Genetic testing identified a heterozygous c.191_192delTC (Leu64Profs*4) mutation in the SDHD gene, along with a variant of uncertain significance in the PDGFRA gene. Upon reviewing his family' genetic test results, it was confirmed that he carried the same SDHD mutation as his mother and maternal grandfather. Postoperatively, his plasma metanephrines normalized. We plan to request tumor gene expression analysis to confirm loss of heterozygosity, further establishing the pathogenicity of the mutation. Additionally, we intend to screen his father to rule out any potential paternal inheritance.
Conclusion
An international consensus on the role of surveillance for maternally inherited SDHD pathogenic variants has not yet been established. Given the rarity of such cases, it is important to discuss genetic testing with the patient and his first-degree relatives, as well as to consider ongoing surveillance for the patient himself.

JOINT340

Adrenal suppression secondary to intranasal corticosteroid use: a case report

Shreya Kishore[1] & Carolina Silva[2]
[1]Griffith University, Gold Coast, Australia; [2]University of British Columbia, Vancouver, Canada

Background
Glucocorticoids are widely used anti-inflammatory drugs for various pediatric conditions. Adrenal suppression is a rare but serious complication, typically associated with systemic glucocorticoid administration: most commonly, oral, intravenous or intramuscular. While the association between inhaled glucocorticoids and hypothalamic-pituitary-adrenal axis suppression is well-established, the systemic absorption of nasal corticosteroids remains controversial. Current international guidelines for allergic rhinitis suggest that the risk of adrenal insufficiency associated with intranasal glucocorticoid use is minimal.
Case Presentation
A previously healthy 6-year-old girl presented to our pediatric endocrinology clinic for evaluation of Cushing syndrome. She had been referred by her pediatrician following multiple visits to family practice, given the family's concerns around changes in facial features and increased hair growth. Her medical history was significant for seasonal allergic rhinitis, treated with intranasal beclomethasone for over three months. This had been prescribed by her family physician, at usual doses, and discontinued two weeks prior to her clinic visit. There was no additional exposure to any other medications or supplements. On physical examination, the patient exhibited facial rounding and increased hair growth along the sideburns and back. Laboratory evaluation revealed an undetectable morning cortisol level (<28 nmol/l) and a low ACTH level (2 pmol/l). Further testing confirmed an insufficient cortisol response to ACTH stimulation (peak cortisol 172nmol/l). Other pituitary hormone levels were within reference range. A diagnosis of adrenal suppression secondary to high-dose intranasal steroid use was made. The patient was started on hydrocortisone replacement with gradual tapering. Her family received education on stress dosing during illness to prevent adrenal crisis.
Discussion
This case underscores the possible systemic effects of intranasal corticosteroids. Prolonged use, high doses, concomitant use of CYP3A4 inhibitors, and the presence of genetic variations that affect steroid metabolism, could increase the risk of adverse effects. Early recognition and intervention are critical to prevent life-threatening adrenal crises.
Conclusion
Awareness of adrenal suppression as a potential side effect of intranasal corticosteroids is essential. This case emphasizes the need for judicious use of any type of glucocorticoids. Patient and family education, along with routine monitoring of at-risk patients, are crucial for mitigating risks.

Giant bilateral myelolipomas in a female patient with untreated classic 21-hydroxylase deficiency: a case report

Ann-Christin Welp[1], Lea Tschaidse[1], Petra Zimmermann[2], Till Braunschweig[3] & Nicole Reisch[1]
[1]LMU Klinikum, Medizinische Klinik und Poliklinik IV, München, Germany; [2]LMU Klinikum, Klinik für Allgemein-, Viszeral- und Transplantationschirurgie, München, Germany; [3]LMU München, Pathologisches Institut, München, Germany

Background
Chronically increased ACTH concentrations in poorly controlled patients with classic 21-hydroxylase deficiency (21-OHD) lead to adrenal hyperandrogenaemia and hyperplasia of the adrenal cortex. Markers of disease control correlate with the adrenal volume and poor disease control is associated with an increased incidence of adrenal tumours, in particular myelolipomas.
Clinical Case
We report the case of a 59-year-old female patient with classic 21-OHD (salt-wasting form). In childhood and adolescence, she had glucocorticoid (GC) and mineralocorticoid (MC) replacement therapy and had normal pubertal development. At the age of 25, she discontinued hormonal replacement therapy, which led to secondary amenorrhea, hair loss, hirsutism and deepening of the voice. She never experienced an adrenal crisis. As she suffered from severe alopecia at 56 years of age, GC and MC therapy was restarted, but the clinical and biochemically signs of hyperandrogenaemia persisted. At the age of 59 years an abdominal mass was palpated in a clinical routine check-up by the family practitioner, the patient was referred to the University Hospital and finally giant bilateral myelolipomas were diagnosed. The left-sided tumour measured 24.5 x 20.5 x 9.7 cm (2230 g), the right-sided measured 14.5 x 11.6 x 6.5 cm (501 g). Due to their massive size and the increased risk of rupture and haemorrhage, bilateral adrenalectomy was performed and the patient was educated for adrenal crisis prevention and sick day rules.
Conclusion
This case highlights the long-term consequences of untreated 21-OHD, as well as the importance of lifelong continuous therapy, good therapeutical management and adherence. In poor disease control in 21-OHD screening for adrenal tumours should be considered.

Achieving spontaneous pregnancy in a patient with classic congenital adrenal hyperplasia through modified-release hydrocortisone

Ann-Christin Welp[1], Lea Tschaidse[1], Hanna F. Nowotny[1], Christian Thaler[2], Nina Rogenhofer[2], Richard J. Ross[3] & Nicole Reisch[1]
[1]LMU Klinikum, Medizinische Klinik und Poliklinik IV, München, Germany; [2]LMU Klinikum, Division of Gynecological Endocrinology and Reproductive Medicine, Department of Obstetrics and Gynecology, Munich, Germany; [3]The University of Sheffield, Sheffield, United Kingdom

Background
Female patients with classic congenital adrenal hyperplasia (CAH) experience significantly reduced fertility due to hormonal dysregulation, psychosocial and psychosexual factors and anatomical changes following surgery for virilised external genitalia. Normal fecundity can be achieved with optimal hormonal management; however, achieving optimal hormonal control is challenging, leading to a prolonged time to pregnancy compared to the general population.
Clinical Case
We report the case of a 33-year-old woman with simple virilising CAH and infertility for over three years. CAH was diagnosed at the age of two; since then, she received glucocorticoid (GC) replacement therapy and had a normal pubertal development. On prednisolone substitution and antiandrogenic contraception, she maintained good hormonal control, showed no clinical signs of hyperandrogenism and had a regular menstrual cycle. At the age of 30, she stopped contraception in order to conceive. She experienced inadequate hormonal control, irregular menstrual cycles and no spontaneous pregnancies occurred. To optimise disease control her treatment was adjusted multiple times, including the use of prednisolone and dexamethasone, dose escalations and additional fludrocortisone. Assisted reproductive technologies, including two cycles of *in vitro* fertilization, were unsuccessful. While the concentrations of follicular 17OHP and androgens normalised with increased GC dosage, morning serum follicular progesterone concentrations remained elevated. The patient was then switched to the newly available modified-release hydrocortisone (MR-HC Efmody®) at a daily dose of 35 mg/day (10-0-0-25mg). A non-stimulated spontaneous dichorial twin pregnancy occurred within 9 weeks. The course of pregnancy was uneventful and the patient delivered two healthy girls via caesarean section. After delivery and breastfeeding hormonal parameters revealed morning serum follicular progesterone concentrations within the target range under MR-HC treatment.
Conclusion
The presented case of a female patient with classic CAH and infertility for over three years highlights the challenges of fertility treatment in CAH. The normalisation of morning follicular progesterone concentrations and the successful spontaneous pregnancy under MR-HC treatment, indicate that due to the circadian release MR-HC normalises adrenal steroid precursor synthesis in a more physiologic manner. Therefore, it could be a promising therapeutic option for fertility treatment in women with classic CAH.

Bilateral macronodular adrenal cortical disease: a case series

Evangelia Makri[1], Fotini Adamidou[1], Georgios Kostopoulos[1], Efstathios Divaris[1], Ioannis Papadopoulos[1] & Zoe Efstathiadou[1]
[1]Endocrinology Clinic, General Hospital of Thessaloniki "Ippokrateio", Thessaloniki, Greece

Introduction
Bilateral macronodular adrenal cortical disease (BMACD) is a heterogeneous condition characterized by the presence of multiple nodules larger than a centimeter in diameter and is associated with mild autonomous cortisol secretion. Its prevalence has recently increased due to the wide use of imaging studies.
Purpose
This study aimed to describe the clinical and biochemical characteristics, as well as comorbidities and responses to dynamic tests aiming to investigate paradoxical adrenal cortical receptor expression, in a series of patients with BMACD monitored at our center.
Methods
This study included a series of patients referred for investigation of bilateral adrenal tumors. Patients were screened for pheochromocytoma, primary hyperaldosteronism, and autonomous cortisol secretion. The possibility of late-onset congenital adrenal hyperplasia was ruled out by measuring 17-OH progesterone. In order to detect paradoxical receptor expression patients underwent dynamic tests, including the Synacthen test, mixed meal test, posture test, LHRH assay, TRH test, glucagon test, desmopressin test, and metoclopramide test. The response to these tests was evaluated based on changes in cortisol values, with an increase of $<25\%$ considered a non-response, 25-49% a partial response, and $\geq 50\%$ a complete response.
Results
The study included 6 female patients with bilateral macronodular adrenal hyperplasia, with a mean age of 56.7 ± 6.6 years and BMI of 30.6 ± 9.8. Three patients had arterial hypertension, and four had dyslipidemia under treatment. Only one patient showed clinical features of Cushing's syndrome. Based on the overnight dexamethasone suppression test, 3 patients were diagnosed with autonomous cortisol secretion, while 2 others had probable autonomous cortisol secretion. During the various dynamic tests, two patients exhibited a response to the mixed meal, one responded to metoclopramide, one responded to both metoclopramide and desmopressin, and one responded to the LHRH test. Notably, one patient did not show a response to any of the tests performed.
Conclusion
The majority of BMACD patients exhibit a mild autonomous cortisol secretion. Identifying paradoxical receptor expression can enhance our understanding of adrenal steroidogenesis and potentially guide personalized treatment.

A patient with pheochromocytoma and MDH2 variant (c.478G > A)

Eleftheria Kakargia[1], Athanasios Fountas[1], Metaxia Tampourlou[1], Amalia Sertedaki[2], Irini Giagourta[1], Dimitra Zerva[1], Labrini Papanastasiou[1] & Athina Markou[1]
[1]Department of Endocrinology and Diabetes Center, Center of Excellence of Rare Endocrine Adrenal Disorders, 'Georgios Gennimatas' General Hospital of Athens, Athens, Greece; [2]Division of Endocrinology, Diabetes and Metabolism, Aghia Sophia Children's Hospital, ENDO-ERN Center for Rare Pediatric Endocrine Disorders, First Department of Pediatrics, Medical School, National and Kapodistrian University of Athens, Athens, Greece

Introduction
Pheochromocytomas and paragangliomas (PPGLs) are rare catecholamine-producing tumours with metastatic potential. Approximately 40% of PPGLs are caused by germline variants. In this report, we present a patient with pheochromocytoma and a *MDH2* variant.
Case Presentation
A 66-year-old man was referred to the Endocrinology Department for investigation of a 5.4 cm right adrenal incidentaloma, detected in a chest CT scan performed due to COVID-19 infection, with imaging features not indicative of adenoma (CT density >20 HU, no signal suppression on out-of-phase T1-weighted MRI imaging). During admission, he presented daily episodes of paroxysmic hypertension, tachycardia, headache and pallor lasting approximately 10-20 minutes. Hormonal evaluation revealed markedly elevated 24h urine metanephrine [4149 μg/24h (52-341)] and normetanephrine [6703 μg/24h (88-444)] levels (measured by HPLC) and a diagnosis of pheochromocytoma was made. After two weeks of doxazocin preparation, an uncomplicated laparoscopic right adrenalectomy was performed. Histology revealed a pheochromocytoma (PASS score 7) with Ki-67 of 6%; intense edema and hemorrhagic infiltration in neoplastic cells was also observed. Whole exome sequencing identified the missense *MDH2* gene (NM_005918.4) variant, c.478G > A, resulting in replacement of valine by methionine at codon 160, p.Val160Met, of MDH2 protein. At the most recent clinical review, six months after adrenalectomy, the patient is asymptomatic with normal 24h urine metanephrine and normetanephrine levels and no evidence of disease recurrence.
Conclusion
MDH2 encodes the mitochondrial malate dehydrogenase which is essential for the conversion of malate to oxaloacetate as part of the proper functioning of the Krebs cycle and it has been, recently, added to the list of potential PPGL susceptibility genes. To our knowledge, this is the second report of a patient with a *MDH2* variant and pheochromocytoma. The p.Val160Met variant of *MDH2* is reported in 0.011% of alleles in European (Non-Finnish) individuals in gnomAD database. Although this specific variant is considered to be of uncertain significance according to ACMG criteria, a recent study showed that p.Val160Met variant causes protein 3D structure destabilization and impairment of MDH2 molecular function, classifying it as likely pathogenic. Further genetic studies are needed to determine the role of p.Val160Met *MDH2* gene variant in the pathogenesis of PPGLs.

Amiodarone-induced thyrotoxicosis type 2 and iatrogenic cushing syndrome in patient with advanced heart failure and left ventricular assist device

Emir Muzurovic[1] & Zlata Kovacevic[2]
[1]Clinical Center of Montenegro, Faculty of Medicine, University of Montenegro, Podgorica, Endocrynology, Podgorica, Montenegro; [2]Clinical Center of Montenegro, Faculty of Medicine, University of Montenegro, Endocrinology, Podgorica, Montenegro

Background
Amiodarone-induced thyrotoxicosis (AIT) is a complication of amiodarone therapy that can be difficult to diagnose and treat, especially in patients with advanced heart failure (HF), because of symptoms that mimic low cardiac output syndrome.
Patient findings
We describe a 19-year-old patient with advanced heart failure due to dilatative cardiomyopathy with surgically implanted left ventricular assist device (LVAD), awaiting heart transplantation. Due to the earlier manifestation of atrial fibrillation (AF), the patient was previously treated with amiodarone, during 18 months, which led to the development of amiodarone-induced thyrotoxicosis (AIT) type 2, as a result of destructive thyroiditis. Despite treatment with various modalities of corticosteroid therapy, AIT was highly resistant to treatment. Due to severe thyrotoxicosis, it was not possible to perform surgical treatment, total thyroidectomy. Prolonged treatment of thyrotoxicosis with various recommended treatment modalities, continuous corticosteroid therapy led to the development of iatrogenic Cushing's syndrome. Also, at that time, the diagnosis of thrombophilia was made, and heparin-induced thrombocytopenia (HIT) was confirmed.
Conclusion
Treatment of patients with severe HF and LVAD, associated with AIT and associated iatrogenic Cushing's syndrome, is an endocrinological emergency, with many challenges and requiring a multidisciplinary approach to treatment. AIT is associated with an increased risk of cardiovascular (CV) events, especially in patients with severe HF, so early diagnosis and adequate and timely treatment are very important.

Case report: trauma - induced adrenal hematoma and pseudopheochromocytoma phenomenon

Bojan Markovic[1], Mirjana Stojkovic[1,2], Tamara Janic[1], Sanja Klet[1], Jovana Babic[1], Ivana Djurkovic[1], Snjezana Erceg[3], Nata Joksimovic[2], Jasmina Ciric[1,2], Biljana Nedeljkovic Beleslin[1,2] & Milos Zarkovic[1,2]
[1]Clinic of Endocrinology, Diabetes and Metabolic Diseases, University Clinical Center of Serbia, Thyroidology, Belgrade, Serbia; [2]Faculty of Medicine, University of Belgrade, Thyroidology, Belgrade, Serbia; [3]Center for Radiology Imaging, University Clinical Center of Serbia, Belgrade, Serbia

Introduction
Adrenal masses are a common finding during routine radiological procedures. While most are commonly benign, some may be malignant and/or have autonomous hormonal secretion. A rare pathology includes adrenal hemorrhage, leading to the subsequent organization of blood collections into hematomas. The most cases of adrenal hematomas are unilateral and traumatic in origin, though systemic infections and hemostatic disorders may affect both adrenal glands.
Case Presentation
A 57-year-old male patient was admitted to our hospital due to an incidentally discovered adrenal mass. A year before his admittance, he suffered a contusion of the right hemiabdomen, which was followed by persistent chronic chest pain, high blood pressure, headache, excessive sweating, and a rapid heartbeat. The chest CT showed pleural effusion and adrenal mass. Abdominal CT showed an altered morphology of the right adrenal gland, which was enlarged to 46x24x52 mm, suggestive of an adrenal hematoma. Surrounding fat tissue showed a characteristic periadrenal reactive change, typically seen in hematomas. Initial functional tests revealed primary hypocorticism (low morning cortisol: 73.9 nmol/l with compensatory elevated ACTH: 54 pmol/l) and normal electrolytes (Na: 135 mmol/l; K: 4.6 mmol/l). Urinary catecholamine levels were elevated (adrenaline: 18.02, noradrenaline: 803.4, dopamine: 3261.7 nmol/24h). Two months later, follow-up CT has detected a reduction in diameter of hypodense lesion in the right adrenal gland, measuring approximately 28x15 mm, suggesting a hematoma in the resorption phase. During hospitalization in our institution, the abdominal MRI showed a hypoplastic right adrenal gland, FDG PET-CT, performed due to elevated catecholamine levels, showed no evidence of increased metabolic activity suggestive of pheochromocytoma. Control catecholamine and their metabolite levels were normal (adrenaline 76.6; noradrenaline 332.3; dopamine 2492; metanephrine 0.21; normetanephrine 0.56; 3-methoxytyramine 0.92 nmol/24h). Evaluation of the HPA axis indicated the continued presence of hypocorticism (ACTH 15.1 pmol/l; Synacthen test: Cortisol: 152…239…120…38 nmol/l). Regarding the duration of hypocorticism in the presence of normal left adrenal gland additional tests, including immunology and virology, were conducted; the results were negative.
Conclusion
We concluded that hematoma formation resulted from trauma, leading to primary hypocoticism, and the increased catecholamine levels in these circumstances were likely due to adrenal medulla cell lysis. The case illustrates that adrenal hematoma can clinically and biochemically mimic pheochromocytoma. This phenomenon, known as**"pseudopheochromocytoma**," is typically characterized by symptoms of sweating, headaches, palpitations, and hypertension, all of which were observed in our patient.

Keywords
adrenal hematoma, primary hypocorticism, pseudopheochromocytoma.

Unfavorable metabolic outcomes in pediatric patients with classic congenital adrenal hyperplasia - study method proposal

Sanja Panic Zaric[1], Rade Vukovic[1,2], Jelena Vekic[3], Tatjana Milenkovic[1], Sladjana Todorovic[1], Katarina Mitrovic[1,2], Dimitrije Cvetkovic[1], Maja Cehic[1], Dragana Bojanin[4] & Katja Dumic[5]
[1]Department of Pediatric Endocrinology, Mother and Child Health Care Institute of Serbia "Dr Vukan Cupic", School of Medicine, University of Belgrade, Belgrade, Serbia; [2]School of Medicine, University of Belgrade, Belgrade, Serbia; [3]Department of Medical Biochemistry, Faculty of Pharmacy, University of Belgrade, Belgrade, Serbia; [4]Department of Medical Biochemistry, Mother and Child Health Care Institute of Serbia "Dr Vukan Cupic", Belgrade, Serbia; [5]Department of Pediatric Endocrinology and Diabetes, University Hospital Centre Zagreb, University of Zagreb School of Medicine, Zagreb, Croatia

Background
Congenital adrenal hyperplasia (CAH) caused by 21-hydroxylase deficiency is an autosomal recessive condition with a prevalence of approximately 1 in 15 000. Children with classic form of CAH (CCAH) experience an increased cardiometabolic risk compared to general population. We conducted a systematic review of published studies regarding the cardiometabolic phenotype in children with CCAH, identifying 25 studies on the subject. Qualitative analysis showed that children with CCAH have elevated multiple cardiometabolic risk factors. Findings concerning lipid metabolism are variable and limited in children with CCAH as well as in adults and there are no data regarding lipoprotein subclasses. Small, dense low-density lipoprotein (LDL) particles are highly susceptible to oxidation, while high-density lipoproteins (HDL) exhibit potent antioxidant properties. This research method was designed to explore the metabolic phenotype regarding alterations in lipoprotein size and subclasses distribution and redox status markers in children with CCAH.
Methods
after obtaining the consent of parents/guardians and children, 20 children with CCAH of both genders were included, with a control group consisting of 20 children without CAH who were assessed due to signs of premature puberty. Basic demographic data were collected on all subjects, as well as other anamnestic and clinical data of importance in the evaluation of CCAH (independent variables: age, gender, anthropometric features, CCAH type (SW or SV), serum androgen levels, total daily dose of hydrocortisone and the outcomes of interest: body mass index, waist and hip circumference, body composition, fasting glycaemia, HOMA IR, heart rate, blood pressure, lipoprotein subclasses and particles, inflammatory status). The size and subclass distribution of lipoprotein particles will be determined by gradient gel electrophoresis. Paraoxonase-1 (PON1) activity will be assessed as a biomarker of HDL's antioxidant properties. The redox status of study participants, including prooxidative markers (TOS, PAB), oxidative damage indicators (AOPP), and antioxidative defense biomarkers (SH-groups, SOD), will be evaluated using spectrophotometric methods.
Results
Comparisons between groups will be conducted using t-tests or Mann-Whitney U tests for continuous variables and Chi-square tests for categorical variables. Spearman correlation coefficients will assess associations between variables, followed by multiple linear regression to identify independent predictors. Binary logistic regression will evaluate associations between independent variables and metabolic outcomes, while ROC (Receiver Operating Characteristic) analysis will assess the diagnostic accuracy of selected biomarkers. Statistical analysis will be performed by SPSS v.18 (Chicago, IL, USA).
Conclusion
Further studies of cardiometabolic phenotype in CCAH are needed especially in children, where present data are scarce.

CAH care in a district general setting: care, safety and preferences

Muhammad Wazirdin[1], Nausheen Akhtar[1], Ajay Ramesh[1], Krishnakanth Khasnavis[1] & Mohit Kumar[1]
[1]WWL Teaching Hospitals NHS Foundation Trust, Department of Diabetes and Endocrinology, Wigan, Greater Manchester, United Kingdom

Introduction
CAH is a heterogeneous collection of rare congenital diseases. Historically, numerous studies have highlighted suboptimal care for patients with these conditions, with guidelines aimed to improve physical health and quality of life, and reduce complications, and as with most rare diseases, suggestion that care is best provided at dedicated clinics and the transition process is a key feature.
Aim
To review the care of patients with CAH at our centre (a District General Hospital)
Methods
The biochemistry database was interrogated to find all patients who had a measurement of 17 OHP over the last 5 years. Patients records were then checked to identify all patients with confirmed CAH (excluding non-classical), and data including mode of referral, laboratory results, treatment, scans and mental health comorbidities collected for these patients.
Results
13 patients were identified, with one exclusion due to being under the paediatric team. Male:female ratio was 4:8. 5/12 had 21-hydroxylase deficiency, in all others the genotype was unknown. 8 patients were looked after historically for >10 years at the centre, 3 referred directly from tertiary paediatric clinics and 1 re-referred after being lost to the transition process. Treatment was with prednisolone in 7/12, hydrocortisone 3/12 and dexamethasone 2/12. None were treated with modified release hydrocortisone or combination therapy. All patients has annual checks for testosterone, 17-OHP, androstenedione, gonadotrophins, U+Es and aldosterone/renin ratio. 8/12 patients had elevated 17-OHP levels, with 4/12 within the reference range. All patients had measurement of lipids, glycaemic assessment and BP checked annually. BMI was checked in 11/12 patients. Only one of the male patients had US assessment for TARTS in the preceding 2 years. Emergency hydrocortisone kits were documented for 10/12 patients, 11/12 patients had the NHS Steroid Alert Card. No patients had been admitted in a hypoadrenal crisis in the preceding 5 years. 8/12 patients had bone densitometry assessed (the younger patients being excluded). 2/10 patients had mental health problems. Care was provided by a total of 4 consultants (three cared for one patient each).
Discussion
Patient preference plays a key part in the location of care for some patients with CAH, and not all want to travel to specialist clinics. Biochemical assessment and radiological assessment was acceptable but not complete in some cases. A single consultant overseeing all cases and a checklist may help address gaps. Patients with CAH in DGHs need access to newer therapies via education for caregivers and research opportunities.

Essential hypertension or primary hyperaldosteronism? Detecting the undetectable

Ghita Khamel[1], Nada Ait Kassi[1], Ghizlane Sabbar[1], Kawtar Rifai[1], Hind Iraqi[1] & Mohamed Hassan Gharbi[1]
[1]CHU Ibn Sina, Rabat, Morocco

Introduction
Arterial hypertension is a common pathology affecting a significant proportion of the population. It can be classified into different forms, including essential hypertension and secondary hypertension essential hypertension accounts for around 90-95% of cases, and is often multifactorial in origin Obesity is a major risk factor, with obese women 3 times more likely to suffer from hypertension. Conversely, endocrine-induced hypertension is rarer. In this observation, we report a case of endocrine hypertension, under-diagnosed due to the presence of multiple cardiovascular risk factors and a borderline age.
Observation
This is a 49-year-old obese patient, with BMI of 39, treated for dyslipidemia, with 11 years history of hypertension discovered at the age of 38, revealed by grade 3 hypertension, initially followed by a cardiologist who put her on dual therapy without any secretory test. The patient was referred to us as part of goitre exploration, and secondary hypertension was suspected in view of the age of onset before 40, with uncontrolled hypertension on tritherapy. Examination revealed a BP of 170/69, grade 2 obesity with no signs of hypercorticism. The workup revealed hypokalemia at 3.5 cardiac and renal Doppler were normal a secretory work-up was requested after correction of the hypokalemia and adaptation of the treatment to avoid any risk of drug interactions. The aldosterone renin ratio was positive at 231, indicating primary hyperaldosteronism. Abdominopelvic CT revealed a 15 mm left adrenal nodule. The patient was referred for surgery with good clinical improvement.
Discussion
Overweight and obesity, especially in women, are a clear risk factor for hypertension. Endocrine hypertension can often be confused with essential hypertension, especially in obese patients, due to a similar symptomatology. To avoid overlooking an endocrine cause, a thorough clinical and biological evaluation is essential. Consideration should be given to age of onset, resistance to treatment, presence of hypokalemia. Failure to consider endocrine causes in the context of obesity can have serious hydroelectrolytic and long-term cardiovascular consequences (cererbral stroke, infarction).
Conclusion
Diagnosis of endocrine hypertension in obese patients can be complex, given the similarity of symptoms between essential hypertension and certain endocrine pathologies. consideration of specific tests can differentiate these two entities and ensure optimal management

Non-functioning adrenal cortical adenomas: analysis of 31 cases

Yesmine Elloumi[1], Mouna Elleuch[1], Yasmine Abdelkafi[1], Malek Hadrich[1], Kouloud Boujelben[1], Hadjkacem Faten[1], Nadia Charfi[1], Mouna Mnif[1], Mohamed Abid[1], Dhoha Ben Salah[1] & Nabila Rekik Majdoub[1]
[1]Hedi Chaker University Hospital, Endocrinology Department, Sfax, Tunisia

Background
While the non-functioning adrenal cortical adenomas do not secrete hormones, they can cause subtle, prolonged cortisol release, potentially contributing to metabolic disturbances. This highlights the need for routine screening and ongoing surveillance to manage and identify early signs of metabolic syndrome associated with this entity.
Methods
This was a retrospective and descriptive study that included 31 patients followed for non-functioning adrenal cortical adenomas in the Endocrinology Department of Hedi Chaker University Hospital in Sfax, Tunisia.
Results
The mean age of patients was 57.9 years. A female predominance was observed 60% of cases. The average BMI was 28.35 kg/m^2, and 25% of patients were classified as overweight. Obesity was identified in 25% of cases, with 3% having morbid obesity. An android obesity pattern was observed in 74% of patients. The average systolic blood pressure was 145.6 mmHg, and 32% of patients had a diastolic blood pressure $\geq$ 85 mmHg. All patients had metabolic syndrome. The mean 11 PM cortisol level was 69 ng/ml, and no patients had pathological cortisol levels. The average post low dose dexamethasone suppression test cortisol level was 10.06 ng/ml, with no patients showing a pathological suppression test. None of the patients had elevated ACTH levels ($\geq$ 50 pg/ml). Fasting blood glucose was pathological ($\geq$ 6.1 mmol/l) in 64.5% of cases. Elevated triglyceride levels ($\geq$ 1.7 mmol/l) were found in 41.9% of patients, and total cholesterol was elevated in 48.3% of patients.
Conclusion
Patients with non-functioning adrenal cortical adenomas often present with metabolic abnormalities, highlighting the importance of thorough screening and continuous monitoring to manage associated risks effectively.

Biochemically negative retroperitoneal paraganglioma: a case report

Chanez Kalboussi[1], Bilel Ben Amor[1], Hamza Elfekih[2], Ines Bayar[1], Taieb Ach[2], Ekram Hajji[1], Ghada Saad[2], Héla Marmouch[1], Yosra Hasni[2], Hanene Sayadi[1] & Inès Khochteli[1]
[1]University Hospital of Monastir, Endocrinology Department, Monastir, Tunisia; [2]University Hospital of Sousse, Endocrinology Department, Sousse, Tunisia

Introduction
Paragangliomas (PGL) are rare neuroendocrine tumors located along the sympathetic or parasympathetic ganglia (1). While these tumors are commonly associated with excessive production of catecholamines, some can be biochemically silent. Biochemically negative PGL (BNPGL) are defined by normal levels of plasma and urinary metanephrines and normetanephrines, as well as plasma methoxytyramine(2). This case report presents a 59-year-old woman who was diagnosed with a biochemically negative retroperitoneal PGL.
Case presentation
She had a 14-year history of hypertension and presented with chronic right lumbar pain evolving for the past 2 years. She had no other clinical signs. Laboratory tests revealed prediabetes with an HbA1c level of 6.3%. The patient's plasma and urinary metanephrine, normetanephrine and 3-methoxytyramin levels were within normal ranges. Imaging studies revealed a 28 mm tumor with a spontaneous density of 34 Hounsfield units (HU) on abdominal CT, which exhibited intense and heterogeneous enhancement. The tumor was located near the diaphragm's pillar and the right border of the inferior vena cava. Further evaluation with MRI showed heterogeneous tumor with hyperintense T2 signal. An octreoscan demonstrated localized hyperfixation, with no additional areas of fixation noted. The tumor was successfully removed through a laparotomy. The histopathological examination of the surgical specimen confirmed the diagnosis of a paraganglioma with a PASS score of 1.
Discussion
Biochemically silent PGL are often difficult to diagnose due to their lack of characteristic biochemical markers, which makes them challenging to distinguish from other retroperitoneal masses. These tumors are more frequently found in the head and neck region, and are often associated with mutations in the SDHx genes (3). Imaging studies play a crucial role in the diagnosis of silent PGLs. Their discovery often occurs incidentally, as in this case, when imaging is conducted for unrelated clinical concerns. The management of BNPGL typically involves surgical resection with careful preoperative management with alpha- and beta-blockers in order to mitigate the risk of perioperative complications
Conclusion
Biochemically silent PGL, although rare, should be considered in the differential diagnosis of retroperitoneal masses, especially when imaging findings are suggestive of a paraganglionic origin.

Osilodrostat as a bridge to surgery in patient with ectopic cushing's syndrome
Jan Drugda[1], Pavel Cee[1] & Filip Gabalec[1]
[1]University Hospital Hradec Králové, The 4th Department of Internal Medicine, Hradec Králové, Czech Republic

Introduction
Ectopic Cushing's syndrome is a rare condition caused by a paraneoplastic secretion of ACTH by a tumor outside the pituitary or adrenal glands. The symptoms associated with hypercortisolism are similar to other types of Cushing's syndrome but they can be more severe and have a rapid onset. Excluding pituitary adenoma and discovering the ectopic source of ACTH is crucial in the diagnostics. The treatment of choice is a surgical removal of the ACTH-secreting tumor. The surgery and recovery could however be complicated by the overt hypercortisolism and that is why a pharmacological treatment is recommended before the surgery in severe cases. There are several steroidogenesis inhibitors available including osilodrostat which is the most novel one.
Observation
We present a case of a 45-year-old man without any significant comorbidities. He was presented to an endocrinologist by his general practitioner because of a rapidly onseting and drug-resistant arterial hypertension and hyperlipidemia along with typical traits of Cushing's syndrome (central obesity, rounded face, swelling…). His early morning cortisol was elevated and not suppressible by dexamethasone and free urine cortisol was 11 times the upper limit of normal. ACTH was extremely elevated however other pituitary hormones were normal. No adenoma was visible on the pituitary MRI nevertheless there was a solitary 22 mm nodule in the upper left pulmonary lobe on the PET/CT scan. The S3 segmentectomy was indicated and to reduce the complications and improve recovery we started the osilodrostat therapy three weeks before the surgery. After one week we increased the initial dose from 20 to 40 mg daily. On the day of surgery we managed to decrease the free urine cortisol to 2 times the upper limit of normal and significantly reduce the antihypertensive therapy. The surgery was performed without any complications and an atypical lung carcinoid was then histologically described with highly positive ACTH staining. We stopped osilodrost the day after surgery and started hydrocortisone replacement instead. ACTH, serum, salivary, and urine cortisol then gradually normalised and we were able to withdraw hydrocortisone slowly. We now only follow the patient in cooperation with the pulmonary oncologist.
Conclusion
Pharmacological treatment is primarily used in patients with Cushing's syndrome who are contraindicated for surgery. However, it can be beneficial as a bridge to surgery, aiming to reduce complications and improve recovery. The novel steroidogenesis inhibitior osilodrostat, in our case, proved itself to be very capable of doing so if properly dosed.

Unusual adrenal incidentaloma: the ganglioneuroma
Chayma Zouna[1], Hasna Ouirar[1], Ikram Qasdi[1], Zineb Habbadi[1], Fatima Toulali[1], Ghizlane Sabbar[1], Kaoutar Rifai[1], Hind Iraqi[1] & Mohamed Hassan Gharbi[1]
[1]CHU Rabat, Endocrinologie, Rabat, Morocco

Introduction
Ganglioneuroma is a rare, benign neurogenic tumor arising from sympathetic ganglion cells. It occurs mainly in the retroperitoneal region. Adrenal localization is rare. We report a case of adrenal ganglioneuroma in a 50-year-old man. The tumour was discovered incidentally on a thoracoabdominal CT scan ordered in the context of exploration for abdominal pain. The diagnosis was confirmed by pathological examination.
Observation
53-year-old patient admitted for investigation of an adrenal mass. Clinically, no hypertension, no Menard's triad and no signs of hypercorticism, with the exception of skin lesions suggestive of a hamartoma. Morphologically, abdominal CT revealed a left retroperitoneal mass, roughly oval, well limited, with regular contours, latero aortic on the left, heterogeneously enhanced after injection of contrast medium in relation to hypodense necrotic areas, measuring 110 *76mm in transverse diameter for 107mm in height. It displaces the pancreas anteriorly, making an imprint on the kidney and displacing it posteriorly, with no sign of invasion; it also displaces the spleen laterally, making intimate contact with the splenic vein anteriorly and the renal vein inferiorly; no vascular thrombosis. A CT scan focused on the adrenal glands or MRI could not be performed due to impaired renal function. Secretory work-up: Plasma methoxylates are negative. Minute braking with cortisol after braking 10ng/ml. Kalemia is normal Tumour markers are negative, as are LDH and b 2 microglobulin. A scan-guided biopsy was indicated and histological examination came back in favor of a ganglioneuroma. A meeting will be held with the urologists to decide on appropriate management.
Discussion
Ganglioneuroma is a rare benign tumor that deserves to be recognized and evoked in the presence of an adrenal mass discovered by chance. It is diagnosed histopathologically after an invasive procedure. However, as with all non-secretory incidentalomas, surgery should always follow an endocrine and radiological work-up. The possibility of local recurrence requires regular monitoring.

Stage IV lung cancer with metastases confined to the adrenal glands: a case report
Miruna-Alicia Marin[1], Alexandra Irina Gîdei[1], Anca Maria Andrei[1], Andreea Maria Manole[1], Ramona Dobre[1,2], Iulia-Florentina Burcea[1,2] & Catalina Poiana[1,2]
[1]National Institute of Endocrinology "C.I. Parhon", Bucharest, Romania; [2]University of Medicine and Pharmacy "Carol Davila", Bucharest, Romania

Clinical case
A 67 years old male patient with a history of right upper lobe lung adenocarcinoma (LUAD) with pleural invasion, treated with surgery, chemo- and radiotherapy, presented a small left adrenal mass documented since the initial LUAD diagnosis. The lesion never posed any interest for three years as it never caused adrenal dysfunction, it was stable in size (14 mm) and it never proved any metabolic activity on two earlier 18F-FDG PET/CT scans. In the fourth year since the LUAD diagnosis, a routine thorax-to-pelvis PET/CT revealed a single metabolically active lesion which was the already documented adrenal mass (SUVmax: 4.19), previously deemed benign, prompting the patient's referral our clinic. No endocrinological evaluation had been performed since the diagnosis. The patient lacked clinical signs of adrenal dysfunction and had normal adrenal hormone levels. Given the left nodule's history and the patient's refusal of surgery, a short-term 'watchful waiting' approach was decided. Three months after the initial presentation, a CT scan showed significant growth of the previously known left nodule (24×21×14 mm vs 14 mm), a new left adrenal mass of 14×9×15 mm and a new right adrenal mass of 16×11×16 mm. An additional head-to-pelvis PET/CT showed intense activity confined only to the left (SUVmax: 10.31 vs 4.19, respectively SUVmax: 4.88) and right (SUVmax: 5.33) adrenals. As metastatic LUAD was suspected due to the rapid changes in an incredibly short period, the therapeutic decision was bilateral adrenalectomy. Due to the patient's reluctance to the recommended treatment, only a left adrenalectomy was performed. The histopathological and immunohistochemical analysis confirmed LUAD histogenesis, with positive expression of TTIF-1 and Napsin A. Three months post-operation, an MRI revealed an increase in the size of the right adrenal nodule (23×24 mm). As the patient refused additional surgery, stereotactic radiotherapy was performed on the remaining lesion following a radiotherapy consultation, resulting in partial adrenal insufficiency.
The adrenal glands are a common site for metastasis in patients with lung cancer. There is controversy regarding the route by which the cancerous cells of the primary disease reach the adrenal gland. Unilateral adrenal metastases are deemed rare and when they do occur, the ipsilateral adrenal is typically affected first. In this case, despite the initially stable solitary lesion limited only to the left contralateral adrenal, alongside the LUAD, we would have advocated for active surveillance since the exact nature and potential progression of the adrenal mass remains uncertain.

Bilateral carotid paraganglioma: a rare entity

Rachida Bouattay[1], May Ferjani[1], Linda Misbah[1], Khaled Harrathi[1] & Jamel Koubaa[1]
[1]ENT and Head and Neck Department, University Hospital of Fattouma Bourguiba, Monastir, Tunisia

Introduction
Paraganglioma is a tumor that develops at the expense of the "carotid body", which is a chemoreceptive structure located at the posteromedial aspect of the carotid bifurcation. Bilateral character is rare. We aim to report clinical and paraclinical features and thearpeutic management of bilateral carotid paraganglioma through a case report and literature review.
Observation
A female aged 68, operated for a left breast carcinoma in 2011 followed by radio-chemotherapy, in remission since 2012, consulted for a left latero-cervical swelling evolving for 2 years without signs of compression. The physical examination showed a left subangulo-mandibular swelling of 5cm, firm, painless, mobile laterally, fixed longitudinally and having a pulsatile character on palpation. A second upper right jugulo-carotid swelling of 2cm with the same characteristics was objectified on examination. The rest of the examination was without abnormalities. The cervical ultrasound showed a left formation of tissue nature, hypoechogenic, well-limited hypervascularized on Doppler, measuring 4cm located at the level of the carotid bifurcation suggesting a paraganglioma. Cervical MRI showed a large tumor mass of the left carotid bifurcation in T1 isosignal, in heterogeneous T2 hypersignal with "Flow void" with intense and heterogeneous enhancement responsible for a widening of the carotid bifurcation. MRI showed a second lesion with the same characteristics located at the level of the right carotid bifurcation. The dosage of blood and urine metanephrines returned normal. The paraganglioma was classified stage I on the right and stage II on the left according to the Shamblin classification. The patient was proposed for external radiotherapy given the bilateral nature of the tumor.
Conclusion
Carotid paragangliomas are rare neuroendocrine tumors, most often benign and non-secreting, with a slow progression. Imaging is of considerable assistance to diagnosis. Management is multidisciplinary, only surgical treatment is curative. When it is not possible, radiotherapy to reduce tumor progression may be an alternative to treatment.

Imaging phenotype over size: two cases of cavernous hemangiomas of the adrenal glands

Velimir Altabas[1], Lora Kirigin Biloš[2], Jelena Marinkovic Radosevic[2] & Ivana Kavelj[3]
[1]University Hospital Center "Sestre Milosrdnice", University of Zagreb, School of Medicine, Zagreb, Croatia; [2]University Hospital Center "Sestre Milosrdnice", Department of Endocrinology, Diabetes and Metabolic Diseases "Mladen Sekso", Zagreb, Croatia; [3]University Hospital Center "Sestre Milosrdnice", Department of Radiology, Zagreb, Croatia

Cavernous hemangiomas are rare benign vascular lesions that are difficult to diagnose preoperatively. We present two cases of cavernous hemangiomas of the adrenal glands and provide radiographic clues that can hint at the correct diagnosis. The first case is an 80-year-old woman presenting with an enlarging hemorrhagic left adrenal mass measuring 72×63×66 mm. Computed tomography (CT) imaging showed that the mass exhibited marginal and nodular enhancement in the venous post-contrast phase, with no evidence of infiltration into surrounding structures. The hormonal workup was consistent with a non-functioning tumor. The mass was first identified 3 years prior and was described as heterogeneous and of unknown etiology, measuring 27×23 mm. The patient was presented at an adrenal multidisciplinary team meeting and because adrenal cortical carcinoma (ACC) could not be ruled out, the patient underwent a laparoscopic adrenalectomy. Pathohistological findings were consistent with a hemorrhagic cavernous hemangioma of the left adrenal gland. The second case is a 71-year-old woman presenting with an incidentaloma of the right adrenal gland measuring 12 mm with radiological characteristics suspicious of a pheochromocytoma (highly vascular tumor with non-contrast CT HU >20). The patient did not have clinical symptoms suggestive of pheochromocytoma, thus the diagnosis of silent pheochromocytoma was considered. The patient underwent a laparoscopic adrenalectomy with pathohistological findings consistent with a hemorrhagic cavernous hemangioma of the right adrenal gland. Adrenal cavernous hemangiomas are rare benign vascular tumors, and to the best of our knowledge, only 90 cases have been described. Due to the increase in abdominal imaging, the incidence of adrenal incidentalomas is on the rise, and cavernous hemangioms should be considered in the differential diagnosis of lipid-poor lesions. These cases highlight several points. Firstly, they demonstrate the importance of imaging phenotype. The CT reports of both cases described the lesions as heterogenous with high HU. This should raise the concern for potentially malignant lesions, metastatic lesions, or pheochromocytomas. Thus, surgical resection or close follow-up imaging should be considered despite tumor size and hormonal activity. Although these lesions are benign, the natural history is unknown because most cases have been operated. Even with close follow-up imaging, it is often difficult to rule out more sinister lesions. Thus, patients should be presented in multidisciplinary teams with a preference for surgical resection despite negative hormonal workup and size.

A rare case of silent metastatic pheochromocytoma with a breast metastasis

Panagiotis Karageorgiou[1], Maria Zotou[1], Vasiliki Antonopoulou[1], Sofia Georgiadi[1], Aggeliki Kyriakou[1], Angeliki Angelidou[1], Kanella Kantreva[1], Anna Louisa Chaliasou[1], Athina Valatsou[2], Georgios Kyriakopoulos[3], Marinella Tzanela[1] & Georgia Ntali[1]
[1]Department of Endocrinology "D. Ikkos"- Diabetes Center- EndoERN-Evangelismos General Hospital, Athens, Greece; [2]Private Clinic, Karditsa, Greece; [3]Department of Pathology, Evangelismos General Hospital, Athens, Greece

Background
Pheochromocytomas are rare neuroendocrine tumors arising from chromaffin cells of adrenal medulla. Their clinical presentation is heterogeneous with various symptoms and signs related to catecholamine excess. Rarely, pheochromocytomas are biochemically and clinically silent. According to WHO 2022 all pheochromocytomas can potentially metastasize in non-chromaffin tissues. Common sites of metastasis are lymph nodes, bones, lungs and liver. Herein, we present a rare case of silent metastatic pheochromocytoma with metastasis to lungs and breast.

Case
A 46-year-old female was diagnosed with a 5 cm left adrenal incidentaloma, four years ago. Its imaging phenotype was indeterminate and endocrine work up revealed no hormone hypersecretion. The patient underwent left adrenalectomy, and the pathology examination indicated a 7 cm pheochromocytoma with intermediate risk stratification Grading system for Adrenal Pheochromocytoma and Paraganglioma (GAPP score 4) and Pheochromocytoma of the Adrenal gland Scaled Score (PASS score 9). Postoperative reevaluation with I131-MIBG and 18F-FDG-PET/CT imaging were negative and the catecholamines levels were within normal levels. During the following years the patient remained asymptomatic and she underwent yearly testing with plasma or urine metanephrines/normetanephrines which remained negative. Four years post-surgery, a "suspicious" right breast lesion appeared on a screening mammogram, and the patient underwent surgical removal of the tumor. Pathology was positive for chromaffin tissue. At the same time, biochemical examination showed increased plasma 3-methoxytyramine levels (33.3 ng/l, normal range < 17), whereas the patient remained asymptomatic. 68Ga-Dotatoc and 18F-FDG-PET/CT imaging detected lung metastases, and a tyrosine kinase inhibitor (sunitinib) was initiated for further treatment. However, two months later, disease progression was noticed, and chemotherapy was recommended.
Conclusions
To our knowledge, there are only two reports in bibliography about pheochromocytomas with metastasis to the breast. In our case, the patient was asymptomatic and plasma metanephrines and normetanephrines levels were constantly normal. However, an increase of dopamine metabolite, 3-methoxytyramine, was observed at the time of metastasis. Dopamine has low affinity for a and β adrenergic receptors and this can explain why patients with dopamine-secreting pheochromocytomas are often asymptomatic.

"Adrenal incidentaloma complicated by adrenal crisis in a critically ill patient "- a case report
Neha Agrawal[1] & Aniruddha Rudra[2]
[1]Health World Hospital, Endocrinology, Durgapur, India; [2]Gouri Devi Medical College And Hospital, Durgapur, India

Introduction
The main goals of evaluating an incidentally detected adrenal mass, termed adrenal incidentaloma (AI), are to characterize the lesion as benign or malignant based on imaging characteristics, and to determine its functionality based on hormone secretion. Non-contrast computed tomography(NCCT) scan is the intial investigation of choice. Washout percentages following intravenous contrast administration are useful in certain cases. A comprehensive endocrine assessment is crucial to rule out hormone secretion abnormalities (e.g. Pheochromocytoma, Cushing syndrome, Primary Hyperaldosteronism). Tumours smaller than 4 cm and with non-contrast attenuation values under 10 HU often do not require long-term follow-up. Management is tailored to clinical presentation and associated comorbidities.
Case Details
A 59-year-old male known case of uncontrolled type 2 diabetes and hypertension presented to the emergency department with a diabetic foot ulcer over right great toe, diffuse abdominal pain, and vomiting. After initial stabilization with iv fluids, empirical antibiotics and insulin for glycemic control, he was planned for surgical debridement. CECT Abdomen revealed cholelithiasis and a right adrenal adenoma. Further, during the hospital stay, the patient's condition deteriorated with sudden shortness of breath, drowsiness, and desaturation, necessitating intubation.

Table 1.

Hba1C	12.1
CBC	Hb-9,tc-24000, platelet-1.6 lakh
Na+	120mEq/L
K+	5.6mEq/l
Cortisol (AM)	1.04 ug/dl
ACTH	208 pg/ml
ECG	Sinus tachycardia
ECHO	Normal LV Function
Trop I	High
24 Hour urinary metanephrines	Normal
USG w/a-	Cholelithiasis
Urine C/s	Candida Albicans
Wound Pus c/s	Acinetobacter Baumanni
CECT Abdomen	Right Adrenal Adenoma (34 mm x 20 mm), baseline HU - 30
CT Adrenal Protocol	Adrenal Nodule (30x 20 mm), homogenous fluid with attenuation value of 14 HU, possibility of resolving adrenal hemorrhage
CT Pulmonary Angiogram	Normal
Renal Function Test / LFT	Normal

Suspecting pulmonary embolism, thromboprophylaxis with IV heparin was initiated, though a CT pulmonary angiogram ruled out embolism. Post-intubation, the patient developed hypotension for which he was placed on inotropes but still maintained low blood pressure. Keeping in mind the clinical profile, an adrenal CT protocol was performed, and it revealed adrenal hemorrhage. Hormonal evaluation confirmed an adrenal crisis. Steroid replacement therapy was started. His condition gradually improved and underwent successful toe amputation.
Conclusion
Although adrenal incidentalomas rarely present as adrenal crisis, critically ill patients—particularly those with infection, sepsis, or septic shock—may develop this life-threatening condition. Prompt clinical recognition and targeted hormonal evaluation are essential for the early diagnosis and treatment of adrenal crisis, which can be a potentially lethal but treatable complication in ICU settings.

JOINT3756
A study on incidence and related characteristics of PPGLs in a well-defined population
Miriam Giordano Imbroll[1,2], Sarah Craus[1,2], Josanne Vassallo[1,2] & Mark Gruppetta[1,2]
[1]Diabetes and Endocrine Department, Mater Dei Hospital, Malta, Department of Medicine, University of Malta Medical School, Malta, Msida, Malta; [2]Department of Medicine, University of Malta Medical School, Malta, Msida, Malta

Phaeochromocytoma/paragangliomas (PPGLs) are relatively rare tumours and the health burden of such tumours is not very well known.
Aim
This population-based study aims to characterise all the phaeochromocytomas, paragangliomas and adrenal medullary hyperplasia diagnosed between 2010 and 2023 in Malta; looking into presentation, hormonal analysis, imaging characteristics and histology findings.
Results
29 patients were identified (22 phaeochromocytoma and 7 paragangliomas). 16 patients (55%) were males and age ranged from 21-81 years (median (IQR) 53.5 years (40-59.8)). The standardised incidence rate (SIR) was 0.35/100,000/year. The SIR for phaeochromocytoma was 0.27/100,000/year and that for paraganglioma was 0.09/100,000/year. Longest radiological tumour size ranged from 20-127mm (median (IQR) 51mm (33.5-65)). Median pre-contrast CT density was 34 Hounsfield units (IQR: 29.5-34.5). All patients except 2 underwent surgical resection of the tumours. The latter 2 patients presented late with metastasis and died soon after diagnosis. Genetic testing was done in the majority of patients and VHL, NF1 and SDHB mutations identified. 6 patients (20%) were found to have a malignant PPGL on follow up.
Conclusion
This study gives a detailed understanding of the epidemiology of PPGL in a very well-defined population. The significant rate of malignant disease emphasizes the need for long-term follow-up.

JOINT1652
Addison's disease initially interpreted as sarcoidosis
Ingrid Nermoen[1] & Kristine Hatlen[1]
[1]Akershus university hospital, University in Oslo, Endocrinology, Lørenskog, Norway

Background
Primary adrenal insufficiency (AI) is a rare and potentially life-threatening condition. The diagnosis can often be delayed for months. We describe a young man with a delayed diagnosis whose condition was initially suspected to be sarcoidosis. So far only four cases of elevated ACE levels as a primary finding in AI have been reported.
Case Report
A 23-year-old man was hospitalized urgently with severe salmonella enteritis in autumn 2022, presenting with total colitis, high fever, bloody stools, abdominal tenderness, and severe hyponatremia (124 mmol/l, normal range 137-145). He

was discharged in much better condition and returned to full-time work. Two months after discharge, he experienced fatigue. There were no more loose stools, and he was afebrile, but became weaker and weaker with periods of dizziness, acid reflux, epigastric pain, nausea, and some vomiting. He had a CT of the abdomen/pelvis and an abdominal ultrasound, both with normal findings. Gastroscopy revealed esophagitis grade A, and duodenal biopsies were negative for coeliac disease. After 10 months of declining general health and a weight loss of 30 kg, he was admitted to the Diagnostic Unit at our hospital due to concerns about malignant liver disease indicated by abnormal liver and bile values, ASAT 56 (15-45) and ALP 151 U/l (35-105). Blood pressure was 113/67 mmHg, pulse rate 115, sodium 135 mmol/l and potassium 4.6 mmol/l (normal range 3.6-5). The first notable finding was a hilar lymph node observed on a thoracal CT scan and an elevated ACE level of 111 U/l (18-65), which raised suspicion of sarcoidosis, and referral for bronchoscopy. The patient had no dyspnea or cough. Ferritin was elevated at 601 mg/l (30-400). Expanded blood tests confirmed primary AI with low cortisol levels at 15 nmol/l (133-537) and high ACTH levels at 362 pmol/l (1.5-14). Additional symptoms such as salt cravings, increased skin pigmentation, and muscle pain appeared. Treatment with mineralocorticoids and glucocorticoids was initiated. He improved quickly and gained 19 kg in less than four months. The bronchoscopy was cancelled, and after 3 months, the lymph node had diminished, and the ACE, liver and ferritin levels had normalized.
Conclusions
This is the fifth published case with debut of AI with high ACE without having sarcoidosis. The patient avoided an unnecessary pulmonary biopsy. Low cortisol levels in untreated AI can lead to increased inflammatory markers as ACE and ferritin.

Is adrenalectomy still required as a treatment in cushing disease?

Cristina Doicin[1], Andreea-Alexandra Grosu[1], Bratu Gratiela[1], Cristina Stancu[1], Adrian Miron[2] & Corin Badiu[1,2]
[1]"C.I. Parhon" National Institute of Endocrinology, Endocrinology 4, Bucharest, Romania; [2]"C Davila" University of Medicine and Pharmacy, Endocrinology, Bucharest, Romania

Introduction
Cushing disease is a very challenging endocrine disorder treated ideally by transsphenoidal surgery, with variable aggressiveness and resistance to medical treatment.
Case Report
A 44-year-old woman known with Cushing disease diagnosed 8 years ago with macroadenoma partially resected (2018) by transsphenoidal surgery (Ki67 10%), with significant tumor remnant, followed by stereotaxic radiotherapy -25Gy/5 sessions (2018). Due to bitemporal hemianopsia, a second surgery was unsuccessfully attempted (2019). In March 2020, the tumor relapse required Pasireotide 1.8 mg/day and cabergoline 1.5 mg/week increased at 8 mg/week with no biochemical or morphological response. In 2021 a partial left adrenalectomy was done. The patient presents typical symptoms of complicated Cushing's disease, including a generally altered state, a moon-shaped face, erythema and chin hirsutism. She has purple striae on the abdomen, skin and vascular fragility in the lower limbs, with multiple bruises and muscular weakness which made her unable to walk by herself. She has secondary hypertension, diabetes, secondary osteoporosis, hypercholesterolemia, gonadotropin deficiency, growth hormone deficiency, hypothyroidism under substitution therapy with Levothyroxinum. Due to local and systemic progression of the disease, she started Temozolomide with in 2022 with no results. Since 2022 she was enrolled on Relacorilant in GRACE clinical trial (CORT125134-455) with clinical response, until June 2024. Afterwards she was treated with Metyrapone 750 mg/day, followed by Ketoconazole 800mg/day without significant improvement. Last imaging showed bilateral macronodular adrenal hyperplasia. As a last therapy, right adrenalectomy was performed, considering the increased hormonal activity (ACTH 540.9 pg/mL, cortisol 48.67 µg/mL). Four days after surgery cortisol decreased to 36.5 mg/dl, and 2 weeks after the surgery, at 15.84 µg/mL. At the time of submission she is recovering from adrenal surgery.
Conclusion
This case highlights the multifactorial treatment of Cushing's disease and emphasizes the aggressiveness that this pathology can have, even after all available lines of treatment were used. Nevertheless, after the adrenalectomy, there was a noticeable improvement in biological markers. The surgery continues to represent a vital stage in the treatment journey.

Prevalence and evolution of diabetes in cushing's syndrome: a 31-year retrospective study

Baltagi Myriam[1], Ibtissem Ben Nacef[1], Sawsen Essayeh[1], Sabrine Mekni[1], Rihab Laamouri[1], Khiari Karima[1] & Rojbi Imen[1]
[1]Hospital of Charles Nicolle, Tunis, Tunisia

Introduction
Cushing's syndrome (CS) is known to induce hyperglycemia, but the long-term prevalence and evolution of diabetes in CS remain poorly understood. This study aims to evaluate the prevalence and evolution of diabetes in CS patients over a 31-year period.
Methods
A retrospective analysis was conducted on 22 patients diagnosed with CS at the Endocrinology Department of Charles Nicolle Hospital. Data collected included demographics, clinical features, cortisol levels, and diabetes status at diagnosis, treatment initiation, and follow-up.
Results
The majority of patients (68%) presented with diabetes at the time of diagnosis, with 32% showing prediabetes. Following successful treatment and remission of hypercortisolism, 70% showed significant improvement in fasting blood glucose and HbA1c levels. Notably, there was a correlation between baseline cortisol levels and glycemic control, with higher cortisol levels associated with poorer control.
Discussion
These findings underscore the significant impact of hypercortisolism on glycemic control. The improvement in glucose metabolism after cortisol suppression further highlights the importance of managing Cushing's syndrome effectively to mitigate diabetes-related complications.
Conclusion
Cushing's syndrome has a substantial impact on the development and progression of diabetes. Remission of hypercortisolism leads to significant improvements in glycemic control, emphasizing the need for early diagnosis and targeted treatment to reduce diabetes burden in these patients.

JOINT2276

Impact of cushing's syndrome treatment on glycemic control and diabetic complications

Baltagi Myriam[1], Ibtissem Ben Nacef[1], Sawsen Essayeh[1], Sabrine Mekni[1], Rihab Laamouri[1], Khiari Karima[1] & Rojbi Imen[1]
[1]Hospital of Charles Nicolle, Tunis, Tunisia

Introduction
Cushing's syndrome (CS) is associated with a high risk of developing diabetes and related complications. This study assesses the impact of CS treatment on glycemic control and the development of diabetic complications.
Methods
A cohort of 22 CS patients was followed from diagnosis through treatment. Glycemic control (fasting blood glucose, HbA1c) was measured before and after treatment, and diabetic complications (retinopathy, neuropathy, nephropathy) were assessed.
Results
Post-treatment, significant improvements in fasting blood glucose (mean decrease of 23%) and HbA1c (mean decrease of 0.9%) were observed. Diabetic complications were present in 36% of patients at diagnosis but reduced to 15% post-treatment. These improvements were associated with a significant reduction in cortisol levels.
Discussion
The findings suggest that successful treatment of CS not only improves glycemic control but also reduces the risk of developing diabetic complications. The relationship between cortisol levels and glycemic control underscores the role of cortisol in the pathogenesis of diabetes in CS patients.

Conclusion
Treatment of Cushing's syndrome significantly improves both glycemic control and diabetic complications. Early and effective management of cortisol excess is essential to prevent or mitigate these complications.

Factors influencing persistence of diabetes after cushing's syndrome remission

Baltagi Myriam[1], Ibtissem Ben Nacef[1], Sawsen Essayeh[1], Sabrine Mekni[1], Rihab Laamouri[1], Khiari Karima[1] & Rojbi Imen[1]
[1]Hospital of Charles Nicolle, Tunis, Tunisia

Introduction
While remission of Cushing's syndrome (CS) generally leads to improved glycemic control, some patients continue to experience persistent diabetes. Identifying factors influencing this persistence is crucial for optimizing long-term metabolic management.
Methods
A cohort of **22 patients**in remission from CS was assessed for glycemic outcomes. Patients were classified into two groups based on the persistence of diabetes post-remission. Several factors were analyzed, including **age, BMI, disease duration, baseline cortisol levels, and pre-remission insulin dependence**. Glycemic parameters were compared before and after remission.
Results
Among the 22 patients, 10 (45.5%) had persistent diabetes post-remission. There were no significant differences in **age (persistent vs. non-persistent: 48.2 $\pm$ 10.4 vs. 45.7 $\pm$ 9.1 years, $P = 0.42$), BMI (29.6 $\pm$ 4.8 vs. 28.9 $\pm$ 4.2 kg/m^2, $P = 0.58$), or disease duration (5.7 $\pm$ 2.1 vs. 5.2 $\pm$ 1.9 years, $P = 0.61$).**However, baseline cortisol levels were significantly higher in patients with persistent diabetes (**522.3 $\pm$ 87.6 vs. 398.4 $\pm$ 74.1 nmol/l, $P = 0.02$**). Additionally, **pre-remission insulin therapy was more frequent in patients with persistent diabetes (70% vs. 30%, $P = 0.04$)**, suggesting a possible association with beta-cell dysfunction.
Discussion
The absence of correlation with traditional metabolic risk factors (age, BMI, disease duration) suggests that **hyperglycemia persistence post-CS remission is mainly driven by the severity of hypercortisolism at diagnosis and its impact on pancreatic function**. The significant association with higher baseline cortisol levels highlights the role of prolonged glucocorticoid exposure in **beta-cell dysfunction and insulin resistance**, potentially leading to irreversible metabolic changes. Patients requiring insulin before remission appear to be at higher risk, supporting the hypothesis of **pre-existing pancreatic damage exacerbated by chronic cortisol excess**. Further studies are needed to explore long-term glucose metabolism recovery and predictive markers for diabetes resolution.
Conclusion
Although remission of CS improves glucose metabolism, **persistent diabetes is associated with higher baseline cortisol levels and pre-remission insulin dependence, suggesting a potential irreversible impact on beta-cell function**. Long-term follow-up and early metabolic interventions may help improve outcomes in these patients.

Diabetes in cushing's syndrome: secondary or type 2 diabetes

Baltagi Myriam[1], Ibtissem Ben Nacef[1], Sawsen Essayeh[1], Sabrine Mekni[1], Rihab Laamouri[1], Khiari Karima[1] & Rojbi Imen[1]
[1]Hospital of Charles Nicolle, Tunis, Tunisia

Introduction
Differentiating between secondary diabetes caused by Cushing's syndrome (CS) and preexisting type 2 diabetes (T2D) remains a clinical challenge. While cortisol excess is known to induce hyperglycemia, it is unclear whether diabetes in CS patients resolves entirely after remission or if some patients continue to exhibit features of T2D. This study investigates the nature of diabetes in patients following CS treatment.
Methods
A cohort of **22 patients diagnosed with CS**was followed after treatment to assess glycemic outcomes. Patients were classified based on their **diabetes status at baseline (diabetic vs. non-diabetic)**, and post-treatment evaluations included **fasting blood glucose (FBG), glycated hemoglobin (HbA1c), homeostatic model assessment of insulin resistance (HOMA-IR), and beta-cell function (HOMA-B)**. Statistical analyses were performed to compare pre- and post-treatment glycemic parameters.
Results
Following remission, the majority of patients experienced **significant improvements in glycemic control**, with a **23% reduction in fasting blood glucose ($P = 0.001$) and a 0.9% decrease in HbA1c ($P = 0.008$)**. Among the **10 patients diagnosed with diabetes before CS treatment**, six (60%) achieved normoglycemia post-remission, while four (40%) remained diabetic despite cortisol suppression. Patients with **persistent diabetes**exhibited metabolic features consistent with **type 2 diabetes**, including **higher baseline insulin resistance (HOMA-IR: 3.7 $\pm$ 0.8 vs. 2.1 $\pm$ 0.6, $P = 0.01$)**and **lower beta-cell function (HOMA-B: 52.4 $\pm$ 12.7 vs. 78.9 $\pm$ 15.3, $P = 0.03$)**compared to those who achieved normoglycemia. Furthermore, this group had significantly **higher baseline BMI (31.2 $\pm$ 3.8 vs. 27.6 $\pm$ 2.9 kg/m^2, $P = 0.02$)**and a greater prevalence of metabolic syndrome components. Interestingly, a subset of patients without prior diabetes ($n = 12$) developed **impaired glucose metabolism post-remission**.
Discussion
These findings highlight the **heterogeneous nature of diabetes in CS patients**. While hyperglycemia in some individuals appears to be directly driven by cortisol excess and resolves post-treatment, others exhibit metabolic profiles characteristic of **underlying type 2 diabetes**. Persistent diabetes in CS patients may be attributed to **preexisting insulin resistance, obesity, or irreversible pancreatic beta-cell dysfunction**, rather than secondary diabetes alone.
Conclusion
Although most patients experience an improvement in glycemic control following **Cushing's syndrome remission**, a subset remains diabetic, exhibiting features suggestive of **type 2 diabetes rather than pure secondary diabetes**. These results emphasize the need for **long-term metabolic monitoring**in CS patients, particularly those with risk factors for insulin resistance. Further studies are required to determine whether targeted interventions, such as weight management and insulin-sensitizing therapies, could improve long-term glycemic outcomes.

Rare association of primary hyperaldosteronism and cushing's syndrome: clinical, hormonal, and imaging insights from a case series

Ghachem Aycha[1], Wiem Saafi[1], Hamza Elfekih[1], Elaa Youssef[1], Imen Halloul[1], Ach Taieb[1], Ghada Saad[1] & Yosra Hasni[1]
[1]Farhat Hached University Hospital, Endocrinology - Diabetology departement, Sousse, Tunisia

Introduction
Hypertension is a major health condition, primarily classified as essential. However, secondary causes, particularly endocrine etiologies, should be considered in specific clinical contexts, such as resistant hypertension. Endocrine etiologies include hyperaldosteronism, Cushing syndrome, and pheochromocytoma among other causes. The association between primary hyperaldosteronism and Cushing's syndrome, though uncommon, represents a documented clinical entity. This case series aims to elucidate the clinical presentations, hormonal profiles, and imaging findings of patients diagnosed with this uncommon association.
Methods
We conducted a retrospective study about patients diagnosed with endocrine hypertension due to association of Cushing syndrome and primary hyperaldosteronism. Clinical data, laboratory findings and imaging results were analyzed.
Results
We present four cases of patients (three men and one woman) referred to our department for the evaluation of secondary hypertension. The average age of the patients was 47 years (28-68). In 75% of cases, hypertension was classified as grade 3, and all patients exhibited hypokalemia, with potassium levels as low as 2 mmol/l (2-3.4). Plasma metanephrine testing returned negative results in all cases. Hormonal assessments indicated primary hyperaldosteronism, with a mean aldosterone level of 644 pg/mL(502 - 1354) and a mean aldosterone-to-renin ratio of 300 (116 - 433). The diagnosis of Cushing's syndrome was confirmed in all patients through a low-dose dexamethasone suppression test, yielding a mean cortisol level of 25 µg/dL. Notably, Cushing's syndrome was found to be ACTH-dependent in two patients, with a ACTH level of 26 pg/mL and 23. Adrenal imaging revealed bilateral adrenal hyperplasia in one patient (ACTH independent), adrenal vein catheterization demonstrated lateralized secretion to the right adrenal gland. The Other patients presented with adrenal nodules; one patient had bilateral nodules. The mean size of these nodules was 17 mm.

Conclusion
The coexistence of Cushing's syndrome and primary hyperaldosteronism is rare. Both conditions are characterized by distinct pathophysiological mechanisms leading to increased blood pressure and electrolyte imbalances. Their simultaneous occurrence poses unique diagnostic and therapeutic challenges, underscoring the importance of a comprehensive evaluation when endocrine etiologies are suspected.

Overcoming the challenge: weaning corticosteroids in glucocorticoid-induced adrenal insufficiency

Debbie Papadopoulou[1,2], Zin Htut[2], Scott Akker[3,4] & Karim Meeran[1,2]
[1]Imperial College Healthcare NHS Trust, Endocrinology, London, United Kingdom; [2]Imperial College, Division of Diabetes, Endocrinology and Metabolism, Department of Metabolism, Digestion and Reproduction, London, United Kingdom; [3]Barts Health NHS Trust, London, United Kingdom; [4]Queen Mary University of London, Department of Endocrinology, London, United Kingdom

High dose prednisolone is commonly used for many inflammatory conditions. A 70-year old woman was referred to the endocrine clinic with a history of long term steroid exposure for eosinophilic granulomatosis with polyangitis (EGPA) which she continued for over ten years. She subsequently commenced biologic treatment for eosinophilia but continued on steroid treatment. She was switched to thrice daily hydrocortisone and the minimum dose she could tolerate was 5 mg on waking, 5 mg at midday and 2.5 mg in the afternoon. She remained on this dose for several years. In May 2024 she was referred to our centre to switch to once daily, low dose prednisolone. Prior to switching her 8am cortisol and ACTH values were undetectable. Following the switch to once daily prednisolone, day curves were arranged to optimize her dose. Prednisolone 3mg/day produced an 8hour level of 30 μg/l (normal values 15 to 25 μg/l). We advised her to reduce to 2mg prednisolone once a day. The patient was keen to try and reduce her steroids, therefore she commenced a weaning protocol to 1mg daily and a prednisolone level on 1mg demonstrated this was a suppressive dose for this patient. A short synacthen test (SST) on 1 mg of prednisolone per day demonstrated showed the following results T = 0min cortisol < 28nmol/l ACTH < 5ng/l T = 30min cortisol 45nmol/l T = 60min cortisol 59nmol/l In order to go below 1mg of prednisolone she switched to an equivalent dose of hydrocortisone 7.5mg once a day which has a shorter half-life. A hydrocortisone day curve confirmed that she was a slow metabolizer of hydrocortisone SST was repeated in on 5mg; T = 0min cortisol 111nmol/l, ACTH 45.6ng/l T = 30min cortisol 120nmol/l T = 60 min cortisol 125nmol/l She continues to wean from 5mg day to 2.5mg according to the protocol below and we aim to wean her off steroids completely. Individualised care for patients on long term steroids wishing to wean is paramount to success. Supporting patients to wean off steroids negates risks such as osteoporosis and diabetes caused by long term steroid use. These results suggest that conventional hydrocortisone replacement in doses as low as 7.5mg/5mg/2.5mg can cause persistent HPA axis suppression. There is a need for prospective studies to evaluate weaning protocols.

Asymptomatic giant cystic pheochromocytoma, a misleading entity: a case report

Amal Riad[1], Kaoutar Rifai[1], Iraqi Hinde[1] & Mohamed Elhassan Gharbi[1]
[1]Ibn Sina Institution, Rabat, Morocco

Introduction
Pheochromocytoma is a rare neuroendocrine tumor. It was a tumor arising from adrenomedullary chromaffin cells that commonly produce one or more catecholamines. They produce and secrete catecholamine. Cystic pheochromocytoma is a rare entity and mostly asymptomatic. Considering the rarity and difficulty to differentiate from simple cysts in the absence of classic clinical symptoms, we present a huge cystic pheochromocytoma.
Case Report
This is a 63-year-old patient with no previous history of the disease, who presented with a cystic phoechromocytoma revealed by low back pain, which prompted an abdominal CT scan showing a 15 cm cystic left surrenal mass, confirmed biologically by a methoxylated derivative assay that was 7 times normal. The patient did not present with Menard's triad or hypertension. She underwent laparoscopic unilateral adrenalectomy after medical preparation. The evolution was marked by the negativation of the biological work-up post-operatively and the anatomopathological examination confirmed the diagnosis.
Discussion
Cystic pheochromocytoma is a rare entity and it may be due to intralesional hemorrhage, necrosis and liquefaction. Patients with cystic pheochromocytomas are usually asymptomatic. Hormonal analysis is generally negative. the main clinical signs are represented by the non-specific triad of low back pain, digestive problems and lumbar mass. These cystic forms of pheochromocytoma pose a real problem of differential diagnosis. The differential diagnosis is made with haemorrhagic lesions, cystic lymphangiomas, adenomas, metastases, vascular tumours of the adrenal gland, hydatid cysts and other cystic masses in the vicinity. The radiological study of the adrenal gland is based on CT. The typical radiological characteristics of pheochromocytoma are a round or oval mass, well-circumscribed, homogeneous or heterogeneous measuring > 4 cm, increased attenuation on unimproved enhancement, significant vascularization of the mass. However, the CT characteristics of cystic pheochromocytomas would be a relatively thick wall, the presence or absence of septa in the mass and persistent enhancement of the wall after the administration of contrast media. On the other hand,123I-MIBG scintigraphy has a higher diagnostic specificity. 18F-FDG positron emission tomography/CT can also allow the successful visualization of pheochromocytomas. Preoperative management is essential to prevent hemodynamic instability during the intraoperative or postoperative period. The treatment of cystic pheochromocy tomas is based on surgery.
Conclusion
Measurement of methoxylated derivatives in the urine should therefore be systematically requested in the presence of any adrenal mass.

Clinical audit of outpatient short synacthen test utilisation and outcomes in a tertiary care cohort

Du Soon Swee[1], Ling Zhu[1], Dawn Lim[1], Peng Chin Kek[1] & Lih Ming Loh[1]
[1]Singapore General Hospital, Endocrinology, Singapore, Singapore

Background
The short Synacthen test (SST), also known as the ACTH (cosyntropin) stimulation test, is widely used to assess adrenal function. Its utilization and performance, however, is not universally standardized. The Department of Endocrinology at Singapore General Hospital has a dedicated outpatient SST service for evaluation and follow-up of patients with suspected or confirmed adrenal insufficiency.
Objective
This study aims to evaluate the utilization patterns and outcomes of SSTs performed at an endocrine unit in a tertiary hospital.
Methods
A retrospective audit of SST data is conducted for patients tested between 8 August 2024 and 7 January 2025. The choice of low-dose 1 mg SST (LD-SST) or standard-dose 250 mg SST (SD-SST) is based on the ordering endocrinologist's clinical discretion. In general, LD-SST is typically preferred for patients with suspected central adrenal insufficiency, while SD-SST is performed for all other indications. A peak stimulated cortisol of $\geq$ 500 nmol/l is considered as an adequate adrenal response.
Results
One hundred and seventy-eight SSTs were performed during the study period. All tests were completed successfully. The majority (n = 120, 67%) were LD-SSTs, and the remaining (n = 58, 33%) being SD-SSTs. Adequate adrenal responses were observed in 56% (n = 67) of LD-SSTs and 64% (n = 37) of SD-SSTs. All except 2 patients listed for LD- SST had known or suspected hypothalamic/pituitary diseases (n = 118, 98%), including pituitary macroadenoma (n = 65), pituitary microadenoma (n = 20), suprasellar meningioma (n = 4), Rathke cleft cyst (n = 4), empty sella syndrome (n = 3), clival chordoma (n = 2), lymphocytic hypophysitis (n = 1), prior cranial irradiation (n = 7), biochemical abnormalities resembling central hypothyroidism (n = 10) and central AVP deficiency (n = 1). The most common indication for standard-dose SST was for the diagnosis or follow-up of adrenal insufficiency in patients receiving exogenous glucocorticoids (n = 32, 55%). The remaining patients had clinical presentations suggestive of adrenal insufficiency (n = 18), hypothalamic/pituitary diseases (n = 4), suspected congenital adrenal hyperplasia (n = 3) and possible autoimmune polyglandular syndrome (n = 1). There were no immediate complications or adverse events following all SSTs.

Conclusion
SST is a useful and relatively easy-to-perform dynamic endocrine test in the evaluation of adrenal function. Most cases were evaluated in the context of possible central adrenal insufficiency due to hypothalamic/pituitary pathology. The high demand for outpatient SST highlights its importance in clinical practice.

Primary hyperaldosteronism: diagnostic approach (endocrine-radiological)

Maria Jose Vallejo Herrera[1], Veronica Vallejo Herrera[2] & Maria Carmen Bautista Recio[1]
[1]Endocrinology and Nutrition. Málaga Regional University Hospital., MALAGA, Spain; [2]Radiodiagnosis. Málaga Regional University Hospital., MALAGA, Spain

Introduction
Primary hyperaldosteronism (PAH) causes secondary arterial hypertension. It requires high clinical suspicion and a hormonal study to confirm hypersecretion. To start an adequate treatment after confirming the diagnosis, it is necessary to demonstrate whether the hormonal hypersecretion is unilateral (surgical treatment) or bilateral (pharmacological treatment).
Objectives
In our Hospital we have endocrinology, interventional radiology and surgery specialized in adrenal pathology to evaluate complex hyperaldosteronism cases and agree on the best diagnostic-therapeutic approach. We collect our experience in adrenal venous catheterization, the gold standard for the study of PAH.
Material and Methods
Retrospective observational study carried out at the Málaga Regional University Hospital on outpatients who underwent adrenal vein catheterization over a period of 8 years (2016-2024). We collected clinical variables, laboratory tests, imaging tests and treatment.
Results
Nine subjects were included, 66.6% women, mean age 53 (35-67) years. Most of them had hypertension, hypokalemia or incidentaloma. All of them had elevated aldosterone/renin ratio. In 5 patients the confirmatory test was captopril test and in 2 patients a saline overload test was performed (as a first test or second test in case of inconclusive captopril test) and in 3 cases no confirmatory test was performed. All of them had S/C adrenal Tc: left nodule (66.6%), right nodule (22.2%) and bilateral nodule (11.1%). To clarify the case, MRI was performed in 4 patients (2 adenomas, 1 non-adenoma criteria and another without nodules) and scintigraphy in 8 cases, most without uptake and 1 discordant (in the 3 confirmed PAHs the gamma coincided with CT in 1 case). Adrenal venous catheterization confirmed lateralization in 3 patients (2 left and 1 right) coinciding with CT findings, 1 without lateralization and 5 inconclusive/valid due to not having correctly catheterized the right adrenal vein or due to taking spironolactone. Surgical treatment (unilateral adrenalectomy) was performed in 2 of the 3 cases confirmed with catheterization. In the third PAH confirmed by catheterization, surgery was not performed due to splenorenal shunt seen on CT. 6 patients receive medical treatment with good control of BP levels.
Conclusions
Catheterization is a fundamental technique for the study and treatment of PAH. It helps with hormonal studies and imaging tests, allowing for greater precision, performing adrenalectomy in cases with clear hyperaldosteronism secondary to unilateral secretion. We need a multidisciplinary team with endocrinologists, surgeons and interventional radiology with experience in performing it.

Implications of new diagnosis of adrenal insufficiency on class 1 commercial pilot licence

Despoina Tseke[1], Safaa Malkat[1], Vidhu Nayyar[1], James Clark[1], Julian Emmanuel[1], Ben Field[1] & Sunil Zachariah[1]
[1]East Surrey Hospital, Surrey and Sussex Healthcare NHS Trust, Redhill, United Kingdom

Case History
We present a case of a 46-year-old female, who has past medical history of Graves disease, treated with radioiodine in 2020 and rendered hypothyroid, on a stable dose of levothyroxine 100 mg daily. She works as a commercial airline pilot holding Class 1 licence. Four years later, she presented with lethargy, dizziness and reduced exercise tolerance. Mentstrual periods were regular. She had postural hypotension and investigations revealed low 9 am cortisol of 67 nmol/l, elevated ACTH of 124 ng/l (normal <50), Renin level of 88 mU/l (normal 5.4-30) and positive adrenal antibodies. Synacthen test confirmed adrenal insufficiency. Remaining of pituitary profile was normal. She was diagnosed with primary adrenal insufficiency (Addisons disease) and her symptoms resolved after initiation of hydrocortisone and fludrocortisone. She is aware of sick day rules and has been issued an emergency steroid pack. She is deemed unfit to fly by the Civil Aviation Authority (CAA) and is currently awaiting an appointment with Occupational health and the Aviation Medical Examiner to discuss next steps.
Discussion
Both the UK Civil Aviation Authority and the European Aviation Safety Agency regard commercial pilots with Addisons disease by default as unfit to fly. A licence may be issued, valid only in multipilot operations, and provided pilots carry with them the necessary cortisone replacement and are trained to use it. The Federal Aviation Administration does not set out any specific rules and decides on a case-by-case scenario. It is also worth noting the challenges pilots with Addisons face. They need to carry their emergency hydrocortisone injection kit and an adequate supply of their medications during their working days, in case of flight delays or cancellations. Furthermore, they may need additional doses of hydrocortisone replacement when travelling across time zones. Finally, pilots will have less access to urgent medical treatment should they develop an adrenal crisis, and their co-workers will need appropriate education. For all those reasons, a careful occupational health assessment needs to be undertaken. This case highlights the impact a diagnosis of adrenal insufficiency can have on various aspects of a person's life. Its professional implications are often less well recognised and addressed, especially when compared to other endocrinology disorders such as diabetes.

Adrenal tumor in a child with salt-wasting 21-hydroxylase deficiency congenital adrenal hyperplasia

Ke Zhang[1] & Ma Huamei[1]
[1]The First Affiliated Hospital, Sun Yat-sen University, Guangzhou, China

Background
Congenital adrenal hyperplasia (CAH) has been associated with adrenal tumors (ATs). International guidelines recommend against routine adrenal imaging in adult with CAH.
Objective
To report a case of 6.4-year-old boy with salt-wasting 21-hydroxylase deficiency congenital adrenal hyperplasia (CAH 21OHD SW) complicated with adrenal tumor.
Methods
Case study.
Result
A 6.4-year-old boy of non-consanguineous Chinese parents with CAH 21OHD SW went to our clinic for a regular endocrinological follow-up. 17OHP was 125ng/ml in newborn screening. At the age of 4 weeks, he was diagnosed with CAH 21OHD SW confirmed by genetic analysis and treated with oral hydrocortisone and fludrocortisone. His CAH was being adequately managed with normal linear growth and skeletal maturation with properly adherent to therapy. The adrenal ultrasound did not show abnormalities 5.5 months ago. On physical examination, height 116cm, weight 20kg, BP 90/60mmHg. Slightly increased skin pigmentation was noted, normal male prepubertal external genitalia was observed. Laboratory tests showed FSH 0.7 IU/l, LH 0.12 IU/l, E2 <10 pg/ml, T <0.13 ng/ml, P 0.5 ng/ml. Serum 17OHP 11.54 ng/ml, A4$<$ 1.05nmol/l, Renin 8AM (supine) 12.4 UIu/mL. Normal serum AFP, ferritin and 24h urine VMA were normal with slightly elevated NSE 22.06 ng/ml. Ultrasound showed a right adrenal soft-tissue mass measuring 4.3×3.2cm. CT scan demonstrated a right adrenal soft-tissue mass measuring 3.9×3.1cm. The mass was between the right adrenal gland and the anterior part of the upper pole of the right kidney, with a clear boundary, small punctate calcification. A few patchy enhancement shadows supplied by a small branch of the abdominal aorta in the enhanced scan. The upper edge of the mass is not clearly demarcated from the lower edge of the lateral limb of the right adrenal gland. Though the mass was non-functional according to the laboratory, we decided manage the patient surgically due to the mass rapidly growth. During the open surgical approach, it was found that the right AT was hard and elastic with a clear boundary measuring 5*5*3cm. A pathology report indicated ganglioneuroma. He was followed up in our clinic at regular intervals, and was last seen about 2 years postoperatively without clinical evidence of recurrence.
Conclusion
This paper firstly reports a 6.4-year-old boy with CAH 21OHD complicated with adrenal ganglioneuroma. This benign tumor rarely occurring in CAH patients. It is recommended that imaging monitoring of ATs be an important issue of CAH management.

Outcomes of bilateral adrenalectomy in patients with severe and persistent cushing's disease: a case series

Mariem Ayedi[1], Hamza Elfekih[1], Wiem Saafi[1], Ach Taieb[1], Elaa Youssef[1], Imen Halloul[1], Ghada Saad[1] & Yosra Hasni[1]
[1]University of Sousse, Faculty of Medicine of Sousse, Farhat Hached University Hospital, Endocrinology Diabetology Department, Sousse, Tunisia

Introduction
Cushing's disease, characterized by hypercortisolism due to ACTH-secreting pituitary adenoma, requires accurate diagnosis and effective management to optimize patients' outcomes. Transsphenoidal surgery is the first-line treatment, but persistent or recurrent disease may need alternative therapies. Bilateral adrenalectomy is effective in controlling hypercortisolism. However, it carries the risk of corticotrophin tumor progression or Nelson's syndrome, necessitating long-term monitoring.
Case Presentations
We present three cases of Cushing's disease in male patients who underwent bilateral adrenalectomy after unsuccessful transsphenoidal surgeries with persistent hypercortisolism and severe comorbidities. **Case 1:**A 51-year-old male was diagnosed with Cushing's disease at the age of 44, initially presenting with hypogonadotropic hypogonadism attributed to a 7 mm pituitary microadenoma. Bilateral adrenalectomy was performed because of the disabling impact of the disease with severe hypertension, stroke, coronary artery disease, proximal muscle weakness, and worsening of preexisting diabetes. Postoperatively, the patient's comorbidities improved, ACTH levels remained elevated at 1544 pg/mL under 30 mg/day of hydrocortisone and MRI showed 3 mm microadenoma. **Case 2: The diagnosis in a** 37-year-old male was revealed by bilateral aseptic osteonecrosis of the femoral heads. The patient underwent two transsphenoidal surgeries for two different pituitary adenomas, but remission was not achieved. Persistent hypercortisolism led to disabling complications, including osteoporosis and a suspicious left adrenal mass. Afet bilateral adrenalectomy, ACTH levels were markedly elevated at 1692 pg/mL under 20 mg/day of hydrocortisone. MRI at 5 years, revealed a 3 mm pituitary microadenoma. **Case 3:**A 37-year-old male was diagnosed at the age of 20 by a 7 mm right-sided ACTH-secreting pituitary microadenoma. Over the years, the patient developed prediabetes, osteoporosis, and grade 2 hypertension. Despite undergoing two pituitary surgeries, Cushing's disease persisted. Postoperative pituitary imaging was normal, but adrenal imaging revealed four bilateral adrenal nodules ranging from 8 to 25 mm. Due to the disabling nature of the disease and the presence of adrenal nodules, bilateral adrenalectomy was performed. Postoperatively, ACTH levels were elevated at 405 pg/mL under 30 mg/day of hydrocortisone, but follow-up pituitary MRI showed no abnormalities.
Conclusion
Bilateral adrenalectomy is an effective treatment for refractory Cushing's disease, particularly in cases where transsphenoidal surgery fails to achieve remission. However, elevated ACTH levels and the potential for corticotrophin tumor progression underscore the importance of long-term monitoring with serial pituitary imaging and biochemical assessments. Early detection of tumor progression allows for timely intervention with surgery, radiotherapy, or medical therapy, optimizing patient outcomes.

JOINT2057

Adrenal schwannoma: a case report

WIssame Debbah[1], Mouna Mezoued[1] & Malha Azzouz[2]
[1]Endocrinology-Diabetology Department of the Public Hospital Establishment (EPH) of Bologhine Ibn Ziri, Algiers, Algeria; [2]dr_malhazzouz@yahoo.fr, Algiers, Algeria

Introduction
Schwannomas are tumors of the Schwann sheath of peripheral or cranial nerves. Visceral schwannomas are rare, accounting for 1 to 10 percent of all primary retroperitoneal tumors, and only a few cases of adrenal schwannomas have been reported.
Case report
A 23-year-old female patient consulted for abdominal pain, progressing in a context of weight loss of 12 kg over two months. Abdominopelvic CT scan suggested a right suprarenal retroperitoneal mass, seemingly originating from the adrenal gland, measuring 48×61 mm. It was well-defined, with a spontaneous density of 55 HU, heterogeneous, and contained calcifications. Biological tests ruled out pheochromocytoma, Conn's adenoma, and cortisol-producing adenoma. A right adrenalectomy was performed without complications, revealing a benign schwannoma (spindle cell proliferation, PS100 expression).
Discussion/Conclusion
Schwannomas are often asymptomatic and incidentally discovered during imaging for an unrelated condition, as observed in our case. Radiological diagnosis is challenging. However, imaging typically shows a solid tumor with calcifications, a cystic component, and a well-defined capsule, allowing localization and assessment of its retroperitoneal positioning. Definitive diagnosis is confirmed by histological analysis of the surgical specimen (presence of Schwann cells, positivity for S-100).

Silent pheochromocytoma: an insidious surgical finding

Georgios Kostopoulos[1], Evangelia Makri[1], Efstathios Divaris[1], Ioannis Papadopoulos[1], Athanasia Michou[1], Fotini Adamidou[1] & Zoe Efstathiadou[1]
[1]Endocrinology Department, Hippokration General Hospital of Thessaloniki, Thessaloniki, Greece

Introduction
Silent pheochromocytomas constitute a rare and heterogeneous clinical entity. These tumors are characterized by the absence of signs and symptoms of catecholamine excess and normal plasma and/or urinary metanephrines. We present three cases of silent pheochromocytomas.
Case 1
A 45-year-old female was referred for evaluation of a right adrenal incidentaloma detected on abdominal ultrasound. Subsequent imaging revealed a heterogeneous 2.9 cm mass with increased density (40 HU) on CT, and a slight loss of signal intensity in out-of-phase MRI images. Clinical and laboratory evaluations were normal; the patient was normotensive, and testing for cortisol, aldosterone, and urinary metanephrines was negative. The patient underwent uneventful laparoscopic adrenalectomy without preoperative α-adrenergic receptor blockade. Histology confirmed a pheochromocytoma with a potential biologically aggressive behavior (PASS = 4).
Case 2
A 68-year-old male with hypertension and diabetes was diagnosed during COVID-19 workup with a large right adrenal incidentaloma and a lesion with irregular borders in the left kidney. On CT, the adrenal mass measured 3.6 cm, had a high density (~30 HU), and showed no signal loss in out-of-phase MRI images. The 4.9 cm kidney lesion appeared heterogeneous. Clinical examination was unremarkable, while hormonal testing excluded hypersecretion of cortisol, aldosterone, or catecholamines. A PET-CT scan confirmed both lesions' hypermetabolic nature. After multidisciplinary team discussion, the patient underwent resection of the kidney mass, followed by right adrenalectomy. No prior α-blockade was prescribed. Hemodynamic instability occurred during adrenalectomy. Histology revealed a clear-cell renal carcinoma and a pheochromocytoma with aggressive biological behavior (PASS = 9).
Case 3
A 64-year-old female with hypertension, prediabetes, and a history of surgical excision of a parathyroid adenoma was diagnosed with a 3 cm left adrenal incidentaloma upon work-up of an incident urinary track infection. Imaging suggested a non-benign lesion (high attenuation values and heterogeneity). Clinical examination was unremarkable except for paroxysmal hypertension over the previous four months. Hormonal evaluation (1 mg dexamethasone suppression test, plasma renin activity, serum aldosterone, and urinary metanephrines) was negative. ^{123}I-MIBG scintigraphy was suggestive of pheochromocytoma, and the patient was scheduled for left adrenalectomy with preoperative α-adrenergic receptor blockade. Histology confirmed the diagnosis of pheochromocytoma.
Conclusion
Despite negative biochemical testing, silent pheochromocytomas may retain some functionality. A personalized approach in terms of preoperative α-adrenergic blockade is warranted.

Ganglioneuroma in a patient with primary adrenal insufficiency: a case report

Georgios Kostopoulos[1], Ioannis Papadopoulos[1], Efstathios Divaris[1], Evangelia Makri[1] & Zoe Efstathiadou[1]
[1]Endocrinology Department, Hippokration General Hospital of Thessaloniki, Thessaloniki, Greece

Background
Adrenal ganglioneuroma is a rare, benign tumor originating from neural crest cells. It is usually asymptomatic and incidentally detected during imaging studies. The coexistence of adrenal ganglioneuroma with primary adrenal insufficiency (PAI) is exceptionally rare, with only one prior case reported in the literature. This case emphasizes the diagnostic challenges and management strategies in patients presenting with concurrent endocrine disorders.
Case Presentation
A 17-year-old male with a history of PAI and Hashimoto's thyroiditis was referred to our Department during the transition from pediatric to adult endocrine care. At age 14, he presented with fatigue, malaise, nausea, and skin hyperpigmentation, leading to a diagnosis of PAI after confirmatory testing. Autoimmune adrenalitis was presumed based on the positive personal/family history of autoimmunity and he received hydrocortisone and levothyroxine replacement, without adrenal imaging. At the time of referral, the patient had normal physical, sexual (Tanner V) and cognitive development. However, also clinical signs of corticosteroid overreplacement, such as overweight (BMI = 31.7 kg/m^2) and wide, purple abdominal striae were present, along with symptoms of postural hypotension and salt craving. Consequently, hydrocortisone dose was decreased, and fludrocortisone was initiated. Basal hormonal workup was consistent with PAI (low morning cortisol, elevated plasma ACTH and renin). Elevated 17-hydroxyprogesterone (17-OHPRG, 8.49 ng/ml) and negative 21-hydroxylase antibodies testing, prompted further investigation. Adrenal CT scan revealed atrophic adrenal glands, and a 5.5 cm heterogeneous lesion proximal to the left adrenal gland with high attenuation (HU > 10). In MRI, the mass appeared slightly hypointense in T1 and hyperintense in T2-weighted images. Normal very long-chain fatty acid (VLCFA) levels excluded X-linked adrenoleukodystrophy. During ACTH stimulation testing, suboptimal cortisol response (8.41 mg/dl) and increased peak 17-OHPRG (11.2 ng/ml) levels were suggestive of congenital adrenal hyperplasia (CAH). However, family screening was negative and genetic screening is pending. The patient underwent laparoscopic left adrenalectomy. Histopathological and immunohistochemical analysis confirmed adrenal ganglioneuroma.
Conclusions
This case underscores the need for a multidisciplinary approach to adrenal masses in patients with autoimmune endocrinopathies. The coexistence of ganglioneuroma and PAI, although rare, necessitates histological confirmation for accurate diagnosis and individualized management, ultimately improving patient outcomes.

Acromegaly and high-grade heart blocks: a rare situation

Hamza El Jadi[1] & Amine Maliki Alaoui[2]
[1]Oued Eddahab Military Hospital, Cadi Ayyad University, Marrakech, Morocco, Endocrinology, Agadir, Morocco; [2]Oued Eddahab Military Hospital, Agadir, Morocco

Introduction
Acromegaly is a rare hormonal disorder due to hypersecretion of growth hormone (GH) by a benign pituitary tumor. Cardiac damage is a constant feature of this rare disease and is the leading cause of death in acromegaly. The specific cardiac involvement of acromegaly is characterized by myocardial hypertrophy associated with diastolic dysfunction. A significant increase of Intraventricular conduction defects and arrhythmias has been described in acromegaly. However, high-grade atrioventricular blocks are less common.
Case Report
75 years old acromegalic male with a history of hypertension and dyslipidemia, ongoing obstructive sleep apnea and exertional chest tightness. He was admitted to the Otorhinolaryngology department to undergo tracheotomy for an upper airway obstruction. The pre-anesthesia evaluation found a Mobitz II Atrioventricular block. In view of the impact of the obstructive syndrome, a tracheotomy was performed, but a shift to severe bradycardia then a transient ventricular pause occurred. Cardiac auscultation revealed normal S1 and S2 without additional heart sounds. Electrocardiogram at admission showed a bradycardia at 47 bpm related to a 2/1 Mobitz II Atrioventricular block, a right bundle branch block with QRS duration at 138ms, a left anterior fascicular bloc and an isolated premature ventricular beat. Electrophysiological study revealed prolonged HV interval indicating the need for pacemaker implantation. The patient has been implanted with a dual-chamber pacemaker then discharged from hospital.
Discussion and Conclusion
Cardiac arrhythmias and sudden cardiac death are major contributors to increased mortality in acromegaly. Elevated beat-to-beat QT variability and late potentials correlate with ventricular tachyarrhythmias. Intraventricular conduction defects and arrhythmias are common, and while high-grade atrioventricular blocks are less frequent, prevalence varies (7–40%) due to study size, control group differences, monitoring techniques, and significant arrhythmia definitions. There is evidence of the impact of treatment of acromegaly on cardiac conduction tissue. Treatment with somatostatin analogs can reduce clinically significant arrhythmias in some cases by reducing heart rate, PVBs, and QT interval. Regarded for a long time as the primary contributors to mortality in individuals with acromegaly, recent evidence suggests that acromegalic patients experiencing cardiovascular complications now exhibit a mortality rate comparable to the general population. Interstitial fibrosis and cardiac hypertrophy associated with acromegaly could promote arrhythmias and conduction abnormalities of which high-grade heart block is an exceptional manifestation. Treatments of acromegaly reduce the incidence of cardiovascular complications and have a positive impact on rhythm disturbances.

Not your average cushing syndrome - a case with a series of unusual complications

Viviana Popa[1,2], Alexandru Florescu[1,2], Teodora Vintilă[1], Andra Berigoi[1], Irina Puscasu[1], Miruna Miron[1] & Cristina Preda[1,2]
[1]"Saint Spiridon" Emergency County Hospital, Endocrinology, Ia?i, Romania; [2]"Grigore T. Popa" University of Medicine and Pharmacy, Endocrinology, Iasi, Romania

Cushing syndrome is characterized by specific clinical features and several complications, including diabetes mellitus, hypertension, infections, electrolyte imbalances and pro coagulant status. In these patients, cardiovascular risk and mortality rates remain high (~10%) despite surgical cure, mainly because of the associated complications. We report the case of a 53-year-old male, who was simultaneously diagnosed with type 2 diabetes mellitus and arterial hypertension two years ago. He was referred to our Clinic from the Oro-Maxillo-Facial Surgery department, where he was admitted for multiple dental abscesses. There, hypokalemia (2.3mmol/l) was detected, as well as maximum systolic blood pressure of 180mmHg despite treatment with 3 antihypertensive medications. Biologically, we note an HbA1c level of 8.1%, despite treatment with two oral antidiabetic medications and adherence to dietary recommendations. Endocrinological assessment identified classical features of Cushing syndrome (full moon facies, buffalo hump, proximal myopathy and truncal obesity). Hormonal evaluation confirmed ACTH independent Cushing syndrome (ACTH 9pg/mL, AM cortisol 25.1mg/dL, PM cortisol 24.8mg/dL, no inhibition after 1 and 8mg dexamethasone tests); and secondary hypogonadism and hypothyroidism. The abdominal CT scan identified a 4cm right adrenal adenoma, and the patient was scheduled for surgery one month later. During this time he developed jaundice and hepatic cytolysis (maximum liver enzyme levels – 386U/l, normal hepatic profile at diagnosis), for which toxic, infectious and immunological causes were excluded. During the same time frame, the patient developed plurimicrobial, bacterial cellulitis in both arms (Escherichia coli, Staphylococcus aureus), for which hospitalization and IV antibiotics were necessary, with favorable evolution. Following surgery, treatment with Prednisone was initiated, in gradually decreasing doses until ACTH stimulation test confirmed proper hypothalamic-pituitary-adrenal axis function, so treatment was stopped. Additionally, liver function tests normalized postoperatively, suggesting that liver injury was most likely caused by Cushing-related metabolic dysfunction; systolic blood pressure dropped to around 120-130mmHg, despite a reduction in treatment; and HbA1c levels dropped from 8.1% to 4.7%, so antidiabetic medications were stopped. In conclusion, Cushing syndrome can cause a series of complications which can delay surgical treatment. Our patient developed a series of unusual complications, including plurimicrobial bacterial cellulitis in both arms and metabolic-associated hepatic injury, with normalization of liver function tests after surgery. In conclusion, swift surgical intervention, close monitoring and a highly skilled interdisciplinary team is necessary for managing these patients and the various complications that can arise secondary to Cushing syndrome.

Glycemic control and cortisol levels in patients with cushing's syndrome

Baltagi Myriam[1], Ibtissem Ben Nacef[1], Sawsen Essayeh[1], Sabrine Mekni[1], Rihab Laamouri[1], Khiari Karima[1] & Rojbi Imen[1]
[1]Hospital of Charles Nicolle, Tunis, Tunisia

Introduction
Cortisol excess in Cushing's syndrome (CS) is a well-established cause of insulin resistance and impaired glycemic control. This study investigates the correlation between cortisol levels and glycemic control in CS patients.
Methods
We included 22 patients diagnosed with CS, assessing their baseline cortisol levels, ACTH levels, fasting blood glucose, and HbA1c at diagnosis and after treatment.

Treatment aimed at normalizing cortisol levels was initiated, and glycemic control was reassessed post-treatment.
Results
A strong positive correlation was found between baseline cortisol and fasting blood glucose ($r=0.68$, $P<0.01$), as well as HbA1c ($r=0.72$, $P<0.01$). After treatment, patients who achieved cortisol suppression showed significant improvements in both fasting blood glucose (mean decrease of 23%) and HbA1c (mean decrease of 0.9%).
Discussion
This study confirms that cortisol excess significantly impairs glycemic control in CS patients. The correlation between cortisol levels and both fasting blood glucose and HbA1c suggests that controlling cortisol levels is a key strategy for managing diabetes in this population.
Conclusion
The findings highlight the importance of cortisol suppression in improving glycemic control in CS patients. Monitoring cortisol levels may provide valuable insights into the management of diabetes in this context.

Adrenal ganglioneuroma: a rare mass and diagnostic challenge

Mohamed Khairi Arous[1], Kouloud Boujelben[1], Mouna Elleuch[1], Yassmine Abdelkafi[1], Faten Haj Kacem Akid[1], Fatma Mnif[1], Nadia Charfi[1], Mouna Mnif[1], Mohamed Abid[1], Dhoha Ben Salah[1] & Nabila Rekik Majdoub[1]
[1]Hedi Chaker University Hospital, Department of Endocrinology, Sfax, Tunisia

Introduction
Adrenal ganglioneuroma (AG) is a rare tumor comprising less than 5% of all adrenal masses. Its morphological and radiological characteristics are nonspecific, which can complicate the diagnostic process. We report the case of an AG in a 16-year-old girl.
Case Report
A patient with no medical history was referred for evaluation of an adrenal mass. She reported paroxysmal lumbar pain over the past 4 years. Clinical examination was unremarkable, laboratory tests were notable only for iron deficiency anemia. Computed tomography revealed a right adrenal mass extending across the midline, measuring 83×39×64mm, with a density of 29HU and negative absolute and relative washout. Hormonal exploration indicated that the mass was non-functioning. Magnetic resonance imaging demonstrated close conncections with the inferior vena cava, the portal trunk, the aorta, and the liver. FDG-PET scan showed a mildly hypermetabolic adrenal mass with no other pathological uptake. The pathological study concluded an AG. The patient underwent surgical resection of the mass with a straightforward postoperative course.
Discussion and conclusion
Ganglioneuroma is a benign neuroblastic tumor, with adrenal localization accounting for approximately 21% of cases. The radiological characteristics are nonspecific and can be confused with adrenal cortical carcinoma and pheochromocytoma, thus contraindicating biopsy in this context. It is often sporadic, although associations with ROHHAD syndrome, MEN2A, and Turner syndrome have been reported. Management is based on surgical resection; AG is characterized by close vascular conncetions, which complicates its surgical approach. The prognosis after surgery is favorable, and no adjuvant treatment is required.

Familial form of adrenoleukodystrophy with late diagnosis of chronic adrenal insufficiency (clinical case)

Daria Danilenko[1], Natalia Likharad[1], Tatsiana Mokhort[2] & Alena Mokhort[2]
[1]1 City Clinical Hospital, Minsk, Belarus; [2]Belarusian State medical University, Endocrinology, Minsk, Belarus

Introduction
Adrenoleukodystrophy (ADL) is a rare genetic disease characterized by abnormal metabolism of very long-chain fatty acids due to mutations in the ABCD1 gene, which leads to their accumulation in the central and peripheral nervous system, adrenal cortex and gonads. The disease has a variable clinical spectrum and prognosis.
Results
Patient U., 41 y.o., with complaints of severe general weakness, dizziness, decreased blood pressure, dyspepsia, had chronic adrenal insufficiency for the first time. ADL was established at the age of 6 (family history: my brother has ADL with severe myeloneuropathy, my cousin has cerebral ADL). Since the age of 15, he had not received special treatment, he was constantly worried about weakness, and he added salt to his food. The deterioration of the condition, provoked by errors in the diet, was accompanied by vomiting, hypotension, and progressive weakness. Seeking medical help led to the diagnosis of pancreatitis and relief from infusion therapy during the day. The condition worsened after a day - BMI - 16 kg/ m^2, skin with slight hyperpigmentation, muscles are hypotrophic, blood pressure 80-50 mm Hg. Facial hair is sparse. Laboratory data: hyponatremia (125.68 mmol/l), hyperkalemia (6.71 mmol/l), daily cortisol profile (after administration of glucocorticoids for emergency indications) 185 - 107,8 - 64,1 nmol/l (79-536 nmol/l), ACTH from 01/15/2025: at 8.00 - 1312 pg/ml (7.2 - 63.3 pg/ml), testosterone -2.4 nmol/l (8.64 – 29 nmol/l) with an increase in LH and FSH levels. The diagnosis: primary adrenal insufficiency, hopogonadism on the background of adrenoleukodystrophy with minimal manifestations of myodoneuropathy. Parenteral glucocorticoid therapy was initiated from 300 mg/day with infusion therapy with dose reduction and transfer to oral (hydrocortisone 20 mg /day in the morning, fludrocortisone 0.1 mg in the afternoon). The patient's condition improved, weakness was relieved, blood pressure was 110/70 mmHg, hyperpigmentation decreased, and electrolyte levels returned to normal.
Conclusion
In addition to neurological symptoms, ADL is accompanied by the development of adrenal insufficiency and hypogonadism, which can develop at any age.

A challenging diagnosis in a patient with primary adrenal insufficiency

Livia Celia Lasca[1], Aurora Alina Să?ianu[2] & Alina Cristina Silaghi[3]
[1]Cuore Medical Clinic, Cluj-Napoca, Romania; [2]Medena Clinic, Oradea, Romania; [3]Endocrinology Department, County Clinic Emergency Hospital, Cluj-Napoca, Romania, Cluj-Napoca, Romania

X-linked adrenoleukodystrophy (X-ALD) is a rare, genetically determined metabolic disease with strong clinical heterogeneity. It affects approximately 1/20,000 Caucasian men. Adrenomyeloneuropathy (AMN) is a variant type of X-ALD that usually occurs in adult males and primarily affects the spinal cord, often presenting as progressive spastic paralysis. We present the case of a 43-year-old man, with no family history, diagnosed in adolescence with primary adrenal insufficiency and treated with Prednisone for a relatively short duration of time (six years). Years later, he was presented to the emergency room with nausea and intractable vomiting. Upon examination, his blood pressure was 90/54 mmHg, heart rate 100 beats/min, weight 40 kg, height 165 cm. He had dry mucous membranes and hyperpigmented skin. The neurological examination was unremarkable. Cardiopulmonary examination showed no abnormalities; the abdomen was without alterations; the meningeal tests were negative. Further testing revealed hyponatremia 130 mM/l (135-145), hyperkalemia 5.6 mM/l (3.6-5.5), while routine blood tests for liver function, kidney function, lipids, blood glucose, CRP, urine, and stool routine tests demonstrated no significant abnormalities. Normal thyroid function, baseline cortisol 12 µg/dl (5-25), baseline adrenocorticotropin >2.000 pg/ml (7.2–63.4), renin >630 µUI/ml (2.8-39.9), total testosterone was 2.6 nM/l (4.16-35.36), luteinizing hormone 24.9 UI/l (2.6-6.8), follicle-stimulating hormone 9.79 UI/l (1.5-19.4). After the diagnosis of primary adrenal insufficiency, he started treatment with corticosteroids and mineralocorticoids. Three months later, he presented with rapid, severe neurological deterioration, including apathy, dysarthria, spastic paraplegia, extensive muscle atrophy, urinary, and fecal incontinence. A brain MRI scan revealed active demyelination, high bilateral symmetrical signal intensity of the white matter in T2 and Flair within the corpus callosum, corticospinal tracts at the level of the brainstem, and middle cerebellar peduncles. Spectrographic recordings showed neuronal destruction. No cervical medullary atrophy on MRI imaging of the cervical cord. Additional laboratory findings: Hepatitis B, syphilis, Borelli, and HIV tests were all negative. The determination of very long-chain fatty acids showed a high level in serum. Molecular analysis of the ABCD1 gene reported hemizygous missense pathogenic mutation c.1252C>T, p.(Arg418Trp). After the diagnosis of AMN, he continued with supplementation for his adrenal insufficiency, developed sepsis two months later due to a urinary infection, and died due to complications. This case underscores the importance of considering AMN in patients with primary adrenal insufficiency, particularly when there is neurological decline. Early identification in such cases could facilitate timely interventions that may prevent or delay disease progression.

Case of spontaneous adrenal tumour infarction resembling pheochromocytoma

Olga Wajtryt[1], Elwira Bakuła-Zalewska[2], Dorota Łącka-Lipińska[1], Aleksandra Budrewicz[1], Piotr Góralski[1] & Marek Dedecjus[1]
[1]Maria Sklodowska-Curie National Research Institute of Oncology, Department of Endocrine Oncology and Nuclear and Nuclear Medicine,

Warsaw, Poland; [2]Maria Sklodowska-Curie National Research Institute of Oncology, Department of Pathology, Warsaw, Poland

Case report

We present a case report supplemented with imaging, laboratory, and histopathological diagnostic documentation, and a review of the literature. A 50-year-old man was admitted to the Department of Endocrinology with a suspected pheochromocytoma.

History

The patient had a previously diagnosed left adrenal tumor, 4 cm in diameter, described on high-density CT. Prior to admission, he had been in the Department of Surgery for abdominal pain suggestive of renal colic accompanied by symptoms of a hypertensive crisis. An abdominal CT scan was performed, which showed a left adrenal lesion with dimensions of 5×4.5×6 cm and a density of 50 H.U. There was no evidence of hyperintense blood signal. In laboratory tests, myocardial necrosis markers and inflammatory parameters were elevated. Blood pressure was found to be elevated, ranging from 200/150 to 150/180 mmHg. Hypotensive medication was administered, and improvement was achieved after 8 days. Due to the suspicion of pheochromocytoma, a 24-hour urine collection for methoxycatecholamines was performed, which showed significantly elevated levels. Based on the ESE/ENSAT 2023 algorithm, the Multidisciplinary Team qualified the patient for excision due to a lesion diameter > 4 cm and high density on CT. Subsequently, repeat diagnostic tests were performed, and methoxycatecholamine levels in both blood and the 24-hour urine collection were within normal limits. In order to prepare the patient for surgery, treatment was modified to include an alpha-blocker. Laparoscopic resection of the periadrenal lesion was performed. Histopathological examination revealed a 3.5 cm tumor – 99% of the tumor was necrotic - surrounded by a fibrous capsule, and a fragment of normal adrenal gland with cells of the three-layered cortex was also visible.

Conclusion

The patient most likely experienced infarction or bleeding into the adrenal tumor, with abdominal pain interpreted as a symptom of renal colic. Symptoms such as hypertension, elevated myocardial necrosis markers, and increased inflammatory parameters may indicate ongoing necrosis. Literature and cases of tumor necrosis were also reviewed. There are cases of tumors such as fibroadenoma of the breast, myoma of the uterus, Warthin's tumor of the salivary gland, and even lymphoma that undergo "self-destruction" via a necrosis mechanism.

Prepubertal gynecomastia in a boy with classic 21-hydroxylase deficiency

Aleksandra Szydło[1] & Anna Kucharska[2]
[1]University Clinical Center of Medical University of Warsaw, Warsaw, Poland; [2]Department of Pediatrics and Endocrinology, Medical University of Warsaw, Warsaw, Poland

We report a case of a 4-year-old patient with salt wasting congenital adrenal hyperplasia who developed prepubertal gynecomastia as a symptom of insufficient substitutive therapy. The patient was treated since the 6th day of life with hydrocortisone (HC) and fludrocortisone (FC). At the age of 4years the dose of HC was 10mg/square m. Laboratory tests confirmed elevated levels of adrenocorticotropic hormone (ACTH), androstenedione and 17-hydroxyprogesterone (17-OHP), and 24-hours urine collection also revealed not enough suppression of androgens and 17-OHP metabolites. Following an increase in hydrocortisone dosage, the gynecomastia completely regressed during 3 months. In the described case, TART and other estrogen-secreting tumors were considered in the differential diagnosis, but the complete resolution of gynecomastia after increasing the dose of hydrocortisone indicates that the cause was insufficient replacement. Gynecomastia as a dominant symptom of insufficient replacement therapy in congenital adrenal hyperplasia in a boy is rarely described, and premature pubarche is much more frequently observed. A probable explanation may be the increased aromatization of adrenal androgens to estrogens in prepubertal patients.

Adrenal imaging pitfalls: a case of a giant renal liposarcoma mimicking an adrenal tumor

Yassmine Abdelkafi[1], Khouloud Boujelben[1], Dhoha Ben Salah[1], Yesmine Elloumi[1], Faten Haj Kacem Akid[1], Nadia Charfi[1], Mouna Mnif[1], Mohamed Abid[1], Mouna Elleuch[1] & Nabila Rekik Majdoub[1]
[1]Hedi Chaker University Hospital, Endocrinology Department, Sfax, Tunisia

Introduction

Liposarcomas are rare malignant tumors arising from adipose tissue, with the kidney being an exceptional site of origin. Due to their large size and mass effect, renal liposarcomas can mimic adrenal tumors, leading to diagnostic confusion, especially when the adrenal gland is not clearly visualized. This case highlights the challenges of adrenal imaging and the importance of histopathological confirmation in ambiguous cases.

Observation

A 64-year-old male, with no prior medical history, was referred for the evaluation of a 17 cm adrenal mass, incidentally discovered on an abdominal CT scan performed due to unexplained weight loss (17% in one month) and pelvic pain. MRI revealed a large, solid-cystic right renal mass (18.6 × 14.8 cm in axial diameter, 21.5 cm in height), with heterogeneous peripheral enhancement, multiple cystic areas, and intermediate T2 signal intensity. The mass displaced the right kidney downward, while the right adrenal gland was not visualized, raising strong suspicion of an adrenal origin. There was no vascular invasion, but the mass displaced the inferior vena cava and right renal vein. A mild right pleural effusion was also noted. Upon referral to endocrinology, the patient exhibited no signs of hypercortisolism or hypercatabolism. He had abdominal asymmetry, normal skin examination, and erectile dysfunction without gynecomastia or loss of libido. Biochemical exams showed normal plasma metanephrines, and a 1 mg dexamethasone suppression test ruled out hypercortisolism. Based on imaging and clinical findings, an adrenocortical carcinoma was strongly suspected, leading to surgical resection. However, histopathology unexpectedly revealed a high-grade dedifferentiated renal liposarcoma (FNCLCC grade 3), measuring 22 cm, with perirenal fat invasion but no vascular emboli, perineural invasion, or involvement of the renal hilum, ureter, or right adrenal gland.

Discussion and Conclusion

This case highlights the diagnostic challenges of large renal tumors and the potential pitfalls of adrenal imaging. Despite radiological findings highly suggestive of an adrenal malignancy, the true origin of the mass was renal, demonstrating how large renal tumors can compress or displace the adrenal gland, creating a misleading appearance. The absence of hormonal abnormalities, the lack of vascular invasion, and the atypical imaging characteristics should raise suspicion of non-adrenal neoplasms in similar cases. This case reinforces the importance of a multidisciplinary approach, careful interpretation of imaging findings, and the necessity of histopathological confirmation to avoid misdiagnosis.

Primary adrenal insufficiency due to recurrent episodes of unilateral adrenal infarction

Saori Kitayama[1], Yasufumi Seki[1], Yutaka Kato[2], Saya Takebe[1], Makiko Ikemoto[1], Yuko Inoue[1], Kiyotaka Hirata[1], Kaoru Yamashita[1], Noriyoshi Takano[1], Daisuke Watanabe[1], Satoshi Morimoto[1] & Atsuhiro Ichihara[1]
[1]Tokyo Women's Medical University, Department of Endocrinology and Hypertension, Tokyo, Japan; [2]Tokyo Women's Medical University, Department of Hematology, Tokyo, Japan

Introduction

Adrenal infarction is a rare cause of primary adrenal insufficiency that usually occurs in hypercoagulable states, resulting in life-threatening conditions. Most cases of adrenal infarction involve bilateral lesions complicated with adrenal insufficiency or a unilateral lesion without adrenal insufficiency. Cases of unilateral adrenal infarction resulting in adrenal insufficiency have been rarely reported. Herein, we present a case of recurrent episodes of unilateral adrenal infarction leading to adrenal insufficiency.

Case description

A 72-year-old woman with a history of myelodysplastic syndrome and cerebral infarction presented with sudden-onset left lumbago. The patient had taken lenalidomide for 13 months and cilostazol for thrombocytosis and prevention of cerebral infarction. Abdominal enhanced CT revealed a left swollen adrenal gland with a low-enhanced area and MRI showed a restricted diffusion of the ischemic adrenal gland, confirming the diagnosis as left adrenal infarction. The cosyntropin test revealed a peak cortisol level of 16.9 μg/dL, indicating normal adrenal function. Despite the cessation of lenalidomide, the 2nd episode of adrenal infarction developed on the right adrenal gland 3 months after the 1st episode of adrenal infarction. Plasma levels of adrenocorticotropic hormone, cortisol, and peak cortisol response to 250 μg of cosyntropin were 1996 pg/mL, 27.8 μg/dL, and 14.8 μg/dL, respectively, indicating primary adrenal insufficiency and the patient started to take 15 mg of hydrocortisone.

Conclusion

We present a case of recurrent unilateral adrenal infarction causing bilateral adrenal infarction and adrenal insufficiency. Unilateral adrenal insufficiency is rare but can

cause adrenal insufficiency when it repeatedly develops on the bilateral adrenal glands.

Addison's disease initially interpreted as sarcoidosis

Ingrid Nermoen[1] & Kristine Hatlen[1]
[1]Akershus University Hospital, University in Oslo, Endocrinology, Lørenskog, Norway

Background
Primary adrenal insufficiency (AI) is a rare and potentially life-threatening condition. The diagnosis can often be delayed for months. We describe a young man with a delayed diagnosis whose condition was initially suspected to be sarcoidosis. So far only four cases of elevated ACE levels as a primary finding in AI have been reported.
Case Report
A 23-year-old man was hospitalized urgently with severe salmonella enteritis in autumn 2022, presenting with total colitis, high fever, bloody stools, abdominal tenderness, and severe hyponatremia (124 mmol/l, normal range 137-145). He was discharged in much better condition and returned to full-time work. Two months after discharge, he experienced fatigue. There were no more loose stools, and he was afebrile, but became weaker and weaker with periods of dizziness, acid reflux, epigastric pain, nausea, and some vomiting. He had a CT of the abdomen/pelvis and an abdominal ultrasound, both with normal findings. Gastroscopy revealed esophagitis grade A, and duodenal biopsies were negative for coeliac disease. After 10 months of declining general health and a weight loss of 30 kg, he was admitted to the Diagnostic Unit at our hospital due to concerns about malignant liver disease indicated by abnormal liver and bile values, ASAT 56 (15-45) and ALP 151 U/l (35-105). Blood pressure was 113/67 mmHg, pulse rate 115, sodium 135 mmol/l and potassium 4.6 mmol/l (normal range 3.6-5). The first notable finding was a hilar lymph node observed on a thoracal CT scan and an elevated ACE level of 111 U/l (18-65), which raised suspicion of sarcoidosis, and referral for bronchoscopy. The patient had no dyspnea or cough. Ferritin was elevated at 601 mg/l (30-400). Expanded blood tests confirmed primary AI with low cortisol levels at 15 nmol/l (133-537) and high ACTH levels at 362 pmol/l (1.5-14). Additional symptoms such as salt cravings, increased skin pigmentation, and muscle pain appeared. Treatment with mineralocorticoids and glucocorticoids was initiated. He improved quickly and gained 19 kg in less than four months. The bronchoscopy was cancelled, and after 3 months, the lymph node had diminished, and the ACE, liver and ferritin levels had normalized.
Conclusions
This is the fifth published case with debut of AI with high ACE without having sarcoidosis. The patient avoided an unnecessary pulmonary biopsy. Low cortisol levels in untreated AI can lead to increased inflammatory markers as ACE and ferritin.

JOINT2435

Elevated serum dehydroepiandrosterone sulfate in a young male without visible adrenal tumor

Patrícia Brito[1], Rita Ribeiro[2], Valentim Lopes[1], Diana Borges Duarte[1] & Catarina Matos[1]
[1]ULS Braga, Endocrinology department, Braga, Portugal; [2]ULS Brag, Endocrinology depart, Braga, Portugal

Introduction
Dehydroepiandrosterone sulfate (DHEAS) levels typically increase during adrenarche, decreasing over time. Elevated DHEAS is also found in congenital adrenal hyperplasia and adrenal tumors.
Clinical Case
A 23-year-old male presented with a two-year history of left-sided painful gynecomastia. He denied any complaints of nipple discharge, decreased libido, abdominal pain, or fatigue. Over the previous 6 months, he had gained 7kg, attributing this to a resistance training regimen. He had no chronic medication and denied any previous/current anabolic steroids consumption, reporting only the use of over-the-counter creatine and Whey-protein supplements (since he started his gym routine). Pubertal development was normal. His medical history included childhood testicular trauma without lasting effects. He expressed no desire for children in the near future. Clinical examination revealed mild left retroareolar gynecomastia, normal blood pressure, and no cushingoid features. No abnormalities were found on testicular examination. Blood test revealed a normal gonadotrophic axis, with no thyroid disfunction and normal prolactine, 17-hydroxyprogesterone, and hCG serum levels, as well as normal renal and hepatic function. Two separate blood samples revealed elevated serum estradiol (first sample: 1.9 times the upper limit (TUL); second sample: 1.3 TUL) and DHEAS (first sample: 1.3 TUL; second sample: 1.6 TUL). Breast ultrasound confirmed gynecomastia without additional abnormalities. Adrenal CT did not reveal masses but suggested possible bilateral hyperplasia. A dexamethasone suppression test with 0.5mg every 6 hours for 48 hours effectively normalized DHEAS levels, with a 51% reduction from baseline.
Discussion
This is a challenging case concerning the patient's management and follow-up: is this elevated DHEAS a normal variant? Could it indicate a genetic defect in steroid sulfate transporter proteins, and if so, is it clinically relevant to perform a genetic test as it may impact his descendants? What approach should be taken for monitoring this patient, whether clinical, biochemical, or both?

When hormonal and oncologic pathologies collide: navigating management complexities of primary hyperaldosteronism with an incidental finding of renal cell carcinoma

Nashriq Khan Adam Khan[1] & Sargunann Naidu Krishnasamy Naido[2]
[1]Norfolk and Norwich University Hospitals NHS Foundation Trust, Acute Medicine, Norwich, United Kingdom; [2]Whittington Health NHS, London, United Kingdom

Introduction
Primary hyperaldosteronism (PHA), or Conn's syndrome, is a common yet underdiagnosed cause of hypertension, characterized by excessive aldosterone secretion. It is classically associated with hypertension and hypokalemia. PHA can result from unilateral or bilateral adrenal hyperplasia or aldosterone-producing adenomas. This case highlights the diagnostic and therapeutic challenges of PHA complicated by incidental renal cell carcinoma (RCC). The urgency of managing a potentially malignant renal mass may conflict with the need for precise localization of aldosterone hypersecretion through adrenal vein sampling (AVS).
Case Report
A patient with persistently low potassium levels was referred for endocrine evaluation due to uncontrolled hypertension despite being on three antihypertensive agents. Initial investigations revealed a significantly elevated aldosterone-to-renin ratio (ARR), strongly suggestive of primary hyperaldosteronism. Given the high pre-test probability, further confirmatory testing was deemed unnecessary. A CT scan of the adrenal glands identified an 11 mm left adrenal nodule, consistent with an adrenal adenoma, but also incidentally revealed a suspicious left renal mass, concerning renal cell carcinoma (RCC). This finding prompted an urgent referral to the Urology team, and the patient was subsequently reviewed by a specialized Renal Cancer Unit for multidisciplinary discussion. From an endocrine perspective, adrenal vein sampling (AVS) was recommended to confirm the source of aldosterone hypersecretion. However, this required a 6-week washout period from Spironolactone, which posed a significant delay. Given the urgency of addressing the renal mass, the Urology team advised proceeding with kidney surgery without delay for endocrine concerns. The complexities in management arise from the need to balance timely intervention for the renal mass with the diagnostic precision required for PHA. The adrenal gland will be preserved during kidney surgery to allow for future AVS if needed. Post-surgery, the patient will continue medical management of PHA, with the possibility of targeted treatments such as aldosterone synthase inhibitors in the future.
Conclusion
This case highlights the challenges of managing concurrent primary hyperaldosteronism and renal malignancy, particularly when diagnostic and treatment timelines conflict. Multidisciplinary collaboration between Endocrinology, Urology, and Oncology teams is essential to optimize outcomes.

Bilateral gynecomastia revealing adrenocorticaloma

Mehdi Abir[1]
[1]Hôpital Central D'armée, Algiers, Algeria

Adrenal cortical carcinoma is a rare malignant tumor of the adrenal cortex and represents 0.5-2% cases per million per year with peaks of occurrence in the first decade between 40 and 50 years of age. The main circumstances of discovery are hormonal hypersecretion in 40%-70% of cases and tumor syndrome in 40%-60% of cases. Hyperestrogenism is revealed in men by gynecomastia or a drop in libido with testicular involution. We report the case of a 57-year-old patient, with no particular history, admitted for treatment of a left adrenocortical tumor discovered by bilateral gynecomastia evolving for 6 months. The clinical examination reveals a patient in altered general condition (weight loss, profound asthenia, anorexia), bilateral gynecomastia present for 6 months, decreased libido and abdominal pain. There are no signs of hyperadrenocorticism or palpable abdominal mass. The hormonal assessment shows an increase in the precursors of adrenal androgens 17OHP, D4androstendione, SDHEA. Major hyperestrogenism is found and there is no biological hypercortisolism. Thoraco-abdomino-pelvic CT scan revealed a large left adrenal tumor mass with a malignant appearance suggestive of corticoadrenaloma with hepatic metastases invading the left renal vein and the infrahepatic IVC. A biopsy of the adrenal mass performed externally came back in favor of a left adrenocorticaloma with positive immunohistochemistry, synaptophysin and Melan A. The evolution in the hospital environment was noted by a hypercalcemia probably paraneoplastic, the initiation of bisphosphonates was deferred given the altered general condition of the patient who died following a state of hemorrhagic shock. Feminizing adrenocortical tumors or estrogen-secreting adrenal tumors are extremely rare. They are mainly observed in men and children in whom the main symptoms are breast enlargement. Their diagnosis is mainly based on the assessment of estrogens. A mixed secretion attested by the elevation of adrenal precursors and a large tumor argue in favor of malignancy. Treatment should be based on surgery associated with op'DDD or aromatase inhibitors with or without standard or targeted chemotherapy. The prognosis depends on the stage of the tumor at the time of diagnosis and the course of the disease, but in general the final prognosis is extremely poor, especially in adults in whom benign tumors are exceptional.

Plasma steroid profiling in early diagnosis of adrenocortical carcinoma

Furnica Raluca[1], Cornelis Frank[1], Dominique Maiter[1] & Damien Gruson[1]
[1]Cliniques Universitaires Saint Luc, Brussels, Belgium

Introduction
Early and accurate diagnosis of adrenocortical carcinoma (ACC) is essential for improving prognosis. Recent studies highlight the potential of plasma steroid profiling in diagnosing malignancy in adrenocortical tumors.
Objective
This study aimed to evaluate the diagnostic value of 11-deoxycortisol in identifying ACC.
Materials and Methods
Two patients with suspected ACC and one patient with suspected recurrent disease underwent clinical, biochemical and imaging evaluation in our tertiary care center. Serum steroids, including 11-deoxycortisol, were quantified using liquid chromatography-tandem mass spectrometry (LC-MS/MS).
Results
Two patients with large incidental adrenal masses showed significantly elevated levels of 11-deoxycortisol (1167 ng/dL and 1242.3 ng/dL, respectively, compared to the upper reference limit of 33 ng/dl). These levels correlated with tumor size. Both patients **presented with hyperandrogenism and cortisol secretion.** In the first case, 11-deoxycortisol level normalized following complete tumor resection, but in the second case the level remained elevated as the tumor was not amenable to radical resection. The third patient showed elevated 11-deoxycortisol level during follow-up (689 ng/dL), **allowing early detection of recurrence of a** clinically silent **tumor. Histopathological examination confirmed the presence of ACC in all cases.**
Conclusion
Our findings suggest that 11-deoxycortisol may serve as a valuable biomarker for the early diagnosis of ACC and for monitoring *potential* recurrence after surgery, **thereby improving patient outcomes.**

Non-neoplastic hypercortisolism state and adrenal incidentaloma: a clinical challenge?

Nouhaila Essafir[1], Nada Ait Kassi[1], Vadel Sid Mhamed[1] & Ahmed Anas Guerboub[1]
[1]Mohammed V Military Hospital, Endocrinology and Metabolic Diseases, Rabat, Morocco

Introduction
The diagnosis of Cushing's syndrome (CS) can be challenging for endocrinologists due to its multifaceted presentation. Accurate differentiation between non-neoplastic hypercortisolism (NNH) states, formerly known as Pseudo-Cushing's syndrome (PCS), and true CS is crucial, as their treatment approaches and outcomes vary significantly.
Case Report
A 37-year-old female patient with a medical history of hypertension, Iron-deficiency anemia, and depression. Family history revealed a background of familial hypertension. The patient was admitted for the exploration of a 14mm hypodense left adrenal mass, with radiological features suggestive of adenoma. Clinical examination revealed grade II obesity (body mass index 38 kg/m^2) with an android phenotype, along with a moon face, supraclavicular and dorsocervical fat pads, and a buffalo hump. However, no other overt clinical features of Cushing syndrome were noted such as facial plethora, purple striae marks, or proximal myopathy. Blood pressure was well-controlled with calcium channel blockers. The patient had undergone investigations for secondary hypertension, excluding renal parenchymal disease, renal artery stenosis, coarctation of the aorta, obstructive sleep apnea, thyroid dysfunction and hyperparathyroidism. Laboratory studies were conducted to assess for adrenal hyperfunction. The aldosterone-to-renin ratio (ARR) and catecholamine excess were negative. However, midnight cortisol and urinary-free cortisol tests were elevated. An oral overnight 1mg dexamethasone suppression test (DST) was performed, which revealed appropriate suppression of serum cortisol to 10ng/ml, thus excluding the diagnosis of endogenous hypercortisolism.
Conclusion
Non-neoplastic hypercortisolism (NNH) states refers to various conditions responsible for mild-to-moderate hypercortisolism, resulting from overactivation of the hypothalamic-pituitary-adrenal axis. The main conditions implicated in NNH comprise: neuropsychiatric disorder, alcohol abuse, insulin-resistant obesity, polycystic ovary syndrome, and end-stage kidney disease. We concluded that the cortisol abnormalities in our patient were due to NNH state, caused by obesity and depression. The concomitant presence of a non-functioning adrenal adenoma further complicated the diagnosis in this case.

An incidental adrenal mass misleading to surgical intervention: a case of misleading imaging findings

Arwa Alyamani[1]
[1]King Abdullah Medical City, Makkah, Saudi Arabia

A 15-year-old female with a history of splenectomy following a road traffic accident complicated by intestinal obstruction and laparotomy at age of 8, was referred in 2024 for evaluation of left adrenal incidentaloma. The lesion has been discovered in abdominal CT scan performed to investigate recurrent urinary tract infection (UTIs). Up on her review in our clinic, she had no hypertension, hypokalemia and symptoms suggestive of pheochromocytoma or Cushing's syndrome. Her menarche started at age of 13 and has reported regular menstrual cycles with no hirsutism or acne. There was no personal or family history of endocrinopathies, HTN, or stroke in young. On physical examinations she was well-developed with no Cushingoid features or hyperandrogenism. Biochemical tests were normal including a cortisol suppression of 1.0 mg/dl with 1 mg dexamethasone suppression test and plasma metanephrine. Adrenal CT scan demonstrated a suspicious characteristic of a large (4.8 x 4.5 cm) well-defined left suprarenal homogenous lesion of (49 HU precontrast, 101 HU venous phase and 70 HU delayed) with absolute washout of 59.6% and indeterminate relative washout of 30.7%. For that, androgen levels were requested and came normal and has been referred to urology team for surgical intervention. The patient underwent laparoscopic adrenalectomy, which was converted to open surgery due to extensive adhesions from the previous abdominal surgery. Intra-operatively, the left adrenal gland appeared normal and a left peri-adrenal area mass was noted and excised. The histopathological examination of the excised tissue revealed unremarkable splenic tissue, with no evidence of malignancy.

Adreanal hystopatology in primary aldosteronism: single centre expiriance

Natasa Vujacic[1], Nikola Slijepcevic[1], Goran Zoric[1] & Vladan Zivaljevic[1]
[1]Clinical Center of Serbia, Clinic of endocrinology, diabetes and metabolic disorders, Belgrade, Serbia

Introduction
Primary aldosteronism (PA) is the most frequent secondary hypertension, reaching about 5% of all hypertensive population. It is believed that two thirds of PA cases are caused by bilateral idiopathic hyperplasia (BIH) of adrenal cortex. Subjects with PA due to aldosterone-producing adenoma (APA) are diagnosed easier among hypertensive, mostly due to clinical picture of hypokalaemia.
The aim of this study was to analyse the type of histopathologic features in patients with primary aldosteronism treated in our Centre for Endocrine Surgery and compare to the finding in adrenal tumour operated due to hypercorticism.
Material and methods
Our study included 40 patients with primary aldosteronism (PA group) and one control group, of 20 patients with hypercorticism due to adrenocortical tumour, 10 with Cushing' syndrome (CS) and 10 with subclinical CS (SCS).
Results
There was no significant difference between groups related to the age ($P = 0.147$), nor sex distribution, although a higher number of women in all groups was recorded ($P = 0.099$). Systolic and diastolic blood pressures were significantly higher in PA group ($P = 0.005$ and $P = 0.002$ respectivaly), with the lowest levels in NFA+HT group. The significanteley higher mean arterial pressure (MAP) was also found in PA group ($P = 0.001$). The largest tumour size was measured in CS+SCS group, then in PA group ($P < 0.001$). All patients with PA had low serum potassium level. On light microscopy, aldosterone-producing adrenal cortical adenomas appear partially or completely encapsulated, with a compressed fibrous rim or fibrous "pseudocapsule" at the expansile borders of the tumor. The morphology of individual cells may be quite heterogeneous, with varying proportions of 4 different types of cells: clear cells resembling zona fasciculata cells, cells resembling ZG cells, compact cells indistinguishable from those of the zona reticularis, and a group of cells designatedas "hybrid" cells with cytologic features of both zona fasciculata and ZG cells.
Conclusion
We founded that the hybrid celles indipendetly or with ligt cells like zona fscicullata has been predominated in 60% cases with PA, most frequently then in the group SCS+CS.

A rare case of vanishing bilateral adrenal masses

Vlad Radulescu[1,2], Omar Nouhou Koutcha[1], Meriem Sal[1], Emmanuel Cosson[1], Paulina Kuczma[1], Christophe Tresallet[1] & Bihan Hélene[1]
[1]Hopital Avicenne AP-HP, Bobigny, France; [2]National Institute of Endocrinology "C.I Parhon", Bucharest, Romania

Introduction
With advancements in imaging technology and its widespread use, adrenal incidentalomas have become a frequent finding. Most cases involve non-functional, irreversible adrenal enlargements. However, reports of reversible adrenal enlargements remain limited.
Case Report
We explored a 68-year-old man, with metabolic hyperferritinemia without HFE mutation and partial splenectomy, for bilateral adrenal masses suspect of malignancy. In July 2024, he had a fever and lost weight (4kgs). All infectious causes were excluded (PCR triplex (including SARS-CoV-2), tuberculosis, B/C hepatitis, HIV, tropical diseases) and an empiric antibiotic treatment was suspended after 7 days due to no improvement. After a two months fever, the PET scan (08/2024) showed one 35 mm intensely hypermetabolic left adrenal mass, 2 intensely hypermetabolic right adrenal masses (13 mm on the medial arm, 11 mm in the body) and three intensely hypermetabolic latero-aortic adenopathies. The abdominal scanner (10/2024) detailed basal density, absolute and relative wash out: left adrenal: 30 HU/36%/25%, 1st right adrenal lesion: 19 HU/82%/ 66% and 2nd lower right adrenal lesion: 25 HU/ 55%/41%. The hormonal work-up showed: normal basal ACTH (25.4 pg/ml) and cortisol values (303.9 nmol/l), an optimal response after Synacthene testing (peak at 502.3 nmol/l), correct cortisol after 1mg DST (<27.6 nmol/l), normal midnight serum cortisol (114.7 nmol/l), and free urinary cortisol/24h (28.7 mg/24h), normal serum and urinary metanephrines and normetanephrines, normal Chromogranin A, normal testosterone but a low DHEA-S [0.8 umol/l – (6.2-7.7 umol/l)] and normal 17-OH-progesterone. A surgical excision of the left adrenal mass was preferred to an adrenal biopsy or lymph node biopsy. However, the pre-surgical PET scan (11/2024) showed almost complete regression of the adrenal masses, with only a persistent diffuse and moderately hypermetabolic thickening of the left adrenal, a non-fixing right adrenal and almost complete regression of the latero-aortic adenopathies. The surgery was canceled. We retained an etiological doubt. Adrenal hemorrhage was unsuspected with first images, but an MRI performed in 11/2024 showed a few hypovascular left adrenal nodules, compatible with adrenal hematomas. SARS-CoV-2 infection may cause bilateral adrenal masses compatible with the onset of the febrile episode. Adrenal lymphomas are associated with splenomegaly (impossible to evaluate in our patient), adrenal failure and abnormal hemogram (absent) and no spontaneous regression. An adrenal biopsy will be performed if the suspicion remains high during the follow-up.

A case of sheehan syndrome presenting with acute coronary syndrome: a case report

Norjan Ladja[1]
[1]Zamboanga Doctors' Hospital, Department of Internal Medicine, Zamboanga City, Philippines

Sheehan's syndrome is a form of post-partum complication where pituitary gland necrosis occurs as a result of sudden large volume blood loss during or after delivery. In this case report, index patient presented with chest pain, easy fatigability and dyspnea. The patient was managed as a case of acute coronary syndrome with positive troponin I. On the 3rd day of hospitalization, no clinical improvement noted warranting further work up and deeper review of history and physical examination. Suspicions for the involvement of pituitary gland was include when upon review of history, the patient presented with complains of amenorrhea, agalactorrhea, sparse thin hair and persistent hypotension. Serum cortisol, low thyroid hormones, hypoglycemia and pituitary magnetic resonance imaging were obtained supporting the diagnosis of Sheehan's syndrome with acute coronary syndrome.

Cushing's disease in a patient presenting for oculomotor palsy-a diagnostic and management conundrum

Theodora Nistor[1], Sebastian Botezatu[2], Dorin Bica[3], Marian Mitrica[2], Serban Radian[1,4] & Catalina Poiana[1,4]
[1]National Institute of Endocrinology CI Parhon, Bucharest, Romania; [2]Central Military University Emergency Hospital, Bucharest, Romania; [3]NeuroHope Hospital, Bucharest, Romania; [4]Carol Davila University of Medicine and Pharmacy, Bucharest, Romania

Background
Oculomotor palsy is an infrequent presentation in Pitnet patients, due to pituitary apoplexy or tumour compression, with other causes being exceedingly rare. We present a case of Cushing's disease (CD) which associated a vascular cause of oculomotor palsy.
Aim
To describe the diagnosis and management challenges due to concomitant pituitary and parasellar disease.
Case presentation
A 66-year-old woman presented to the ER in Dec 2024 for recent onset unilateral right eye blindness and ophthalmoplegia. A CT scan demonstrated bilateral cavernous sinus masses with intense contrast uptake and she was referred to our endocrine department, following neurosurgical consultation. On examination there was complete right sided ophtalmoplegia and blindness, and pre-existing right hemiplegia from an ischemic stroke (2012). The history was not suggestive of pituitary apoplexy. No obvious signs of endocrine disease were noted. Prolactinemia was minimally elevated (25.3 ng/ml) and there was no pituitary insufficiency. Baseline cortisolemia was 809,65 nmol/l and ACTH=48.81 pg/ml. 11PM cortisol was high and unsuppressed by 1mg overnight dexamethasone (744 nmol/l) and LDDST (670,3 nmol/l), suggesting an invasive corticotropinoma. Contrast-enhanced

head MRI demonstrated bilateral cystic parasellar masses highly suggestive of intracavernous carotid aneurysms. The pituitary appeared compressed between the cavernous sinuses and presented a T1-hypointense micronodule. Pituitary MDT recommended cerebral angiography with the aim of flow-diverter treatment of aneurysms (pending). We initiated ketoconazole treatment, well-tolerated at 400 mg/day.
Conclusion
The differential diagnosis of compressive parasellar masses includes other lesions besides PitNet. Our patient presented bilateral intracavernous carotid aneurysms and CD, mimicking an invasive corticotropinoma. Aneurysm treatment is prioritary. When pituitary surgery is not feasible, as in this case, medical treatment is necessary for hypercortisolism. Pituitary surgery and radiotherapy remain therapeutic options following carotid aneurysm endovascular repair.

Ectopic secretion of ACTH: diagnosis and management a case report

Rania Dassoufi[1], Oussama Jaddi[1], Sana Rafi[1], Ghizlane El Mghari[1] & Nawal El Ansari[1]
[1]Mohamed 6 University Hospital of Marrakech, Endocrinology-Metabolic Diseases-Nutrition Department, Marrakech, Morocco

Introduction
Cushing's syndrome (CS) is the set of symptoms associated with hypercorticism, the ectopic origin of ACTH, is more expressive and can be caused by a variety of tumours. We report this case in order to highlight this special features.
Case report
33 year old female with frank clinical and biological AXTH dependent cushing's syndrome, with normal pituitary MRI and adrenal CT scan. An octreoscan was performed, showing a thyroid and lymphonodal lesions suggesting ectopic secretion of ACTH. We proposed symptomatic treatment with ketoconazole followed by appropriate surgical management, with a good improvement after surgery.
Discussion
Ectopic ACTH secretion is a rare cause of hypercorticism, and octreoscann is a major diagnostic tool. Surgery combined with symptomatic treatment represents the essence of treatment.
Conclusion
ACTH-dependent cushing's syndrome with ectopic secretion remains a very rare entity that can be difficult to diagnose and manage.

Late diagnosis of classic simple virilizing congenital adrenal hyperplasia in a young female

Anabelle Siyan Seah[1], Daniel Ek Kwang Chew[1] & Timothy Peng Lim Quek[1]
[1]Tan Tock Seng Hospital, Endocrinology, Singapore, Singapore

Introduction
The approach to amenorrhoea, hirsutism and virilisation in a young female is an important though uncommonly encountered scenario in general Endocrinology. We present a case of a 28-year-old patient who presented with secondary amenorrhoea, hirsutism and virilisation, and was subsequently diagnosed with congenital adrenal hyperplasia (CAH), likely secondary to 21-hydroxylase deficiency (classic simple virilising type).
Case Presentation and Management
Our patient is a 28-year-old Chinese lady referred to Endocrinology for secondary amenorrhoea. She had a history of epileptic seizures secondary to a right frontal cavernoma on long term carbamazepine. Other significant history included ambiguous genitalia in infancy requiring corrective surgery at 18 months, and hirsutism with excessive body hair growth starting in adolescence. She was also on long term hydrocortisone 10 mg nightly since childhood for hypocortisolism diagnosed during a hospital admission for fever and diarrhoea. There was no history of a salt wasting crisis in infancy or childhood. On examination, she exhibited significant hirsutism (Ferriman-Gallwey score 9), as well as signs of virilisation including voice deepening, temporal balding, acne on her face and chest, and increased muscle mass. Examination of her external genitalia revealed a normal labia majora and minora and genital orifices. There was some evidence of clitoromegaly, although this was confounded by post-surgical changes and scarring. There were no abdominal masses nor undescended gonads in the inguinal region. Investigations showed a high testosterone level within the male range with a markedly raised 17-hydroxyprogesterone level, confirming the diagnosis of CAH. Morning cortisol levels were low with elevated ACTH levels and lack of cosyntropin response, consistent with primary hypocortisolism. Aldosterone levels were adequate. Trans-abdominal pelvic ultrasound showed a normal sized uterus and ovaries. The patient was diagnosed with CAH likely secondary to 21-hydroxylase deficiency (classic simple virilising type). Our patient was started on oral dexamethasone at night, which was subsequently changed to oral prednisolone twice a day, resulting in significant improvement in hirsutism and acne, as well as return of menses. Special attention was given to her concurrent carbamazepine administration which would increase clearance of the administered glucocorticoids.
Discussion and Conclusion
The presentation of secondary amenorrhoea with virilisation in a young female is uncommon, with CAH being one of the possible causes. We will discuss the management of CAH (particularly with regard to steroid choice) and how it can be individualised to incorporate patient's preferences, desired goals for fertility and comorbidities.

Pheochromocytoma: case report

Sona Maghakyan[1] & Andranik Aleksanyan[1,2]
[1]Mikaelyan University Hospital, Yerevan, Armenia; [2]Yerevan State Medical University, Yerevan, Armenia

Pheochromocytomas are rare tumors located in the adrenal medulla, that derives from the chromaffin cells and produce catecholamines. It has an annual incidence of approximately 0.8 per 100,000 person-years. Sustained or paroxysmal hypertension (HT) is the most frequent sign of pheochromocytoma. Classically, pheochromocytoma manifests as spells with the following 4 characteristics: headaches, palpitations, diaphoresis and severe hypertension. Here we describe the case with classical presentations of pheochromocytoma.
Case presentation
A 41-year-old female, without known co-morbidities, presented with episodes of high blood pressure (BP) of 220/110mmHg, headache, palpitation, tremor and sweating during last 20 days. On physical examination, she had pale skin and no other change. Electrocardiogram showed sinus tachycardia, 140bpm, incomplete RBBB, (-T1) V1-V6. The troponin I level was 5.78pg/mL (N 0-20). Echocardiography was not significantly abnormal. Laboratory studies revealed an elevated urinary metanephrines secretion of 493 mg/24h (normal value under 312 mg/24h) and also an elevated urinary normetanephrine of 515 mg/24h (normal value under 445 mg/24h). An abdominal computed tomography (CT) scan was performed, and a 6 cm large tumor in the left adrenal gland was found in. There were no other significant changes. A diagnosis of pheochromocytoma was made. Treatment with alpha- and beta-adrenergic blockers were initiated to adequately normalize BP prior to surgery. After 10 days, the patient successfully underwent laparoscopic left adrenalectomy. Histopathological evaluations confirmed the diagnosis of pheochromocytoma. After surgery, the patient's medications were discontinued and BP and blood sugar were in a normal range. The patient was advised to do genetic testing and to return regularly for outpatient visits.
Conclusion
Pheochromocytoma responsible for less than 1% of patients presenting with hypertension. Although a rare condition, pheochromocytoma can be life-threatening, due to hypovolemia, catecholamine cardiomyopathy or respiratory disorder and should be considered as a differential diagnosis, especially in young patients presenting with unexplained hypertension, chest pain and cardiac dysfunction.

[1]Asclepeion Hospital, Voula, Department of Rheumatology, Athens, Greece; [2]Asclepeion Hospital, Voula, 1st Department of Medicine, Athens, Greece; [3]St. Paul's Hospital, Department of Rheumatology, Thessaloniki, Greece; [4]Asclepeion Hospital, Voula, Department of Endocrinology, Diabetes and Metabolism, Athens, Greece

COVID-19 virus has been found to attack the endocrine system. In particular, it has been shown to affect the thyroid gland. Cortisol secretion has also been shown to be affected by the SARS-CoV-2 virus. The aim was to describe the case of a patient who developed adrenal crisis due to an acute infection by the SARS-CoV-2 virus. A female patient aged 51 had hypotension and hypoglycemia for a period of about 6 months. She had also noticed hyperpigmentation of her skin and her oral mucosa. She developed an acute infection with fever and cough and was found to be positive for the COVID-19 virus. As the infection developed, she had nausea, hypotension, hypoglycemia and finally shock. Hydrocortisone was administered and the patient improved instantly. Adrenal insufficiency was diagnosed. An interferon-gamma release assay - Quantiferon - performed was negative ruling out tuberculosis. Anti-adrenal antibodies were positive. The patient was given hydrocortisone orally 30 mg daily in divided doses for the treatment of adrenal insufficiency. In conclusion, the case of a patient is described who had adrenal insufficiency of an autoimmune etiology and was diagnosed after acute infection from the SARS-CoV-2 virus which induced circulatory shock and an adrenal crisis. Hydrocortisone administration was followed by instant recovery and the patient was diagnosed with adrenal insufficiency and was treated accordingly.

Revealing adrenal tumors as a primary cause of secondary high blood pressure

Manal Bennani[1], Nassim Essabah Haraj[1], Siham El Aziz[1] & Asma Chadli[1]
[1]Ibn Rochd University Hospital, Clinical Neuroscience and Mental Health Laboratory Faculty of Medicine and Pharmacy - Hassan II University, Department of Endocrinology and Metabolic Diseases, Casablanca, Morocco

Introduction
Adrenal masses include a range of pathologies, with benign forms being more common than malignant ones. These masses are sometimes discovered in patients with paroxysmal or resistant arterial hypertension and may represent a potentially treatable cause, accounting for 5 to 10% of secondary elevated blood pressure cases.
Objective
This study aims to highlight the clinical, biological, and morphological characteristics of adrenal tumors diagnosed in patients with elevated blood pressure.
Patients and Methods
Retrospective, descriptive, and analytical study including 46 patients hospitalized for the management of adrenal masses in the Department of Endocrinology, Diabetology, Metabolic Diseases, and Nutrition at CHU Ibn Rochd in Casablanca, over a 5-year period (2019-2024). Statistical analysis was performed using Excel.
Results
The study involved 46 patients with a sex ratio of 0.77. The average age was 45 years. The average duration of high blood pressure was 7 years, with 34% of patients on triple therapy, 36% on dual therapy, and 30% on monotherapy. Blood pressure was only controlled in 21% of cases. Tumors identified included pheochromocytomas in 30% of cases, adrenal adenomas in 22%, and other types of tumors in 48%. Computed tomography (CT) was performed in 32 patients, and MRI in 14, revealing adrenal tumors with an average size of 41 mm. Surgical management was carried out in 40 patients, with tumor resection, and adrenalectomy was performed in 6 patients. The outcome showed remission in 71% of patients, the other 29% having desecalated from triple therapy to bi-tharpy in 18% and monotherapy in 11% of cases.
Conclusion
Adrenal masses are a diverse group, often underdiagnosed, yet they play a significant role in the potential remission of elevated blood pressure

[1]Hospital of Charles Nicolle, Tunis, Tunisia

Background
A 7-year-old girl was referred for advanced growth (+2 SD), obesity (+3 SD), hirsutism (Ferriman-Gallwey score: 10), and precocious puberty.
Case Presentation
Initial investigations ruled out Cushing syndrome with a normal dexamethasone suppression test. Hormonal evaluation revealed an intermediate 17-hydroxyprogesterone (17-OHP) level (8 ng/mL), and the Synacthen stimulation test confirmed partial 21-hydroxylase deficiency with a rise in 17-OHP to 15 ng/mL. Hyperandrogenism was confirmed with elevated delta-4 androstenedione and testosterone levels. Adrenal insufficiency was excluded.
Management and Outcome
Hydrocortisone therapy (10 mg/m^2/day) was initiated, leading to rapid improvement in hyperandrogenism and stabilization of growth velocity.
Conclusion
This case highlights the importance of considering partial 21-hydroxylase deficiency in children presenting with hyperandrogenism and precocious puberty. Early diagnosis and glucocorticoid therapy ensure favorable outcomes and prevent complications.

Vagal paraganglioma: a diagnostic surprise

Rachida Bouattay[1], May Ferjani[1], Sabrina Farhani[1], Khaled Harrathi[1] & Jamel Koubaa[1]
[1]ENT and Head and Neck Department, University Hospital of Fattouma Bourguiba, Monastir, Tunisia

Introduction
The vagal paraganglioma (VP) arises from paraganglionic tissue located along the vagus nerve. This neoplasm represents less than 5% of all head and neck paragangliomas. Advances in imaging have aided the diagnosis and assessment of this disease.
Aim
To study clinical presentation, radiological features and therapeutic management of vagal paraganglioma through a case report and review of literature.
Observation
A 66-year-old patient with a history of total thyroidectomy followed by iratherapy for papillary thyroid carcinoma consulted for a 2cm high laterocervical swelling in the left IIA sector, mobile and firm. The rest of the ENT examination was without abnormalities. The cervical ultrasound suggested a lymph node recurrence of her thyroid carcinoma. The cervical CT scan showed a left subangulo-mandibular formation, oval, opposite the carotid glomus, heterogeneous, richly vascularized with an intense and heterogeneous PDC suggesting adenomegaly of suspicious appearance, given the clinical context. The patient underwent a cervicotomy. Intraoperatively, the mass was richly vascularized, adherent to the vagus nerve and located at the level of the left carotid bifurcation. A complete excision of the mass was performed with simple postoperative course. The final anatomopathological examination of the surgical specimen concluded that it was a vagal paraganglioma. No recurrence or metastasis was noted after a 2-year follow-up.
Conclusion
Vagal paraganglioma, although rare, should be part of the differential when faced with a hypervascular cervical mass to avoid intraoperative surprises.

Hypertension secondary to primary hyperaldosteronism

Alberto Arbex[1], Gallicchio Carla[2], Minna Schleu[2], Mariana Arbex[1], Luciana Rodrigues[2] & Renata Bussuan[2]
[1]Grossenwiehe Medical Clinic, Endocrinology, Flensburg, Germany; [2]AFYA Medical School, Endocrinology, Rio de Janeiro, Brazil

A 69-year-old male was referred to the Endocrinology clinic for evaluation of adrenal-origin hypertension. Despite being on optimized doses of four antihypertensive drugs, including two diuretics (amlodipine 10 mg, losartan 100 mg, chlorthalidone 50 mg, hydralazine 100 mg, and spironolactone 300 mg), his blood pressure remained poorly controlled. His history revealed resistant hypertension since age 32, raising suspicion of a secondary cause. In 2021,

clinical and cardiological evaluations were undertaken ahead of surgery for a left-sided cervical tumor, initially suspected to be a schwannoma with pheochromocytoma. During surgery, the tumor was identified as a benign fusocellular neoplasm affecting the vagus nerve. Despite this, his hypertension and hypokalemia persisted, prompting further investigation. Initial laboratory tests revealed elevated serum aldosterone levels (39.8 ng/dL), suppressed plasma renin activity (0.1 ng/mL/h), and recurring hypokalemia (ranging between 2.9–3.6 mEq/l). Two assessments of urinary metanephrines showed normal levels, renal function was preserved, and sleep apnea was excluded as a contributing factor. An MRI identified bilateral adrenal nodules, raising the suspicion of an endocrine etiology for his refractory hypertension. By 2023, his persistent hypertension and refractory hypokalemia prompted repeated evaluations, confirming elevated aldosterone levels, suppressed renin, and a high aldosterone-to-renin ratio. Imaging showed stable bilateral adrenal nodules, with the most notable being a 2.2 × 1.8 cm lesion in the left adrenal gland's posterior limb. Adrenal vein sampling revealed markedly increased aldosterone secretion from the left adrenal gland, confirming unilateral primary hyperaldosteronism. In April 2024, the patient underwent successful left adrenalectomy. Histological analysis confirmed a benign corticomedullary adenoma. Postoperatively, blood pressure monitoring in May 2024 demonstrated normalized systolic and diastolic readings throughout the day. Spironolactone was discontinued, and the patient maintained control with atenolol, losartan, and a reduced dose of amlodipine (5 mg). Three months later, all biochemical markers, including creatinine, aldosterone, potassium, and renin levels, were within normal limits. This case underscores the critical need to investigate secondary causes of hypertension, especially in patients with resistant or early-onset disease. Early diagnosis and appropriate treatment of primary hyperaldosteronism not only optimize blood pressure control but also correct electrolyte imbalances and significantly reduce long-term cardiovascular risks. A multidisciplinary approach remains essential for achieving the best outcomes.

A lesson for life!

Wiem Feki[1], Ridwaan Auckburally[1], Siddiqa Soomauroo[2], Mouna Elleuch[2], Rim Khemakhem[3], Nabila Rekik[2] & Zeinab Mnif[1]
[1]Hedi Chaker University Hospital, Department of Radiology, Sfax, Tunisia; [2]Hedi Chaker University Hospital, Department of Endocrinology, Sfax, Tunisia; [3]Hedi Chaker University Hospital, Department of Respiratory Medicine, Sfax, Tunisia

Introduction

The discovery of a suspicious pulmonary nodule with adrenal metastasis is a frequent occurrence in the context of a work-up for pulmonary neoplasia. Pathological evidence is usually provided by biopsy of the primary mass. Biopsy of the secondary lesion, particularly the adrenal lesion, is also a second alternative in the event of failure or inaccessibility of the primary lung tumour. We report the case of a patient whose biopsy of the adrenal mass revealed a pheochromocytoma without any complications.

Observation

The patient was 63 years old and smoked 20 packs a year. He complained of a cough that had been treated as acute bronchitis. Physical examination was unremarkable. There was no biological inflammatory syndrome. A chest X-ray was performed when the clinical symptoms persisted. It revealed a pulmonary nodule projecting from the right pulmonary hemichamber. A chest CT scan was performed to better characterise the nodule. We found a lobulated pulmonary nodule with a 12*6mm long axis. The patient also presented with a left adrenal lesion of 10 mm whose enhancement kinetics were consistent with malignancy and in particular a secondary lesion. A pet-scan showed fixation of the 2 lesions with an SUV of 3 and 2.6 respectively. A CT-guided biopsy of the pulmonary nodule concluded that there was chronic and acute pulmonary inflammation. The decision taken at the multidisciplinary consultation meeting was to biopsy the adrenal mass. Metanephrine assay was not requested. The biopsy was performed without incident. Pathological examination revealed a pheochromocytoma. The patient underwent wedge surgery for his pulmonary nodule and left adrenalectomy.

Conclusion

The originality of our case lies in the fact that this patient, who was not hypertensive, underwent a biopsy of an adrenal mass to obtain anatomopathological proof of his bronchopulmonary cancer, which was carried out without incident. Pathology revealed a pheochromocytoma for which the biopsy should have been contra-indicated. It was a non-secreting pheochromocytoma. The lesson to be learnt is that adrenal nodules, regardless of their size or the context of suspected pulmonary neoplasia, even in the absence of known hypertension, should not be manipulated before assessing metanephrine levels.

Diagnosis and management of recurrent ipsilateral pheochromocytoma due to medium sized adrenal tumor with renal vascular invasion

Natia Margvelashvili[1], Nino Zavrashvili[2] & David Nikoleishvili[3]
[1]Tbilisi Institute of Medicine, Davit Tvildiani Medical University, Endocrinology, Tbilisi, Georgia; [2]Tbilisi Institute of Medicine, Tbilisi, Georgia; [3]Caucasus Medical Center, Urologic Surgery, Tbilisi, Georgia

Introduction

Pheochromocytoma, a relatively rare (<0.05%), catecholamine-secreting tumor, is almost always lethal unless recognized and appropriately treated. Clinical and biochemical manifestations are mainly caused by excess circulating catecholamines and hypertension. Sustained or paroxysmal hypertension associated with headaches, sweating, or palpitations, occurs in 95% of patients, but at least 5% are normotensive. All patients with manifestations should be investigated for pheochromocytoma. Plasma free metanephrines and fractionated urinary metanephrines are the most sensitive (≅100%) chemical tests for diagnosing sporadic and familial pheochromocytomas. For suspected metastatic disease use of 18F-fluorodeoxyglucose (18F-FDG) positron emission tomography (PET)/CT scanning is recommended. 2 Surgical resection is successful in 90% of cases. Pheochromocytomas <5 cm in diameter can be removed laparoscopically; larger tumors should be removed by open surgery. Drug treatment prior to and during surgery is mandatory.

Care Report

54 y/o male patient was hospitalized in our clinic due to hypertensive crises. Upon investigation recurrent pheochromocytoma was suspected and was recommended to repeat laboratory tests, including urinary and plasma metanephrines and normetanephrines, which revealed significantly elevated values and patient was advised to perform 18F-fluorodeoxyglucose (18F-FDG) positron emission tomography (PET)/CT. Further MRI imaging revealed nonhomogenous, hypovascular adrenal tumor of about 5-6 cm with suspected left renal artery and vein invasion. Imaging tests demonstrated recurrent disease. Patient was referred to a high volume adrenal surgeon. Laparoscopic adrenalectomy and ipsilateral nephrectomy was performed in short time with patient's perioperative management by a multidisciplinary team approach. During a follow up visit 1 week after surgery patient doesn't complain of increased blood pressure or palpitations, has no need of antihypertensive medications. Patient is advised to perform genetic testing to exclude familial pheochromocytoma. Follow up laboratory tests of metanephrines and normetanephrines are planned 4 weeks after surgery.

Conclusion

Pheochromocytomas are rare, mostly benign catecholamine-producing tumors of chromaffin cells of the adrenal medulla or of a paraganglion. If remaining unrecognized or untreated, they can be a life-threatening condition. Therefore, the most important message of this case report is to stress the importance of patient education about the diagnosis and follow up visits with the specialist. Phosphate as the earliest marker of metabolic bone disease of prematurity

EunJeong Kim[1], Eungu Kang[1], Hyo-Kyoung Nam[1], Kee-Hyoung Lee[1], Byung Min Choi[1] & Young-Jun Rhie[1]
[1]Korea University College of Medicine, Department of Pediatrics, Seoul, South Korea

Objectives

Metabolic bone disease of prematurity (MBDP) is characterized by skeletal undermineralization. The risk of MBPD increases significantly in infants born before completing 28 weeks of gestation or those with extremely low birth weight (ELBW; <1,000 g). The most common biochemical changes in MBDP include hypophosphatemia and hyperphosphatasemia. Serum phosphate levels tend to decrease earlier than the elevation of serum alkaline phosphatase (ALP). In this study, we aimed to investigate the optimal screening time and cutoff values of phosphate for MBDP screening.

Methods

We conducted a retrospective study of medical records from premature infants hospitalized in the neonatal intensive care unit (NICU) at Korea University Ansan Hospital between 2020 and 2023. Infants with gestational age <32 weeks or birth

weight <1,500 g were included. Those who died or had incomplete data were excluded. MBDP was defined as a serum ALP level >900 U/l and serum phosphate below 5.5 mg/dl within the first 3–5 weeks of life. We evaluated serum calcium, phosphate, and ALP that measured every week, along with wrist radiographs at 6 weeks of age.
Results
A total of 95 infants were included in this study. Of these, 23 (24.2%) met the MBDP criteria. The prevalence rate of MBDP was 57.7% (15/26) in ELBW infants. The MBDP group had a significantly lower mean gestational age [26.8±2.2 weeks vs. 29.7±2.2 weeks, $P<0.001$] and lower mean birth weight [885.5±269.2 g vs. 1296.6±314.9 g, $P<0.001$]. The duration of TPN, establish of full feeds, caffeine use, and steroid use were longer in MBDP group: 30 (21-48) vs. 15.5 (10-23.5) days, 34 (21-51) vs. 15.5 (11-26) days, 74.0±26.9 vs. 40.0±27.2 days, and 10 (0-13) vs. 0 (0-0) days, respectively ($P<0.001$). Infants with MBDP had significantly higher serum ALP levels at 2 weeks [741.09±48.18 U/l vs. 516.26±27.23 U/l, $P<0.001$], and lower serum phosphate levels at 1 week [3.38±0.30 mg/dl vs. 4.07±0.17 mg/dl, $P<0.001$]. The optimal phosphate cutoff at 1 week was 3.85 mg/dl, with 70% sensitivity and 53% specificity. Wrist X-rays at 6 weeks revealed signs of rickets in 16 (69.6%) infants with MBDP, compared to 13 (18.1%) infants without MBDP ($P<0.001$).
Conclusion
Decreased serum phosphate levels in the first week of life were associated with an increased risk of developing MBDP. Since phosphate levels decline earlier than ALP levels rise, meticulous monitoring of infants with low phosphate levels in the first week of life is necessary for early detection and intervention.

Double trouble: when combination therapy does more harm than good

Maxim Barnett[1], Justin Riley Lam[1], Carlo Casipit[2] & Ana Rivadeneira[2]
[1]Jefferson-Einstein Hospital, Philadelphia, United States; [2]Jefferson-Einstein Hospital, Internal Medicine, Philadelphia, United States

Introduction
Osteoporosis management is often tailored to the specific risk of the patient. Treatment classes include anti-resorptive medications versus anabolic agents. Theoretically, synergistic activity would provide greater efficacy than monotherapy, yet this has not been studied in detail.
Objectives
The purpose of this study is to assess the effectiveness of combination therapy with both bisphosphonates and teriparatide compared to sole therapy with bisphosphonates in relation to pathological fractures and bone mineral density.
Methods
A retrospective study was performed with TriNetX Global Collaborative Network, accessing de-identified data from 143 healthcare organizations. Cohorts A was defined based on the diagnosis of osteoporosis and receiving treatment with both a bisphosphonate and teriparatide ($n = 16,308$), and cohort B was defined based on the presence of osteoporosis and receiving treatment with a bisphosphonate alone ($n=548,405$). All genders were analyzed, and no age-limit was included. An observation period was defined as 1 day after the index event, ending 5 years after. Cohorts were balanced with propensity score matching, with $n = 16,754$ per cohort. Cohorts were balanced for age at index, race, tobacco use, systemic corticosteroid therapy, body mass index, alcohol abuse, calcium and vitamin D supplementation, diagnosis of vitamin D deficiency, family history of osteoporosis, prior history of fractures, and baseline Z-score of the lumbar spine and hip. Key outcomes assessed included pathologic fractures at the hip, vertebrae and unspecified sites, and bone mineral density (Z-score) at both the hip and lumbar spine.
Results
The average age at index was 69.3 +/- 11.3 years, with 73.3% white and 85% female. Data demonstrated there was a greater risk for pathologic fracture (site unspecified) with combination therapy over monotherapy (Relative Risk 3.734, 95% CI: 2.821-4.944, $P< 0.0001$), as well as for collapsed vertebra (Relative Risk 1.816, 95% CI: 1.507-2.187, $P< 0.0001$). There was no significant difference in risk of pathologic fracture between the two cohorts (Relative Risk 1.285, 95% CI: 0.693-2.378, $P = 0.4255$), nor of the Z-score of the hip ($P = 0.8839$) and lumbar spine ($P=0.3612$).
Conclusion
This study demonstrates bisphosphonate monotherapy outperformed combination therapy (bisphosphonate and teriparatide) in reducing fracture risk, with no difference in bone mineral density enhancement. These findings suggest an antagonistic relationship (rather synergistic) in the presence of two differing therapeutic classes (anti-resorptive and anabolic). Further studies are needed to concur such findings.

Compromised muscle strength in patients with hypophosphatasia

María Del carmen andreo-lopez[1,2], Victoria Contreras- Bolívar[1,2,3], Francisco Andújar-Vera[4], Luis Martínez-Heredia[2], Beatriz García-Fontana[1,2,3], Cristina García-Fontana[1,2,3] & Manuel Muñoz-Torres[1,2,3]
[1]Endocrinology and Nutrition Unit, Hospital Universitario Clínico San Cecilio, Granada, Spain; [2]Institute of Biosanitary Research of Granada (ibs. GRANADA), Granada, Spain; [3]CIBER on Frailty and Healthy Aging (CIBERFES), Instituto de Salud Carlos III., Madrid, Spain; [4]Andalusian Institute for Data Science and Computational Intelligence Research (DaSCI Institute), Granada, Spain

Introduction
Hypophosphatasia (HPP) is a rare metabolic bone disorder characterized by low levels of tissue-nonspecific alkaline phosphatase (TNSALP) due to mutations in the ALPL gene. Deficiency of this alkaline phosphatase (ALP) isoform has been associated mainly with bone and dental disorders. However, although muscle alterations are frequent, muscle functionality is a scarcely evaluated aspect in patients with PPH. The aim of this study was to demonstrate the functional and structural impairment of bone and skeletal muscle in HPP.
Materials and Methods
Observational study of adult subjects with a genetic diagnosis of HPP and healthy controls, matched for sex, age and body mass index (BMI). The following clinical variables were collected: muscle strength measured with Jamar dynamometer; quadriceps rectus femoris muscle mass (Y-axis, X-axis, area and circumference) measured with ultrasound (Sonosite S-Nerve®); fat-free mass (FFM) and bone mineral density (BMD) in total hip, femoral neck (FN) and lumbar spine determined by dual-energy X-ray absorptiometry. Statistical analysis was performed with IBM SPSS v.26.
Results
Thirty-four PPH cases (48 years±18; 55% women), matched for age, sex and BMI with a control group, were analyzed. Median and interquartile range (IQR) of bone (BMD), muscle (dynamometry, Y-axis, X-axis, area and circumference), adiposity and biochemical (ALP) parameters were determined in both groups. Age-adjusted dynamometry values were significantly lower in the HPP group (28.6Kg vs 34.3; $P = 0.039$). Similarly, significant differences were observed in BMD of FN (0.8g/cm2 vs 0.9; $P = 0.034$) with the HPP group presenting lower values. No significant differences were observed in muscle mass. Analyzing muscle strength values in relation to ALP quartiles, a positive correlation was observed between both variables, highlighting significant differences between the first and fourth quartiles ($P = 0.003$). Multiple linear regression results showed an independent association between ALP levels and muscle strength (B=0.103 (95%CI 0.032-0.175), $P = 0.005$).
Conclusions
Impaired muscle strength was observed independently of muscle mass in patients with HPP, especially in those with more decreased ALP levels, suggesting that ALP level seems to be an important determinant of muscle strength. This could be related to bone status, particularly at the femoral level.

Background
There is limited data regarding adolescent weight among healthy individuals and its trajectory through early adulthood with respect to bone health. We assessed the association between adolescent body mass index (BMI) and osteoporosis risk while accounting for BMI change during early adulthood.
Methods
A retrospective cohort study including Israeli-born adolescents (468,907 women; 614,584 men) aged 16-19 years, who were evaluated for military service from 1967-2019 and followed for osteoporosis outcome until 2022 using the Maccabi Healthcare osteoporosis registry. Weight and height were measured to calculate BMI at adolescence and additional sociodemographic and medical data were collected. Cox proportional hazard models were applied. Adult BMI measurement was available for 74% of the study population and was used to assess the effect of adolescence-to-adulthood weight trajectory on incident osteoporosis. Health status at baseline and incident cancer and diabetes throughout adulthood were strictly controlled.
Results
21,497 (4.58%) women and 6,929 (1.13%) men were enrolled in the osteoporosis registry during a cumulative follow-up of 19,400,208 person-years. There was a gradual decrease in crude incidence rate (event/10^5 person-years) from 330.2 among extreme underweight ($<$3rd percentile) toward 78.9 in the obese group ($\geq$95th perc.). Corresponding adjusted HRs for osteoporosis ranged from from 1.89 (1.74-2.04) to 0.83 (0.77-0.88) in women and 1.79 (95%CI 1.62-1.99) to 1.05 (0.94-1.16) in men (with normal BMI as the reference group). There were no differences in incident risk for those with mild vs. severe adolescent obesity. The highest risk was recorded for those who sustained underweight from adolescence to adulthood. Weight gain from underweight at adolescence was associated with a lower risk for osteoporosis. These findings persisted when analysis was restricted for individuals with unimpaired health.
Conclusion
BMI category at a young age and its trajectory to adulthood have a significant effect on the risk for osteoporosis in adult life.

Mineral-bone disorder in chronic kidney diseases as early atherosclerosis indicators

Snjezana Popovic Pejicic[1,2] & Andreja Figurek[3]
[1]Faculty of Medicine, University of Banja Luka, Banja Luka, Bosnia and Herzegovina; [2]Academy of Science and Arts of the Republic of Srpska, Banja Luka, Bosnia and Herzegovina; [3]University of Zurich, Institute of Anatomy, Zurich, Switzerland

Introduction
The complex pathophysiology of mineral-bone disorders in chronic kidney disease (CKD) starts very early, when calcium and phosphorus are deposited in the walls of blood vessels and heart valves instead of bones, increasing the cardiovascular (CV) risk in these patients. An additional aggravating circumstance is the onset of secondary hyperparathyroidism, which, in addition to increasing CV risk, also contributes to increasing the risk of bone fractures. In this vicious circle, one of the biggest treatment challenges is how to regulate serum calcium levels, bearing in mind that calcium substitution with necessary vitamin D leads to an increase in the product of serum calcium and phosphate (CaxP), which contributes to the development of vascular calcifications and CV risk.
Objective
To determine the serum calcium values in patients with CKD in relation to the disease stage and to examine the relation with other parameters of mineral-bone disorder and the carotid intima media thickness (IMT) as well, as indicators of the early process of atherosclerosis.
Methods
This study was conducted as a cross-sectional study. It included 88 patients with all stages of CKD. The patients were classified into stages according to the estimated glomerular filtration rate (eGFR) according to MDRD (Modification of Diet in Renal Disease Formula). The carotid IMT was measured in accordance with the recommendations of the Mannheim Consensus.
Results
Of tested individuals 56% were women, average age of 63. The mean value of calcium was 2.35 ± 0.21 mmol/l and stayed within the reference values in all stages of CKD, while the mean value of IMT was 1.10 ± 0.20 mm with pathological values already identified from stage 2 of CKD. The CaxP values were positively correlated with serum creatinine ($r=0.65$, $P<0.001$). The pathological values of parathyroid hormone (PTH) were registered from stage 3 of CHD and were positively correlated with CaxP ($r=0.46$, $P<0.001$). The patients with PTH $>$600 ng/l had significantly higher values of serum calcium and phosphate, CaxP and IMT. The IMT was positively correlated with CaxP ($r=0.25$, $P<0.5$), PTH ($r=0.24$, $P<0.5$) and creatinine ($r=0.28$, $P<0.01$).
Conclusion
Advanced CKD is accompanied by an increase in calcium and phosphate products with the onset of the atherosclerosis, which is why careful monitoring of the mineral status of these patients is of significance for their outcome. A difficulty in correcting the mineral status would be a reason to consider a bone biopsy and adjustment of the treatment approach.

Bridging osteoporosis and glucose metabolism: the insulin sensitivity benefits of denosumab

Marta Vaz Lopes[1], José Vicente Rocha[1,2], Carolina Peixe[1,2], Mariana de Griné Severino[1], Catarina Isabel Lopes[1], Miguel António Duarte[1], Mariana Agapito Fonseca[1], Ines Cosme[1,2], Maria Inês Alexandre[1,2], Ana Gomes[1,2], Francisca Costa[2,3], Eva Alves[2,3], Francisco Sampaio[2,3], EMA PAula Ricca Lacerda Nobre M Caetano[1,2] & Ana Paula Barbosa[1,2,3]
[1]Serviço de Endocrinologia, Diabetes e Metabolismo - Hospital de Santa Maria, Lisbon, Portugal; [2]Faculdade de Medicina da Universidade de Lisboa, Lisbon, Portugal; [3]Consulta Multidisciplinar de Osteoporose Fraturária - Hospital de Santa Maria, Lisbon, Portugal

Introduction
Denosumab is a monoclonal antibody used in osteoporosis treatment because of its role in reduction of bone turnover through the inhibition of the RANKL/RANK pathway. While this pathway is primarily found in bone tissue, it is also expressed in the liver. Recent research suggests that inhibition of this pathway with denosumab therapy may lead to enhanced insulin sensitivity. However, data is still limited on this topic.
Methods
This retrospective study included patients with severe osteoporosis treated with denosumab in a tertiary center. Data at most recent follow-up were compared with data before denosumab treatment initiation, via paired-samples t-tests. Insulin resistance was estimated using the homeostasis model assessment of insulin resistance (HOMA-IR).
Results
A total of 59 patients were included, with a mean age of 73.5 ± 10.5 years; 89.9% (n =53) were female. Mean denosumab treatment duration was 37.9 ± 16.9 months. Before denosumab treatment, 18.6% (n =11) of patients had type 2 diabetes (T2D), 61% (n =36) were prediabetic and 20.4% (n =12) had no glucose metabolism abnormalities. Out of the patients with T2D, all but one had good glycemic control before initiating denosumab therapy: 10 patients had HbA1c levels $<$7.5%, and 1 patient had a HbA1c level of 8.8%. At most recent follow-up, both mean fasting insulinemia (13.8 ± 1.8mg/dL vs 9.1 ± 0.9mg/dL, $P=0.016$) and mean HOMA-IR (4.01 ± 1.5 vs 2.38 ± 0.9, P = 0.019) significantly decreased compared to pre-denosumab treatment levels. However, this was not accompanied by a significant decrease in mean fasting plasma glucose levels (111.7 ± 28mg/dL vs 100.5 ± 25mg/dL, P = 0.35) nor in mean HbA1c levels (6.1 ± 0.8% vs 5.9 ± 0.6%, P = 0.064).
Discussion and conclusions
Denosumab was associated with significant reductions in insulin resistance in this population of patients with severe osteoporosis. These results are particularly relevant considering insulin resistance is a known risk factor for osteoporotic

fractures. However, it is still unclear whether this reduction in insulin resistance can lead to actual improvement of clinical outcomes in T2D and prediabetes. The fact that most patients included in this study either did not have diabetes or had good glycemic control pre-denosumab may have contributed to the lack of significant decrease in HbA1c and fasting plasma glucose levels. Further studies including a larger sample of patients with T2D may help show whether the effects of denosumab on insulin resistance could improve glycemic control.

Diagnostic accuracy of choline pet in primary hyperparathyroidism with negative localization studies: a preliminary analysis

Carmen Costas Arcenegui[1], Sara Hami Gil[1], Jose Antonio Ariza Jimenez[2], Virginia Hernando Jimenez[1], Juan Ignacio Cuenca Cuenca[3] & Guillermo Martinez de Pinillos Gordillo[1]
[1]Hospital Universitario Virgen de Valme, Endocrinology and Nutrition, Sevilla, Spain; [2]Hospital Universitario Costa del Sol, Endocrinology and Nutrition, Marbella (Málaga), Spain; [3]Hospital Universitario Virgen del Rocio, Nuclear Medicine, Sevilla, Spain

Introduction
In patients with primary hyperparathyroidism (PHPT), preoperative localization of hyperfunctioning parathyroid glands is essential for proper surgical planning, particularly for minimally invasive procedures. The most used localization techniques include ultrasound, thyroid scintigraphy, and four-dimensional computed tomography (4D-CT). When these conventional imaging modalities yield inconclusive or negative results, choline positron emission tomography (PET) has emerged as a promising alternative for gland localization.
Objective
To describe the baseline characteristics of patients who required choline PET as a localization study for PHPT.
Materials and Methods
This is a preliminary descriptive study including 16 patients diagnosed with PHPT between January 1 and December 31, 2023. The primary aim of this phase was to analyze the baseline characteristics of these patients, with a second phase planned to evaluate the correlation between PET findings and surgical outcomes. Demographic data, biochemical parameters, and imaging results were assessed.
Results
A total of 16 patients were included, of whom 75% were women, with a mean age of 59 $\pm$ 14 years. The mean baseline biochemical values were parathyroid hormone (PTH) 119 $\pm$ 45 pg/mL (reference range: 15–65 pg/mL), total serum calcium 10.6 $\pm$ 0.6 mg/dL, and vitamin D 34 $\pm$ 16 ng/mL. Regarding imaging studies, thyroid ultrasound identified a suspicious lesion in 25% of cases, scintigraphy in 20%, and 4D-CT in 28%. In 50% of cases, all conventional imaging techniques were negative, and no complete agreement among the three modalities was observed. Choline PET detected a suggestive lesion in 87.5% of cases. Localization findings on PET were concordant with scintigraphy in 19%, with ultrasound in 19%, and with 4D-CT in 19% of cases.
Conclusions
Choline PET appears to be a promising imaging modality for the localization of hyperfunctioning parathyroid glands in patients with PHPT, particularly when conventional imaging techniques yield negative or inconclusive results. This preliminary study provides a foundation for future research aimed at evaluating the correlation between PET findings and surgical outcomes.

Juvenile primary hyperparathyroidism revealed by genu valgum

Mohamed Khairi Arous[1], Faten Haj Kacem Akid[1], Dhoha Ben Salah[1], Kouloud Boujelben[1], Nadia Charfi[1], Mouna Mnif[1], Mohamed Abid[1], Mouna Elleuch[1] & Nabila Rekik Majdoub[1]
[1]Hedi Chaker University Hospital, Department of Endocrinology, Sfax, Tunisia

Introduction
Primary hyperparathyroidism is a rare condition in young individuals, primarily characterized by renal manifestations such as nephrolithiasis or nephrocalcinosis. Bone involvement, although less frequent, may present as limb deformities, often misdiagnosed as other bone lesions, thereby delaying diagnosis and appropriate management.
Case Report
An 18-year-old male with no significant medical history was hospitalized for primary hyperparathyroidism with severe hypercalcemia (3.28 mmol/l) and markedly elevated PTH levels (1500 ng/mL). His medical history revealed progressive asymmetry of the lower limbs, culminating in genu valgum and gait disturbances, which led to an orthopedic consultation. Initial MRI findings suggested an aneurysmal bone cyst of the left femur, prompting surgical indication. However, a second orthopedic opinion noted diffuse bone demineralization on standard radiographs, leading to a phosphocalcic workup. The diagnosis of primary hyperparathyroidism was confirmed by biochemical tests. Cervical ultrasound revealed a left parathyroid adenoma (24 $\times$ 16 mm), further corroborated by parathyroid scintigraphy showing hyperfunction in the same region. No renal involvement was identified. A multiple endocrine neoplasia (MEN) panel was negative, ruling out a syndromic origin. The patient underwent surgery, with favorable clinical and biochemical outcomes.
Discussion and Conclusion
This case highlights an atypical form of juvenile primary hyperparathyroidism dominated by bone manifestations, such as brown tumors, misdiagnosed as benign lesions like aneurysmal bone cysts, leading to a genu valgum deformity. Although less common than renal manifestations, bone involvement should prompt a phosphocalcic workup, especially in the presence of diffuse bone demineralization, before considering precipitous surgical management.

Boxed in: should the black box warning for osteosarcoma be retired for good?

Maxim Barnett[1], Justin Riley Lam[1], Carlo Casipit[2] & Zurab Azmaiparashvili[2,3]
[1]Jefferson-Einstein Hospital, Philadelphia, United States; [2]Jefferson-Einstein Hospital, Internal Medicine, Philadelphia, United States; [3]Jefferson Einstein, Internal Medicine, Philadelphia, United States

Introduction
Two anabolic agents, namely teriparatide (parathyroid hormone analogue) and abaloparatide (parathyroid hormone-related peptide analogue), are approved by the Food and Drug Administration for osteoporosis. *in vitro* studies however, noted a heightened risk for osteosarcoma among rodents, for which a black box warning was given, as well as a limit of exposure; only recently has the two-year limit for Teriparatide been removed, however, an 18-month limit persists with abaloparatide. It should be noted, however, that the dosages used *in vitro* were supraphysiologic compared to those used in humans. Current recommendations are to only continue teriparatide beyond two years after shared decision making.
Objectives
Teriparatide has been on the market since 2002, and abaloparatide since 2017; as a result, the purpose of this retrospective cohort study is to evaluate the risk for osteosarcoma in patients with osteoporosis who are treated with an anabolic agent (teriparatide or abaloparatide). This study will address the validity of the black box warning of osteosarcoma in anabolic agents.
Methods
Anonymized data was collated through TriNetX Collaborative Network, encompassing 143 healthcare organizations globally. Cohorts were defined based on osteoporosis and the presence of an anabolic agent (teriparatide or abaloparatide) (n = 47, 489) and those with osteoporosis without an anabolic agent (n = 2, 686, 945). Cohorts were balanced with propensity scoring, delivering a balance of n = 46, 909. There was no age limit (upper or lower) for study inclusion, and all genders were included. The primary outcome of interest was the relative risk for the development of osteosarcoma (malignant neoplasm of bone). Timeframe was set as from at least one day following drug exposure to the present. Cohorts were matched for age at index and current age, gender, race, history of malignancy, and Paget's disease of bone.
Results
After matching, the mean age at index was 68.3 +/- 11.6 years, with 84.5% of the cohort being female, and 70.4% white. When assessing the risk for osteosarcoma, there was no significant difference between the group treated with anabolic agents and those without (Relative Risk 0.714, 95% CI: 0.476-1.072, P = 0.1024).
Conclusion
The results from this study suggest there is no heightened risk for osteosarcoma with anabolic agents teriparatide or abaloparatide. Perhaps the black box warning is unnecessary and should be dropped upon further advisory committees.

Risk factors for osteoporosis in children with hyperthyroidism under iodine-deficient conditions in the Republic of Uzbekistan

Shakhlo Muratova[1]
[1]Republican Specialized Scientific-and-Practical Medical Centre of Endocrinology named after academician Yo. Kh. Turakulov under the Ministry of Health of the Republic of Uzbekistan, Tashkent, Uzbekistan

Relevance
Childhood is critical for skeletal development, with peak bone mass accrual during this period. By puberty's end, bone mass reaches 86–100% of adult levels. Thyrotoxicosis disrupts bone remodeling, causing osteoporosis, osteosclerosis, and a 10% loss per cycle, with BMD declining by up to 28%. Identifying predictors of bone metabolism impairment is essential for early diagnosis, prevention, and treatment.
Materials and Methods
This study included 97 healthy children and 146 with hyperthyroidism. Thyroid hormones, autoantibodies, osteocalcin, parathyroid hormone (PTH), vitamin D, calcium, phosphorus, and alkaline phosphatase were quantified using the Cobas e 411 Hitachi immunochemical analyzer (Hoffmann-La Roche, Switzerland). BMD was assessed via dual-energy X-ray absorptiometry (DXA) using the Stratos densitometer (Diagnostic Medical Systems, France).
Results
ROC analysis demonstrated that osteocalcin (AUC = 0.72; 95% CI: 0.52–0.91; P= 0.05), anti-TSH receptor antibodies (AUC = 0.71; 95% CI: 0.51–0.91; P = 0.05), anti-TPO antibodies (AUC = 0.70; 95% CI: 0.51–0.90; P = 0.05), b-CrossLaps (AUC = 0.70; 95% CI: 0.50–0.90; P = 0.05), and vitamin D (AUC = 0.63; 95% CI: 0.53–0.74; P = 0.01) were significant predictors of total-body BMD reduction in pediatric hyperthyroidism. Conversely, thyroid hormone levels, PTH, calcium, and alkaline phosphatase had an AUC of 0.5, aligning with the null hypothesis. Further stratification of vitamin D and osteocalcin levels in relation to BMD reductions at different DXA sites identified osteocalcin >100 ng/mL (AUC = 0.65; 95% CI: 0.55–0.74; P = 0.05) and vitamin D <20 ng/mL (AUC = 0.70; 95% CI: 0.59–0.80; P = 0.05) as reliable markers. These were "good" predictors for total-body and femoral BMD loss and "satisfactory" for lumbar spine BMD. The strongest predictor of vitamin D deficiency-related outcomes in pediatric hyperthyroidism was anti-TSH receptor antibodies (AUC=0.84; 95% CI: 0.68–0.99; P< 0.001).
Conclusions
ROC analysis in pediatric hyperthyroidism highlights the role of autoimmune activity and vitamin D deficiency in bone metabolism dysregulation. Autoimmune mechanisms may accelerate bone demineralization, underscoring the need for targeted diagnostic and therapeutic strategies.

Autosomal dominant hypocalcemia type 1 (ADH1): management during pregnancy

Simone Della Valentina[1], Anna Dal Lago[1], Laura Pierotti[1], Chiara Sardella[1], Elena Pardi[1] & Filomena Cetani[1]
[1]University of Pisa, Department of Clinical and Experimental Medicine, Pisa, Italy

Autosomal dominant hypocalcemia type 1 (ADH1) is a genetic disorder caused by a heterozygous activating mutation in the calcium-sensing receptor (*CASR*) gene. This mutation decreases the receptor's sensitivity to low serum calcium, leading to hypocalcemia and low or inappropriately normal levels of parathyroid hormone (PTH). There are only a few reported cases of pregnancies in individuals with ADH1 likely due to the complex physiological changes that occur during pregnancy. These include placental production of PTH-related protein (PTH-rp), expansion of plasma volume, increased fetal calcium demands, and renal hyperfiltration. These factors can disrupt calcium homeostasis, potentially exacerbating maternal hypocalcemia and increasing the risk of fetal hyperparathyroidism as a result of chronic intrauterine hypocalcemia. In women with ADH1, an additional mechanism of non-PTH-mediated hypercalciuria is present, which can worsen renal dysfunction during pregnancy. Furthermore, there is a risk that the fetus may inherit the condition, further complicating the management of these pregnancies. We present the case of a 39-year-old woman who has been under follow-up at our clinic, since being diagnosed with ADH1 at age 30 due to asymptomatic hypocalcemia. Her initial biochemical profile revealed corrected serum calcium (cCa) of 7.64 mg/dL, PTH 17 ng/l and 24-hour urinary calcium excretion of 138 mg/24h. At her most recent pre-pregnancy follow-up, her cCa level was 8 mg/dL. At 15 weeks of pregnancy, her cCa level was of 7.76 mg/dL, while on a regimen of 250 mg of elemental calcium and no calcitriol. Her treatment was progressively increased, and by week 27, with calcium supplementation of 1000 mg/day and calcitriol at 1.25 mg/day, her cCa had risen to 8.6 mg/dL, PTH was 5.1 ng/l and 24-hour urinary calcium was 250 mg/24h. Therapy was maintained, and at 36 weeks, her cCa reached 9.6 mg/dL, PTH was <4 pg/mL, and 24-hour urinary calcium had increased to 572 mg/24h. A cesarean section was performed at 38 weeks. Five days after birth, the neonate exhibited normal calcium levels of 10.1 mg/dL. One month postpartum, during lactation and with unchanged therapy, her cCa level was 8.7 mg/dL. This case highlights the importance of continuous monitoring of calcium levels in individuals with ADH1 to prevent both maternal and fetal complications. Although the literature report urinary complications such as pre-eclampsia and eclampsia, no such events occurred in this patient. Ongoing surveillance of calcium levels in both the mother and the infant remains critical during lactation.

Do patients with ehlers–danlos syndrome and a history of fractures have lower bone mineral density?

Jan Domański[1,2], Ivan Rychlik[3], Jakub Podstawka[1,2], Aleksandra Żuk - Łapan[1,2], Bernadetta Kałuża[1,2] & Edward Franek[2,4]
[1]Students Scientific Group of the Medical University of Warsaw at the Department of Internal Medicine, Endocrinology, and Diabetology, National Medical Institute of the Ministry of the Interior and Administration, Warsaw, Poland; [2]Department of Internal Medicine, Endocrinology, and Diabetology, National Medical Institute of the Ministry of the Interior and Administration, Warsaw, Poland; [3]Department of Internal Medicine, Third Faculty of Medicine, Charles University, and Královské Vinohrady University Hospital, Prague, Czech Republic; [4]Department of Human Epigenetics, Mossakowski Medical Research Institute, Polish Academy of Sciences, Warsaw, Poland

Background
Joint hypermobility and instability are among the main risk factors for fractures in patients with Ehlers–Danlos syndrome (EDS). Such fractures, which may affect bone biomechanics, may be due to low bone mineral density (BMD). The purpose of this study was to assess bone density in patients with a hypermobile and classical subtype of EDS and a history of fractures.
Material and methods
The study involved a prospective assessment of 30 female patients, with either hypermobile or classical EDS. The patients were divided into two groups. Group 1 comprised patients with no history of fractures (n =13), and group 2 comprised patients with a history of fractures (n =17). All patients were evaluated in terms of their lumbar spine and femoral neck BMD (g/cm2) and parameters of calcium and phosphate metabolism.
Results
The evaluated groups showed no differences in terms of such parameters as neck left femur BMD (0.947±0.135 vs. 0.931±0.113, P = 0.934), total left femur BMD (0.975±0.115 vs. 0.932±0.141, P = 0.408), L1 BMD (1.242±0.252 vs. 1.113±0.147, P = 0.113), L2 BMD (1.296±0.198 vs. 1.202±0.195, P = 0.157), L3 BMD (1.359±0.205 vs. 1.264±0.188, P = 0.123), L4 BMD (1.280±0.200 vs. 1.244±0.194, P = 0.483), or L1–L4 BMD (0.129±0.206 vs. 1.212±0.171, P = 0.263). There was no significant correlation between a history of fractures and femoral neck BMD (Spearman's R -0.016, P = 0.935), total (Spearman's R -0.159, P = 0.4), or L1–L4 (Spearman's R -2.09, P = 0.266).
Conclusions
A history of fractures in patients with classical or hypermobile EDS is not associated with significantly lower BMD in such locations as neck and total left femur or L1–L4.

Duchenne muscular dystrophy and risk of fracture

Ruben Abdala[1], Kelly Maury[2], Sandra Piamonte[2], Debora Ramirez[2], Indiana Caccia[2] & Oscar Brunetto[2]
[1]IDIM, Buenos Aires, Argentina; [2]Hospital Pedro Elizalde, IDIM, Buenos Aires, Argentina

A high risk of fractures was reported in a patient with duchenne muscular dystrophy (DMD) which could be due to inmobilization, the pathophysiology of the disease, treatment with glucorticoids (GCs) and increased BMI. Knowledge of the risk factors for the disease contributes to creating preventive strategies that reduce co-morbidities and improve the quality of life in these patients.
Objetive
To assess the incidence of first fractures and factors contributing to risk of first fracture in children with DMD
Methods
A retrospective analysis of a cohort of patients with Duchenne Muscular was carried out A total of 27 children under 18 years of age with clinical and molecular diagnosis of DMD were enrolled. The study was approved by the ethics committee and all procedures were performed following the Declaration of Helsinki. The study began in 2010, a total of 27 children were referred to our endocrinology service for their evaluation. Anthropometric variables were evaluated at the start of the study and during follow-up. In addition, annual spine radiographs were performed. Data on long bone (LBF) and vertebral fractures (VF) were recorded. Questionnaires about calcium intake and mobility were also administered. The variables are summarized in mean (SD), median (IQR) and percentage according to their nature.
Results
The age of DMD diagnosis was 6.52 ± 2.83y and the follow-up time was 7.77 ($\pm$ 4.57y). Age of starting GCs was 8.12 ± 2.45y and average daily was 0.6 ± 0.12 mg/k/d. 7 children with new fractures (VF or LBF) were observed during this period, median time 5.07 (RIQ 3-6.66y). Cumulative incidences was 0.26 or 26%. Children with fractures presented a delay in the age of diagnosis (8 vs 5.5 y) and increased BMI ($P = 0.01$). No differences were observed in biochemical markers, vitamin D, time and dose of corticosteroids between fractured and non-fractured.
Conclusion
We observed a high incidence of fractures in this population, which highlights the importance of a multidisciplinary approach and the creation of strategies to reduce modifiable risk factors to improve the quality of life of these children. BMI could be a risk factor to take into account when considering treatment strategies in these patients.

Osteogenesis imperfecta: a novel mutation in the COL1A1 gene and 8 new patients in Greece

Anna Papadopoulou[1], Artemis Doulgeraki[2], Maria Yavropoulou[3] & Christina Kanaka Gantenbein[4]
[1]University General Hospital "Attikon" & Saint Sophia Children's Hospital, Medical School, National & Kapodistrian University of Athens, Athens, Greece; [2]Institute of Child Health, Department of Bone and Mineral Metabolism, Athens, Greece; [3]LAIKO General Hospital of Athens, National and Kapodistrian University of Athens, First Department of Propaedeutic and Internal Medicine, Endocrinology Unit, Athens, Greece; [4]Saint Sophia Children's Hospital, Medical School, National & Kapodistrian University of Athens Athens, Greece, First Department of Paediatrics, Division of Paediatric Endocrinology, Diabetes and Metabolism, Athens, Greece

Background
Osteogenesis imperfecta (OI), is a rare, generalized connective tissue disorder comprising a heterogeneous group of inherited bone dysplasias with variable phenotypic features and genetic causes. Patients present with low bone mass and bone fragility, substantial growth deficiency and, occasionally, other associated secondary features, including blue sclerae, hearing loss and dentinogenesis imperfecta. The disease is caused mainly by autosomal dominant mutations in type I collagen, or in collagen-related genes with different inheritance patterns. Although there is no clear phenotype – genotype association, the genetic classification of OI helps in detecting specific phenotypic features of the different types of the disease. In the present study, we performed the genetic analysis of 8 new patients with clinical features of osteogenesis imperfecta, in the frame of definitive diagnosis, management and family genetic counselling.
Materials and Methods
Whole exome sequencing was performed and a panel of genes associated with short stature, joint hypermobility, bone fragility or blue sclerae was analysed. The acceptable mean depth of the analysis was 60 and the gene coverage 97%. Any detected pathogenic or likely pathogenic variant was confirmed by Sanger sequencing. The detailed clinical features of the patients were recorded and further analysed based on the type of the genetic change observed.
Results
We found 7 different pathogenic genetic variants in 8 different patients, including frameshift (5/8), missense (2/8) and splicing changes (1/8) in the *COL1A1* gene and a missense mutation in the *COL1A2*. One of the observed genetic variants in exon 46 of the *COL1A1* gene has not been previously reported (p.Ala1134Leufs*39). Almost all patients (90%) had severe generalized osteoporosis, mild joint hypermobility, varying degree of multiple fractures and blue sclerae. None of the patient-carriers of frameshift mutations had experienced fractures in utero, during labour or during the newborn period. The patient-carriers of point mutations were diagnosed perinatally. No differences were found regarding the phenotypic variability between the two groups of mutations.
Conclusions
Eight new patients with phenotypic features of osteogenesis imperfecta were genetically diagnosed with pathogenic mutations in *COL1A1* and *COL1A2* genes, thus, being classified in OI type I, III and IV. Despite the small number of genetically tested patients, it is noteworthy that no phenotypic sign has been reported in utero or during the newborn period for the patients-carriers of frameshift *COL1A1* mutations.

Background
X-linked hypophosphataemia (XLH;#307800), is a rare metabolic disorder and the most common form of hereditary hypophosphatemic rickets. Patients present with renal phosphate waste resulting in hypophosphataemia, rickets and osteomalacia due to elevated serum FGF23. The disease is caused by inactivating variants throughout the *PHEX* gene (*300550) which encodes a 749 amino acid transmembrane protein. These variants are predicted to cause loss of protein function, with the majority producing a truncated protein, while controversy exists regarding genotype-phenotype correlation. In the present study, we performed the genetic analysis of 14 new patients with clinical features of hypophosphatemic rickets, in the frame of definitive diagnosis and selection of treatment.
Materials and Methods
All 22 exons and their flunking intronic regions of the *PHEX* gene were analysed using direct sequencing. The detailed clinical features of the patients were recorded and genotype-phenotype correlations were performed.
Results
We found 10 different pathogenic genetic variants in 13 different patients, including frameshift, splicing, missense and nonsense changes in the *PHEX* gene, affecting the extracellular sequence of the protein. Two of the observed genetic variants have not been previously reported (c.2051_2061dup; c.1525A>C). One patient did not reveal any pathogenic variant either by sequencing or MLPA. All patients presented with disproportionate short stature and bowing of the legs; 4/14 osteoarthritis, 8/14 bone pain, 5/14 fractures, hypophosphatemia, and normal to high serum PTH and ALP. Patients carriers of truncated mutations experience more severe phenotypes than patients with missense mutations.
Conclusions
This is the first study describing the detailed molecular and clinical profiles of X-linked hypophosphatemic patients in Greece. Most of them have, recently, started receiving burosumab, a fully humanized monoclonal antibody that neutralizes circulating FGF23, and their response to treatment is being recorded.

Bone metabolism in refractory rickets: a comparative study of treatment-compliant, non-compliant, and healthy children

Anju Bala[1], Sayan Banerjee[1], Arun George[1], Inusha Panigrahi[1], Naresh Sachdeva[1], Priyanka Srivastava[1], Savita Attri[1] & Devi Dayal[1]
[1]Post Graduate Institute of Medical Education and Research, Department of Pediatrics, Chandigarh, India

Background
Refractory rickets, though rare, significantly contributes to bone health-related morbidity in both children and adults. Non-invasive biochemical markers can offer insights into bone remodelling, but their use in children with resistant rickets remains largely unexplored.
Objective
To assess the bone metabolism in children with refractory rickets using bone turnover markers.
Methods
In this single-center, cross-sectional study, children ($\leq$18 years) with refractory rickets were enrolled. Refractory rickets was defined as failure to achieve radiological healing after 12 weeks, despite a cumulative dose of 300,000 IU of vitamin D. Exclusions included nutritional rickets, chronic kidney disease, and use of glucocorticoids or anticonvulsants. Diagnosis was confirmed either biochemically or via clinical exome sequencing. Patients were categorized into hypophosphatemic rickets (HPR), vitamin D–dependent rickets (VDDR), and renal tubular acidosis (RTA). Rickets severity was assessed using the Rickets Severity Score (RSS). Non-compliance was defined as worsening of RSS with non-adherence to prescribed therapy for 3 months over past year. Age- and gender-matched normal controls were also included. Bone turnover markers, C-telopeptides of type I collagen (CTX, resorption) and procollagen I N-propeptide (P1NP, formation) were assessed early morning after overnight fasting.
Results
Thirty-nine children [53% female, 9.69 (4.39) years and 64% compliant] were included, with genetic confirmation in 29 (75%) cases (HPR: 62%, VDDR: 20%, RTA: 18%) along with 39 controls. Bone resorption marker CTX was 2077 pg/ml (1532–2886), and bone formation marker P1NP was 690 ng/ml (586–1080) in our patient cohort, with no significant intergroup differences [CTX: $P = 0.289$, P1NP: $P = 0.465$]. However, both markers were significantly higher in patients than controls [CTX: 1561 (1250–1860) pg/mL, $P = 0.004$; P1NP: 450 (400–484) ng/mL, $P<0.001$]. A significant positive correlation was found between serum CTX with P1NP ($r=0.405$, $P = 0.016$), and between CTX with RSS ($r=0.400$, $P= 0.026$). Notably, P1NP was significantly elevated in the compliant group as compared to the control group [753.1(293.7) versus 449.8 (57.7) ng/ml, $P<0.001$] while no significant difference was noted in CTX [1818.4 (610.2) versus 1542.8 (380.1) pg/ml, $P = 0.09$]. In contrast, both CTX and P1NP were significantly elevated in the non-compliant group compared to controls [CTX 3482.5 (1340.9) versus 1542.8 (380.1) pg/ml, $P<0.001$; P1NP 939.6 (359.3) versus 449.8 (57.7) ng/ml, $P<0.001$].
Conclusions
To conclude, children with refractory rickets exhibit higher bone turnover compared to controls. Treatment adherence disproportionately reduces bone degradation relative to bone formation. This can contribute to improved bone health on follow up.

Relationship between vitamin D deficiency and low bone mineral density in children with inflammatory bowel diseases

Youn Kyoung Kim[1], Kyoung Won Cho[1], Seo Jung Kim[1] & Junghwan Suh[1]
[1]Department of Pediatrics, Severance Children's Hospital, Yonsei University College of Medicine, Seoul, South Korea

Objective
Inflammatory bowel disease (IBD), including Crohn's disease (CD) and ulcerative colitis (UC), is a chronic inflammatory condition associated with gastrointestinal and bone complications like vitamin D deficiency and osteoporosis. Inflammation during childhood and adolescence, critical periods for bone growth, can impair bone development. This study examines the prevalence of vitamin D deficiency and impaired bone health in pediatric IBD patients and evaluates the impact of vitamin D supplementation on bone metabolism.
Methods
This retrospective study included 287 pediatric patients under 19 years old who visited the pediatric gastroenterology and nutrition clinic. Among these, 230 (80.1%) were diagnosed with CD and 57 (19.9%) with UC. Data collected at diagnosis included height, weight, dual-energy X-ray absorptiometry (DEXA) results, 25-hydroxyvitamin D levels, and various biochemical markers.
Results
At diagnosis, vitamin D deficiency ($<$20 ng/mL) was observed in 87.3% of CD patients and 71.9% of UC patients ($P = 0.004$). Average 25-OH vitamin D levels were 13.76 ± 6.77 ng/mL in CD and 16.49 ± 9.96 ng/mL in UC. Lumbar z-scores were -0.74 ± 1.12 for CD and -0.25 ± 1.03 for UC ($P = 0.028$). In 249 patients receiving vitamin D supplementation, serum vitamin D levels significantly increased from a baseline of 13.83 ± 7.06 ng/mL to 27.32 ± 10.25 ng/mL at one year ($P = 0.003$). Additionally, lumbar spine z-scores improved significantly from -1.03 ± 1.05 to -0.54 ± 1.06 during the same period ($P< 0.001$).
Conclusion
Pediatric IBD patients have a high prevalence of vitamin D deficiency and reduced bone density at diagnosis. Early initiation of vitamin D supplementation significantly improves bone health, highlighting its role in managing bone complications in pediatric IBD.

JOINT3425

Novel association between cohen syndrome and low alkaline phosphatase, a potential new subgroup of hypophosphatasia

Rasha Amin[1], Elwaeila Hamdoun[1] & Raji Katibe[2]
[1]Sidra Medicine, Pediatric Endocrinology, Doha, Qatar; [2]Sidra Medicine, Pediatrics, Doha, Qatar

Introduction
Cohen Syndrome is a rare autosomal recessive disorder caused by mutations in the VPS13B gene. It is characterized by distinct facial features, mitral valve prolapses, and neurological defects, along with endocrine and musculoskeletal manifestations such as joint laxity, scoliosis, knee deformities, short stature, pubertal delay, and growth hormone deficiency. The underlying pathophysiology is thought to involve impaired protein glycosylation, particularly at the Golgi apparatus. Alkaline Phosphatase (ALP), a glycosylated enzyme involved in bone metabolism and turnover, is affected by glycosylation defects. We hypothesized that individuals with Cohen Syndrome may exhibit low ALP levels, which could potentially represent a new form of hypophosphatasia.
Aim
This study aimed to explore the relationship between Cohen Syndrome and low ALP levels, investigating whether this could signify a new subgroup of hypophosphatasia.
Method
A retrospective review was conducted on nine Cohen Syndrome cases diagnosed at our institution. ALP levels were measured for all patients, and radiologic evaluations were performed to assess skeletal abnormalities. The incidence of low ALP in this cohort was compared to the general population rate of approximately 5%.
Results
Among the nine patients with Cohen Syndrome, 44% (4/9) had low ALP levels, significantly higher than the general population rate ($P = 0.0006$). Radiologic evaluations revealed bone abnormalities in some patients, including fractures. Specifically, 22% of the individuals had fractures, and one patient with a low-trauma fracture and diffuse osteopenia on X-rays. These findings suggest a potential link between low ALP and skeletal manifestations in Cohen Syndrome, pointing to disturbances in bone metabolism that may be indicative of a new form of hypophosphatasia.
Conclusion
This study identifies a novel association between Cohen Syndrome and low alkaline phosphatase levels, suggesting the possibility of a new subgroup of hypophosphatasia. The significantly high rate of low ALP among our cohort warrants further investigation into the role of bone metabolism in Cohen Syndrome. Confirmatory tests (serum pyridoxal 5'-phosphate and urine phosphoethanolamine) for hypophosphatasia are planned, and these findings could inform future therapeutic strategies. This novel subgroup could provide valuable insights into bone health in genetic disorders, potentially guiding targeted treatments.

A rare cause of short stature: the journey to diagnosing hypophosphatemic rickets with hypercalciuria

Maria Manaila[1], Andra Dorneanu[2], Nada Akad[3,4], Elena-Diana Cozma[4] & Stefana Bilha[2,5]

[1]"Sf. Spiridon" Clinical Emergency Hospital Iasi, Romania, "Grigore T. Popa" University of Medicine and Pharmacy Iasi, Endocrinology, Iasi, Romania; [2]"Sf. Spiridon" Clinical Emergency Hospital Iasi, Romania, Endocrinology, Iasi, Romania; [3]"Grigore T. Popa" University of Medicine and Pharmacy Iasi, Endocrinology, Iasi, Romania; [4]"Sf. Spiridon" Clinical Emergency Hospital Iasi, Endocrinology, Iasi, Romania; [5]"Grigore T. Popa" University of Medicine and Pharmacy, Iasi, Romania

Background

Bone metabolic conditions causing short stature result from genetic, hormonal, or metabolic abnormalities that impair bone growth and strength. Among them, hereditary hypophosphatemic rickets with hypercalciuria (HHRH) is an extremely rare autosomal recessive disorder caused by mutations in the SLC34A3 gene, which encodes for the proximal tubular transporter NaPi-IIc, thus leading to impaired phosphate reabsorption and subsequent hypophosphatemia, hypercalciuria and impaired bone mineralization. The diagnosis can be challenging, particularly when presenting with severe growth impairment. We report a case of HHRH initially suspected as growth hormone deficiency due to short stature and delayed bone age, ultimately leading to an unexpected diagnosis.

Case Presentation

A 10-year-old boy presented with severe short stature (-4.13 SDS), genu varum, and chronic joint pain. He was born at term with a normal birth history, breastfed for 13 months, and had normal psychomotor development. There is no family history of rickets or other metabolic bone disease. Initial evaluation revealed low IGF-1 (105 ng/mL), bone age delayed by 2 years, and an appropriate growth hormone response to arginine stimulation testing, ruling out growth hormone deficiency. Laboratory investigations showed persistent hypophosphatemia (serum phosphate 2.3 mg/dL), with normal levels of serum calcium (9.54 mg/dL) and 25-hydroxyvitamin D (34.89 ng/mL), and elevated alkaline phosphatase (543 U/l). Urinary analysis confirmed hypercalciuria (292 mg/24h) and reduced tubular phosphate reabsorption (TMP/GFR = 0.92 mmol/l). Additionally, 1,25-dihydroxyvitamin D was elevated (126 pg/mL), whereas serum PTH was reduced (8.19 pg/mL) and fibroblast growth factor 23 (FGF23) was undetectable, supporting the diagnosis of HHRH. The radiologic assessment revealed a rickets severity score of 7/10. No images of renal calcifications were found on the abdominal ultrasound.

Conclusion

The biochemical profile—persistent hypophosphatemia, suppressed PTH, hypercalciuria, elevated 1,25-dihydroxyvitamin D, and low FGF23—helped differentiate HHRH from other phosphate-wasting disorders, such as X-linked hypophosphatemia, autosomal dominant/recessive hypophosphatemic rickets, Dent disease or Fanconi syndrome. Nonetheless, genetic testing remains necessary for confirmation. Unlike other forms of hypophosphatemic rickets, phosphorus supplementation alone is the primary treatment, while active vitamin D metabolites should be avoided due to their potential to worsen hypercalciuria. Despite linear growth improvement seen with oral phosphate supplementation, isolated case reports additionally considered human recombinant growth hormone therapy with improved outcomes.

Successful treatment of autosomal dominant hypophosphatemic rickets with burosumab: a case report

Matej Rakusa[1] & Tomaž Kocjan[1]

[1]Department of Endocrinology, Diabetes and Metabolic Disease, University Medical Centre Ljubljana, Ljubljana, Slovenia, Department of Internal Medicine, Faculty of Medicine, University of Ljubljana, Ljubljana, Slovenia, Ljubljana, Slovenia

Background

Autosomal dominant hypophosphatemic rickets (ADHR) is a rare genetic disorder characterised by FGF23-mediated phosphate wasting and impaired bone mineralisation. Mutation renders FGF23 resistant to degradation. Iron deficiency stimulates transcription levels of FGF23 and aggravates the disease. Conventional treatment with phosphate and active vitamin D analogues is challenging and commonly not optimal. Treatment with oral iron has no long-term results. Burosumab, a monoclonal antibody against FGF23, has shown efficacy in X-linked hypophosphatemia (XLH), but its use in ADHR remains unexplored. We present data for the first 12-month treatment with burosumab in ADHR patients.

Case Presentation

A 19-year-old female with ADHR, confirmed by FGF23 R176Q/W mutation, presented with severe symptoms, including bone pain and muscle weakness. Her weight was 40 kg, height 145 cm, sitting height 77 cm, arm span 142 cm, BMI 19.0 kg/m^2. One year prior, she had a low-energy fracture of the diaphysis right femur, which was complicated by non-union. Her bone mineral density (BMD) was low for age and sex (Z-score L1-L4 -4,4 SD, Z-score femoral neck -4,4 SD, Z-score hip -4,7 SD) and TBS was normal (1.358). Laboratory tests were as follows: 25OH vitamin D 37,7 nmol/l, P 0,39 mmol/l (0,74-1,52), corrected Ca 2,18 mmol/l (2,10-2,60), alkaline phosphatase (AP) 4,95 µkat/l (0,55-1,64), bone-specific AP (BSAP) 93,6 µg/l (4,7-27,0), iPTH 31 ng/l (16-68), TRP 80 % (>85 %), TmP/GFR 0,41 mmol/l (0,84-1,23). Treatment with calcitriol and phosphate did not resolve the symptoms. We started treatment with burosumab (40 mg every 28 days). Phosphate supplementation was discontinued seven days before initiation. Her fracture healed. Within 2 months, the patient reported significantly reduced bone and muscle pain, improved muscle strength, and regained mobility without crutches. BMD increased by 11.7% at the lumbar spine and 14.2% at the hip after 5 months, with further improvements of 46.6% and 36.2%, respectively, after 10 months. Serum phosphate levels increased but did not normalise, and AP rose to 12,96 µkat/l and BSAP to 350 µg/l in the first 3 months before starting to normalise. Transient hyperphosphatemia occurred with concurrently increased iron supplementation, necessitating dose adjustment of burosumab.

Conclusion

Burosumab is potentially an effective treatment for ADHR, demonstrating rapid symptom relief, improved BMD, and enhanced fracture healing. While burosumab was well-tolerated, careful management of concurrent iron therapy is essential to avoid hyperphosphatemia. Further studies with larger cohorts are needed.

Buschke–ollendorff syndrome in a mother-child duo: a rare cause of short stature and skeletal dysplasia

Simge Eren[1], Dilay Kızılçay Ali[2], Eymen Ali[3] & Olcay Eren[4]

[1]Şişli Etfal Research and Training Hospital, Pediatric Endocrinology, İstanbul, Turkey, Pediatric Endocrinology, İstanbul, Türkiye; [2]Gaziosmanpaşa Research and Training Hospital, Radiology, İstanbul, Türkiye; [3]Fatih Sultan Mehmet Research and Training Hospital, Department of Orthopedics and Traumatology, İstanbul, Türkiye; [4]Fatih Sultan Mehmet Research and Training Hospital, Department of Orthopedics and Traumatology, Yeditepe University, Department of Biotechnology, Department of Orthopedics and Traumatology, İstanbul, Türkiye

Introduction

Buschke–Ollendorff syndrome (BOS) is a rare, autosomal dominant skeletal dysplasia caused by LEMD3 gene mutations. It is characterized by osteopoikilosis (OPK), benign sclerotic bone lesions, and connective tissue nevi. Although often asymptomatic, BOS may be mistaken for malignant or metabolic bone diseases, leading to misdiagnosis. Short stature, scoliosis, and other skeletal anomalies have been associated with BOS. We present a mother and child diagnosed with BOS after evaluation for bone pain and short stature.

Case report

A 40-year-old woman presented to the orthopedic clinic with progressive bone pain, particularly in both shoulders and arms, for one year. Radiographs revealed multiple, well-defined, symmetrical sclerotic lesions in the epiphyses and metaphyses of both shoulders. These points were located in the cancellous bone tissue and the inner bone cortex bilaterally located in the epiphyses and metaphyses. She has been consulted the radiology department and diagnosed osteopoikilosis. Due to her history of short stature (146 cm, -2.66 SD), and skeletal findings, her 7-year-old son was referred for endocrinological evaluation. The child presented with short stature and intermittent right knee pain. He was born at 37 weeks gestation, weighing 2650 g. His height was 107 cm (-3 SD), weight 19 kg (-1.67 SD), and BMI 16.6 kg/m^2 (+0.62 SD) with a target height of 167 cm (-1.37 SD). There was a proportional short stature. He was prepubertal. His father's height was within the normal range His neurodevelopment and dentition were normal. His physical examination revealed multiple connective tissue nevi on the anterior abdominal wall and left gluteal region. Radiographs of the child's right knee showed multiple sclerotic lesions resembling the "dripping wax" pattern of melorheostosis, consistent with OPK. Whole-body imaging confirmed widespread poikilotic bone lesions. Laboratory tests, including calcium, phosphorus, alkaline phosphatase, inflammatory markers, and IGF-1

and GH test, were normal. Bone age corresponded with chronological age. Genetic testing was cofirmed an LEMD3 mutation leading to a BOS diagnosis. Mother also presented with the same LEMD3 mutation.
Conclusion
BOS is a rare disorder that can present with skeletal dysplasia, short stature, and unexplained bone pain. In cases of familial OPK or unexplained short stature, genetic testing is crucial for accurate diagnosis and appropriate management. Due to the broad spectrum of clinical manifestations, establishing a strong pediatric-adult transition in care a multidisciplinary approach is vital for long-term monitoring and preventing complications associated with BOS.

At the crossroads: femoral osteonecrosis in β-thalassemia major

Nada Ait Kassi[1], Riad Amal[2], Habbadi Zineb[2], Fatima Toulali[1], Ghizlane Sabbar[1], Kaoutar Rifai[1], Hinde Iraqi[1] & Mohamed El Hassan Gharbi[1]
[1]Ibn Sina Hospital Mohamed V University, Rabat, Morocco; [2]Ibn Sina Hospital Mohamed V University, Endocrinology, Rabat, Morocco

Introduction
β-thalassemia major is a chronic hemolytic disorder that leads to iron overload due to frequent blood transfusions. This iron accumulation can cause a range of metabolic, endocrine, and skeletal complications. One rare but severe complication of β-thalassemia major is femoral osteonecrosis, a condition characterized by the loss of blood supply to the femoral head, resulting in progressive bone death. While more common in sickle cell disease, femoral osteonecrosis is less frequently reported in thalassemia patients. Early detection and management of this condition are crucial to preventing irreversible joint deformities and improving long-term functional outcomes.
Case Presentation
A 17-year-old female patient with β-thalassemia major, diagnosed at birth, was receiving regular blood transfusions every three weeks and iron chelation therapy. She was admitted for the evaluation of primary amenorrhea. On physical examination, the patient showed severe growth retardation with a weight of 30 kg and a height of 145 cm (BMI = 14 kg/m^2). Vital signs were stable, and cardiovascular and pulmonary exams were unremarkable. Orthopedic examination showed limited hip movement with pain on mobilization. Imaging studies included a pelvic MRI confirmed bilateral femoral osteonecrosis. Additionally, a pituitary MRI demonstrated anterior pituitary atrophy, likely secondary to iron overload. Laboratory tests showed elevated ferritin levels, indicating iron overload, along with reduced FSH and estradiol levels, suggesting endocrine dysfunction.
Discussion
Femoral osteonecrosis is a rare but serious complication in β-thalassemia major patients, with potential mechanisms including chronic anemia, iron overload, and marrow hyperplasia. Iron overload can damage tissues and disrupt blood flow, particularly in bones such as the femoral head, contributing to osteonecrosis. Marrow hyperplasia in thalassemia can also compress blood vessels, further compromising blood supply. Although femoral osteonecrosis is commonly seen in sickle cell disease, its occurrence in β-thalassemia major underscores the importance of vigilant musculoskeletal monitoring in these patients. Early detection through clinical and radiological assessment is crucial, as delayed diagnosis can lead to joint deformities, chronic pain, and loss of function.
Conclusion
This case emphasizes the need for early identification and regular monitoring of skeletal complications in patients with β-thalassemia major. While femoral osteonecrosis is a rare complication, its impact on a patient's quality of life can be significant if not detected and managed promptly. Multidisciplinary care, including appropriate management of iron overload and timely orthopedic intervention, is essential to prevent long-term functional impairment. Regular musculoskeletal evaluation is recommended to ensure early detection and intervention for this potentially debilitating condition.

JOINT1334

Treatment conundrums in newly recognized early-onset osteoporosis caused by heterozygous WNT1 mutation

Carmen Sorina Martin[1,2], Miruna-Viorela Nacu[1], Carmen Barbu[1,2] & Simona Fica[1,2]
[1]Elias Emergency University Hospital, Department of Endocrinology, Diabetes Mellitus, Nutrition and Metabolic Disorders, Bucharest, Romania; [2]Carol Davila University of Medicine and Pharmacy, Department of Endocrinology, Diabetes Mellitus, Nutrition and Metabolic Disorders, Bucharest, Romania

Introduction
As molecular genetic testing became more available, we are now able to better identify different molecular causes of monogenic osteoporosis. Unfortunately, their treatment remains uncertain.
Clinical case
An 18-year-old male presented in our clinic with a history of multiple fractures preceded by medium intensity traumas, occurring from age seven. Although none of them were classic fragility fractures, their frequency prompted further investigation. He had normal development and no other clinical features. Endocrine work-up was normal, except for a mild functional hyperprolactinemia. Serum osteocalcin and beta-crosslaps were within range. He had a low bone mineral density for age and sex, with Z scores of -2.5 DS (lumbar) and -2.9 DS (left femoral neck). We suspected osteogenesis imperfecta, advised genetic consult and recommended oral bisphosphonates (not administered due to poor compliance). Five years later, the patient managed to obtain a genetic test, showing a heterozygote mutation of WNT1 gene, consistent with autosomal dominant early onset osteoporosis. No new fractures occurred since last visit. Repeated osseous metabolism markers showed a slightly elevated alkaline phosphatase and normal, though in the lower range, osteocalcin and beta-crosslaps. He had a slight leukopenia and no other notably endocrine or metabolic disturbances with stationary BMD.
Discussion
Fratzl-Zelman *et al*[1] demonstrated that this mutation is associated with low bone turnover osteoporosis, rendering bisphosphonate treatment inefficient, in line with other reports[2] of bisphosphonates showing no effects in these patients. Moreover, they showed that teriparatide treatment produced little to no improvement. Other study showed a positive effect of teriparatide, although rising questions regarding increased bone marrow adiposity in these patients[3]. Romosozumab could be a potential targeted treatment.
Case resolution and conclusions
Lifestyle modification was advised and given the stable clinical and densitometric evaluation, treatment initiation was postponed. As more cases of monogenic WNT1 osteoporosis are recognized, more studies are necessary to find an appropriate treatment plan. So far, different treatment choices have conflicting outcomes.

Hypercalcemia in primary hyperparathyoidism: when should ENT be alerted?

May Ferjani[1], Mahdi Ferjaoui[1], Nour Kraiem[1], Nawres Bouaziz[1], Rachida Bouatay[1], Amel Korbi[1], Nawrez Kolsi[1], Khaled Harrathi[1] & Jamel Koubaa[1]
[1]Fattouma Bourguiba Hospital, ENT and Cervicofacial Surgery, Monastir, Tunisia

Introduction
Primary hyperparathyroidism is the leading cause of hypercalcemia. It can be asymptomatic and discovered incidentally, or revealed by recurrent kidney stones, bone pain, or cardiac and digestive symptoms.
Materials and Methods
This retrospective study includes 22 cases of primary hyperparathyroidism treated with parathyroidectomy between 2021 and 2023.
Results
The study involved 22 patients, predominantly women, (M/F ratio: 0.18) with a mean age of 58.72 years. All patients had hypercalcemia with elevated

parathyroid hormone (PTH) levels. The average preoperative calcium and PTH levels were 2.82 mmol/l and 389 pg/mL. Twenty-three percent of patients were asymptomatic, 45% reported bone pain, and 27% had a history of kidney stones. Other symptoms were present in 32% of patients. ENT examinationwas normal in 21 cases. One patient had a left paramedian anterior basicervical swelling, measuring 1 cm firm, mobile. Ultrasound suggested a retrothyroidal nodule, with some uncertainty regarding its origin. Scintigraphy confirmed the diagnosis in all cases. All patients underwent parathyroidectomy, with removal of the pathological parathyroid gland. Four patients also underwent a lobectomy for thyroid nodules. Histopathology revealed parathyroid adenoma in 86% and pseudo-adenomatous hyperplasia in 14% of the cases. Postoperative calcium and PTH levels decreased starting on postoperative day 2, with average values of 2.36 mmol/l and 39 pg/mL respectively.

Conclusion

Primary hyperparathyroidism remains the most common cause of hypercalcemia. The role of the ENT surgeon is crucial in the therapeutic management once the diagnosis is established. Postoperative outcomes following surgery are remarkable.

Cartilage -hair hypoplasia due to double heterozygosity for the RMRPn.97_98dup mutation and the RMRPn.25_-12dup mutation in a girl with asymmetrical short stature and brachydactyly

Vasiliki Rengina Tsinopoulou[1], Eleni P Kotanidou[1], Petra Loid[2], Outi Mäkitie[2] & Assimina Galli-Tsinopoulou[1]

[1]Pediatric Endocrinology and Metabolism Unit, 2nd Department of Pediatrics, School of Medicine, Faculty of Health Sciences, Aristotle University of Thessaloniki, University General Hospital AHEPA, Thessaloniki, Greece; [2]Pediatric Endocrinology, Children's Hospital, University of Helsinki, Helsinki, Finland

Introduction

Cartilage-Hair Hypoplasia (CHH) is presenting as a group of disorders resulting from mutations in the RMRP gene, which produces a non-coding RNA to which proteins bind to form an enzyme called mitochondrial RNA processing endoribonuclease (RNaseMRP). The RNaseMRP enzyme is involved in important cellular processes (DNA replication in mitochondria/ribosome assembly/cell cycle control). Biallelic loss-of-function mutations in RMRP have been reported in individuals with CHH, which present clinically as growth failure/skeletal abnormalities (metaphyseal dysplasia/brachydactyly/delta-shaped epiphyses) and extraskeletal features (hair hypoplasia/immunodeficiencies/anemia/malignancies).

The aim is to present a girl with short stature with continuous failure to growth, thin scalp hair and concomitant pathological radiological findings.

Patients/Methods

A 13-year-old adolescent girl (height 128cm/Tanner stage III/no menarche) has been followed since the age of 23/12 years. She is the 4th child of parents with tall stature (father187cm/mother170cm/without phenotypic deformities), born by cesarean section (weight 3010gr/length 50cm). Individual's history reports a decrease in body length and growth rate since infancy, whereas family history reveals father with a single kidney/mother with cardiac arrhythmia. At the first visit short stature/lordosis of the spine/short phalanges of the fingers of upper and lower extremities/mild varus knee patterns /hyperextensibility of the joints and fine hair on the head were found. Radiologically, widening and hardening of the articular surfaces with a beak-like appearance on the medial surface were found. A comprehensive investigation was performed (nutrition/karyotype/growth hormone secretion tests/thyroid function/celiac disease/bone metabolism). Genetic analysis of the RMRP gene was performed.

Results

Laboratory investigation revealed normal findings. The short stature gradually worsened with a striking increase in the asymmetry of the upper/lower body ratio. The patient presented with multiple lateral elbow dislocations. New bone metabolism tests showed pathological findings (low procollagen I levels/ high DPD/cre levels), indicative of reduced bone formation-increased bone resorption. The combination of clinical and laboratory findings led to genetic testing for skeletal malformations and RMRP gene, which confirmed the patient's double heterozygosity of RMRPn.97_98dup mutation (pathogenic) and RMRPn.25_-12dup mutation (likely pathogenic), inherited from the father and mother, respectively. The patient is closely monitored for growth/puberty but also for early diagnosis of any concomitant events of the disease (immunodeficiencies/-malignancies/anemia).

Conclusions

This rare case is the first description of CHH in Greece. In the diagnosis of the disease, clinical and radiological suspicion is very important. RMRP gene should also be required in genetic testing since its mutations lead to early diagnosis of comorbidities that are crucial for the patients' lives.

JOINT262

Effect of sacubitri/valsartan on bone turnover markers in patients with dilated cardiomyopathy

Ipsita Mishra[1,2] & Hrudananda Mishra[3]

[1]IMS & SUM II, Endocrinology and Metabolism, Cuttack, India; [2]IMS & SUM II, Endocrinology, Cuttack, India; [3]Apollo Hospital, Cardiology, Cuttack, India

Background

Heart failure (HF), particularly dilated cardiomyopathy (DCM), is frequently associated with comorbidities, including osteoporosis and increased fracture risk. This heightened risk is potentially linked to shared pathophysiological mechanisms, such as chronic inflammation and neurohormonal activation. Sacubitril/valsartan, an angiotensin receptor-neprilysin inhibitor (ARNI), has demonstrated significant benefits in HF management. However, its impact on bone metabolism remains unclear. This study investigated the effect of sacubitril/valsartan on bone turnover markers in patients with DCM.

Methods

This prospective, observational study enrolled 60 patients diagnosed with DCM (left ventricular ejection fraction $\leq 40\%$) and New York Heart Association (NYHA) functional class II-III. Patients were divided into two groups: the sacubitril/valsartan group ($n = 30$) received standard HF therapy plus sacubitril/valsartan, while the control group ($n = 30$) received standard HF therapy alone. Serum levels of bone turnover markers, including bone-specific alkaline phosphatase (BSAP, a marker of bone formation), C-terminal telopeptide of type I collagen (CTX, a marker of bone resorption), and osteocalcin (OC, another marker of bone formation), were measured at baseline and after 6 months of treatment.

Results

At baseline, no significant differences were observed in bone turnover markers between the two groups. After 6 months, the sacubitril/valsartan group demonstrated a significant decrease in CTX levels (mean change -12.5 pg/mL, $P < 0.05$) compared to the control group (mean change $+2.1$ pg/mL, $P = 0.32$). BSAP and OC levels did not show statistically significant changes in either group. The change in CTX correlated positively with the change in N-terminal pro-B-type natriuretic peptide (NT-proBNP), a marker of cardiac stress, in the sacubitril/valsartan group ($r = 0.45$, $P < 0.05$). This suggests that the reduction in bone resorption may be related to improved cardiac function.

Conclusion

This study suggests that sacubitril/valsartan may have a beneficial effect on bone metabolism in patients with DCM by reducing bone resorption, as evidenced by a decrease in CTX levels. The correlation between changes in CTX and NT-proBNP suggests a potential link between improved cardiac function and reduced bone resorption. Further large-scale, randomized controlled trials are needed to confirm these findings and explore the underlying mechanisms. These findings highlight the potential pleiotropic effects of sacubitril/valsartan beyond its established cardiovascular benefits.

Introduction

Alterations in the low-density lipoprotein receptor-related protein 5 (*LRP5*) gene are associated with primary bone fragility, leading to recurrent low-energy fractures. Heterozygous carriers typically exhibit a milder phenotype, with reduced bone mass observed early in childhood. This study aims to describe the clinical features and therapeutic outcomes of a pediatric cohort with heterozygous LRP5 gene variants.

Case Series

This retrospective study includes 7 pediatric patients (5 males, 2 females) from 3 Italian Pediatric Endocrinology Centers, aged 6 to 17 years (mean age at diagnosis: 9.1 years). Their height ranged from -1.2 to +1.3 SDS, and BMI from -0.7 to 3.0 SDS. Eight distinct heterozygous LRP5 variants were identified (6 missense, 2 nonsense), with most classified as variants of uncertain significance (VUS) and 2 deemed likely pathogenic. One patient carried the c.1709G>A; p.(Arg570Gln) variant, previously reported as pathogenic in the homozygous state. Before diagnosis, patients had between 0 and 4 low-trauma fractures, with 4 out of 7 presenting multiple spontaneous vertebral fractures. Bone and joint pain were reported by 5 out of 7 patients (71%) at presentation. All but two underwent bisphosphonate therapy (one is scheduled to start), and one patient also received denosumab. During a follow-up period ranging from 9 months to 4 years, none experienced new fractures. Bone mineral density (BMD) improved in all patients, with an observed increase ranging from 3% to 103% (mean increase: 51%). Those with vertebral compression fractures showed evidence of stabilization or partial reshaping. No adverse effects related to therapy were reported in this cohort.

Discussion and Conclusion

This case series highlights the clinical variability associated with *LRP5* gene variants in pediatric patients and underscores the effectiveness of bisphosphonate therapy in improving BMD and reducing fracture risk. The identification of predominantly VUS variants provides valuable insight into the genetic landscape of LRP5-related bone disorders. Our findings contribute to the expanding knowledge of LRP5 mutations and their association with primary bone fragility in children, underscoring the critical role of molecular diagnostics. Understanding the genetic basis of the disease not only improves diagnosis but also offers deeper insights into its pathophysiology, potentially informing more targeted therapeutic approaches. While bisphosphonates remain the current standard of care, further research is needed to explore precision therapies targeting Wnt signaling and other pathways affected by LRP5 mutations. A personalized approach, tailored to the specific genetic variant and clinical presentation, may further optimize long-term bone health in affected children.

Bone turnover markers and their associations with longitudinal changes in bone mineral density and trabecular bone score in children and adolescents with graves' disease

Pattara Wiromrat[1], Ratikorn Chaisiwamongkol[1], Nantaporn Wongsurawat[2], Yutapong Raruenrom[2], Piyanan Suparattanagool[3], Ouyporn Panamonta[1] & Chatlert Pongchaiyakul[4]

[1]Khon Kaen University, Pediatrics, Khon Kaen, Thailand; [2]Khon Kaen University, Nuclear Medicine, Khon Kaen, Thailand; [3]Khon Kaen University, Epidemiology, Khon Kaen, Thailand; [4]Khon Kaen University, Internal Medicine, Khon Kaen, Thailand

Background

Adults with Graves' disease (GD) exhibit reduced bone mineral density (BMD) and impaired trabecular bone microarchitecture, both of which typically improve with euthyroid status. However, data on these changes in adolescents are limited, and factors influencing them remain unclear.

Objectives

To evaluate bone turnover marker (BTM) concentrations, longitudinal changes in BMD and trabecular bone score (TBS), and factors associated with these changes in adolescents with GD.

Methods

We enrolled 42 adolescents with GD who had baseline data available for lumbar spine BMD (LSBMD) and BTM concentrations measured on the same date. BTM concentrations were converted to Z-scores. On the study date, follow-up LSBMD was measured. TBS, a measure of trabecular bone microarchitecture, was analyzed using iNsight™ software version 2.2. Annual percentage changes in LSBMD (%ΔLSBMD/y) and TBS (%Δ206;TBS/y) were calculated. Time-weighted (TW) concentrations of free T3 (FT3), free T4 (FT4), and TSH were determined over the follow-up period.

Results

Participants (74% female, mean age 13.5 ± 3.1 years, 90% Tanner stage ≥2, median [Q1–Q3] disease duration 1.3 [0.3–4.2] years, 45% receiving levothyroxine following radioiodine therapy [RAIT]) had a median follow-up duration of 2.2 (1.3–2.9) years. At baseline, four (10%) participants had a height-adjusted LSBMD Z-score ≤-2, and 2 (5%) had a TBS Z-score ≤-2. Participants with RAIT had longer disease duration ($P<0.001$), higher LSBMD Z-score ($P = 0.002$), and lower total procollagen type 1 N-terminal propeptide (P1NP) Z-score ($P = 0.01$) compared to those receiving antithyroid drug (ATD) therapy. %ΔLSBMD/y correlated positively with baseline FT3 ($P = 0.011$), TW FT3 ($P<0.001$), P1NP Z-score ($P = 0.001$), and osteocalcin Z-score ($P = 0.011$), and negatively with disease duration ($P<0.001$), RAIT ($P<0.001$), baseline TSH ($P<0.001$) and TW TSH ($P = 0.037$). %ΔTBS/y correlated positively with body mass index (BMI) Z-score ($P = 0.022$). Regression analysis revealed that P1NP Z-score was positively associated with %ΔLSBMD/y adjusting for age, sex, Tanner stage, BMI Z-score, disease duration, TW FT3, and TW TSH ($P<0.001$).

Conclusions

Adolescents with GD have a high prevalence of low LSBMD. Improvement in LSBMD during treatment is positively associated with FT3 and negatively with TSH concentrations over the follow-up period, while TBS improvement is associated only with BMI. Furthermore, P1NP independently predicts LSBMD improvement, suggesting its potential as a prognostic bone biomarker.

Warwickshire NHS Trust, Institute for Cardiometabolic Medicine, Coventry, United Kingdom; [10]Department of Endocrinology-Growth and Development, Children's Hospital P. & A. Kyriakou, 11527, Athens, Greece

Introduction
Autosomal dominant hypocalcemia (ADH) type 1 is a rare form of hypoparathyroidism, caused by heterozygous, inherited or de novo, activating mutations in the CASR. The management of patients with ADH1 is challenging. They are usually treated as "common" primary hypoparathyroidism with conventional therapy or PTH analogues due to either absence of accurate diagnosis or to limited access to the proper therapy (calcilytics which function as negative allosteric modulators of the CaSR).
Case presentation
A 33-year-old man, diagnosed with ADH1 and Bartter's Syndrome (c.2486A>G in exon 7 of the *CaSR* gene) and Chronic myeloid leukemia (CML) was followed at the outpatient department. He was treated with calcium carbonate 500mg 1x2, alfacalcidol 1 mg 1×1, cholecalciferol 800UI 1×1, hydrochlorothiazide 25mg 1×1, rhPTH (Natpar) 75-100 mg 1×1 and magnesium supplements. He also received dasatinib for the CML. However, his management was not optimal. His serum corrected calcium was ranged from 6.1 to 8.9 mg/dl (normal range: 8.5 to 10.5 mg/d), serum phosphate level was ranged from 3.7 to 4.5 mg/dL (2.7-4.5), serum magnesium was ranged from 1.3-1.6 mg/dl (1.6-2.4), and he had a pronounced hypercalciuria (urine calcium: 520- 863 mg/24h). In October 2024 palopegteriparatide (Yorvipath) was initiated (18mg 1×1) and titrated. Almost three months after the initiation of the treatment (January 2025) the patient is treated with palopegteriparatide (Yorvipath) 30mg 1×1 and hydrochlorothiazide 25mg ½ x1) while he is independent form calcium supplements and alfacalcidol. His serum corrected calcium is 9.6 mg/dl, serum phosphate level is 3.3 mg/dL, serum magnesium was 2.1 mg/dl (1.6-2.4), and the 24h urine calcium is 390 mg/24h.
Conclusion
Until the launch of the calcilytics, palopegteriparatide (Yorvipath) may represent a valuable alternative for the management of ADH1.

Vitamin d replenishment and its effectiveness on bone health in children receiving antiepileptic drugs: a randomized controlled trial
Siddhnath Sudhanshu[1,2], Navya Kurien[2], Shruti Sajjan[2], Vijayalakshmi Bhatia[2] & Vimal Paliwal[2]
[1]All India Institute of Medical Sciences, Patna, Additional Professor, Patna, India; [2]Sanjay Gandhi Postgraduate Institute of Medical Sciences, Lucknow, India

Background
Antiepileptic drugs (AEDs) are well known to affect bone health adversely, most importantly due to vitamin D deficiency associated with use of AEDs. It is rational to monitor vitamin D status in such children to detect vitamin D deficiency/insufficiency and then to replenish vitamin D (cholecalciferol). Currently there is no consensus regarding the recommended dose of vitamin D supplementation in children receiving AEDs.
Objectives
Our objective was to detect vitamin D insufficiency in children on AEDs at baseline and then, to determine the effectiveness of two internationally accepted vitamin D (cholecalciferol) supplementation dosage (1200 IU daily vs. 400 IU daily) on bone health and vitamin D status in children on AEDs.
Methods
A Randomized controlled trial on subjects receiving antiepileptic drugs and attending Neurology outpatient department at SGPGIMS, Lucknow. We supplemented cholecalciferol in subjects receiving AEDs and having vitamin D insufficiency (serum 25OHD < 20 ng/ml) in two randomized oral dosage groups 1 and 2 (1200 IU daily vs. 400 IU daily, respectively) along with 500 mg of elemental calcium. Subsequently, we analyzed the changes in serum 25OHD and other bone health markers (Serum calcium, phosphorus, alkaline phosphatase, intact PTH, P1NP and beta CrossLaps) at the baseline and at 3 months between the two groups.
Results
Out of 70 participants, 60 (86%) were found to have vitamin D insufficiency (25OHD < 50 nmol/l). At 3 months follow-up, the group 1 had achieved vitamin D sufficiency status in all participants (23/23) whereas only 18/25 (70%) participants in the group 2 achieved vitamin D sufficiency status. The 25OHD level (mean ± SD, nmol/l) was significantly higher in group 1 as compared to group 2 (80.5 ± 24.2 vs. 50.1 ± 14.5; $P < 0.001$). Group 1 had significantly lower intact PTH level (mean ± SD, pmol/l) (3.4 ± 1.4 vs. 5.2 ± 1.8; $P < 0.01$), significantly lower ALP level (186 ± 68 vs. 298 ± 145; $P < 0.01$) and significantly lower beta CrossLaps level (1186 ± 208 vs. 1592 ± 428; $P < 0.001$), when compared to group 2. On paired t-test to analyze the changes (from the baseline to the 3 months follow-up), revealed that the changes towards improvement in the serum 25OHD level, ALP, intact PTH and beta CrossLaps were significantly more in group 1. The intervention was safe as none developed toxic levels of serum 25OHD (> 250 nmol/l), hypercalcemia and nephrocalcinosis.
Conclusion
A higher oral vitamin D replacement dose (1200 IU per day) is safe and achieves a better vitamin D level and vitamin D sufficiency state along with significantly improved biochemical markers of bonehealth.

The achondroplasia roadmap
Marco Sessa[1], Josè Sim-Sim[2], Nathalie Meunier[3], Stephanie Birch[4], Marta Skierkowska[5], Kenia Rio[6], Andrea Verónica Fraschina[7], Rosa Brumberg[8], Fernanda Cornejo[9] & Susana Noval[10]
[1]AISAC Odv, MILANO, Italy; [2]ANDO, EVORA, Portugal; [3]APPT, PARIS, France; [4]FEST, KIDWELLY, United Kingdom; [5]Odblokuj-zycie, WARSAW, Poland; [6]ANNABRA, RIO DE JANEIRO, Brazil; [7]ACONAR, MAR DEL PLAT, Argentina; [8]ACONUR, MONTEVIDEO, Uruguay; [9]Asociación Padres Acondroplasia, SANTIAGO DEL CHILE, Chile; [10]ALPE, GIJON, Spain

Introduction
Achondroplasia is a type of skeletal dysplasia that effects the length and shape of bones, most apparent in the arms, legs and head. While it is the most common cause of short stature, only 1 in 25,000 children are born with achondroplasia, with about 250,000 people world-wide with the condition. Parents, healthcare professionals and others lack resources to support children in navigating the emotional and social challenges they face growing up.
Methodology
Leaders from 11 achondroplasia patient associations among them also parents and individuals with the condition participated in guided discussions to define the life milestones and related medical, emotional and social issues families and children often face. The co-created Achondroplasia Roadmap is an interactive, visual information tool that presents topics including genetic counseling, medical issues, navigating the social environment and promoting independence, presenting each topic at key phases of development: pre-natal, birth-2 years of age, 3-6 years, 7-12 years and 13-18 years. After 12 months, the same patient representatives were asked to report on key indicators to assess how and in what contexts the Roadmap has been utilized, along with metrics including number and type of events where it was presented, audience, and social media reach and impressions.
Results
Data will be presented on the utilization of the Achondroplasia Roadmap and feedback from the community in the first 12 months.
Conclusions
In addition to improving parents' knowledge about the condition, expectations are that the Roadmap is an important resource for facilitating conversations with healthcare professionals, teachers, peers and others, in order to increase understanding about the challenges faced by families and children with achondroplasia. *The Roadmap was developed by the International Council of Achondroplasia Patient Association Leaders, an ad hoc body representing 11 countries, with support from BioMarin*.

A rare case of genetically confirmed X-linked dominant hypophosphatemic rickets in a 7-year-old girl from Kazakhstan

Marzhan Rakhimzhanova[1], Ayazhan Abikenova[1], Dariya Gosman[1] & Karlygash Medegali[1]
[1]CF UMC, Astana, Kazakhstan

Introduction
X-linked dominant hypophosphatemic rickets (XLH) is a rare hereditary disorder characterized by chronic progressive phosphate wasting due to excessive fibroblast growth factor 23 (FGF23) activity. This condition typically manifests with delayed motor development, gait abnormalities, progressive skeletal deformities, lower limb pain, impaired growth, craniosynostosis, dental abscesses, and hypotonia. Biochemically, it presents with hypophosphatemia, elevated alkaline phosphatase (ALP), and a reduced tubular maximum phosphate reabsorption per glomerular filtration rate (TmP/GFR). Radiographic findings include widened growth plates in both upper and lower limbs, reflecting severe rickets-related skeletal abnormalities.
Case Report
We present the case of a Kazakh girl born in 2017, who was admitted to the pediatric endocrinology department with complaints of lower limb deformities, gait disturbances, and shin pain during prolonged walking. Clinical examination revealed significant growth retardation, severe varus deformity of the lower limbs, hypertelorism, and multiple dental caries. Additional phenotypic characteristics included an antimongoloid slant of the eyes, a flat nasal bridge, and a prominent forehead. Renal ultrasound detected bilateral nephromegaly, while radiographic imaging confirmed severe lower limb deformities, cortical thinning, and metaphyseal irregularities in both upper and lower limbs. The severity of rickets was assessed as 2 points out of 5 on the Radiographic Severity Score (RSS) scale. Genetic analysis through whole-genome sequencing identified a heterozygous deletion on the X chromosome (chrX:22202815-22216826) encompassing 16 exons of the *PHEX* gene (NM000444.6), confirming a pathogenic variant associated with XLH. Biochemical analysis further demonstrated disturbances in phosphorus metabolism, including elevated ALP 522.90 U/l (82.00 - 383.00), hypophosphatemia 0.85 mmol/l (0.95 - 1.85), increased urinary phosphorus excretion, and decreased TmP/GFR 0.71 mmol/l (1.15 - 2.6).
Conclusion
The patient was diagnosed with X-linked dominant hypophosphatemic rickets based on clinical, biochemical, genetic, and imaging findings. Targeted therapy with burosumab (Crivit) was initiated at a dose of 0.8 mg/kg subcutaneously every two weeks. This case highlights the importance of early genetic testing, comprehensive metabolic evaluation, and targeted treatment in improving outcomes for patients with XLH.

Tumor-induced osteomalacia: the bone metabolism version of the princess and the pea

Andra Ionescu[1], Emanuel Palade[2,3] & Cristina Alina Silaghi[1,2]
[1]Cluj County Emergency Hospital, Endocrinology, Cluj-Napoca, Romania; [2]"Iuliu Ha?ieganu" University of Medicine and Pharmacy, Cluj-Napoca, Romania; [3]"Leon Daniello" Pneumology Hospital, Department of Thoracic Surgery, Cluj-Napoca, Romania

Tumor-induced osteomalacia (TIO) is a rare cause of bone demineralization, primarily affecting adults. It results from the hypersecretion of fibroblast growth factor 23 (FGF23) by typically benign, small, and elusive mesenchymal tumors, which can arise anywhere in the body, but are most commonly found in the lower limbs. Excess FGF23 reduces renal phosphate reabsorption in the proximal tubules, and inhibits the activation of 25-OH-vitamin D, thereby impairing intestinal phosphate absorption. Consequently, patients develop non-specific yet debilitating symptoms, including fatigue, chronic pain, muscle weakness, fragility fractures, and mobility impairment. We report the case of a 59-year-old female referred to our endocrinology department for progressive bone pain, muscle weakness, and multiple fragility fractures (ribs, femur, tibia, talus, and calcaneus). Extensive hematologic, rheumatologic and orthopedic evaluations revealed persistent hypophosphatemia. Renal phosphate wasting was confirmed by a low tubular maximum reabsorption of phosphate to the glomerular filtration rate (TmP/GFR) for her age. Elevated FGF23 levels, along with low 25-OH-vitamin D and 1,25-$(OH)_2$-vitamin D, raised suspicion of an FGF23-secreting tumor. Magnetic resonance imaging (MRI) identified a 50/24/64 mm mass in the retrocrural space, initially suggesting a paraganglioma. However, biochemical studies ruled out a secretory paraganglioma. Surgical excision confirmed a mesenchymal neoplasm, establishing the diagnosis of TIO. Postoperatively the patient experienced significant symptomatic improvement, including relief from pain and depression, along with restored mobility. Biochemical follow-up demonstrated normalization of FGF23, high 25-OH-vitamin D, 1,25-$(OH)_2$-vitamin D, normal serum phosphate, and phosphaturia. Diagnosing TIO remains challenging due to the difficulty in locating the causative tumor. However, it should be considered in patients with unexplained progressive muscle weakness, bone pain, and multiple fragility fractures. Early recognition and appropriate biochemical and imaging workups are crucial for timely diagnosis and treatment. While wide surgical resection remains the gold standard, newer approaches such as minimally invasive radiofrequency ablation, radiotherapy, or cryoablation are under investigation. This case is particularly notable due to the tumor's unusual size and retrocrural location, initially raising the suspicion of an alternative diagnosis.

Premature girl with unusual skeletal dysplasia

Diana Swolin-Eide[1,2], Gabriella Seidal[3], Maria Forsberg[2], Anders Elfvin[4] & Sofia Thunström[5]
[1]Sahlgrenska University Hospital, University of Gothenburg, Deptartment of Pediatric endocrinology, Gothenburg, Sweden; [2]Queen Silvia's childreńs hospital, Deptartment of pediatrics, Gothenburg; [3]Sahlgrenska University Hospital, Deptartment of Pediatric gastroenterology, Gothenburg, Sweden; [4]Sahlgrenska University Hospital, University of Gothenburg, Deptartment of Pediatric, Gothenburg, Sweden; [5]Sahlgrenska University Hospital, Clinical genetics and genomics, Gothenburg, Sweden

Background
Girl six months old was referred in Sept. 2020 to the pediatric endocrinologist, due to short stature approximately -6 SD and skeletal changes. Antenatally: growth retardation, acute section in week 29+4, SGA was noted. Birth weight was 745 gram, birth length was 33 cm. Head circumference normal. Apnea episode early. Initial feeding difficulties. Bilateral conductive hearing loss was discovered.
Material
X-ray findings: Full body X-ray showed shorter humerus, ulna and femur. Single longitudinal vertebrae with suggested fish shape. Lab. values: Jon-Calcium 1,38 mmol/l, Phosphate 2,0 mmol/l, Mg 0,97 mmol/l, TSH 11 mIE/l, T4 17 nmol/l, Alat 0,35 µkat/l, ALP 3,4 µkat/l, PTH 1,07 pmol/l- new sampling 3,3 pmol/l, 25-OH Vitamin D 101 nmol/l (new sampling 84 nmol/l).
Results
Microarray and skeletal dysplasia panel testing returned negative results, prompting whole-genome analysis. This analysis identified two pathogenic DNA variants in the *SLC10A7* gene in a compound heterozygous state: c.722-16A>G and c.773+1G>A. These variants lead to the production of a truncated and dysfunctional protein, impairing glycosylation. The parents were found to be heterozygous carriers, each for one of the variants. The findings are consistent with the condition "Short stature, amelogenesis imperfecta, and skeletal dysplasia with scoliosis" (OMIM# 618363). This rare skeletal dysplasia is caused by a congenital glycosylation defect and follows an autosomal recessive inheritance pattern. Associated features may include abnormal facial characteristics, hearing impairment, and intellectual disability. To date, this diagnosis has been reported in only a small number of patients. In January 2025 the girl is followed in the endocrine clinic, neonatal clinic including psychologist contact, the audiologist, specialist dentist, pediatric orthopedist, and nutrition team. Now at age 4 her height is 91,9 cm (-3 SD) and weight is 14 kg (-2 SD). She has an increasingly abundant vocabulary and has become more independent in her physical movement.
Conclusion
Whole genome sequencing (WGS) analysis revealed an unusual form of skeletal dysplasia caused by a congenital glycosylation defect. The condition is characterized by disproportionate short stature, defective tooth enamel formation and sometimes severe scoliosis. In cases with unclear symptoms and suspected syndrome perform WGS analysis and follow the patient over time.

Isolated mild hypocalcemia as the initial manifestation of previously undiagnosed Coeliac disease

Shyam Seshadri[1], Jaiminkumar Patel[1], Murtaza Rashid[1] & Fawad Raziq[1]
[1]Queen Elizabeth Hospital Foundation NHS Trust, Department of Diabetes and Endocrinology, Kings Lynn, United Kingdom

Background
Coeliac disease (CD) is an autoimmune disorder triggered by gluten in genetically predisposed individuals causing intestinal inflammation and villous atrophy leading to malabsorption of essential nutrients. While hypocalcaemia is a known complication due to impaired absorption of calcium and vitamin D, it is rarely the presenting symptom of undiagnosed coeliac disease. This case highlights the diagnostic challenge when mild hypocalcaemia leads to the discovery of an underlying gastrointestinal disorder.
Case Presentation
A 63-year-old male presented with a history of fatigue, intermittent paraesthesia, and muscle cramps. He denied any symptoms of overt tetany. Laboratory investigations revealed low serum calcium (2.12), borderline low 25-hydroxyvitamin D level (35), normal phosphate, magnesium, and raised PTH suggesting secondary hyperparathyroidism. Renal and liver function test results were normal. A 24-hour calcium-to-creatinine ratio was less than 0.01. He was commenced on Vitamin D replacement. After being adequately replaced with Vitamin D, he however remained persistently hypocalcaemic. PTH or even partial Vitamin D resistance was initially suspected as potential causes. The patient was started on a trial of Calcium carbonate. However, the patient's symptoms persisted, prompting further investigations. The patient underwent a screening test for coeliac disease at a primary care centre, which revealed elevated Anti-transglutaminase (anti-tTG) antibody levels. Notably, the patient had no gastrointestinal symptoms, such as diarrhoea or weight loss, which are commonly associated with coeliac disease. The patient declined endoscopy and biopsy and hence could not ascertain the tissue diagnosis of coeliac disease. However, strong positive anti-tTG antibody levels and a family history of coeliac disease were sufficient to confirm the diagnosis clinically.
Management and Outcome
The patient was started on a strict gluten-free diet. Over several months, his serum calcium normalised, and his symptoms resolved. Emphasis was placed on nutritional counselling, including fortified foods and lifestyle modifications.
Conclusions
This case emphasises the importance of considering coeliac disease in patients presenting with unexplained hypocalcaemia, especially when accompanied by nonspecific symptoms such as fatigue and muscle cramps. Early recognition of coeliac disease can prevent the complications associated with nutrient malabsorption and lead to effective management. This case also underscores the need for comprehensive evaluation when mild hypocalcaemia is detected without clear dietary or metabolic causes and emphasis on further evaluation and investigation given persistent symptoms albeit in the setting of mild hypocalcemia should be made as was evident in this patient.

JOINT2704

New clues that may connect the circulating irisin levels to glucose status and bone turnover markers in postmenopausal women (project IRI-OP-OB)

Sorina Schipor[1], Dana Manda[1], Luminita Suveica[2], Oana-Claudia Sima[1], Veronica Cumpata[2], Daniela Galea-Abdusa[2], Maria-Mihaela Vovc[2], Ana Popescu[2] & Mara Carsote[1]
[1]"C. I. Parhon" National Institute of Endocrinology, Bucharest, Romania; [2]"Nicolae Testemitanu" State University of Medicine and Pharmacy, Chisinau, Moldova

Background
Irisin, a muscle-released hormone, interferes with the metabolism regulation, including settling the metabolic rate, and recently proved being pro-active in the mater of bone formation.
Objective
To check the circulating irisin levels in menopausal women in relationship with glucose profile assays and bone turnover markers on two different age groups.
Methods
This was a bi-centric, transversal, clinical study, in menopausal women without prior diagnosis of osteoporosis. Inclusion criteria were: confirmation of menopausal status and age over 50. Exclusion criteria were: insulin therapy, specific anti-osteoporotic medication, active cancers or functioning endocrine tumors at any gland, current exposure to glucocorticoid or GLP-1 agonists, end-stage CKD. The protocol included blood testing for irisin (ELISA, MyBioSource), bone turnover markers: osteocalcin, P1NP, beta-CrossLaps (ECLIA, Roche), fasting glucose (photometry, Abbott), insulin (CLIA, Beckman Coulter) and 2-hour assays amid oral 75 g-glucose tolerance test and A1c glycated hemoglobin (photometry, Roche).
Results
Two age groups: A (older than 50 to 60 y, $n = 18$) and B (older than 60 to 70 y, $n = 19$) were analyzed. Group A (55.61 $\pm$ 2.99 y) versus group B (66.11 $\pm$ 2.92 y) showed no significant differences with respect to irisin, osteocalcin, P1NP, beta-CrossLaps, fasting glycaemia, insulin, HbA1c. We found no correlation between irisin and bone turnover markers but a statistically significant positive correlation with 2-h glucose in each group ($r = 0.394$, $P = 0.042$ and $r = 0.462$, $P = 0.028$), and fasting insulin plus 2-h insulin for group A ($r = 0.543$, $P = 0.005$ and $r = 0.41$, $P = 0.033$). A borderline significance was established in group A with respect to irisin-HbA1c correlation ($r = 0.294$, $P = 0.08$).
Discussions and conclusions
So far, the correlation with glucose profile markers seems more important than the correlation with bone turnover markers. Circulating irisin levels are relevant for the muscle-bone-fat cross talk and they might serve as metabolic biomarkers.

Evaluation of a new IDS beta crosslaps® (CTX-I) assay for the iSYS automated analyzer

Michael Schønemann Rand[1,2], Jutarat Charoenpatrawut[1], Lasse Kristoffer Bak[1,2,3], Etienne Cavalier[4] & Niklas Rye Jørgensen[1,2,5]
[1]Rigshospitalet, Department of Clinical Biochemistry, Glostrup, Denmark; [2]Rigshospitalet, Translational Research Centre, Glostrup, Denmark; [3]University of Copenhagen, Department of Drug Design and Pharmacology, Copenhagen, Denmark; [4]University of Liege, Department of Clinical Chemistry, Liège, Belgium; [5]University of Copenhagen, Faculty of Health and Medical Sciences, Department of Clinical Medicine, Copenhagen, Denmark

Introduction
The bone resorption marker C-terminal telopeptide of Type I collagen (β-CTX-I), measured in plasma or serum is used to assess bone metabolism and therapeutic response in bone disorders. Studies have shown poor agreement in results between commercial assays for β-CTX-I and harmonization of assays has been proposed by the IFCC-IOF Committee for Bone Metabolism to achieve widely and interchangeably use of the assays.
Objective
To evaluate the performance of a new Beta CrossLaps® (CTX-I) (IDS-NEW) assay from Immunodiagnostic Systems (IDS) and to compare it with the existing IDS-iSYS CTX-I (CrossLaps®) assay (IDS-OLD) and the Roche Elecsys® β-CrossLaps/serum assay (ELECSYS).
Methods
Patient EDTA plasma samples were obtained. Precision of the IDS-NEW assay was assessed by measuring two patient pools (one around the geometric mean for premenopausal women and one at a higher level). Each level was run on every weekday in a period of two weeks, $n = 30$. Both the IDS-ISYS (iSYS) and IDS-i10 (i10) platforms were used. Correlation between the IDS-NEW assay, the current IDS-OLD assay and the ELECSYS assay were evaluated by measuring patient samples in parallel on the different assays.
Results
Precision of the IDS-NEW assay is shown in table 1. Parallel analysis of patient samples ($n = 68$) using the IDS-NEW assay on the iSYS and i10 system showed a high correlation ($R^2 = 0.994$, $P < 0.0001$) with a negligible bias of 0.5 ng/l ($P = 0.9177$). Method comparison between the IDS-NEW and IDS-OLD assays ($n = 93$) showed a high correlation ($R^2 = 0.983$, $P < 0.0001$) with a non-significant bias of 28 ng/l ($P = 0.1203$). However, a complex systematic bias with the IDS-NEW assay giving higher values at low concentrations and lower values at high concentrations compared to the IDS-OLD was seen. Finally, parallel analysis of patient samples ($n = 40$) on the IDS-NEW assay and the Elecsys assay showed a high correlation (0.9841, $P < 0.0001$) with a mean bias of 14 ng/l ($P = 0.2523$). A possible lower correlation between the assays was observed at concentrations below 200 ng/l. New reference intervals for children will be presented.

Table 1.

Level	CV (%)	SD
Medium (340 ng/l)	4.6	15.5
High (839 ng/l)	3.9	33.0

Conclusions
- There is a high correlation between the IDS-NEW and the ELECSYS assay.
- Steps towards harmonization of the IDS-NEW assay with the ELECSYS assay have now been taken. However, whether interchangeable use of the two assays for monitoring individual patients over time is yet to be determined

Evaluation of children with persistently low ALP levels

Gonul Buyukyilmaz[1], Serkan Bilge Koca[2], Refika Goren[1], Andac Uzdogan[1], Keziban Toksoy Adıguzel[3], Gonul Yardimci[4], Aylin Kılınç Uğurlu[5], Pınar Kocaay[1], Derya Tepe[1], Fatih Gürbüz[1,6] & Esra Kilic[1]
[1]Ankara Bilkent City Hospital, Ankara, Türkiye; [2]Kayseri City Hospital, Kayseri, Türkiye; [3]Dr. Burhan Nalbantoğlu State Hospital, Nicosia, Cyprus; [4]Gulhane Training and Research Hospital, Ankara, Türkiye; [5]Gazi University Faculty of Medicine Hospital, Ankara, Türkiye; [6]Ankara Yıldırım Beyazıt University, Pediatric Endocrinology, Ankara, Türkiye

Objectives
Alkaline phosphatase (ALP) consists of a group of isoenzymes found in many body tissues including the liver, bone, kidney, placenta, and intestine. ALP levels change with age and are measured at the highest level with increased growth. Elevated serum ALP levels are a marker of some pathological conditions, and the approach to increased serum ALP levels is better determined. In contrast, information about the approach to patients with low ALP levels is more limited. We aimed to evaluate the etiological distribution of patients with persistently low ALP levels and the demographic and clinical characteristics of infants and children diagnosed with hypophosphatasia (HPP).
Methods
This retrospective study included 0-18 years of children having low ALP levels between September 2019 and July 2024. Patients were divided into permanent and transient low ALP levels. Patients diagnosed with HPP were further examined.
Results
1825 patients with low ALP levels according to age and gender were identified. Of these patients, 79 patients were between 0-1 age (1 patient permanent, 78 patient transient) 1320 patients were between 1-11 ages (48 patient permanent, 1272 patients transient), 352 patients were between 11-13 ages (16 patient permanent, 336 patient transient), 74 patients were between 13-18 ages (15 patient permanent, 59 patient transient). 10 (0.54%) patients had a diagnosis of HPP. In the permanent subgroup without a diagnosis of HPP, calorie depletion (anorexia, malnutrition) was most frequent. Six of the children diagnosed with HPP were female and four were male. Two patients were investigated for short stature; one patient for hypercalcemia, hypercalciuria, epilepsy, and neuromotor developmental delay; one patient for respiratory distress and hypotonia; a patient was diagnosed while being followed up and treated with acute myeloid leukemia, one patient was diagnosed during a routine check-up, and one patient was diagnosed while his sibling was diagnosed. Seven different variants were detected in 9 families, all previously reported variants. Two of the variants were homozygous and five were heterozygous.
Conclusions
In our study involving a pediatric patient group, a wide range of disorders associated with low ALP activity were examined. In the case of persistent low ALP and additional specific symptoms, HPP should always be considered as a differential diagnosis. HPP presents differently in different age groups. While severe forms in young children are better known, unawareness or misinterpretation of symptoms in milder forms may lead to a delay in the diagnosis of milder cases in childhood or adolescence.

A rare cause of hypoparathyroidism: kenny caffey type 2 - case report

Kelly Maury[1], Soledad Perez[1], Fabiana Vacile[2], Romina Flores[2], Gabriela Bidal[2], Gabriel Faraj[2] & Oscar Brunetto[1]
[1]Hospital General de Niños Pedro de Elizalde, Buenos Aires, Argentina; [2]Hospital Médico Policial Churruca Visca, Buenos Aires, Argentina

Background
Hypoparathyroidism is a disorder in calcium homeostasis that is caused by inadequate secretion of parathyroid hormone, either due to an alteration in its synthesis, secretion or action. In children there may be different genetic etiologies. It can be classified as isolated or syndromatic hypoparathyroidism, within which we find Kenny Caffey syndrome. We describe a patient with a diagnosis of Kenny caffey type 2.
Case report
A two-month-old child was referred to the Pedro Elizalde hospital with a diagnosis of hypocalcemia secondary to hypoparathyroidism and suspicion of Degeorge syndrome. On physical examination, her phenotype was peculiar, finding elphoid fascies and hypoplasia of the facial mass, with micrognathia and microphthalmia, relative macrocephaly, large anterior fontanelle, severe short stature and a micropenis. Laboratory tests showed normocytic normochromic anemia, elevated transaminases, inhibited pH with hypocalcemia, hyperphosphatemia and increased vitamin D for the age range. His kidney function and other hormonal axes were normal. The echocardiogram showed an atrial septal defect and mild pulmonary stenosis. Whole body x-rays revealed tubular long bones and medullary space with stenosis. Fish was performed for 22q11.2 deletion and was normal. A clinical exome was performed without finding positive results, and ruling out Kenny Coffey type 1 and alterations in the CASR, PTH and GCMB. Kenny coffey type 2 is suspected, and exome expansion is requested and a variant of uncertain significance in heterozygosity was identified in the. FAM111A, c.913A>G p.(Arg305Gly). At this time, the genetic results of the parents are awaited.
Conclusions
Kenny Caffey syndrome type 2 is a heterogeneous disorder with multiple manifestations. Early diagnosis helps prevent comorbidities and provide better interdisciplinary follow-up.

The role of surgery in tertiary hyperparathyroidism with ectopic localization

Oussama Jaddi[1], Sana Rafi[1], Sara Ijdda[1], Ghizlane El Mghari[1] & Nawal El Ansari[1]
[1]Mohammed VI University Hospital of Marrakesh, Department of Endocrinology, Diabetes, Metabolic Diseases and Nutrition, Marrakesh, Morocco

Introduction
Tertiary hyperparathyroidism (THPT) results from prolonged secondary hyperparathyroidism, often following hemodialysis, when the parathyroid glands become autonomous, leading to overproduction of PTH and persistent hypercalcemia. This condition may involve ectopic glands (thymus, mediastinum, or other locations), complicating diagnosis and treatment. Clinically, THPT manifests as severe hypercalcemia, vascular and tissue calcifications, osteopathy, and cardiovascular complications. When medical treatment (cinacalcet, vitamin D) fails, surgery becomes an essential option, particularly in cases involving ectopic glands.
Case Observation
A 20-year-old female patient with chronic kidney failure (on hemodialysis for 4 years) presented with a progressively developing swelling of the maxillary bone over the past 2 years. PTH levels were measured at 4028 pg/mL.
Renal ultrasound: Chronic nephropathy with simple renal cysts on the right kidney.
Cervical ultrasound: Two nodular formations in the mediastinal region suspected to be ectopic parathyroid nodules.
CT scan (thorax-abdomen-pelvis): Multiple axial and peripheral lytic lesions associated with signs of bone resorption, an expansive lytic lesion centered on the maxillary bone consistent with a brown tumor, fibrous dysplasia of the mandible and cranial vault, and homogeneous splenomegaly.
Discussion
Ectopic parathyroid glands, present in 14–45% of cases, pose diagnostic challenges that require precise localization using Tc99m-sestamibi scintigraphy or MRI. Surgical indications include refractory tertiary hyperparathyroidism unresponsive to medical treatment (cinacalcet, vitamin D), persistent hypercalcemia (>11 mg/dL) with complications (calcifications, osteopathy), and identified or suspected ectopic glands. Total parathyroidectomy with autotransplantation, combined with bilateral thymectomy and, if necessary, mediastinal exploration, is the optimal surgical strategy for these complex cases. This approach enables rapid reduction of PTH and calcium levels, significant clinical improvement, and prevention of long-term complications. A multidisciplinary approach involving endocrine surgeons, nephrologists, and radiologists is essential to ensure durable outcomes.
Conclusion
Surgery plays a central role in the management of tertiary hyperparathyroidism with ectopic glands. Accurate preoperative localization and appropriate postoperative management (calcium and vitamin D supplementation) are essential to minimize complications and ensure long-lasting outcomes.

Do patients with ehlers–danlos syndrome and a history of fractures have calcium and phosphate metabolism disturbances?

Aleksandra Żuk - Łapan[1,2], Ivan Rychlik[3], Jan Domański[1,2], Jakub Podstawka[1,2], Bernadetta Kałuża[1,2] & Edward Franek[1,4]
[1]Department of Internal Medicine, Endocrinology, and Diabetology, National Medical Institute of the Ministry of the Interior and Administration, Warsaw, Poland; [2]Students Scientific Group of the Medical University of Warsaw at the Department of Internal Medicine, Endocrinology, and Diabetology, National Medical Institute of the Ministry of the Interior and Administration, Warsaw, Poland; [3]Department of Internal Medicine, Third Faculty of Medicine, Charles University, and Královské Vinohrady University Hospital, Prague, Czech Republic; [4]Department of Human Epigenetics, Mossakowski Medical Research Institute, Polish Academy of Sciences, Warsaw, Poland

Background
Patients with Ehlers–Danlos syndrome (EDS) are at an increased risk of fractures whose etiology is chiefly associated with joint hypermobility and instability. One of the possible risk factors for fractures are calcium and phosphate metabolic disorders. The purpose of this study was to investigate calcium and phosphate metabolic disorders in patients with a hypermobile or classical EDS subtype and a history of fractures.
Material and Methods
The study involved a prospective assessment of 30 female patients, with either hypermobile or classical EDS. The patients were divided into two groups based on their fracture history. Group 1 comprised patients with no history of fractures (n =13); group 2 comprised patients with a history of fractures (n =17). All patients were evaluated for parameters of calcium and phosphate metabolism.
Results
The two study groups showed no differences either in terms of such parameters as total calcium (2.41±0.09 vs. 2.39±0.08, P = 0.691 [mmol/l]), parathyroid hormone (41.68±15.63 vs. 43.73±15.19, P = 0.805 [pg/ml]), vitamin 25OH-D (28.2±10.8 vs. 32.44±20.35, P = 0.786 [ng/ml]), alkaline phosphatase (8.6±2.33 vs. 10.24±2.78, P = 0.133 [µg/l]), beta-CrossLabsCTX (0.43±0.2 vs. 0.36±0.2, P = 0.336 [ng/ml]), and osteocalcin (21.7±6.59 vs. 19.72±8.04, P= 0.341 [ng/ml]) levels, or in terms of EDS subtypes: classical (n =5 (38.5%) vs. n =6 (35.3%), P = 0.901) and hypermobile (n =8 (61.5%) vs. n =13 (76.5%), P = 0.399) EDS. Inorganic phosphorus levels were significantly lower in group 2 than in group 1 patients (3.19±0.51 vs. 3.85±0.59, P = 0.003). There was a significant negative correlation between a history of fractures and inorganic phosphorus levels (Spearman's R -0.559, P = 0.001).
Conclusions
Patients with EDS and fracture history may exhibit abnormal calcium and phosphate metabolism manifesting in the form of low phosphorus levels.

Not just another adenoma: the diagnostic challenges of atypical parathyroid lesions

Teodora Vintilă[1], Alexandru Florescu[1,2], Viviana Popa[1,2], Irina Puscasu[1], Andra Berigoi[1], Miruna Miron[1] & Cristina Preda[1,2]
[1]Saint Spiridon County Hospital, Endocrinology, Iaşi, Romania, Ia?i, Romania; [2]Grigore T Popa University of Medicine and Pharmacy, Endocrinology, Ia?i, Romania

Atypical parathyroid adenomas are rare and difficult to diagnose, since their histopathological features overlap with both benign parathyroid adenomas and parathyroid carcinoma. These tumors lack definitive criteria for malignancy, but exhibit worrisome histologic findings such as: increased mitotic activity, trabecular growth patterns and fibrous bands. Clinically, these tumors cause signs and symptoms of primary hyperparathyroidism and hypercalcemia; while imaging modalities, including neck ultrasound, Sestamibi scintigraphy, can identify them. However, definitive diagnosis requires histopathological assessment. We report the case of a 74 year old male, with a history of prostate cancer, who was undergoing routine follow up imaging when a CT scan incidentally identified a lesion posterior to the left thyroid lobe; the scan also revealed multiple pelvic and spinal osteolytic bone metastases, the largest measuring 40x16 mm. Of note, the patient was completely asymptomatic. Endocrinological assessment revealed normal thyroid function, hypercalcemia(Ca=13,3 mg/dl), hyperparathyroidism(1741 pg/ml), low-normal vitamin D levels (20,59 ng/ml) and hypercalciuria (367,2 mg/24h). Neck ultrasound showed a well defined, hypoechoic, highly vascularized mass(3,22x4,9x2,86cm) posterior to the left thyroid lobe, raising suspicion of a parathyroid lesion. BMD-DXA revealed severe osteoporosis in the distal forearm(T score= 5,9) and decreased bone mineral density in the lumbar spine and femoral neck. Hypercalcemia persisted despite intravenous and oral hydration, so intravenous ibandronic acid was administered. A sestamibi thyroid and parathyroid scintigraphy confirmed a large hyperfunctioning parathyroid lesion on the left side, along with a smaller hyperfunctioning inferior right parathyroid lesion and a suspicious thyroid nodule in the lower two-thirds of the left lobe. Additionally, a bone scan identified suspicious bone lesions in the skull as well as the axial and appendicular skeleton. One month later, the patient underwent parathyroidectomy and thyroidectomy, and the histopathological report confirmed an atypical parathyroid adenoma. A bone biopsy was recommended, but has not yet been performed. This case highlights the diagnostic challenge of hypercalcemia in a patient with a history of malignancy. Although the presence of osteolytic bone lesions initially suggested metastatic prostate cancer, distinguishing between malignancy and parathyroid bone disease proved more difficult than expected. This distinction is crucial, since parathyroid bone disease may improve postoperatively, while metastatic disease would persist or progress. Close follow-up and monitoring are essential to reach a correct diagnosis and ensure patient's well-being in the postoperative period.

Bone and mineral metabolism alterations in newly diagnosed hyperthyroid patients

Wafa Ben Hilel[1], Imen Rojbi[1], Asma Krir[2], Sabrine Mekni[1], Sawsen Essayeh[1], Rihab laamouri[1], Karima Khiari[1] & Ibtissem Ben Nacef[1]
[1]Charles Nicolle Hospital, Endocrinology, Tunis, Tunisia; [2]Pasteur Institute, Clinical Biochemistry and Hormone Laboratory, Tunis, Tunisia

Introduction
Advanced hyperthyroidism (HT) is characterized by high bone turnover, leading to osteoporosis. This disorder has rarely been reported in newly diagnosed hyperthyroid patients. This study aimed to determine the calcium-phosphate metabolism profile and bone mineral density (BMD) in patients with newly diagnosed HT.
Methods
A cross-sectional study was performed at the endocrinology department of Charles Nicolle Hospital in Tunis, Tunisia including newly diagnosed patients with HT from Juin to December 2023. We didn't include pregnant, breast-feeding or menopausal women, subjects with co-morbidities (hyper or hypoparathyroidism, inflammatory bowel disease, malabsorptive disorder, renal disease, chronic liver disease, Cushing's disease, hypogonadism) or having history of drug use (steroid, bisphosphonates, calcium or vitamin D). Biochimical markers of calcium-phosphate metabolism involving: corrected calcium, phosphate, parathyroid hormone (PTH) and 25-hydroxyvitamin D (25(OH)D) were assessed. BMD measurements were performed at the lumbar spine and the femoral neck.
Results
The study included 43 newly diagnosed hyperthyroid patients. The majority were female, comprising 31 individuals (72.1%). Mean age of participants was 39.1 ± 10.3 years. Graves' disease was the most frequent etiology (90%) followed by toxic multinodular goiter. Mean levels of free thyroxine (FT4) and thyrotropin (TSH) were respectively 3.2 ± 1.8 ng/dl [NR: 0,7–1,8 ng/dl] and 0,03 ± 0,01 mUI/l [NR: 0,4 – 4 mUI/l]. Hypercalcemia (corrected calcium >2.5 mmol/l) and hyperphosphatemia (phosphate >1.45 mmol/l) were observed in 23.3% and 18.6% of patients, respectively. The majority of patients (60%) had a PTH level below 40 pg/ml, within the lower half of the normal range [NR: 15–60 pg/ml]. Twenty-nine patients (76.4%) had vitamin D insufficiency (25(OH)D <20ng/dl). Osteoporosis (T-score ≤ -2.5) and osteopenia (T-score between -2.5 and -1.0) were found in 14.7% and 26.5% of patients, respectively. The comparison between patients with and without osteoporosis showed significantly higher FT4 levels in patients with osteoporosis (P = 0.01). Receiver operating characteristic (ROC) analysis identified a significant FT4 cut-off value for predicting osteoporosis. The ROC-determined cut-off was 4,7 ng/dl (2.6 times the upper limit of normal) with a sensitivity of 60 % and a specificity of 93 % for predicting osteoporosis. Calcium, phosphate, PTH and 25 (OH)D were similar in the two groups of patients (P>0.05).
Conclusion
Our study showed that accelerated bone turn over occurs early in HT, causing an imbalance in calcium-phosphate metabolism. Reduced BMD correlates with disease severity. Osteoporosis should be assessed when FT4 levels exceed 2.6 times the upper limit of normal in newly diagnosed HT.

JOINT2031

Parathyroid cysts: about 10 cases

Rachida Bouattay[1], Linda Misbah[1], Sabrina Farhani[1], Khaled Harrathi[1] & Jamel Koubaa[1]
[1]ENT and Head and Neck Department, University Hospital of Fattouma Bourguiba, Monastir, Tunisia

Introduction
Parathyroid cysts are a rare clinical and histological entity; they represent 0.5% of parathyroid pathology and 1% of cervical cystic masses. They are rarely revealed by a palpable cervical swelling and are often an operative discovery. They can be non-functional or responsible for hyperparathyroidism. The aim of this work is to specify the clinical, paraclinical and therapeutic profile of these cysts
Material and methods
Our work is a retrospective study of 10 cases of parathyroid cyst discovered peroperatively collected in the ENT and CCF department.
Results
Our series has collected 10 cases of parathyroid cyst. There were 10 women, with an average age of 50 years. The reason for consultation was paramedian cervical swelling in all cases. The cervical ultrasound performed in all cases was in favor of a thyroid nodule in most cases. The biological assessment was normal. Fine needle aspiration cytology was not performed given the significant size of the swellings (> 3 cm) leading to the indication of surgery. The diagnosis was made intraoperatively. The anatomopathological examination confirmed the diagnosis of parathyroid cyst.
Conclusion
Parathyroid cyst is rarely considered in the presence of cervical swelling. They are generally discovered intraoperatively, however the diagnosis can be made by measuring parathyroid hormone in the puncture fluid. The treatment is surgical. Monitoring of calcemia postoperatively is necessary.

JOINT1101

A complex case of developmental anomalies, endocrinopathies, and neurological symptoms: albright hereditary osteodystrophy (AHO)

Hasmik Khachatryan[1,2], Dalar Tumasyan[3] & Renata Markosyan[2,3]
[1]Muratsan University Hospital Complex, Endocrinology Department, Yerevan, Armenia; [2]Yerevan State Medical University, Endocrinology Department, Yerevan, Armenia; [3]Wigmore Women's & Children's Hospital, Endocrinology Department, Yerevan, Armenia

Background
Albright hereditary osteodystrophy (AHO) is a rare genetic disorder caused by mutations in the stimulatory GTP-binding protein, Gαs, in the GNAS gene. It exists both with and without multihormone resistance-termed pseudohypoparathyroidism type 1A(PHP1A) and pseudo-pseudohypoparathyroidism(pseudo-PHP). AHO is characterized by obesity, short metacarpals, subcutaneous ossifications, round facies, varying degrees of cognitive impairments, and typically short adult stature.
Case Presentation
A 13-year-old female with the following complaints: retardation of psychomotor development, short stature, disturbance of gait, and pain in the joints admitted to the endocrinological department. She is the 2nd child of the family, was born at 38 months gestational age and antenatally was found to have deformity of the skull. In the 7th month, she was diagnosed with "Congenital hypothyroidism" with hypocalcemia and was prescribed Levothyroxine, which she takes up to this day. On physical examination: Height-114cm, weight-58kg, BMI-44.6kg/m2, height SDS- - 7.05. The patient presents with developmental anomalies, including short stature and macrocephaly, with moon-shaped facies and a flat nasal bridge. The proximal segments of the upper limbs are shortened, accompanied by brachydactyly and positive metacarpal sign. The left lower extremity is shorter than the contralateral limb and there is evident hemihypertrophy and subcutaneous thickening is palpable in the area of the tarsal joint. The lower extremities are deformed, contributing to gait disturbances. The skin examination reveals numerous hyperpigmented macules distributed over the face and body, resembling dark moles. Since the age of 3, she has had focal seizures, 1-2 times a year, and is under the supervision of a neurologist, Carbamazepine was prescribed, which later was switched to Letiram. For hypocalcemia, she takes oral calcium daily, now 3000 mg. She also takes Calcitriol 2 tablets daily (since 10 years of age), and Vitamin D3 5000 IU daily. As the patient's complex presentation including phenotypic overlap, hormonal and metabolic abnormalities, multisystem involvement, and seizures requires multidisciplinary involvement, in 2022, a medical genetic consultation was performed followed by whole genome sequencing, which confirmed GNAS gene mutation likely PHP or pseudo-PHP.
Conclusions
This case highlights the diagnostic complexity of a patient with a rare genetic disorder, multiple developmental anomalies, endocrinopathies, and neurological symptoms. The overlapping phenotypic features and systemic involvement underscore the importance of a multidisciplinary approach to diagnosis and management.

Growth failure and chondrodysplasia following early hematopoietic stem cell transplantation for familial lymphohistiocytosis: a case report

Caroline Gernay[1], Marie-Christine Lebrethon[1], Julie Fudvoye[1] & Parent Anne-Simone[1]
[1]CHU Liège, Paediatric Endocrinology, Liège, Belgium

We report the case of a 3-year-old boy referred for short stature and growth failure, with a history of familial lymphohistiocytosis (FHL), for which he underwent allogenic hematopoietic stem cell transplantation (HSCT) at 3 months of age. The child was born at term with a birth weight of 4.010 kg and length of 51 cm. At 5 weeks, he was hospitalized for fever, leading to the diagnosis of FHL, confirmed by genetic analysis revealing a pathogenic variant in the PRF1 gene. Initial treatment with corticosteroids, cyclosporine, and alemtuzumab failed to induce remission, resulting in an HSCT. Following successful transplantation, growth was impaired. Family history revealed a target height of 176.5 cm (-0.58 SD), with both parents of Pakistani origin and first cousins, but no history of short stature or endocrine disorders. At the time of the HSCT, the height was 59 cm (-1.17 SD) and the weight was 6kg800 (0.7 SD). Clinical examination at 3 years 9 months revealed a height of 85.6 cm (-4.12 SD), weight of 14.8 kg (-0.86 SD), and a BMI of 20.2 kg/m^2 ($+2.91$ SD). He exhibited relative macrocephaly, rhizomelic shortening, but no other dysmorphic features. Growth velocity was measured at 4.3 cm/year. The differential diagnosis included growth hormone deficiency, skeletal dysplasia, and glucocorticoid-induced growth suppression. Hormonal evaluation showed IGF1 levels of 39 ng/ml, IGFBP3 at 1.8 mg/l, and normal thyroid function and cortisol levels. A normal glucagon test ruled out growth hormone deficiency. Radiographic imaging revealed dysplastic changes, including shortened humeral diaphyses, proximal epiphyseal dysplasia of the humerus, and iliac bone dysplasia. Despite a normal skeletal dysplasia panel, these findings were consistent with possible chondrodysplasia. At the follow-up visit at age 6 years 3 months, height was 96.5 cm (-4.52 SD), with a growth velocity of 3.3 cm/year. The diagnosis of probable chondrodysplasia and growth failure following early HSCT was made, based on the findings of Botto *et al.* (2020), who described a series of 7 children with similar growth failure and radiographic changes after HSCT for non-oncologic pediatric diseases, suggesting a new potential complication. This case highlights the importance of careful monitoring of growth and skeletal development in children undergoing HSCT for non-oncologic conditions, as they may be at risk for both endocrine and skeletal complications.

JOINT2223

Case report and follow-up of juvenile paget's disease caused by TNFRSF11B mutations in sibling pair

Wenjing Li[1] & Hanfei Guo[1]
[1]Beijing Children's Hospital, Capital Medical University, National Center for Children's Health, Beijing, China

Background
Juvenile Paget's Disease (JPD; OMIM 239000) is a rare autosomal recessive disorder characterized by accelerated bone remodeling and elevated serum alkaline phosphatase (ALP) levels. Mutations in TNFRSF11B, which encodes osteoprotegerin (OPG), have been implicated in JPD.
Methods
This report describes two siblings with compound homozygous loss-of-function mutations in TNFRSF11B, leading to OPG deficiency and consequent typical symptoms of JPD. Case 1 (male, 7 years 3 months) presented with severe bone deformities with multiple fractures and hearing impairment. He cannot walk

indecently without any help. Case 2 (female, 4 months) presented with minor bone deformities and initial hearing impairment. Whole exon gene examination confirmed the homozygous mutation of TNFRSF11B gene c.412C>T (p. R138X). Their parents were non-consanguious. Traditional calcium and vitamin D treatments have limited effects on JPD patients. After alendronate sodium was administered, the symptoms of the siblings were alleviated, they could stand and walk without any help, and the serum total alkaline phosphatase (ALP) level was significantly decreased.
Results
After bisphosphonate treatment, ALP levels decreased significantly and skeletal symptoms improved in both cases.
Conclusions
Early identification and treatment of JPD caused by TNFRSF11B gene mutation can significantly improve the quality of life of patients. Bisphosphonates are effective therapeutic agents, and early intervention can prevent severe bone deformities and functional impairment.
Keywords
Juvenile Paget's Disease; Alkaline Phosphatase; Bone Remodeling; Bisphosphonates; TNFRSF11B.

Evaluation of the Impact of Therapeutic Patient Education (TPE) on Quality of Life Compared to Standard Care and Injectable Parathyroid Hormone Treatment in Chronic Hypoparathyroidism

Manon Chiffoleau[1], Clémence Maillard[1], Delphine Bessonies[2], Nidercorn Christelle[2], Anouk Sorin[3], Samuel Frey[1] & Figueres Lucile[4]
[1]CHU de Nantes, Service de Chirurgie endocrinienne, CRMR Filière OSCAR, Nantes, France; [2]Association Hypoparathyroïdisme France, Annecy, France; [3]CHU de Nantes, Service de Néphrologie, CRMR Filière ORKID, Nantes, France; [4]CHU de Nantes, Université de Nantes, CR2TI ITUN, CRMR Filière OSCAR, Nephrology, Nantes, France

Background
This study assesses the impact of Therapeutic Patient Education (TPE) on quality of life in patients with chronic hypoparathyroidism.
Methods
We extracted Quality of Life results (assessed by SF36) on our cohort of patients with hypoparathyroidism (post-surgery or genetic), divided into three groups: (1) Standard Care (Control, $n = 10$), (2) included in our program of Therapeutic Patient Education (TPE, 6 online sessions co-animated with a patient expert and our referent center, $n = 28$), and (3) TPE + Teriparatide initiated before TPE (TPE + Teriparatide, $n = 11$). SF36 questionnaires were completed by the patients at Baseline (before TPE), 3 and 6 months later. Kruskal-Wallis tests were performed to assess group comparability at baseline and to analyze score evolution over time. A post-hoc Mann-Whitney test was applied to identify specific inter-group differences.
Results
Kruskal-Wallis tests indicated significant baseline differences in Physical Functioning ($P = 0.0058$), Role Physical ($P = 0.0013$), Role Emotional ($P = 0.0392$), Energy/Fatigue ($P = 0.0327$), and General Health Perception ($P = 0.0058$), indicating that groups were not comparable at baseline. At 3 months, no significant differences in score evolution were found among groups. At 6 months, Physical Functioning ($P = 0.0101$), Social Functioning ($P = 0.0023$), Pain ($P = 0.0043$), and General Health Perception ($P = 0.0039$) were significantly different between groups. The TPE and the TPE + Teriparatide groups showed significant improvement in Social Functioning compared to the Control group ($P = 0.0017$ and $P = 0.0077$, respectively). No significant difference was found between the TPE and TPE + Teriparatide groups. Regarding pain, both the TPE ($P = 0.0075$) and TPE + Teriparatide ($P = 0.0070$) groups showed significant improvement compared to the Control group.
Conclusions
SF-36 scores were significantly more impaired in the TPE and TPE + Teriparatide groups compared to the Control group, which is consistent with the fact that these treatments are preferentially targeted at more severe patients. Our findings suggest that TPE significantly improves social functioning and pain perception compared to standard care. The absence of a difference between TPE and TPE + Teriparatide indicates that TPE alone may provide substantial benefits. These results highlight the potential of TPE as a valuable intervention for enhancing the quality of life in patients with chronic hypoparathyroidism. The key role of patient support networks and the long-term effects of TPE should be further evaluated.

Osteopenic males PHPT patients: prevalence and clinical features

Elena Castellano[1], Anna Garelli[1], Andrea Craparo[1], Chiara Bona[1], Borretta Giorgio[1] & Anna Rosa Pia[1]
[1]Endocrinology, Diabetology and Metabolism, Santa Croce and Carle Hospital, Cuneo, Italy

PHPT is nowadays the third more common endocrine disease, with an estimated prevalence in the general population of 0.5%-1% that increase more than 2% with age in both sexes. PTX is the only definitive treatment for PHPT with very high cure rate and it is recommended for all PHPT patients with symptomatic disease and for asymptomatic patients meeting surgical criteria, updated over time in an inclusive way toward. To date osteoporosis is the surgical criteria more ofteen met while osteopenia is not taken into account as surgical indication. PTX improves bone mineral density and reduce bone remodeling biomarkers also in patients with milder PHPT forms, on the other hand whether PTX is linked to fracture risk reduction also in milder forms of PHPT is still debated. Recently, it has been reported that PTX was associated with a lower risk of fracture in older adults independently by frailty categories, presence of osteoporosis, and criteria for operative management suggested by guidelines. Our study aimed to evaluate the prevalence and clinical features of osteopenic males PHPT patients. From a consecutive series of 435 subjects with PHPT and densitometric data available on 3 sites (lumbar, femoral and radial) we selected 90 male subjects. In this subgroup, we focused on the 31 with osteopenia (34.4% of males). They were classified as symptomatic in 61.3% and asymptomatic in 38.7% of cases. Among the symptomatic, 94.7% have renal involvement. Among asymptomatics, the most frequently met criteria are age (100%) and 24-hour Urinary Calcium (80%). In conclusion, male PHPT subjects with osteopenia are almost 1/5 of PHPT patients with osteopenia and are symptomatic in the majority of cases, mostly due to renal involvement. Among asymptomatic subjects, 54.5% did not meet any criteria for surgery.

Prevention of rebound hypercalcemia in giant cell bone lesions treated with denosumab: a critical comparison of two different approaches

Alessandro Barbato[1,2], Nicolò Chiti[1], Matteo Cerutti[1,2], Renato Vaiasuso[1,2], Matteo Pontone[1,2], Giovanni Beltrami[3], Carmela Enrichiello[4], Ilaria Brizzi[5], Franco Ricci[1] & Stefano Stagi[1,2]
[1]Meyer Children's Hospital IRCCS, Auxo-endocrinology Unit, Florence, Italy; [2]University of Florence, Department of Health Sciences, Florence, Italy; [3]Meyer Children's Hospital IRCCS, Department of Orthopedic, Traumatology and Paediatric Orthopaedic Oncology, Florence, Italy; [4]Meyer Children's Hospital IRCCS, Nephrology and Dialysis Unit, Florence, Italy; [5]Meyer Children's Hospital IRCCS, Pediatric Unit, Florence, Italy

Background
Denosumab is a monoclonal anti-RANK-L receptor antibody used to treat a wide range of bone lesions, including fibrous dysplasia, osteogenesis imperfecta, aneurysmal bone cysts, giant cell granuloma (GCG) and giant cell tumor of bone (GCTB) in both adults and children. The use of denosumab in pediatric patients is associated with a high risk of rebound hypercalcemia upon discontinuation. This condition often requires hospitalization and, in some cases, bisphosphonates to normalize calcium levels. Based on the clinical course of two patients with GCG treated with denosumab, we propose a preventive approach to rebound hypercalcemia.
Case presentation
Patient 1 was a 7-year-10-month-old boy who presented with maxillary swelling. MRI revealed a left maxillary mass (50x50x57mm), and pathology confirmed the diagnosis of GCG. Neoadjuvant treatment with denosumab (120 mg) was initiated with loading doses at T0, followed by doses at T15 and T45. T8 was not performed due to phosphaturia. Loading doses were followed by monthly doses of 100 mg for 8 months. The dose was gradually reduced to 20 mg over 6 months and discontinued after a total of 16 months of treatment. Follow-up MRI showed size reduction of the lesion to 45x54x37mm. Despite the tapering, the patient developed severe rebound hypercalcemia 2 months after discontinuation (total serum calcium increased to 15.8 mg/dl), requiring hospitalization and treatment with intravenous hydration, furosemide, oral glucocorticoids and endovenous zoledronate (dose 0.05 mg/kg/dose). Patient 2 was a 16-year-2-month-old boy referred for a costal lesion, which was diagnosed as GCTB after biopsy. Denosumab treatment was started with a dose of 120 mg at T0, followed by 100 mg (due to hypophosphatemia) at T8 (T15 was not performed due to hypophosphatemia) and T45. Monthly doses were then

administered and reduced to 40 mg within 3 months. One month after suspension, the patient received 2 mg (dose 0.03 mg/kg/dose) of intravenous zoledronate. Follow-up CT scan showed a stable size of the lesion with increased calcification. Six months after discontinuation, the patient successfully underwent surgical removal of the lesion, and his serum calcium levels remained within the normal range.
Discussion
Prevention of rebound hypercalcemia after suspension of denosumab may be challenging and tapering alone may not suffice. We propose a stepwise approach to the adverse events associated with denosumab involving strict monitoring for hypocalcemia and hypophosphatemia (which should be promptly corrected), and the administration of zoledronate at least one month after suspension to prevent rebound hypercalcemia.

Bone-specific alkaline phosphatase as a complementary diagnostic marker for the assessment of children and adolescents with secondary osteoporosis

Eunha Bae[1], Soo Yeun Sim[1], Su Jin Park[1], Byung-Kyu Suh[1] & Moon Bae Ahn[1]
[1]The Catholic University of Korea, Pediatrics, Seoul, South Korea

Introduction
With increasing cases of osteoporosis in children and adolescents, the need for timely diagnosis, management, and follow-up has become important. In adults, the use of bone turnover markers (BTMs) to monitor anti-osteoporotic treatments has been studied and is being recommended. However, how BTMs can be used in children and adolescents with osteoporosis is not fully known, as well as its possible use as diagnostic criteria and/or as predictors of fracture risk. This study aimed to determine whether BTMs, particularly bone-specific alkaline phosphatase (BsALP) and C-telopeptide of collagen type 1 (CTx), accurately reflect bone mineral density (BMD).
Methods
In this retrospective study, 280 post puberty males, aged 12.5-18 years old, and females, aged 10.5-18 years old, who were previously diagnosed with hemato-oncologic, rheumatoid, gastrointestinal, and endocrinologic diseases at a single tertiary care center were reviewed. The association between the lumbar spine bone mineral density (LSBMD) Z-scores and BTMs, such as BsALP and CTx, were assessed.
Results
Of the 280 patients, 95 were male (33.9%), and the mean age was 15.4 ± 2.07 years. The mean LSBMD Z-score was -0.52 ± 1.23, with 61.4% being ≤ 0, 34.6% being $\leq$-1.0, 13.6% being $\leq$-2.0, and 3.2% being $\leq$-3.0. With multivariate regression analysis, LSBMD Z-scores and BsALP showed a negative correlation with $p < 0.007$, while CTx was not statistically significant. The logistic regression models showed that after adjusting for underlying diseases and sex, as BsALP increased, the probability of LSBMD Z-score being $\leq$-2 increased with an odd ratio of 1.043 ($p = 0.048$). When comparing BTMs with vertebral fracture while adjusting for underlying diseases and sex, as BsALP increased, the probability of vertebral fracture increased with an odd ratio of 1.035 ($p = 0.005$). When the same comparison was made with CTx, the odd ratios of LSBMD Z-score being $\leq$-2 and with the presence of vertebral fracture were 0.419 and 1.001, respectively ($p = 0.156$, 0.997), which were not statistically significant.
Conclusion
BTMs change during growth as a function of age and sex; thus, comparing BTMs directly with LSBMD without any adjustments will not give any correlation in children. This study suggest that BsALP can be used as a complementary tool to evaluate secondary osteoporosis in children and adolescents if adjustments for underlying disease and sex are made. However, further studies with a larger sample size are required to adjust for age, which will better reflect the characteristics of pediatric patients.

Novel allelic variants in Sanjad-Sakati and Kenny-Caffey syndromes identified by whole exome sequencing

Florencia Martinez-Mendoza[1], Ilan Remba-Shapiro[1], Amayrani Cano-Zaragoza[1], Jacobo Kerbel[1], Rebecca Kerbel[1], Alberto Moscona-Nissan[1], Sophia Mercado-Medrez[1], Itzel Ramírez-Ramos[1], Daniel Marrero-Rodríguez[1], Keiko Taniguchi-Ponciano[1] & Moisés Mercado[1]
[1]Unidad de Investigación Médica en Enfermedades Endocrinas, Hospital de Especialidades, Centro Médico Nacional Siglo XXI, Instituto Mexicano del Seguro Social, Mexico City, Mexico

Introduction
Hypoparathyroidism-retardation-dysmorphia syndrome (HRD), also known as Sanjad-Sakati syndrome (SSS), is an autosomal recessive disorder characterized by permanent parathyroid hormone (PTH) deficiency, hypocalcemia, hyperphosphatemia, facial dysmorphism, and occasionally, psychomotor retardation. A similar syndrome, with additional features such as osteosclerosis and recurrent infections, is the autosomal recessive Kenny-Caffey syndrome (KCS1). Both syndromes have been associated with abnormalities in the gene encoding tubulin folding cofactor E (TBCE, 1q42.3). Mutations in *FAM111A* (11q12.1), which encodes a serine protease FAM111A, have also been described in a clinical variant of Kenny-Caffey syndrome (KCS2). We here-in describe a male patient with HRD, presenting previously unreported molecular abnormalities in both, the *TBCE* and *FAM111A* genes.
Methods
Whole exome sequencing was performed on peripheral blood genomic DNA of a 15-year-old male who sought medical care because of severe hypocalcemia and hyperphosphatemia, as well as facial dysmorphism. Born to non-consanguineous parents of Syrian-Jewish origin, he was found to have micrognathia, low ear implantation and retention of primary teeth. On the physical exam he was found in frank tetany with positive Trousseau and Chvostek signs, as well as bilateral cataracts. He has adult-like axillary and pubic hair and external genitalia were fully developed. Neuropsychological testing was normal, without evidence of mental retardation. Relevant laboratory results included a serum Ca of 4 mg/dL, P 7 mg/dL, intact PTH undetectable, 25-hydroxi-vitamin D3 10 ng/mL and mild eosinophilia. Renal and hepatic function tests, as well as thyroid function tests were all within normal limits. The ECG showed prolonged QT interval. Head CT revealed multiple bilateral calcifications, particularly in basal ganglia, thalami and cerebellum. He started on large doses of calcium carbonate, calcitriol and teriparatide with important symptomatic improvement.
Results and conclusions
The patient showed a highly polymorphic exome but none of the known mutations in *TBCE* and *FAM111A* genes. However, he harbored several compound heterozygous variants that have not been previously described. An insertion, two deletions and 5 single nucleotide changes in the intronic region of *TBCE* were identified (235372627insAG, 235380162_183delTGTGTGTGTGTGTGTGTG, 235412798_803delATTATT, 235427244G>A, 235430867A>G, 235435658C>T, 235438643G>T, 235439089G>A). An apparently non-pathogenic, synonymous variant in *FAM111A* (c.A672G p.Ala224Ala) was also found. HRD syndrome represents an overlapping spectrum, as illustrated by our patient, who despite having an unequivocal clinical and biochemical phenotype, he lacked the *TBCE* and *FAM111A* mutations known to be associated with SSS and KCS. Further research is needed to ascertain if the polymorphic intronic variants found in our patient are of pathogenic relevance.

Iatrogenic hypoparathyroidism revealed by amicrobial pustulosis following total thyroidectomy; a case report

Ftouh Wiam[1], Smouni Meryem[1], Boucht Aouatif[1], Aziouez Fatim[1] & Benkacem Mariem[1]
[1]University Hospital Center Mohamed VI, Faculty of Medicine and Pharmacy of Tangier, Department of Endocrinology and Diabetology, Tangier, Morocco

Introduction
Iatrogenic hypoparathyroidism is a well-documented complication of total thyroidectomy, often manifesting as hypocalcemia-related neuromuscular symptoms. However, atypical dermatologic presentations, such as amicrobial pustulosis, remain poorly recognized. This case highlights the importance of suspecting hypoparathyroidism in patients presenting with unusual post-surgical dermatologic manifestations [1,2].
Case Presentation
A 52-year-old female underwent total thyroidectomy in November 2021 for a multinodular goiter. She had no immediate postoperative complications and was not placed on calcium or vitamin D supplementation. In August 2022, she developed widespread pustular skin lesions consistent with amicrobial pustulosis. During her

dermatologic evaluation, severe hypocalcemia (34 mg/l) was incidentally discovered, prompting an endocrine assessment that confirmed iatrogenic hypoparathyroidism. Treatment with intravenous calcium and vitamin D supplementation led to the resolution of both her cutaneous and biochemical abnormalities within one month. However, four months after discontinuation of vitamin D due to supply issues, she presented again with similar pustular lesions associated with severe hypocalcemia, reaffirming the link between her skin manifestations and calcium metabolism disorder.

Discussion and Conclusions

This case illustrates an unusual presentation of iatrogenic hypoparathyroidism, where amicrobial pustulosis was the initial and predominant manifestation. The pathophysiological link between hypocalcemia and pustular dermatoses remains unclear, but calcium plays a critical role in keratinocyte differentiation and immune response regulation. Hypocalcemia-induced alterations in epidermal homeostasis may predispose to inflammatory skin conditions, such as pustulosis [3,4]. A major challenge in this case was the delayed diagnosis of hypoparathyroidism, as the patient had no classic neuromuscular symptoms like tetany or paresthesia. Instead, the recurrent pustular lesions were the primary indicator of underlying metabolic imbalance. This underscores the need for clinicians to consider calcium and parathyroid hormone (PTH) levels in cases of unexplained pustular eruptions, particularly in post-thyroidectomy patients [5]. In conclusion, this case emphasizes the necessity of maintaining a high index of suspicion for hypoparathyroidism in post-thyroidectomy patients with atypical dermatologic presentations.

Hypoparathyroidism: clinical and genetic characteristics with long-term outcomes

Özge Köprülü[1], Durdugül Emecen[2], Murat Karataş[1], Ibrahim Mert Erbas[1], Özlem Nalbantoğlu[1], Filiz Hazan[3] & Behzat Ozkan[1]

[1]University of Health Sciences Turkey, Izmir Dr. Behcet Uz Pediatric Diseases and Surgery Training and Research Hospital, Department of Pediatric Endocrinology, Izmir, Türkiye; [2]Dr. Behçet Uz Children's Hospital, Izmir, Turkey, Department of Pediatric Genetics, Izmir, Türkiye; [3]Dr. Behçet Uz Children's Hospital, Izmir, Turkey, Department of Medical Genetics, Izmir, Türkiye

Introduction

Hypoparathyroidism is a rare endocrine disorder in children which is mainly characterized by insufficiency or inefficiency of parathyroid hormone (PTH) leading to hypocalcemia and hyperphosphatemia. Hypoparathyroidism most commonly results from anterior neck surgery in adults while the most common cause is genetic abnormalities in children. In order to improve the diagnosis and expand the knowledge of the disease, we analyzed relevant data of clinical diagnoses, laboratory findings, molecular determination and long-term follow-up in 24 children with hypoparathyroidism in our center.

Method

A total of 24 patients with hypoparathyroidism, monitored and treated at Department of Pediatric Endocrinology in the SBU Izmir Dr. Behçet Uz Children's Hospital between 2010 and 2024 years, were retrospectively analyzed for the clinical, laboratory and genetic data. Genetic results of the patients were obtained by Next Generation Sequencing (NGS) or Sanger sequencing methods.

Results

This retrospective study included 24 patients (9 females and 15 males) with hypoparathyroidism. The most common initial presentation was convulsions (33.3%) and muscle spasms in hands (20.8%). Three of the patients were asymptomatic and diagnosed with incidental hypocalcemia. Parents were consanguineous in seven (35%) cases. The mean age of presentation was 6.7±5.9 (1 months-17.3 years). Twenty-three of the patients were followed up with a diagnosis of primary hypoparathyroidism and one patient with a diagnosis of secondary hypoparathyroidism due to thalassemia. Of the patients diagnosed with primary hypoparathyroidism, 12 had syndromic and 11 had isolated hypoparathyroidism. The most common cause of syndromic hypoparathyroidism was Di George syndrome (n:5), followed by *GATA3* mutations (n:3); two cases were diagnosed as pseudohypoparathyroidism and one case was diagnosed as Kenny-Caffey syndrome due to a variant in the *FAM111A* gene. The mean duration of follow-up was 6.9 ± 5.0 years (1.01-17.83). Ten patients had reached their final height at the time of the study and, for whom, long-term outcome data were analyzed. Their mean final height SDS was −1.98 ± 0.46 (Median: −1.85; min: −5.71; max: 0.78). No complications were observed in any of the patients during long-term follow-up.

Conclusions

In this study, clinical and genetic features and long-term follow-up of our patients with hypoparathyroidism were presented. Also, we presented a rare case of Kenny-Caffey syndrome, which presented with hypoparathyroidism. Reporting detailed features of the cases with hypoparathyroidism will increase the knowledge and awareness about the disease.

Cinacalcet in primary hyperparathyroidism: QEHB audit

Ahmed Malik[1], Chona Feliciano[2], Sherwin Criseno[2,3,4], Zaki Hassan-Smith[2,3,4] & Neil Gittoes[2,3,4]

[1]University of Birmingham, Birmingham, United Kingdom; [2]University Hospitals Birmingham NHS Foundation Trust, Birmingham, United Kingdom; [3]Metabolism and Systems Science, University of Birmingham, Birmingham, United Kingdom; [4]Centre for Endocrinology, Diabetes and Metabolism, University of Birmingham, Birmingham, United Kingdom

Background

The first line treatment for primary hyperparathyroidism (pHPT) is parathyroidectomy, however, some patients are unfit for or do not accept surgery. In such cases, cinacalcet (a calcimimetic) can be initiated with the aim to normalise blood calcium levels and mitigate direct effects associated with hypercalcaemia. For patients who are not suitable for parathyroidectomy, the UK's national guidelines suggest use of cinacalcet if hypercalcaemia-related symptoms are present and serum aCa is 2.85-3.00mol/l or if aCa is > 3.00mmol/l, irrespective of symptoms.

Aims

To assess local practice against NICE guidance [NG132] for prescribing cinacalcet in patients with primary hyperparathyroidism. To evaluate treatment effect on adjusted calcium levels and investigate treatment duration required to achieve normocalcaemia, including any intolerances and reasons for discontinuing cinacalcet.

Method

A retrospective study of all patients initiated on cinacalcet from June 2011 to February 2024 at Queen Elizabeth Hospital, Birmingham. This includes collection of biochemical data, inpatient and outpatient records and prescribing data.

Results

Of the 61 patients started on cinacalcet, 40 were commenced following the release of the national guidance in May 2019. 37 of these 40 patients (92.5%) were prescribed cinacalcet according to the NICE guidance. Most outpatients had accompanying prescribing checklist forms (21/27) since local introduction. A significant reduction in serum aCa was seen in patients after cinacalcet treatment (mean 2.56, 95%CI 2.49-2.63 mmol/l) when compared to baseline figures (mean 3.06, 95%CI 3.00-3.11 mmol/l). Additionally, 45 patients (73.8%) achieved normocalcaemia after a median duration of 30 days and 120 days each for inpatients and outpatients respectively. 16/61 patients reported side effects, and of these, 3 patients stopped their medication (nausea, vomiting, worsened dyspepsia).

Conclusion

Local prescribing generally adhered to national NICE guidance. The specialist team initiation and input, as well as thorough prescribing checklists when starting the medication in outpatient endocrine clinics, greatly contributed to this. Although a small number of patients were started on cinacalcet outside the guidance, reasons for doing so included symptom control in those unfit for surgery, persistent hypercalcaemia following surgery and bridging therapy due to COVID-19 pandemic related delays for elective surgery. Despite being a long-term treatment, cinacalcet was generally well tolerated. The quantitative reduction seen in serum adjusted calcium correlates with existing literature and highlights the benefit of cinacalcet as the mainstay of medical management of hypercalcaemia of pHPT for those unable to have surgery.

JOINT2188

Intravenous Bisphosphonates for Severe Hypercalcemia in Primary Hyperparathyroidism: Do We Need to Draw an Analogy From Osteoporosis Experience?

Maria Varughese[1], Cosmina Schiteanu[1] & Lakshminarayanan Varadhan[1]
[1]University Hospitals of North Midlands NHS Trust, Royal Stoke University Hospital, Endocrinology and Diabetes, Stoke-on-Trent, United Kingdom

Introduction
Intravenous (IV) bisphosphonates can effectively lower calcium levels in primary hyperparathyroidism (PHPT). However, in recurrent severe hypercalcemia, it may be used more frequently than what is ideal. Atypical femur fractures and osteonecrosis of the jaw are reported to be rare side effects from prolonged bisphosphonate use in osteoporosis and the risk is higher with IV compared to oral preparations. Local hospital guidelines recommend IV pamidronate for PHPT patients with severe hypercalcemia. According to the British National Formulary, IV pamidronate can be given at 4-weekly intervals in osteolytic bone metastases, but no similar guidelines exist regarding the number and frequency of infusions for PHPT patients with hypercalcemia. The aim of this single-centre study was to establish the frequency of IV bisphosphonate therapy in these patients and consider subsequent plans for monitoring.
Methods
Patients who had ≥ 3 pamidronate infusions per year, over the last 3 years ($n = 19$) were reviewed. Concurrent use of cinacalcet and clinical outcomes were analysed. Total infusions per patient was divided by their respective follow-up time (in months, from first IV treatment until surgery or till date) and multiplied by 12 to provide a comparative measure of the equivalent annualised frequency.
Results
All 19 patients were given IV pamidronate for severe hypercalcemia. The dose varied from 30-90mg per infusion. 63.2% ($n = 12$) were on concurrent cinacalcet treatment; 7 patients were completely intolerant to cinacalcet. In 14/19 patients, IV pamidronate was used to manage hypercalcemia whilst waiting for surgery. The other 5 patients opted for a conservative approach for various reasons: lack of localisation and reluctance for open surgery ($n = 2$), failed surgery ($n = 2$) and frailty ($n = 1$). These 5 patients were on cinacalcet but intolerant to higher doses. The mean follow-up time was 13 months (range 4-36 months). Pamidronate use ranged from 3-28 infusions during this time. The average equivalent annualised frequency of infusions was 7/year (range 2-12/year) in this cohort.
Discussion
A small but significant number of PHPT patients needed frequent IV bisphosphonate therapy. Reasons include longer waiting time for surgery (majority of patients), severity of hypercalcemia and intolerance to cinacalcet. The chronic use of pamidronate may increase the risk of atypical side effects in PHPT management too, which is well recognised from osteoporosis experience but less routinely perceived in endocrine clinical practice. This risk should therefore be emphasised (e.g. information leaflets, nurse-led clinics) as part of the counselling process when consenting PHPT patients for longer-term IV bisphosphonate therapy.

Bone mineral density alterations in primary hyperparathyroidism: clinical and diagnostic implications

Ewa Zalewska[1,2], Łukasz Cieszyński[1,2], Monika Berendt-Obołończyk[1,2], Julia Tarnowska[1], Bartosz Żegleń[1] & Renata Świątkowska-Stodulska[1,2]
[1]University Clinical Centre, Gdańsk, Poland; [2]Medical University of Gdansk, Department of Endocrinology and Internal Medicine, Faculty of Medicine, Gdańsk, Poland

Background
Primary hyperparathyroidism (PHPT) is a common endocrine disorder characterized by excessive parathyroid hormone (PTH) secretion, disrupting calcium and phosphorus metabolism. Among its systemic effects, bone health is particularly affected due to reduced bone mineral density (BMD) and an increased risk of skeletal fragility and fractures.
Objectives
1) To compare BMD and fracture risk (using the FRAX calculator) between PHPT patients and controls. 2) To analyze T and Z scores at different skeletal sites: spine, proximal femur, and distal one-third of the radius.
Methods
The study included PHPT patients diagnosed at the University Clinical Center's Endocrinology and Internal Medicine Department (2014–2024) who underwent densitometry using a Hologic device. The control group consisted of patients from the same period who also underwent densitometry but were not diagnosed with PHPT. Exclusion criteria included chronic kidney disease, antiresorptive or glucocorticoid therapy, rheumatoid arthritis, congenital bone fragility, diabetes mellitus type 1, hypogonadism, premature ovarian failure, malabsorption syndrome, and chronic liver disease.
Results
Among 441 patients evaluated for hypercalcemia, 237 met the inclusion criteria: 191 with PHPT and 46 controls. The study and control groups were matched for age, gender, and BMI. No significant differences in BMD were found between the PHPT and control groups in women ($P = 0.13$) or men ($P = 0.26$). Similarly, major osteoporotic and hip fracture risks did not significantly differ ($P = 0.28$ and $P = 0.19$, respectively). Notably, in the PHPT group, T-scores differed significantly among the lumbar spine, femoral neck, and radius ($P < 0.01$), while Z-scores did not (radius vs. femur: $P = 0.665$; radius vs. lumbar: $P = 0.14$). In the control group, no significant differences were observed in either T-scores ($P = 0.556$) or Z-scores ($P = 0.384$).
Conclusions
Consistent with prior research, our findings confirm a preferential loss of cortical bone in PHPT patients. However, femoral neck BMD and fracture risk were not significantly higher compared to controls.

Perspectives of patients and families on X-linked hypophosphatemic rickets (XLH) and its impact on quality of life: a qualitative study

Frank Hernández García[1,2], Pablo Martino Redondo[3], Julián Rodríguez Suárez[1,2,3], Rocío Fuente Pérez[4], José López García[2,5] & Helena Gil Peña[2,3]
[1]Universidad de Oviedo, Medicine, Oviedo, Spain; [2]Instituto de Investigación Sanitaria del Principado de Asturias, Grupo de Investigación en Pediatría, Oviedo, Spain; [3]Hospital Universitario Central de Asturias, AGC Infancia y Adolescencia, Oviedo, Spain; [4]Universidad Europea de Madrid, Facultad de Enfermería y Ciencias de la Salud, Madrid, Spain; [5]Universidad de Oviedo, Morfología y Biología funcional, Oviedo, Spain

Background
X-linked hypophosphatemic rickets (XLH) is a rare genetic disorder causing chronic hypophosphatemia, impaired bone mineralization, and musculoskeletal complications. Despite advances in treatment, patients continue to experience a significant disease burden affecting their quality of life. This study explores the lived experiences of patients and caregivers to identify key challenges in disease management.
Methods
This qualitative study collected data through an open-ended survey distributed by the Spanish Association of Hereditary Rickets and Osteomalacia (AERyOH). A total of 11 responses (7 patients, 4 family members) were analyzed using MAXQDA software to identify key themes.
Results
Four major themes emerged. (1) Diagnostic delay: Many patients, especially adults, reported years of misdiagnosis, leading to delayed treatment and irreversible complications. (2) Treatment burden: The need for frequent phosphate and vitamin D intake, along with side effects, posed adherence challenges. (3) Physical limitations and chronic pain: Mobility issues and persistent pain significantly impact daily life. (4) Psychosocial impact: Participants experienced stigmatization, social isolation, and work-related challenges. Family members also reported emotional distress and caregiving burdens.
Conclusions
XLH affects not only physical health but also emotional and social well-being. Early diagnosis, optimized treatments, and psychosocial support are essential to improving patient outcomes. A multidisciplinary, patient-centered approach is needed to address these challenges and enhance the quality of life for individuals with XLH.

An exceptionally cause of fahr's syndrome: pseudohypoparathyroidism

Nada El Idrissi Dafali[1], Sana Rafi[1], Sara Ijdda[1], Ghizlane El Mghari[1] & Nawal El Ansari[1]
[1]Mohamed VI University Hospital Center VI, Department of Endocrinology, Marrakech, Morocco

Introduction
Fahr's syndrome is a rare anatomo-clinical entity, characterised by bilateral and symmetrical intracerebral calcifications in the basal ganglia, most often associated with disorders of phosphocalcium metabolism. Hypoparathyroidism is the most common anomaly. Pseudohypoparathyroidism is exceptionally reported as a cause of Fahr's syndrome.
Observation
Patient aged 28, followed in psychiatry for delusional psychotic disorders evolving for 3 years, under neuroleptic treatment, without clear improvement. Complicated 1 day after her admission to the medical intensive care unit by the onset of confusion-type consciousness disorders evolving in a febrile and atraumatic context, and by the appearance of tetany crises involving the 4 limbs, the nape of the neck and the chest wall giving rise to respiratory disorders. On admission, the clinical examination revealed a confused patient with a Glasgow score of 13/15, a blood pressure of 100/70 mmhg and a heart rate of 102 bpm. The patient was polypnoeic and had an oxygen saturation of 99% on 4 litres of oxygen therapy, with a temperature of 38.5 C. The patient had a stiff neck and a soft abdomen, and the rest of the clinical examination was unremarkable. A lumbar puncture was performed, which returned normal. Cerebral CT revealed bilateral and symmetrical calcifications involving the basal ganglia. Biological tests showed hypocalcaemia at 61.76 mg/l (N:84-102), hyperphosphaemia at 49 mg/l (N:27-45), and a normal serum parathyroid hormone level of 12.8 pg/ml (N:12-80). Given this picture, the diagnosis of pseudohypoparathyroidism was accepted. Treatment consisted of calcium and vitamin D replacement therapy. Progress was favourable.
Discussion
The clinical manifestations of Fahr's syndrome include primarily neuropsychiatric signs: behavioural disorders, confusional or delusional syndrome. Other neurological manifestations are possible but less common. Fahr's syndrome is most often associated with dysparathyroidism: hypoparathyroidism is the most common anomaly. The association of Fahr's syndrome with hyperparathyroidism or pseudohypoparathyroidism, as in our patient's case, has rarely been described; a review of the literature found less than a dozen cases. Other pathologies can cause intracerebral calcifications, such as endocrinopathies, systemic diseases and infections, but with different sites and appearances. The diagnostic test of choice is computer tomography. The prognosis for Fahr's syndrome is good, as the clinical and neuropsychological signs regress once the phosphocalcic disturbances have been corrected.
Conclusion
Although Fahr's syndrome is a rare entity, this clinical case shows the importance of brain imaging and phosphocalcium assessment in the investigation of neuropsychiatric disorders, with a view to initiating appropriate therapeutic measures.

Severe hypocalcemia and psoriasis: an intriging link

Mouna Elleuch[1], Oumeyma Trimeche[1], Khadija Sallemi[2], Rihab Khochtali[1], Khouloud Boujelben[1], Nadia Charfi[1], Faten Haj Kacem Akid[1], Mouna Mnif[1], Fatma Mnif[1], Abderrahmen Masmoudi[2], Mohamed Abid[1], Dhoha Ben Salah[1] & Nabila Rekik Majdoub[1]
[1]Hedi Chaker University Hospital, Endocrinology, Sfax, Tunisia; [2]Hedi Chaker Hospital, Dermatology, Sfax, Tunisia

Introduction
Down syndrome is a genetic disorder resulting from the presence of an extra copy of chromosome 21. The spectrum of this disorder is very broad, including endocrine and dermatological manifestations. Through this observation, we discuss an extremely rare cause of psoriasis: hypocalcemia. We demonstrate the improvement of skin lesions under prompt calcium treatment.
Observation
This is an 18-year-old patient who was hospitalized in the endocrinology department for the management of severe hypocalcemia at 0.9 mmol/l. The diagnosis of Down syndrome was made at birth due to typical dysmorphia. He has a history of seizures that have occurred for a year and have not been investigated. One month before his hospitalization, the appearance of well-defined, generalized erythemato-squamous plaques was noted, particularly on the scalp and extensor surfaces of the limbs, consistent with psoriasis. The patient was treated with topical corticosteroids without improvement, hence their discontinuation. An assessment revealed severe hypocalcemia at 0.9 mmol/l. The etiological investigation concluded to a vitamin D deficiency of less than 8 ng/ml and hypomagnesemia at 0.6 mmol/l. Vitamin and calcium supplementation, as well as magnesium, was initiated, leading to normalization of the phosphorocalcic balance and a spectacular improvement of the psoriatic lesions.
Discussion
Vitamin D deficiency is a known risk factor for psoriasis. Elsewhere, the association between hypocalcemia and psoriasis is not coincidental. Indeed, hypocalcemia can impair cell adhesion, thus favoring the onset of psoriasis. Moreover, psoriasis can cause extensive skin inflammation, resulting in extravasation of albumin and albumin-bound calcium into the interstitial space.

The potential (secondary) use of a calcilytic drug to prevent post-operative hypoparathyroidism

Christian Nanoff[1], Roland Hellinger[1] & Michael Hermann[2]
[1]Medizinische Universität Wien, Institute of Pharmacology, Vienna, Austria; [2]Klinik Landstraße des Wiener Gesundheitsverbunds, Department of Surgery, Vienna, Austria

Parathyroid gland insufficiency is a frequent complication following thyroid surgery (total/near-total thyroidectomy) and the leading cause of secondary hypoparathyroidism with its consequence, hypocalcaemia. Surgical precautions devised to protect parathyroid glands from traumatic injury have largely failed to eliminate the problem. We propose a mechanism behind postoperative hypoparathyroidism that may account for the high incidence rate and the transient course it takes in most of the instances. After its closure the surgical wound regularly fills with fluid bound to soak parathyroid gland parenchyma. Wound exudate differs from blood plasma by its low pH and because it is replete with products from ongoing enzymatic proteolysis. Hence contact with wound fluid may expose the calcium-sensing receptor on the parathyroid epithelial cells to potential activators such as protons, polyamines, amino acids and/or peptides. Wound fluid-mediated receptor activation would result in an inadvertent suppression of parathyroid hormone secretion. To explore this possibility, we assayed the levels of receptor-activating compounds in thyroid drainage fluid which comprises wound exudate. The human calcium-sensing receptor heterologously expressed in HEK293 cells was used as an experimental model to assay receptor activation, NPS-2143, a negative allosteric modulator to ascertain receptor specificity of the effects. In addition, we reviewed patient records collected during an uninterrupted case series of thyroidectomies, which was done to identify surgery-inherent variables that may impinge on the risk of hypoparathyroidism. The patient records showed that on day one after surgery the levels of both parathyroid hormone and serum calcium were lower than the respective preoperative values in 83 and 90% of the patients, respectively. Consistent with these rates we found that from a set of thyroid drainage fluid specimens the majority of the samples (some 80%) was capable of activating the calcium-sensing receptor. Receptor activation was attributable to a subfraction of drainage fluid with acidic pH and rich in hydrophilic amino acids. Probing the molecular mechanism, we observed that glutamate and aspartate at millimolar concentrations enhanced proton-dependent receptor activation (pH_{50} ~ 6.0) that was completely blocked by NPS-2143. The concentrations in drainage fluid of calcium ions and of spermine, the cognate agonists however were below the activation threshold. The data support the assumption that wound fluid can produce secretory insufficiency of the parathyroid glands. A clinical trial of a calcilytic drug to inhibit aberrant activation of the calcium-sensing receptor in thyroidectomy patients is called for to test the hypothesis and assess the option for a preventive treatment.

Genetic skeletal disorders: phenotypic-genotypic characteristics and rhgh therapy responses of a pediatric cohort from a single center in china

Yiyun Huang[1], Yan Peng[1], Chuan Li[1], Bobo Xie[1], Xianda Wei[1], Baoheng Gui[1], Juan Meng[1], Shaoke Chen[1] & Xin Fan[1]
[1]The Second Affiliated Hospital of Guangxi Medical University, Nanning, China

Objectives
The primary objectives of this study are to elucidate the genotype-phenotype correlations in individuals with Genetic Skeletal Disorders (GSD), evaluate the efficacy of recombinant human Growth Hormone (rhGH) therapy, and enhance clinical acumen among practitioners regarding GSD.

Methods
The retrospective analysis involved 80 pediatric GSD patients diagnosed from August 2019 to September 2024. Patients were diagnosed with GSD through whole-exome sequencing, and genetic variant information was systematically collected.
Results
The study included 80 GSD patients, diagnosed at a median age of 4.88 years, with a median height standard deviation score (HT-SDS) of -3.58. The most common clinical manifestations included skeletal deformities (87.5%), short stature (81.3%), and distinctive facial features (65.0%). Those with pathogenic genes linked to Fundamental Cellular Processes had more severe short stature and prenatal phenotypes. Thirty patients received rhGH treatment for a median of 2.25 years (0.33~8.92), showing HT-SDS increases of 0.66 ± 0.42 and 0.84 ± 0.52, after one and two years, respectively ($P < 0.001$). In contrast, eight untreated patients had an average HT-SDS decrease of -0.46 ± 0.55.
Conclusion
In this cohort, pediatric GSD patients predominantly presented with short stature, skeletal deformities, and distinctive facial features, indicating a genotype-phenotype correlation. Compared to untreated GSD patients, those receiving rhGH treatment demonstrated varying degrees of height improvement, however, the long-term efficacy of this treatment warrants further investigation.

Analysis of the therapeutic effect of burosumab in the treatment of 6 children with x-linked hypophosphatemia
Liya Wei[1]
[1]Beijing Children's Hospital, Capital Medical University, National Center for Children's Health, Beijing, China

Objectives
To evaluate the effectiveness and safety of treatment with burosumab in pediatric X-linked hypophosphatemia (XLH) patients.
Methods
In this retrospective case study, six pediatric XLH patients treated with burosumab admitted to Beijing Children's Hospital, Capital Medical University from July 2022 to December 2024 were selected as the study objects. We colleceted clinical characteristics, biochemical indicators, imaging data of patients, treatment and follow-up (follow-up every three months until December 2024), and analyzed the clinical outcomes and adverse drug reactions after treatment.
Results
Among the 6 patients, there were 3 males and 3 female, aged 1.58 - 11.67 years. 4 patients had previously received treatment with phosphate supplements and active vitamins, but their wadding gait and lower limb deformities did not improve significantly, neither did their imaging changes of active richets. The initial dose of burosumab in 6 patients was 0.68 - 1.03 mg/kg, administered subcutaneously every two weeks, with a treatment period of 0.75 - 2.25 years. After treatment, gait abnormalities were improved in all 6 children, and the Knee width was reduced from 3.6 $\pm$ 2.5cm to 1.3 $\pm$ 1.5cm. The fasting serum phosphorus and TmP/GFR of 6 patients before treatment were 0.87 ± 0.10 mmol/l and 0.81 ± 0.11 mmol/l, respectively. After 3months of treatment with burosumab, both the fasting serum phosphorus and TmP/GFR levels increased (serum phosphorus 1.07 ± 0.11 mmol/l, TmP/GFR 1.02 ± 0.10 mmol/l). During the treatment, only 1patient reached the normal values of fasting serum phosphorus, while 3 patients had normal TmP/GFR). At the last follow-up, the serum phosphorus and TmP/GFR were 1.00 $\pm$ 0.14mmol/l and 0.90 $\pm$ 0.11mmol/l, respectively. After treatment, the alkaline phosphatase levels of all patients gradually decreased, from 574.83 $\pm$ 96.12U/l to 364.33 $\pm$ 107.69U/l. At the last visit, 4 patients returned normal level of ALP. At the last follow-up, only one child had elevated parathyroid hormone levels. The severity score of rickets decreased from 1.38 $\pm$ 1.47 points to 1.33 $\pm$ 1.21 points. One patients showed nephrocalcinosis, while the other patients did not experience any adverse drug reactions such as nephrocalcinosis, local skin injection reaction, hyperphosphatemia, or vitamin D deficiency were observed.
Conclusion
Treatment with brosuzumab can improve clinical symptoms in children with XLH, and no adverse drug reactions have been observed.

utility of parathyroid index and calcium to phosphorous ratio in diagnosis of normocalcemic primary hyperparathyroidsm
C V Harinarayan[1,2], Shabnam Roohi[1] & Khushal Updenkumar[2]
[1]Sakra Word Hospitals, Bangalore, India; [2]Sakra World Hospital, Institute of Endocrinology, Bengaluru, India

Normocalcaemic primary hyperparathyroidism(NCPHPT) is diagnosed as elevated parathyroid hormone(PTH), normal albumin-corrected serum calcium(sCa) and ionized calcium(iCa) after excluding secondary causes of PTH elevation. Parathyroid index(PF index) and calcium to phosphorous ratio(C/P ratio) are useful tools to differentiate NCPHPT from other causes of PTH elevation. We studied 40 consecutive patients with primary hyperparathyroidism(PHPT). Biochemically, serum albumin(S.Alb-gm/dl; N 3.5-5), creatinine(S.Cr-mg/dl; N 0.61-1.2), alkaline phosphatase(SAP-IU/l; 32-126), sCa(mg/dl;N 8.5-10.5), iCa(mmol/l;N 1.12-1.32), phosphorous(S.Phos- mg/dl;N 2.5-4.6), PTH(pg/ml; N 12-88), and 25 Hydroxy vitamin D (25OHD-ng/dl;N > 30) were evaluated. C/P ratio (N < 2.11) and PF index (N < 25.8) were calculated from these parameters. Mean $\pm$ SD was used to depict variables normally distributed, and median with interquartile range(IQR) for variables that do not conform to normality. The male-to-female ratio is 1:2(55 $\pm$ 16 years of age). Results for the whole group were S. Alb 4.2(3.9-4.48); S.Cr 0.86(0.64-1.26); SAP 88.5(73.75-121.5); sCa10.82 $\pm$ 1.58; iCa 1.42 $\pm$ 0.22;S.Phos 3.14 $\pm$ 0.83; S.PTH 206(140-316); 25OHD 32(25.73-43); C/P ratio3.74 $\pm$ 1.3;PF index 54.7(34.54-108.4). The data were analyzed as the normocalcaemic group(-NsCa)(sCa < 10.5) ($n = 19$) and the Hypercalcaemic group (HsCa)(sCa > 10.5)($n = 21$). The results for NsCa were 4.44 $\pm$ 0.43; 0.73(0.64-1.19); 78(71-89); 9.61 $\pm$ 0.62; 1.32 $\pm$ 0.19; 3.48 $\pm$ 0.74; 201 $\pm$ 117; 35.5(30-45); 2.89 $\pm$ 0.68; 44.75(26-55.4), respectively. In HsCa group 4.1(3.45-4.25); 1.06 $\pm$ 0.56; 102(85-160); 11.4(10.85-12.64); 1.51 $\pm$ 0.21; 2.83 $\pm$ 0.81; 284(178.4-352); 32.81 $\pm$ 16.5; 4.51 $\pm$ 1.26; 101(53-154), respectively. The sCa, iCa; SAP, S.Phos, PTH, C/P ratio, and PF index significantly differed between the groups(Mann Whitney $P < 0.005$). The data were analyzed based on 25OHD-low Vit D < 30($n = 16$) and Vit D > 30($n = 24$) the values of sCa11.5 $\pm$ 1.67*Vs*10.33 $\pm$ 1.34($P = 0.007$);iCa1.5 $\pm$ 0.25*Vs*1.38(1.23-1.43)($P = 0.25$); S.Phos 2.67 $\pm$ 0.62*Vs*3.45 $\pm$ 0.82($P < 0.002$) PTH 293 $\pm$ 205*Vs*196(127-281)(P = NS); 25OHD 21 $\pm$ 8.4*Vs*41.35(33.63-54.1)($P = < 0.0001$); C/P ratio 4.55 $\pm$ 1.26*Vs*3.2 $\pm$ 1.04($P = 0.01$);PF ratio112.43 $\pm$ 88.83*Vs*50.77(27.42-56)($P = 0.012$)(Mann Whitney P). The data were analyzed based on normal sCa, iCa, and 25OHD (rubric criteria for NCPHPT;$n = 8$), and the results were 4.41 $\pm$ 0.47; 83(74-92); 1.13 $\pm$ 0.44; 9.23 $\pm$ 0.52; 1.19 $\pm$ 0.07; 3.7 $\pm$ 0.65; 36.8(34-65); 2.57 $\pm$ 0.54; 40.67 $\pm$ 16.55, respectively. The data were grouped as NCPHT; normal 25OHD, calcium but elevated ionic calcium($n = 7$) and classic PHPT($n = 7$). The sCa, iCa, SAP, CP ratio, and PF index were statistically significant in all three groups(Kruskal Wallis H $P < 0.001$). The highest values were obtained for PHPT, and the lowest for the NCPHT category. Bone mineral density of the lumbar spine, hip, and, non-dominant forearm, were in the osteoporosis range among all categories and were not significantly different. All patients had parathyroid adenoma, which was confirmed histologically after surgery. The weight of the adenoma ranged from 26 mg to 15 gms. The C/P ratio and PF index were above the normal and predicted the hyperparathyroidism status across the spectrum; whole group, normocalcaemic and hypercalcaemic groups and normal Vs low vitamin D

Effect of bisphosphonates on parathyroid adenoma in patients undergoing focused parathyroidectomy for primary hyperparathyroidism with hypercalcemic crisis
Sabaretnam Mayilvaganan[1], Spandana Jagannath[1], Sushil Gupta[1] & Vinita Agrawal[1]
[1]Sanjay Gandhi Postgraduate Institute of Medical Sciences, Lucknow, India

Introduction
Patients with large adenoma and hyperparathyroidism induced hypercalcemic crisis are managed with bisphosphonates and mostly operated in the same sitting. The use of bisphosphonates provides the knife happy endocrine surgeon valuable time for imaging and protects the patient from cardiac effects of hypercalcemia. The effect of bisphosphonates on parathyroid gland is not clearly understood. In this study, we describe the texture of parathyroid gland after giving zoledronic acid.
Methodology
Prospectively maintained surgical data (October 2022 – October 2023). All patients who underwent focused parathyroidectomy for PHPT in hypercalcemic

crisis who received bisphosphonates preoperatively were included in the study and compared with no Zoledronic acid group. Patient demographics, Serum Calcium, PTH, Vitamin D, size and weight of the gland ex vivo and percentage fall in IOPTH value were noted. All patients received Zoledronic acid 4mg and the duration between administration of bisphosphonate and surgery recorded. Histopathology of all adenoma was reviewed by a single pathologist trained in Endocrine pathology. Data was statistically analysed using SPSS 15.
Results
Among 10 studied patients (mean age: 45.0 ± 15.02 years, M:F ratio 2:3), mean S.PTH was 75.60 ± 50.09 pmol/l, S.Calcium 14.28 ± 0.74 mg/dL, and ex vivo weight 5.14 ± 6.92 g. One patient had parathyroid carcinoma; most had parathyroid adenomas. Intraoperatively, adenomas showed reduced vascularity and increased peri-gland adhesions. HPE showed more fibrosis when compared to no zoledronic acid group
Conclusions
While the effect of bisphosphonates on spinal metastasis is documented, their mechanism in lowering hypercalcemia remains unproven. The observed reduced vascularity and increased adhesions suggest a potential direct impact on enlarged parathyroid glands. Notably, zoledronic acid rapidly lowered calcium levels within 48 hours, persisting over 2 weeks in some patients, with added cardioprotective benefits during anesthesia

Body fat mass influences hip geometry in adult male diabetic patients: A community-based study from North India

Archana K[1], Sushil Gupta[1] & Manisha Kakaji[1]
[1]Sanjay Gandhi Postgraduate Institute of Medical Sciences, Endocrinology, Lucknow, India

Introduction
Fat mass positively correlates with hip geometry and may influence fragility fractures. However, the impact in adult diabetic males is unexplored.
Objective
To evaluate the influence of body fat composition on hip geometry and predict fragility fracture.
Methods
83 urban-dwelling diabetic males, aged ≥60 years underwent dual-energy X-ray absorptiometry scan (DXA, HologicQDR-4500A/Bedford/MA). Hip structural analysis (HSA) at narrow neck (NN), inter-trochanteric region (IT), and femoral shaft (FS) sites were recorded. At these sites, cross-sectional area (CSA), cross-sectional moment of inertia (CSMI), section modulus (Z) and buckling ratio (BR) were analyzed. Also, fat composition at different sites from DXA were recorded. Pearson correlation coefficients (r) and reciprocator operating characteristic curves were calculated.
Results
Amongst the HSA variables, CSMI at NN showed significant positive correlation with total (r=0.52, $P = 0.005$), left (r=0.47, $P = 0.01$) and right (r=0.54, $P = 0.003$) arm, and trunk (0.53,$P = 0.004$) fat mass. CSMI at IT and FS also showed significant but weaker positive correlations with these fat variables. While CSA, Z and BR exhibited significant correlations with fewer fat sites, but were low. However, none of the fat mass sites predicted fracture on ROC curve analysis.
Conclusions
Fat mass positively influences hip geometry, particularly CSMI, primarily at femoral narrow neck followed by inter-trochanteric and femoral shaft sites in adult diabetic males. However, its limited predictive value for fragility fracture, suggesting additional factors like bone quality and metabolic changes may influence.

Familial hypocalciuric hypercalcemia due to a novel CASR mutation: diagnostic challenges and clinical implications

Sinéad Cadogan[1] & Brendan Kinsley[1]
[1]Mater Misericordiae University Hospital, Department of Diabetes and Endocrinology, Dublin, Ireland

Introduction
Familial hypocalciuric hypercalcemia (FHH) is a typically benign condition marked by elevated serum calcium levels alongside relatively low urinary calcium excretion. In most cases, FHH arises from loss-of-function mutations in the *CASR* gene, which encodes the calcium-sensing receptor (*CASR*), a G-protein coupled receptor predominantly expressed in the parathyroid glands and kidneys. The condition is often asymptomatic and generally does not require treatment. Identifying *CASR* mutations through genetic testing is crucial to distinguish FHH from primary hyperparathyroidism and prevent unnecessary parathyroidectomy.
Case Report
An 18-year-old male undergoing medical assessment as part of a job application was incidentally found to have elevated serum calcium. Repeat measurements of corrected calcium ranged from 2.9 to 3.0 mmol/l. He was asymptomatic with no evidence of end-organ damage. His medical history was unremarkable, and he took no regular medications. His family history was notable for his mother, who was diagnosed 15 years earlier with PTH-mediated hypercalcemia, presumed primary hyperparathyroidism. Her imaging was negative, and she had not required surgery or treatment. There was no family history of nephrolithiasis, pheochromocytoma, or pituitary disorders. Further biochemical evaluation showed a PTH level of 5.0 pmol/l (RR: 1.6–6.9) and a vitamin D level of 62 mmol/l. Urinary calcium excretion was low, with a calcium-to-creatinine clearance ratio of 0.012. A sestamibi scan suggested a possible right parathyroid adenoma; however, ultrasound did not confirm this finding. Genetic analysis identified a novel pathogenic *CASR* gene mutation, c.1793G>C (p.Cys598Ser) (chromosome 3: 122002594), confirming familial hypocalciuric hypercalcemia type 1 (FHH1). The patient was counselled on the benign nature and inheritance of FHH and and this confirmation allowed him to proceed with his intended career path without unnecessary medical restrictions. Given the family history of hypercalcemia, genetic testing of his mother is planned to determine if she carries the same mutation.
Discussion
This case expands the spectrum of pathogenic *CASR* mutations linked to FHH. The identified missense variant disrupts an intramolecular disulfide bond essential for receptor function. Although this specific mutation has not been reported before, similar mutations affecting this bond have been classified as pathogenic, supporting its pathogenicity. Distinguishing FHH from primary hyperparathyroidism can be challenging, especially when imaging suggests a parathyroid adenoma, increasing the risk of unnecessary surgery. In this case, genetic testing was crucial in confirming the diagnosis and avoiding unnecessary intervention.

Severe hypercalcemia with persistent nausea and vomiting in a child with new-onset graves' disease

Goo Lyeon Kim[1] & Jeesuk Yu[1]
[1]Dankook University Hospital, Pediatrics, Cheonan, South Korea

Introduction
Graves' disease (GD) is the leading cause of hyperthyroidism in children and the most common etiology of thyrotoxicosis. Clinical manifestations resulting from

excessive thyroid hormone production affect multiple systems. Among these, disturbances of mineral homeostasis, particularly calcium, phosphorus, and magnesium, are often overlooked. Increased osteoclast numbers and activity driven by excess thyroid hormones contribute to these changes. Hypercalcemia occurs in approximately 20% of patients with hyperthyroidism and is usually mild and asymptomatic. Severe hypercalcemia is rare but requires immediate intervention to prevent serious complications, including nephrocalcinosis, cardiac dysfunction, and skeletal abnormalities.
Case
An 8 years and 11 months old girl was admitted to our hospital due to persistent nausea and vomiting for the past month. Seven months prior to admission, she visited the hospital due to 2 episodes of unprovoked seizure and started to take the antiseizure medication. After 1 month of medication, she was hospitalized for drug reaction with eosinophilia and systemic symptoms (DRESS) syndrom and was treated with intravenous (IV) corticosteroids. During the tapering period of steroid treatment, she developed new-onset facial palsy that progressed to bilateral lower extremity weakness, leading to re-admission and a diagnosis of acute inflammatory demyelinating polyneuropathy (AIDP). During admission, she was treated with IV immunoglobulin (IVIG) and IV corticosteroids, which was gradually tapered over 2 weeks. One month prior to admission, after discontinuation of corticosteroids, nausea and vomiting occurred. Both symptoms temporarily improved after IV hydration, but recurred and persisted for more than a month. Thyroid function tests revealed elevated T3 and free T4 levels with suppressed TSH. Thyroid autoantibody testing, thyroid ultrasonography, and scintigraphy showed results consistent with GD. Complete blood count, serum electrolytes, and liver function test results were all within normal limits. However, abnormalities of mineral metabolism, including hypercalcemia, hypophosphatemia, hypomagnesemia, and decreased serum alkaline phosphatase levels, have been identified. Intravenous hydration with diuretics and steroid therapy, and antithyroid medications led to rapid improvement in clinical symptoms and normalization of mineral and thyroid hormone levels. During the 7-month follow-up period, the patient continued to take antithyroid medications and remained in good condition.
Conclusion
This is a case of severe hypercalcemia manifested in a new-onset pediatric GD. This case demonstrates that severe hypercalcemia, although rare, has clinical significance in pediatric GD and highlights the importance of performing thyroid function tests in addition to calcium monitoring in patients with persistent nausea and vomiting.

Pseudohypoparathyroidism type 1c - a rare cause of obesity in children- a case report

Karolina Stożek[1], Stanislaw Trzebuchowski[1], Jolanta Kowieska[1], Anna Jakubiuk- Tomaszuk[1] & Artur Bossowski[1]
[1]Medical University of Bialystok, Department of Pediatrics, Endocrinology, Diabetology, with Cardiology Divisions, Bialystok, Poland

Introduction
Pseudohypoparathyroidism (PTH) represents a group of diseases characterized by by tissue resistance to parathormone and other endocrine disorders like hypothyroidism. Albright osteodystrophy phenotype consists of a number of symptoms concerning the patient's skeletal system and may often coexist with PTH. Patients in the majority are obese and with developmental delay.
Aim
We present the case of familial Albright osteodystrophy
Material and method
A 3-year-old male was admitted to Endocrinologic Ward with suspected hyperparathyroidism. He was originally referred to the Metabolic Disease Outpatient Clinic for obesity, but tests performed there showed elevated parathormone levels. A baby born from a second pregnancy, by cesarean section, on time, with a birth weight of 2920g. At birth, there was a disproportion in the size of the head and chest, a smooth philtrum, and a thin upper lip. Diagnosis performed for TORCH infection was negative. The boy had currently the following health problems: hypothyroidism, delayed psychomotor development, hypertrophy of the pharyngeal tonsil, frequent respiratory infections. Excessive weight gain has been observed since birth. Prader-Willi syndrome was ruled out. The patient's mother was diagnosed with short stature (finall height: 145 cm) as a child. The boy's older brother suffers from hypothyroidism, autism and elevated parathormone levels as well. The mother and brother have a body disproportions.
Results
Anthropometric measurement revealed patient's weight: 23.9 kg (>97 pc) and height: 91.5 cm (25-50 pc). The physical examination showed features of obesity, a large head, prominent forehead, bowed lower limbs, brachydactyly and enlarged palatal tonsils. Laboratory tests revealed hypertriglyceridemia, elevated parathormone and phosphate levels, slightly reduced vitamin D3 levels, normal total and ionized calcium levels. Thyroid ultrasound did not visualize parathyroid glands. Whole exome sequencing (WES) was performed and analysis of the detected variants. A known pathogenic heterozygous c.1006C>T variant (p.Arg336Trp) in the GNAS gene was detected. The older brother underwent genetic analysis which confirmed the presence of the same mutation. We are awaiting the results of genetic testing of the patient's mother anf father.
Conclusion
Although PHP is a rare condition, it should be considered in the diagnosis of obesity with concomitant skeletal problems and calcium-phosphate disorders. We emphasise the meaning of genetic investigation in confirming the etiology of hyperparathyroidism.

Pseudohypoparathyroidism type 1B and thyroid hemiagenesis: a case report

Beatriz R Pereira[1], Joana Vinhais[1], David Veríssimo[1], Catarina Ivo[1], Ana Cláudia Martins[1], Dolores Passos[1], Luís Lopes[1], Mafalda Marcelino[1], João Jácome de Castro[1] & João Nunes e Silva[1]
[1]Endocrinology Department, Portuguese Armed Forces Hospital, Lisbon, Portugal

Introduction
Pseudohypoparathyroidism (PHP) refers to a heterogeneous group of rare disorders characterized by resistance to parathyroid hormone (PTH). PHP type 1A is associated with Albright's osteodystrophy and resistance to multiple hormones (including TSH). In contrast, PHP type 1B develops PTH resistance over time, exhibiting mild clinical manifestations and low-level resistance to other hormones. The estimated prevalence of PHP is approximately 1 in 100,000 individuals. Thyroid agenesis, although rare, has been described in association with phospho-calcium metabolism disorders. However, its exact prevalence in patients with PHP remains unclear.
Case Report
A 21-year-old female has been followed since the age of 5 for hypothyroidism with positive antibody levels (antithyroid peroxidase > 2000mUI/mL and antithyroglobulin > 266mUI/mL), currently treated with levothyroxine (175 micrograms daily). Notably, neck ultrasound revealed thyroid agenesis of the right lobe. Her family history included hypothyroidism spanning three generations, but no other endocrinological disorders. At the time of hypothyroidism diagnosis, she also presented with markedly elevated PTH levels (296pg/mL), low serum calcium levels, phosphate in the upper limit of normal range and mildly increased urinary calcium excretion. She exhibited no clinical features or symptoms related to bone metabolism. After excluding more common causes for phospho-calcium abnormalities, genetic testing for PHP was performed. Methylation pattern analysis revealed changes across all differentially methylated regions (DMRs), a gain of methylation in NESP55 and loss of methylation in GNAS-AS1, GNASXL, and GNASAB, consistent with the diagnosis of PHP 1B. Subsequently, she has been treated with oral calcium, calcitriol and cholecalciferol, leading to normalization of both serum and urinary calcium and phosphate levels.
Discussion
Although PHP 1A is known to present with TSH resistance, PHP 1B is generally associated with minimal TSH resistance, which does not typically account for thyroid agenesis. Additionally, only a few cases of PHP 1B associated with Hashimoto's thyroiditis have been reported in the literature. Given the high prevalence of Hashimoto's thyroiditis, it has been assumed that its coexistence with PHP 1B is incidental.
Conclusions
This case highlights an unusual presentation of PHP 1B with concurrent thyroid agenesis and Hashimoto's thyroiditis. While the link between PHP and thyroid agenesis remains unclear, this case suggests the need for further investigation into potential shared pathomechanisms. Genetic testing remains crucial for diagnosis and management in atypical cases.

A case of resistant hypocalemia and hungry bone syndrome after parathyroidectomy

Özlem Alkan[1], Berrin Cetinarslan[1], Zeynep Canturk[1], Alev Selek[1], Emre Gezer[1], Mehmet Sözen[1], Fatma Öktem[1], Saadet Acar[1] & Büşra Karaca[1]
[1]Kocaeli University, Endocrinology, Kocaeli, Türkiye

Introduction

Hypocalcemia is a common problem after parathyroidectomy. When high-turnover bone disease is suddenly corrected by the reduction in parathyroid hormone (PTH) after surgery, reduced bone resorption and increased bone formation can cause insistent hypocalcemia.

Case

A 49-year-old female patient was admitted to our clinic with weakness, fatigue, polydipsia, polyuria, and constipation. She lost 5 kilos in the last 6 months. Her tongue was dry. She had elevated creatinine, alkaline phosphatase (ALP), and calcium (Ca) levels, and her phosphorus (P) level was decreased. She had serious hypercalcemia (Ca: 16,18 mg/dL) electrocardiography (EKG) was performed. There was no arrhythmia, but short QT was present (QTc:330 msn). Oral and İntravenous (iv) hydration was given. PTH, and 24-hour urinary Ca were elevated too. And 25 hydroxy vitamin D and glomerular filtration rate (GFR) was decreased. She had 9 to 29 liters of urine, and she had nephrogenic diabetes insipidus due to hypercalcemia. A 30*20*35 mm parathyroid adenoma was seen at ultrasonography and Tc-99 MIBI parathyroid scintigraphy also confirmed the parathyroid pathology. Subperiosteal bone resorptions, the 'salt and pepper' appearance, and brown tumors were seen in X-rays. Zoledronic acid 4 mg was administered, and surgery was. Her PTH was 12,5 ng/l, Ca was 7,13 mg/dl, P was 1,82 mg/dl, and Mg was 1,51mg/dl. Both Trousseau's and Chvostek's signs were positive. Iv and oral Ca replacement were initiated active vitamin D (calcitriol) was started and 25-OH vitamin D that started before the operation was continued. After 7 days of operation, she had hip pain. Bilaterally femur fracture was detected at radiography. And she underwent surgery. After 15 days, despite of 10 g oral calcium carbonate per day and 1,5 mg of oral calcitriol per day, the iv-calcium requirement continued. Calcitriol gradually increased to 4 mg per day and iv-calcium requirement decreased. After 54 days she was discharged. 6 months after surgery, oral calcium and calcitriol were still required.

Conclusion

Although the lack of well-defined clinical criteria for the diagnosis of hungry bone syndrome makes it difficult to determine its true incidence. It is an acute clinical condition characterized by hypocalcemia, hypophosphatemia and hypomagnesemia. Ca drops to its lowest level in 36 hours after operation. It is temporary and although it usually improves within a few weeks it can continue longer. It is important to closely monitor these patients during replacement therapy to avoid iatrogenic hypercalcemia and related complications.

Fahr's syndrome with hypoparathyroidism: a case report

Andrew Gerges[1] & Andrei Oprescu[1]
[1]Doncaster Royal Infirmary, Diabetes and Endocrinology, Doncaster, United Kingdom

Introduction

Fahr's syndrome is a rare condition that was first described by German neurologist, Theodor Fahr, in 1930. It's characterized by the presence of symmetrical bilateral calcifications in the brain including the thalamus and the basal ganglia. Clinical features include neuropsychiatric symptoms like behavioural changes, cognitive impairment, seizures, extrapyramidal signs, etc. Fahr's syndrome is secondary to other conditions, most commonly hypoparathyroidism but it can also be associated with certain infections, neurodegenerative or mitochondrial disorders. Fahr's syndrome is not the same as Fahr's disease. The latter also causes intracranial calcifications but they are not associated with any abnormality in phosphate or calcium metabolism. We report a case of Fahr's syndrome and Hypoparathyroidism.

Case Report

This is a 57 years old gentleman who presented to the acute ambulatory unit reporting worsening headache, sleeping disturbances and non-specific tingling sensation in his arms. There was no weakness or visual field defects. He does not smoke or drink Alcohol. He reported his father had problems with his calcium that needed calcium supplements. His bloods showed significant hypocalcaemia with hypoparathyroidism. His adjusted calcium was 1.57 mmol/l, phosphate was 1.7 mmol/l, Parathyroid hormone was 0.3 pmol/l and his magnesium was 0.68 mmol/l. He was treated for his hypocalcaemia urgently. History included being involved in an explosion back in his home country where the bullet/Shrapnel scraped but did not penetrate his skull. CT head showed extensive bilateral symmetrical calcifications in the basal ganglia (caudate and lentiform nuclei), corona radiata pulvinar and dentate nuclei of the cerebellar hemispheres with no mass effect. These findings are consistent with Fahr's disease or Fahr's syndrome. Patient was started on Alfaclcidol 1 mg TDS and calcium 1 gm TDS aiming to prevent a calcium phosphate balance shift towards hyperphosphatemia which might trigger further calcifications. Patient's symptoms improved and has been stable on this dose of Calcium and Alfacalcidol. His bone profile is being checked every 2 months to ensure target levels achieved.

Conclusions

Fahr's syndrome is a rare but treatable condition that should be distinguished from Primary familial brain calcification (Fahr's disease) as the latter's etiology and management are unknown. Parathyroid abnormalities count are the most common causes of Fahr's syndrome, specially hypoparathyroidism. Management is with calcium and activated vitamin D which if given early, can prevent further calcifications.

Evaluation of cinacalcet prescribing and monitoring in primary hyperparathyroidism: a single-centre audit

Lakshmi Pichaipillai[1], Aya Eladl[1], Salman Khan[1] & Daniel Plowman[1]
[1]Fairfield General Hospital | Northern Care Alliance NHS Foundation Trust, Greater Manchester, United Kingdom

Primary hyperparathyroidism(PHPT) is a common endocrinological disorder causing hypercalcaemia, with potential complications affecting bones and kidneys. Diagnosis requires exclusion of secondary causes, and management typically involves parathyroidectomy. Cinacalcet is an alternative for a selected group of patients, necessitating careful patient selection and biochemical monitoring. This study evaluates the adequacy of PHPT diagnostic workup and the efficacy of Cinacalcet prescribing and monitoring in PHPT patients.

Methods

A retrospective audit was conducted in a single-centre endocrinology outpatient clinic, reviewing 42 patients with PHPT prescribed cinacalcet. Data on diagnostic work-up, cinacalcet initiation criteria, calcium monitoring, and treatment outcomes were analysed.

Results

While PHPT was confirmed in all patients ($n = 42$), diagnostic work-up revealed that urinary calcium assessment was performed in 61.9% of patients with clinical suspicion of familial hypocalciuric hypercalcaemia. Most patients ($n = 38$) had vitamin D measured as part of their assessment. Screening for end-organ damage using DEXA scan and ultrasound and/or CT KUB was performed in 93% of patients, with 40% showing evidence of complications. Regarding calcium levels, 47.6% of patients had serum calcium levels ≥ 2.85 mmol/l with symptoms, while 33.3% had levels > 3 mmol/l. A small proportion ($n = 8$) were started on cinacalcet for symptomatic PHPT despite having serum calcium < 2.85 mmol/l. Overall compliance with prescribing criteria was 66.7%. Importantly, none of the patients developed hypocalcaemia during treatment. At initiation, mean serum calcium was 2.93 mmol/l, decreasing to 2.69 mmol/l at one month following starting cinacalcet, with further reduction to 2.49 mmol/l in patients achieving normalisation. However, 23% had persistently elevated calcium despite treatment.A weak negative correlation was observed between cinacalcet starting dose and calcium levels at one month ($\rho = -0.30, P = 0.061$), and no significant correlation with final calcium normalisation ($\rho = 0.068, P = 0.58$). 35.7% of patients had serum calcium checked at one week after starting cinacalcet, while 61% had testing every 2-3 months. Overall compliance with BNF monitoring guidelines was 21.4%, with only 14.3% of patients meeting both prescribing and monitoring standards. No significant association was found between monitoring frequency and calcium normalisation ($P = 0.127$).

Conclusion

Our study shows that Cinacalcet effectively reduces serum calcium in PHPT. Monitoring of serum calcium during cinacalcet treatment could be more robust, to assess its efficacy and safety. The weak correlations between the starting dose of cinacalcet and serum calcium levels indicate that the current dosing strategy may

not fully account for the variability in response to treatment. Further research is needed to identify potential barriers to optimal prescribing and monitoring, and develop targeted interventions to improve adherence and patient safety. We would like to acknowledge Alexander Jones, Clinical Pharmacist, for their invaluable contribution to this audit by providing a list of patients who were dispensed Cinacalcet by the hospital pharmacy between 2017 and 2024, including the dates of dispensing, and quantities dispensed.

Experience of using cinacalcet for the treatment of secondary hyperparathyroidism in uzbekistan

Olimkhon Sharapov[1,2] & Sherzod Abdullaev[1,3]
[1]Tashkent Pediatric Medical Institute, Internal diseases, nephrology and hemodialysis, Tashkent, Uzbekistan; [2]Republican Specialized Scientific Practical Medical Center of Nephrology and Kidney transplantation, Adult and Pediatric Nephrology, Tashkent, Uzbekistan; [3]Republican Specialized Scientific Practical Medical Center of Nephrology and Kidney transplantation, Immunogenetics, Tashkent, Uzbekistan

Aims
We decided to study the effectiveness of cinacalcet in dialysis patients in the Uzbek population.
Method
We randomly selected 50 patients (28 men and 22 women) on dialysis in our center. We divided the patients into two groups: group A consisted of 30 patients who were prescribed cinacalcet at a dose of 30 mg/day in addition to the treatment, and group B consisted of 20 patients who served as a control group. The patients were examined for 3 months, the control points were the 30th and 90th days. Both groups were similar in calcium, vitamin D and PTH levels, and ultrasound parameters.
Results
The indices of MBD improved in group A in relation to group B. The calcium level in patients of group A before treatment was 2.48 ± 0.47 mmol/l and significantlydecreased after treatment, amounting to 2.17 ± 0.38 mmol/l ($P < 0.05$). In group B, it was 2.51 ± 0.56 mmol/l and 2.49 ± 0.97 mmol/l ($P > 0.05$), respectively. Blood phosphorus in group A, according to the results of 90 days, decreased from2.83 ± 0.86 mmol/l to 1.72 ± 0.76 mmol/l, and in group B from 2.81 ± 0.91 mmol/l to 2.73 ± 0.65 mmol/l. Before the study, the PTH level in group A was 1132.3 ± 182.7 pg/ml, in group B – 1083.9 ± 169.3 pg/ml. After 30 days of the study, in group PTH decreased by 18% and was 928.5 ± 98.7 pg/ml ($P < 0.05$), while in group B it changed insignificantly – 1053.7 ± 158.6 pg/ml ($P > 0.05$). On the 90th day of treatment, the PTH level in group A decreased by another 16%, amounting to 779.9 ± 83.7 pg/ml ($P < 0.05$), thereby decreasing by 31.1% ($P < 0.05$) from the initial level. And in group B it remained at approximately the same level, amounting to 1032.1 ± 143.8 pg/ml. Also, in group A, the symptoms of hyperparathyroidism symptoms such as pain in bones and joints, muscle weakness, fatigue, decreased tone decreased in patientsand the well-being of patients improved, which was not observed in patients in group B. No patient experienced any side effects or intolerance to the drug, and there were no cases of overdose.
Conclusion
A single-center trial of cinacalcet in dialysis patients was found to be quite effective. In patients who received cinacalcet at a dose of 30 mg/day in addition to their current treatment, PTH levels decreased by more than 30% compared to the control group without cinacalcet. Patients taking cinacalcet showed improvement in MBD (calcium, phosphorus) indices. The subjective state of dialysis patients also improved, which confirms the safety of the drug.

JOINT2201

Novel VDR gene mutation in a vitamin D-dependent rickets type 2A compound heterozygote:a case report

Shanghelin Yin[1] & Xingxing Zhang[1]
[1]The Second Xiangya Hospital, Central South University, Changsha, China

Background
Vitamin D-dependent rickets type 2A (VDDR2A) is a rare autosomal recessive disorder caused by mutations in the vitamin D receptor gene (*VDR*), which is marked by end-organ resistance to 1,25-dihydroxy vitamin D ($1,25(OH)_2D$). The phenotype varies depending on the *VDR*'s domain affected, and alopecia is typically included.
Objective
To investigate the genotype and its correlation with alopecia in a VDDR2A case.
Methods
A consanguineous family of Chinese Han origin with one proband of VDDR2A was recruited. The patient was evaluated clinically, biochemically and radiographically. Gene sequencing was performed to all family members.
Results
The 3-year-old proband showed early-onset *al*opecia, rickets, hypocalcemia, hypophosphatemia, secondary hyperparathyroidism, elevated alkaline phosphatase and low level of 25-hydroxy vitamin D (25(OH)D). He had compound heterozygous variants of *VDR*. c.376G>T(p.E126*) was a novel mutation, mainly affecting Ligand-binding domain. The other variant, c.122G>A(p.C41Y), which was restricted to DNA-binding domain, had been identified to cause alopecia in homozygotes. The proband presented mild alopecia compared with homozygotes of c.122G>A mutation.
Conclusion
We identified a novel *VDR* mutation in a compound heterozygote. Though alopecia is the typical clinical feature of VDDR2A, this phenotype could be variable depending on the synergy of alleles.
Keywords
Rickets, VDDR2A, VDR, Alopecia

Evaluation of the effect of hypercortisolemia treatment on bone metabolism and structure in patients with endogenous cushing's syndrome- a single center experience

Karolina Cylke-Falkowska[1], Maria Stelmachowska-Banas[2] & Wojciech Zgliczyński[2]
[1]Doctoral School of Translational Medicine, Centre of Postgraduate Medical Education, Warsaw, Poland; [2]Department of Endocrinology, Centre of Postgraduate Medical Education, Warsaw, Poland

Introduction
Cushing's syndrome is a very rare disorder characterised by a variety of clinical manifestations that result from cortisol excess, which can lead to multiple comorbidities such as diabetes mellitus, hypertension and bone disease. Prospective studies on large groups of patients with endogenous hypercortisolaemia assessing calcium-phosphate and bone metabolism over time are scarce.
The aim
Toevaluate the effect of hypercortisolaemia treatment on bone metabolism and structure in patients with endogenous Cushing's syndrome.
Patients and Methods
This is a controlled, prospective single-centre study involving a total of 30 consecutive patients diagnosed with endogenous Cushing's syndrome hospitalised at the Department of Endocrinology at Bielański Hospital in Warsaw. We evaluated patients' medical records, hormonal results (with special emphasis on calcium-phosphate and bone metabolism) at diagnosis and after implementation of surgical or pharmacological treatment. Bone turnover markers such as sclerostin, DKK-1, CTx, PINP will be assessed before and 3, 6, 12 months after achievement of normocortisolemia. A control group was matched based on sex, age and BMI, excluding hypercortisolemia.
Results
To date, we have enrolled 10 patients with endogenous Cushing's syndrome Male gender was predominant (M:F = 7:3). The mean age at diagnosis was 47.9 ± 16.6 years and ranged from 27 to 64 years. Nine out of 10 patients were diagnosed with ACTH-dependent hypercortisolemia (Cushing's disease). Average cortisol concentration at the diagnosis was 22.17 mg/dL. At follow-up at 3 months after achieving normocortisolemia, calcium-phosphate metabolism tests showed increase in total serum calcium (2.46.....2.53mmol/l), phosphorus (1.13....1.45mmol/l) and decrease in calciuria (4.78....3.64mmol/24h) and phosphaturia (23.18.... 16.95mmol/24h). There was a decrease in parathormone concentration (36,5…. 26,45pg/ml) and the active form of vitamin D [1,25(Oh2) D] (48,42……..35,92pg/ml). At baseline, mean bone mineral density was reduced L1-L4 T-score: -1.53 SD, femoral neck T-score: -1.28 SD, TBS T-score: -1.48

SD. The mean sclerostin concentration at the time of diagnosis of hypercortisolemia was 62,94 ng/ml, while Dkk-1 was 5078 ng/ml.
Conclusions
Our results confirmed that normocortisolemia improved calcium-phosphate metabolism. Further conclusions regarding changes in calcium-phosphate levels and bone turnover markers over time in normocortisolemic patients can be drawn when a larger study group has been enrolled.

JOINT2355

PTH-independent hypercalcemia in a young adult due to a compound heterozygous CYP24A1 mutation

Alina Sucaliuc[1] & Daniel Grigorie[1,2]
[1]National Institute of Endocrinology, Bucharest, Romania; [2]Carol Davila University of Medicine, Bucharest, Romania

CYP24A1, encoding the vitamin D-24-hydroxylase, regulates the catabolism of 1,25-(OH)2vitamin D. Inactivating biallelic mutations of the CYP24A1 gene are associated with elevated serum 1,25(OH)2vitamin D concentrations, hypercalcemia, hypercalciuria, nephrolithiasis and suppressed PTH concentrations. We describe the clinical and molecular basis of long-standing hypercalcemia and nephrocalcinosis in a young adult. The patient is a 19-year-old male presented for PTH-independent hypercalcemia (serum total calcium 11.6 mg/dl, serum PTH 2.6 pg/ml) and nephrocalcinosis. He had a history of recurrent episodes of vomiting and constipation in childhood, when he was supplemented with vitamin D. From the age of 13, annual blood tests have been performed, revealing mild hypercalcemia and 25OH vitamin D values between 39-56 ng/ml. Family history was relevant for high normal serum calcium (mother) and nephrolithiasis (grandmother). The patient's biochemistry in our clinic: serum calcium 11 mg/dl, urinary calcium 400 mg/24hrs, creatinine 1.22 mg/dl, PTH 2.4 pg/ml, 25OH-vitamin D 39 ng/ml, 1,25(OH)2vitamin D 66 pg/ml; serum phosphate 3.3 mg/dl, urinary phosphate 700 mg/24hrs, FGF23 224 pg/ml, normal PTHrP and ACE. Bone turnover markers were: cross laps 0.69 ng/ml, osteocalcin 50.4 ng/ml, P1NP 86.3ng/ml and he has a high bone mass (DXA): L1-L4 Z-score = 2.6 DS, femoral neck Z score = 3.8 DS, total hip Z-score = 4.2 DS. Analysis of whole exome sequence variants revealed that the patient is heterozygous for CYP24A1 c.1186C>T, p. (Arg396Trp) and c.428_430del, p(Glu143del), which are both pathogenic. With low-calcium diet, high water intake and limited sunlight exposure, after 3 months, the biochemistry improved: serum calcium 9.7 mg/dl, urinary calcium 360 mg/24hrs, creatinine 1.03 mg/dl, PTH 6.7 pg/ml, 25OHvitamin D 24 ng/ml, 1,25(OH)2vitamin D 62 pg/ml.
Conclusion
CYP24A1 mutations should be considered in the differential diagnosis of PTH-independent hypercalcemia in both children and adults.

An adolescent with spondyloepiphyseal dysplasia congenita and nephrocalcinosis: value of genetic testing in understanding complex clinical presentations

Chathupani Wettasinghe[1], Yasas Kolambage[2], Vijitha Veerasingam[1], Vajira Dissanayake[2] & Sumudu Seneviratne[2]
[1]Lady Ridgeway Hospital for Children, Colombo, Sri Lanka; [2]Faculty of Medicine, University of Colombo, Lady Ridgeway Hospital for Children, Paediatrics, Colombo, Sri Lanka

Introduction
Spondyloepiphyseal dysplasia congenita (SEDC) is a rare autosomal dominant skeletal dysplasia (incidence 1:100,000 live births), caused by mutations in the COL2A1 gene, leading to abnormal type II collagen. Reported clinical manifestations include disproportionate short stature, cleft palate, scoliosis, kyphosis, hip deformities, atlantoaxial instability, hearing loss and visual abnormalities. Hereditary hypophosphatemic rickets with hypercalciuria (HHRH) is a rare autosomal recessive disorder (1:250,000) caused by mutations in the SLC4A3 gene, associated with urinary phosphate wasting. While homozygous mutations cause rickets, heterozygous mutations typically cause hypercalciuria without bone disease and potential treatment options include oral phosphate/fluconazole. We report the co-occurrence of SEDC with a heterozygous HHRH mutation in a Sri Lankan adolescent, where extended genetic testing helped clarify the complex clinical picture and guide management.
Case Presentation
A 14-year and 9-month-old boy, the fourth child of healthy non-consanguineous parents, was admitted with exertional dyspnoea and orthopnoea for 3 months. He had multiple congenital anomalies, including cleft palate (surgically repaired), atrial septal defect (spontaneous closure), and congenital talipes equinovarus, with poor growth, kyphoscoliosis, coxa vara, and flat feet. He had normal intelligence. On examination, he had extreme short stature (height age: 6 years) with low BMI, muscle wasting, joint deformities, upper motor neuron signs in upper and lower limbs, and no abnormalities in cardiovascular and respiratory systems. There were no features of rickets. He was peripubertal (Tanner III). His skeletal survey was suggestive of skeletal dysplasia, while cervical spine MRI showed odontoid hypoplasia and atlantoaxial instability. Sleep study showed nocturnal hypoventilation and pulmonary function tests indicated reduced vital capacity. He also had bilateral nephrocalcinosis with hypercalciuria, with normal serum calcium, phosphate, alkaline phosphatase, 25-OH-D and PTH levels. Whole exome sequencing confirmed SEDC, caused by a likely pathogenic heterozygous COL2A1 variant; however, this did not explain nephrocalcinosis. Further analysis revealed another heterozygous likely pathogenic variant in the SLC34A3 gene, with elevated serum 1,25-dihydroxy vitamin D levels, consistent with a mild phenotype of HHRH. He underwent neurosurgical stabilisation, leading to significant improvement in respiratory and neurological complications, while phosphate supplementation was commenced to reduce the hypercalciuria associated with HHRH. Genetic counselling was provided.
Conclusion
This case highlights the value of genetic testing in managing patients with complex clinical features not attributable to a single disorder. While genetic testing is not easily accessible in low-middle-income countries, it can be of great value in diagnosing and managing patients with complex manifestations where diagnosis remains elusive.

The outcome of parathyroidectomy for secondary hyperparathyroidism in hemodilaysis patients

Oumaima Benkhalifa[1]
[1]Fattouma Bourguiba Hospital Monastir, ENT Department, Monastir, Tunisia

Objective
Secondary hyperparathyroidism (SHPT) is a complication of end stage renal disease. Parathyroidectomy is a surgical treatement option for hyperparathyroidism that is commonly performed. We aim in our study to evaluate the outcomes of PTX as a therapeutic strategy for SHPT in hemodilaysis patients.
Methods
We present a retrospective descriptive and monocentric study involving hemodiaysis patients with SHPT who underwent PTX in our ENT departement.
Results
We present 61 hemodialysis patients with dialysis duration ranging from 1 to 20 years who have SHPT. The mean age is 34 years, the sexe ratio is 1,54 and the most common cause of nephropathy is of indeterminate origin in about 50,81%. 52,46% presented with normocalcemia while 45,9% with hypercalcemia and 1,64% with hypocalcemia. The average level of PTH is 1808 pg/ml [334-3263]. the most frequent symptoms are bone pain in75,4%, pruritis in 32,7%, asthenia and weight loss in24,6%. 59 patients underwent cervical ultrasound that was normal in 52,42% while scintgraphy was performed in 60 patients that was pathologic in 98,33% with focal increased uptake in the 4 glands in 31,66%.87% of patients underwent a 7/8th PTX while 14,7% had a ¾ th PTX,1,63% a total PTX with autotransplantation and 1,63% total PTW without transplantation.85% experienced an hypocalcemia with an average of 1,76 on day 1 post operative and 86,66% presented a decrease of >80% of PTH level. the persistance of SHPT was observed in 8 patients and the recurrence in only 2 patients.
Conclusion
Parathyroidectomy is an effective surgical strategy for patients with SHPT that reduce PTH levels and improves the phosphocalcic metabolism, hence it it boost the quality of life and reduces the handicap index.

Pseudohypoparathyroidism revealed by bone pain: a case report

Zeineb Baraket[1], Sabrine Mekni[2], Sawsen Essayeh[2], Laamouri Rihaab[2], Nadia Mchirgui[2], Karima Khiari[2], Imen Rojbi[2] & Ibtissem Ben Nacef[2]
[1]Charles Nicolle Hospital, Tunis, Tunisia; [2]Charles Nicolle Hospital, Department of Endocrinology, Tunis, Tunisia

Introduction
Pseudohypoparathyroidism (PHP) is a rare endocrine disorder of genetic origin, which can be either sporadic or hereditary. It results from target tissue resistance to parathyroid hormone (PTH), leading to clinical and biological abnormalities. Several forms exist, varying according to resistance to other hormones and the presence of dysmorphic syndromes, with heterogeneous clinical expression, even among patients carrying the same mutation. We report the case of a patient in whom pseudohypoparathyroidism was revealed by bone pain.
Case Report
A 15-year-old patient, born to non-consanguineous parents and without notable family history, presented to our department with bone pain. Physical examination was unremarkable. Laboratory tests revealed hypocalcemia (1.5 nmol/l), hyperphosphatemia (2.26 nmol/l), and elevated PTH (455 pg/mL). Further investigations showed no hypomagnesemia, vitamin D deficiency, or renal insufficiency. A follow-up assessment was conducted and revealed no abnormalities. The patient exhibited no cardiovascular, including QT prolongation, and no neuromuscular signs of hypocalcemia, such as cramps, paresthesias, or tetany. Additionally, there were no morphological anomalies like brachydactyly, rounded face, obesity, or growth retardation. The stomatological examination was normal, and no resistance to other hormones, particularly TSH or gonadal hormones, was identified. The diagnosis of PHP was established. Genetic testing was not performed due to its unavailability. The patient was treated with oral calcium carbonate and an alpha-hydroxylated vitamin D derivative, leading to significant improvement in bone pain.
Discussion and conclusion
PHP is characterized by elevated PTH, hypocalcemia, and hyperphosphatemia, in the absence of vitamin D deficiency, hypomagnesemia, or renal insufficiency. Its different subtypes are defined based on clinical criteria (Albright hereditary osteodystrophy, Progressive osseous heteroplasia, Acrodysostosis) and biological features, notably resistance to TSH and other hormones. In our patient, the absence of short stature, Albright's dysplasia, ectopic ossifications, hypothyroidism, and hypogonadism suggests PHP type 1B. Genetic testing would be necessary to confirm the diagnosis.

A rare parathyroid lipoadenoma in a patient with sporadic multiglandular primary hyperparathyroidism – pitfalls in preoperative localization and pathological diagnosis

Katerina Zajickova[1,2], Zora Serkova[3], Jana Drozenova[4], Zdenek Novak[5] & Josef Vcelak[2,3]
[1]Institute of Endocrinology, Endocrinology, Prague, Czech Republic; [2]First Faculty of Medicine Charles University, Prague, Czech Republic; [3]Department of pathology and molecular medicine University hospital Motol, Prague, Czech Republic; [4]Department of pathology and molecular medicine University hospital Kralovske Vinohrady, Prague, Czech Republic; [5]Institute of Endocrinology, Prague, Czech Republic

Sporadic primary hyperparathyroidism (PHPT) is usually caused by a single-gland adenoma, which on histopathology has a marked cellularity with a reduced amount of stromal fat. A 72-year-old woman was referred for evaluation of PHPT. Laboratory tests showed hypercalcemia (2.69 mmol/l, normal range 2.20-2.55) and elevated parathyroid hormone (14.40 pmol/l, normal range 1.58-6.03). She had been treated with alendronate for osteoporosis of the distal third of the radius, fulfilling an indication for parathyroidectomy in asymptomatic PHPT. Ultrasonography showed a 0.2 ml oval hypoechoic nodule inferior to the right lobe of the thyroid, which was confirmed by MIBI scintigraphy. However, an enlarged parathyroid below the right thyroid lobe was not found during the parathyroidectomy. The surgeon therefore extended the operation to include a right exploration and found an enlarged parathyroid behind the middle part of the right thyroid lobe. Although the blood calcium level normalized on the first postoperative day, two weeks after surgery it was at the same level as before the parathyroidectomy, consistent with persistent PHPT. The right upper parathyroid gland was initially described as an enlarged but normal parathyroid gland (13x5x7mm). After the second reading it was corrected to a parathyroid lipoadenoma due to the abnormal size and clinical context of PHPT. The patient has stable mild hypercalcemia with isolated osteoporosis in the radius. Reoperation for persistent PHPT is under consideration, the conservative approach may also be acceptable. Parathyroid lipoadenoma is a rare histological finding in PHPT with a prevalence of 0.2-1.0%. The presence of stromal fat in lipoadenoma resembles a normal parathyroid gland, which may confuse not only the pathology but also parathyroid imaging. While typical parathyroid adenomas are hypoechoic on ultrasound, lipoadenomas are hyperechoic due to the fat-rich content, which may contribute to the failure of both preoperative ultrasonography and scintigraphy. Both methods correctly localized only one of two pathological parathyroid glands in the present case, highlighting the fact that multiglandular PHPT is often associated with equivocal parathyroid imaging and a high rate of surgical failure. Supported by MH CZ - DRO (Institute of Endocrinology - EÚ, 00023761)

A young case of hyperparathyroidism-jaw tumor syndrome carrying a large deletion of the CDC73 gene

Anna Dal Lago[1], Laura Pierotti[1], Simone Della Valentina[1], Chiara Sardella[1], Elena Pardi[1] & Filomena Cetani[1]
[1]University of Pisa, Department of Clinical and Experimental Medicine, Pisa, Italy

Hyperparathyroidism-Jaw Tumor Syndrome (HPT-JP) is a rare autosomal dominant syndrome with incomplete penetrance characterized by the combination of primary hyperparathyroidism (PHPT), renal lesions, jaw tumors and benign and malignant uterine lesions. Atypical parathyroid tumor and carcinoma are overrepresented in HPT-JT than in sporadic or other forms of familiar PHPT. The syndrome is caused by the germline mutation of *CDC73* encoding parafibromin. A 13-years old adolescent was referred to our outpatient clinic shortly after the surgical resection of the left inferior parathyroid gland which was diagnosed as atypical parathyroid tumor. The clinical history begun 2 months earlier with severe symptomatic PHPT (total serum calcium 16,6 mg/dl and PTH: 221 pg/mL). Neck ultrasound revealed a 1-cm lesion consistent with the left inferior parathyroid gland. This lesion was also detected by ^{18F}-Fluorocholina PET-CT but not by planar TC-sestamibi parathyroid scintigraphy. The family history was significant for PHPT affecting the patient's mother, three maternal first cousins and one maternal second cousin. Given the histology, the young age and the family history, genetic testing was performed, revealing a heterozygous germline deletion of all exons of the *CDC73* gene. This confirmed the diagnosis of HPT-JT. The patient's mother and one maternal first cousin carried the same deletion. Following this result, imaging of the jaw and kidney was performed, but no abnormalities were detected. After surgery, the patient developed hungry bone syndrome, which was managed with calcium carbonate and calcitriol. These treatments were gradually tapered over five months until they were discontinued. The patient has undergone regular biochemical and instrumental evaluation and remains in remission 16 months after surgery (total serum calcium level 10 mg/dl and PTH 17,20 ng/l). In conclusion, in young patient with PHPT, it is mandatory to thoroughly explore the family history and perform genetic testing to ensure an accurate diagnosis and to guide the appropriate follow up.

JOINT2708

Is burosumab a good choice?: experience in adult X-linked hypophosphatemic rickets in a turkish patient

Ezgi Yılmaz[1] & Mümtaz Takır[1]
[1]Prof. Dr.Süleyman Yalçın City Hospital, İstanbul, Türkiye

Background
X-linked recessive hypophosphatemic rickets (XLH), also known as the Dent Disease, is a rare bone diasease which estimated prevalence is about 1 in 20.000 live births. It causes skeletal deformities, pain, stiffness and fatigue and impairs

quality of life. Burosumab, a fully human IgG1 monoclonal antibody directed against the fibroblast growth factor 23 (FGF 23), is a promising new drug in the treatment of hypophosphatemic rickets.

Case Report

A 26-year-old female patient was referred to the orthopedic clinic when she was 1 year old and noticed curvature in her legs. The patient with genu varum and coxa varum was consulted to the endocrinology department upon detection of hypophosphatemia and high alkaline phosphatase levels (Calcium:9,4, phosphorus: 2,1, Alkaline Phosphatase: 2440). Hypophosphatemic rickets was considered in the patient. And the patient received treatment with oral phosphate supplements and active vitamin D during childhood. In genetic analysis, PHEX mutation c.1645+1 G>A heterozygote was detected. No similar disease or mutation was detcted in her 3 sisters. The patient developed urinary incontinence when she was 4 years old. Urinary ultrasonography revealed that the right kidney was 65*23 mm, the left kidney was 70*27 mm, and type 3 nephrocalcinosis was detected in both kidneys. The 24-hour urine calcium, citrate and oxalate values of the patient were normal. After the age of 18, follow up began in the adult endocrinology department and conventional therapy was continued. Subcutaneous Burosumab treatment every 2 weeks was started in the patient whose phosphorus and vitamin D levels continued to be low despite conventional therapy and who developed hyperparathyroidism. There were no side affects releated to Burosumab treatment. At the followup 3 monts after the treatmet the patient report improvements in pain, mobility, physical function, energy, fatigue and mental wellbeing also there is improvement in laboratory values (f.e phosphorus levels increased from 2.1 to 3)(shown in Table 1 and Table2).

Conclusion

In our case we reported that a positive laboratory and clinical response with Burosumab treatment in the diagnosis of X-linked hypophosphatemic rickets, and observed no side effects developed in the short term. The lack of a significant improvement in 25-OH vitamin D and ALP values may be due to the early period. However, since Burosumab treatment is a new and promising option, its effectiveness and safety are unknown. We emphasize that there is a need for studies with more case reports and a larger number of patients to monitor long term effects.

A curious case of trips and falls: pseudohypoparathyroidism

Connor S Brett[1], Matilda G W Brown[2], Ved Bhushan Arya[3], Meena Raj[1] & Ritika R Kapoor[3]

[1]Lewisham and Greenwich NHS Trust, Queen Elizabeth Hospital, London, United Kingdom; [2]Barts and The London School of Medicine and Dentistry, London, United Kingdom; [3]Faculty of Life Sciences and Medicine, King's College London, Variety Children's Hospital, King's College Hospital NHS Foundation Trust, Department of Paediatric Endocrinology, London, United Kingdom

We present a 7-year-old black African girl with no significant past medical history. The patient presented to the acute paediatric assessment unit following a fall whilst running for the bus. In the preceding week, she experienced multiple falls, several of which occurred where she had fallen from standing still without identifiable cause. The falls were preceded by a 2-month history of abnormal gait and arm positioning. No prodrome occurred prior to the falls, with no recollection of the fall itself. She was not post-ictal and become responsive immediately after. She denied any recent coryzal illness or fever. There was no birth, personal or family history of note. At initial assessment, her weight was 39.3kg (>99.6th centile), height 1.3m (>92.0nd centile) and BMI 23.18kg/m^2 (99.7th centile). She had a normal clinical examination, excluding difficulty performing heel-to-toe gait movements and left-sided dysdiadochokinesia. CT imaging of her head demonstrated symmetrical intra-axial calcifications predominantly involving subcortical white matter, basal ganglia and thalami. No evidence of intracranial haemorrhage or space-occupying lesions existed. Based on the distribution of calcifications, the imaging suggested a metabolic or genetic origin. X-ray of her hands showed normal contour and length of metacarpal bones. The appearance was within normal limits, with no bony exostosis or soft tissue calcifications. Laboratory investigations revealed significant hypocalcaemia, adjusted Ca^{2+} 1.43 mmol/l, high serum phosphate 3.25 nmol/l, low 25-hydroxy vitamin D 38 nmol/l and markedly elevated PTH 619 pmol/l. Further studies demonstrated a calcium:creatinine ratio of 0.04 and normal thyroid function. She responded to treatment with oral calcium, colecalciferol and alfacalcidol, with normalisation of bone biochemistry and resolution of gait/ coordination deficits. Methylation-specific MLPA demonstrated almost complete loss of the maternal methylation pattern at all four differentially methylated regions (DMRs) of the GNAS locus. No deletion was detected within GNAS or STX16. These findings confirmed a diagnosis of pseudohypoparathyroidism (PHP) type 1b. Pseudohypoparathyroidism is a rare heterogeneous group of disorders characterised by end-organ resistance to parathyroid hormone (PTH), in which other hormonal deficiencies, such as hypothyroidism and hypogonadism, may coexist. In PHP-1b, defective methylation leads to impaired Gsα expression, causing renal resistance to PTH. The basal ganglia are the most common sites of CNS calcification in PHP. This case highlights a rare but important cause of CNS calcifications. Early diagnosis and genetic confirmation are crucial for effective management, precise family counselling, and identifying at-risk relatives for early intervention.

Hypercalcaemia with unsuppressed parathyroid hormone level: a diagnostic dilemma; a case series

Tahir Omer[1,2] & Luqman BinchemohdFauzi[1]

[1]University hospitals of Northamptonshire, Northampton, United Kingdom; [2]university of South Wales, Cardiff, United Kingdom

Introduction

Hypercalcemia is a common disorder, with primary hyperparathyroidism (pHPT) and malignancy accounting for most of the cases. The parathyroid hormone level (PTH) is crucial in differentiating between the two conditions being raised in the former and suppressed in the latter. In a few instances, the picture can be clouded by additional factors that alter the hormonal level and can lead to misdiagnosis. **Case 1:**A 72-year-old male known dementia, diabetes and COPD presented with increasing confusion. Initial work up revealed corrected calcium 3.16nmol/l (2.20-2.60). PTH 3.2pmol/l (1.7-1.9). Vitamin D 21.3 nmol/l. The unsuppressed PTH raised the possibility of pHPT. It was, however, difficult to ascertain given that PTH is lower normal. Serum ACE and protein electrophoresis were unremarkable, eGFR> 90. The endocrinologist advised checking Magnesium which was low 0.4nmol/l (0.7-1.00). The patient received i.v fluids and Mg. A test following correction showed suppressed PTH of 1.5pmol/l with corrected calcium level 2.95nmol/l in keeping with hypercalcaemia of malignancy. A CT scan showed abdominal lymphadenopathy measuring 2cm. At the MDT, the impression was this is likely lymphoproliferative malignancy but given his co-morbidities, the plan was to manage palliatively. **Case 2:**A 56-year-old female patient with a recent history of subarachnoid haemorrhage due to ruptured aneurysm was undergoing rehabilitation under the care of the stroke team when she was noted to have raised corrected calcium 2.83nml/l(2.20-2.60). PTH 4.7pmol/l (1.7-1.9). Vitamin D 29.2nmol/l, eGFR>90. Similarly, it was not clear if this is pHPT given the unsuppressed PTH level. Magnesium level was subsequently checked and found to be low 0.35nmol/l (0.7-1.00). Correcting the magnesium revealed suppressed PTH 1.0pmol/l. A CT scan showed a mediastinal mass which is currently been evaluated by the chest physician for consideration of biopsy.

Discussion

Whilst hypercalcaemia with suppressed PTH typically raises concerns of malignancy, unsuppressed PTH in the context of hypercalcaemia usually indicates parathyroid pathology. This is commonly encountered in parathyroid adenomas/ hyperplasia but also in familial hypercalciuric hypercalcaemia and parathyroid malignancy. Nevertheless, many other factors could be contributing to the raised PTH level including magnesium or vitamin D deficiencies or chronic kidney disease. This could lead to confusion when trying to reach a diagnosis and formulate plans for further investigations. Our two cases are unusual as both demonstrate hypercalcaemia of malignancy in the presence of unsuppressed PTH due to unchecked hypomagnesaemia. It is of paramount importance to rule out these confounding factors prior to making a firm diagnosis.

The management of X-linked hypophosphatemia: oral phosphate and calcitriol supplementation vs. burosumab. a case report

Cristina Ilies[1], Monica-Simina Mihuta[2,3,4], Orsolya Olah[1], Ioana-Monica Mozos[5], Adela Chirita-Emandi[6,7,8] & Corina Paul[2]

[1]Department of Doctoral Studies, "Victor Babes" University of Medicine and Pharmacy, Timisoara, Romania; [2]Department of Pediatrics, "Victor Babes" University of Medicine and Pharmacy, Timisoara, Romania; [3]Center of Molecular Research in Nephrology and Vascular Disease, "Victor Babes" University of Medicine and Pharmacy, Timisoara, Romania; [4]Centrul Medical Dr. D, Timisoara, Romania; [5]Department III of Functional Sciences - Pathophysiology Discipline, "Victor Babes" University of Medicine and Pharmacy, Timisoara, Romania; [6]Department of Microscopic Morphology, Genetics Discipline, "Victor Babes" University of Medicine and Pharmacy, Timisoara, Romania; [7]Regional Center of Medical Genetics, "Louis Turcanu" Clinical Emergency Hospital for Children, Timisoara, Romania; [8]Center for Genomic Medicine, "Victor Babes" University of Medicine and Pharmacy, Timisoara, Romania

X-linked hypophosphatemia (XLH) is a rare genetic disorder caused by PHEX mutations, leading to excessive FGF23 activity, renal phosphate wasting, and chronic hypophosphatemia, resulting in rickets and skeletal deformities. Management has evolved from phosphate and calcitriol supplementation to burosumab, a targeted therapy blocking FGF23.
Case report
A 3 y 4 mo girl presents with mild facial dysmorphia (narrow forehead, low anterior hairline, bilateral epicanthus, short neck) and general rachitic signs (flaring thorax at the basis, rachitic rosary, thickened wrists and ankles, short stature and bilateral genu varum -intercondylar distance = 19 cm), with normal dental status. Blood tests showed normal serum Calcium, PTH, and 25-OH-Vitamin D, low serum phosphate and very high ALP. Normal renal and liver function. Lower limbs X-Ray show widened and cup-shaped with irregular margins distal femoral metaphysis. Delayed bone age: 2 y (-1.4 y delay). Thatcher score = 9. Normal 24-h urine analysis (particularly normal urinary phosphate and calcium) and normal TRP and TmP/GFR. The available Cento Metabolic panel excluded autosomal dominant and autosomal recessive hypophosphatemic rickets. Abdominal ultrasound, nephrology and neurology consult - normal. The suspicion of XLH was high, but genetic testing of the PHEX gene was lacking. We dosed FGF-23 (high) and 1,25-(OH)2-Vitamin D (low). We started conventional treatment, initially with Joulie solution (phosphate supplements are not available in Romania), 1 g of elemental phosphorus/day (divided in 5 doses) for a year, then managed to procure effervescent phosphate (2 × 500 mg/day, increasing adherence to therapy). Treatment also included Calcitriol (2 × 0.25 mg/day). Bilateral orthoses and physiotherapy were recommended. Over 2 years of conventional treatment, intercondylar distance worsened (19 cm to 20.5 cm). Phosphate levels were always low, ALP levels very high, Thatcher score still 9. At 5 yo, sequencing analysis discovered a nonsense variant in heterozygous status (NM_000444.5:c.264G > A) in the PHEX gene (Xp22.11), with a coverage of 339X at the variant site, confirming the XLH diagnosis. Burosumab treatment was initiated. Under the treatment, the intercondilar distance slowly decreased and the stature improved. Serum phosphate normalized and ALP levels decreased gradually. After 3.5 y of treatment with Burosumab (8 y 3 mo), the Thatcher score is 4.5, and intercondilar distance is 13 cm. No nephrocalcinosis and no other complications.
Conclusions
In severe XLH, conventional therapy often fails to correct hypophosphatemia and skeletal deformities. This case underscores Burosumab's superior efficacy, significantly improving phosphate homeostasis, bone health, and overall quality of life.

Family hypomagnesemia and hypercalciuric nephrocalcinosis: a case report and literature review

Chunyan Cai[1] & Ruimin Chen[1]
[1]Fuzhou First General Hospital Affiliated with Fujian Medical University, Fuzhou Children's Hospital of Fujian Medical University, Fuzhou, China

Objective
To report the clinical features and management of a child with familial hypomagnesemia and hypercalciuric nephrocalcinosis (FHHNC) in order to enhance awareness of this condition. Methods: The medical history, laboratory tests, and treatment process of one FHHNC patient were analyzed, and genetic testing was performed on the proband, parents, and elder brother. Results: An 11-year-old girl presented with "growth retardation, polydipsia, and polyuria for over seven years." Seven years prior, she gradually exhibited growth retardation accompanied by excessive drinking, consuming 3-4 liters of water daily, polyuria, and nocturia, with two episodes of febrile convulsions (details unknown). On examination, her height was 117cm (-4.72SD), weight 21kg, presenting with disproportionate short stature, breast Tanner stage B1, no abnormalities in the heart or lungs, and bilateral X-shaped legs. Her parents were healthy, non-consanguineous, and there were no similar diseases reported in the family. Laboratory tests revealed serum calcium 1.5mmol/l↓, serum phosphorus 0.95mmol/l↓, alkaline phosphatase 1151u/l↑, parathyroid hormone 418pg/ml↑, 25-hydroxyvitamin D 17.97ng/ml↓, 1.25-hydroxyvitamin D 58.8pg/ml, serum magnesium 1.11mmol/l↓, urinary calcium 8.5mmol/24h↑, urinary phosphorus 3.6mmol/24h, serum creatinine 69.2umol/l↑, urinary alpha-1 microglobulin 39.8mg/l↑, urinary beta-2 microglobulin 29.3mg/l↑, urinalysis showing leukocytes 2+, renal ultrasound indicating nephrocalcinosis, cranial CT scan showing bilateral basal ganglia high-density shadows, and X-rays showing slight expansion and roughness at the distal metaphysis of the radius and ulna. Genetic testing identified a splice site mutation c.427+5G>A (homozygous) in the CLDN16 gene [Chr3(GRCh37):g.190120233G>A], which her parents and brother carried as heterozygous carriers without phenotypic expression. The diagnosis for the patient was 1. FHHNC; 2. Urinary tract infection.
Conclusion
FHHNC is a rare autosomal recessive disorder characterized by excessive renal excretion of magnesium and calcium, bilateral nephrocalcinosis, and progressive chronic renal failure. The disease often presents with severe renal impairment before diagnosis, with symptomatic treatment being the main approach, including low-dose hydrochlorothiazide, potassium citrate, and calcium-magnesium tablets to significantly improve hypomagnesemia and hypercalciuria. The prognosis is poor, with approximately one-third of patients presenting with chronic kidney disease at diagnosis, requiring renal transplantation for end-stage renal failure. Genetic testing can confirm the diagnosis. Routine magnesium blood tests are recommended for children with short stature. Clinicians should consider FHHNC in patients presenting with short stature, polyuria, hypocalcemia, hypomagnesemia, and nephrocalcinosis. This case reports a novel CLDN16 gene mutation site in China.

Association between bone turnover markers, bone mineral density, and serum osteoglycin in middle-aged men with Type 2 Diabetes mellitus

Salma Mohamed[1], Ibrahim Elebrashy[1], Hemmat El Hadad[1], Olfat Shaker[1] & Ahmed Fayed[1]
[1]Kasr Alainy Teaching Hospital, Cairo University, Internal Medicine, Cairo, Egypt

Background
Patients with Type 2 diabetes mellitus (T2DM) have decreased bone health. We aimed to investigate serum levels of bone turnover markers (BTMs) (markers of bone formation and bone resorption) and bone mineral density (BMD) at three sites (lumbar, neck femur, and total femur) in middle-aged men with type 2 diabetes and to analyze the relationship between them. Also to evaluate serum osteoglycin as a novel marker and its relation to BTMs, BMD, and diabetic status.
Methods
We recruited seventy-eight patients with T2DM and thirteen non-diabetic, male volunteers as a control group. BMD was measured using a DEXA scan. BTMs (carboxy-terminal crosslinking telopeptide of type 1 collagen [CTX] and procollagen type 1 N propeptide [P1NP]), osteoglycin, PTH, and vitamin D were estimated. Data was compared among subjects and statistical analysis was performed.
Results
Most of the patients were having normal BMD with no significant difference between patients and the controls. BTMs and osteoglycin were significantly higher and vitamin D was significantly lower in the diabetic patients. Serum osteoglycin was positively correlated with DEXA Neck Femur ($r = 0.233$; p-value < 0.05).
Conclusion
Body mass index and Serum osteoglycin have a significant positive effect on BMD. Both markers of bone formation and bone resorption were increased indicating a state of increased bone turnover in T2DM.

Clot twist: deep vein thrombosis uncovers primary hyperparathyroidism

Nada Ait Kassi[1], Taleb Chaimae[2], Habbadi Zineb[1], Fatima Toulali[2], Ghizlane Sabbar[2], Kaoutar Rifai[2], Hinde Iraqi[2] & Mohamed El Hassan Gharbi[2]
[1]Ibn Sina Hospital Mohamed V University, Endocrinology, Rabat, Morocco; [2]Ibn Sina Hospital Mohamed V University, Endocrinology, Rabat, Morocco

Introduction
Primary hyperparathyroidism (PHPT) is an endocrine disorder characterized by hypercalcemia, leading to various systemic complications. Recent evidence suggests a potential link between hypercalcemia and an increased risk of venous thromboembolism (VTE), an association warranting further exploration.
Case Presentation
We report the case of a 47-year-old male with a history of recurrent nephrolithiasis treated by extracorporeal shock wave lithotripsy in 2019. He was admitted for a deep vein thrombosis (DVT) of the right lower limb and initiated on anticoagulation therapy. Workup revealed PHPT with serum calcium of 107 mg/l, phosphorus of 18 mg/l, parathyroid hormone (PTH) levels 5.5 times the normal limit, and elevated 24-hour urinary calcium excretion. Complications included bilateral hydronephrosis secondary to renal calculi, osteolytic lesions, and osteoporosis in the lumbar spine and right femur. Cardiovascular evaluation was unremarkable. Cervical ultrasound identified a 20×14 mm left inferior parathyroid nodule, confirmed on MIBI scintigraphy. A multiple endocrine neoplasia (MEN) workup was negative. The patient was referred for surgical management.
Discussion
Recent studies, including large-scale investigations, highlight PHPT as an independent risk factor for acute VTE. Elevated calcium levels in PHPT patients may activate the coagulation cascade, increasing the propensity for thrombosis. In our case, the temporal association between PHPT and DVT reinforces this link. Early identification and treatment of PHPT can mitigate thrombotic risk, emphasizing the importance of integrating calcium-related disorders into VTE risk stratification models.
Conclusion
This case illustrates the multifaceted complications of PHPT, including its potential role in venous thromboembolism. Surgical intervention remains the cornerstone for resolving PHPT and reducing systemic complications. Further studies are needed to establish standardized guidelines for managing thrombotic risks in PHPT patients.

Primary hyperparathyroidism and monoclonal gammopathy of undetermined significance: a misleading association? A case report

Amal Riad[1], Kaoutar Rifai[1], Iraqi Hinde[1] & Mohamed Elhassan Gharbi[1]
[1]Ibn Sina Institution, Rabat, Morocco

Introduction
Primary hyperparathyroidism (PPH) and monoclonal gammopathy (MGUS) are two causes of hypercalcaemia. The association of the two is rare. Nevertheless, it has been reported in the literature, although the link has not yet been identified.
Case report
This is a 57-year-old patient who had been treated in internal medicine for MGUS for 6 months and had moderate hypercalcaemia. She presented to the emergency department with asthenia and worsening of her hypercalcaemia. A work-up showed confirmed HPP with hypophosphataemia, hyperpathormonemia and high 24-hour calciuria. A cervical ultrasound identified a parathyroid adenoma confirmed by MIBI scintigraphy.
Discussion
The association of MGUS or Multiple Myeloma (MM) and HPP is rare and may lead to diagnostic uncertainty as to the contribution of each aetiology to hypercalcaemia. In our patient, MGUS was diagnosed 6 months before HPP. One study showed that the prevalence of MGUS was 10% in patients presenting with HP. A recently published series of 5 cases (2020) reports 4 cases were diagnosed simultaneously for MM and HPP. The main hypothesis cited in the literature for this association is the induction of myeloma by high levels of PTH, which induces antiapoptotic effects on plasma cells.
Conclusion
The coexistence of two aetiologies of hypercalcaemia, MGUS and HHP, should encourage simultaneous diagnosis.

Autoimmune polyglandular syndrome type 2: when calcium steps in

Nada Ait Kassi[1], Habbadi Zineb[1], Fatima Toulali[1], Ghizlane Sabbar[1], Kaoutar Rifai[1], Hinde Iraqi[1] & Mohamed El Hassan Gharbi[1]
[1]Ibn Sina Hospital Mohamed V University, Endocrinology, Rabat, Morocco

Introduction
Autoimmune polyglandular syndrome type 2 (APS-2) is a rare endocrine disorder characterized by the coexistence of multiple autoimmune conditions, including type 1 diabetes, autoimmune thyroid disease, and others. Primary hyperparathyroidism (PHPT) is rarely associated with APS-2. This report discusses a complex case of APS-2 presenting with PHPT, illustrating the diagnostic challenges and therapeutic considerations.
Case Presentation
A 44-year-old female with a history of APS-2, including type 1 diabetes (diagnosed at age 10), autoimmune hypothyroidism, and premature ovarian insufficiency, presented for evaluation of hypercalcemia. Laboratory investigations revealed serum calcium at 111 mg/l, phosphorus at 27 mg/l, elevated parathyroid hormone (PTH) levels (twice the upper limit), and 24-hour urinary calcium excretion of 433 mg with fractional excretion of calcium exceeding 2%. Secondary causes were excluded through normal vitamin D levels and a 70 mL/min glomerular filtration rate. Imaging identified a right inferior parathyroid adenoma. Further evaluations ruled out multiple endocrine neoplasia (MEN) syndromes. Bone densitometry demonstrated femoral and lumbar osteoporosis, but there was no renal or cardiac damage. The patient was referred for surgical management of PHPT.
Discussion
PHPT in APS-2 is an uncommon finding, often masked by overlapping autoimmune conditions. This case emphasizes the importance of considering hypercalcemia and evaluating PTH in APS-2 patients presenting with osteoporosis or other metabolic bone diseases. The literature highlights the role of autoimmunity in parathyroid dysfunction, including potential contributions of anti-calcium-sensing receptor autoantibodies. While rare, PHPT should prompt careful screening to avoid misdiagnosis or delayed treatment.
Conclusion
This case underscores the complexity of diagnosing and managing APS-2 with PHPT. Multidisciplinary approaches are crucial to address the interplay of autoimmune conditions, ensuring timely diagnosis and optimal outcomes. Further research is needed to explore the prevalence and pathophysiological mechanisms linking PHPT and APS-2.

Alfacalcidol shortage in morocco and its impact on patient care: a retrospective study

Nabil Skouta[1], Nassim Essabah Haraj[1], Siham El Aziz[1] & Asma Chadli[1]
[1]UHC Ibn Rochd, Department of Endocrinology, Diabetology, Metabolic Diseases and Nutrition, Casablanca, Morocco

Introduction
The year 2024 was marked by a significant shortage of Alfacalcidol in our country, leading to notable challenges in daily medical practice. Alfacalcidol, a crucial vitamin D analog, plays a vital role in managing calcium homeostasis particularly in patients with hypoparathyroidism. The unavailability of this essential medication has had direct consequences on patient care, particularly an observed increase in hospital admissions for hypocalcemia.

Objectives
To evaluate the impact of the Alfacalcidol shortage on our routine clinical practice by analyzing hospitalization rates, patient outcomes, and alternative treatment strategies.
Patients and Methods
This is a retrospective study including 34 patients hospitalized in the Endocrinology and Diabetology Department of Ibn Rochd University Hospital in Casablanca for acute hypocalcemia in 2024. Data were analyzed using IBM SPSS Statistics 27.0.
Results
In 2024, hospitalizations for acute hypocalcemia saw a significant rise, reaching a peak of 34 cases. The mean age was 50.88 years with a female predominance of 85.9%. The average duration of symptoms was 13 days. Patients experienced tetany episodes, with 23% showing QT interval prolongation on ECG. The mean corrected calcium level at admission was 61 mg/l. Etiologies included 88.2% post-surgical hypoparathyroidism, 11.8% autoimmune hypoparathyroidism. Before hospitalization, all patients were on replacement therapy (calcium and alfacalcidol was replaced with cholecalciferol). Patients received intravenous calcium infusion with a good clinical and biological response.
Conclusions
The 2024 Alfacalcidol shortage had a significant impact on clinical practice, leading to a sharp increase in hospitalizations for acute hypocalcemia. This highlights the crucial role of Alfacalcidol in preventing severe complications and underscores the need for better strategies to mitigate the effects of future drug shortages.

Secondary hyperparathyroidism in patients with chronic renal failure

Mahdi Ferjaoui[1], Mahdi Ferjaoui, Linda Misbah[1], Nawres Bouaziz[1], Rachida Bouatay[1], Amel EL Korbi[1], Naourez Kolsi[1], Khaled Harrathi[1] & Jamel Koubaa[1]
[1]ENT Department, Fattouma Bourguiba University Hospital, Monastir, Tunisia

Objectives
Identify the indications for parathyroidectomy (PTX) in secondary hyperparathyroidism (SHPT), report postoperative evolution, and describe early and late complications of PTX.
Materials and Methods
We carried out a retrospective study on patients with chronic renal failure who underwent parathyroidectomy (PTX) in our ENT department over a 13-year period, from January 2010 to December 2023. Clinical, biological, and radiological parameters were analyzed both preoperatively and postoperatively.
Results
Our study included a total of 70 patients with a mean age of 41 years. The median preoperative PTH and calcium levels were 1680 pg/mL [368,3742] and 2.2 mmol/l, respectively. The main clinical manifestation in our series was bone pain. In our study, 66 patients (94.28%) underwent cervical ultrasound, whereas parathyroid scintigraphy was performed in all cases. Cervicothoracic computed tomography was performed in only three patients (8.57%) to investigate ectopic parathyroid glands. No patient underwent magnetic resonance imaging (MRI). Surgical treatment consisted of subtotal parathyroidectomy in 66 patients, either 7/8th ($n = 56$) or 3/4th ($n = 10$). Three patients underwent total parathyroidectomy. The final histopathological examination revealed hyperplasia of the resected parathyroid glands in all patients. The cure rate was 78.57%. Persistent hyperparathyroidism was observed in 15 patients, including two cases associated with vitamin D deficiency. Three cases of recurrence were noted in our series.
Conclusion
Secondary hyperparathyroidism is a common and serious complication of chronic renal failure. Surgery is the treatment of choice when medical therapy fails.

Suspected growth hormone deficiency as a mask of hypophosphatasia in a male patient with verified compound heterozygous variant in ALPL gene

Zhanna Belaya[1,2], Anastasia Zhdanova[3], Natalia Kalinchenko[4], Liudmila Rozhinskaya[2], Elizaveta Drachuk[1], Ekaterina Pigarova[1] & Ekaterina Zakharova[5]
[1]Endocrinology Research Centre, Moscow, Russian Federation; [2]Endocrinology Research Center, Moscow, Russian Federation; [3]Endocrinology Reasearch Centre, Moscow, Russian Federation; [4]Endocrinology Reaserch Centre, Moscow, Russian Federation; [5]Medical Genetic Research Center named after. acad. N. P. Bochkova, Moscow, Russian Federation

Introduction
Hypophosphatasia (HPP) is a rare inherited disease caused by mutations in the *ALPL* gene which encodes tissue-nonspecific alkaline phosphatase (ALP). The clinical presentation of HPP varies from lethal neonatal forms, severe skeletal dysplasia to minimal symptoms in adults.
Clinical case
We present a clinical case of a family with HPP, who were diagnosed after evaluation of a 20-year-old male patient due to complaints of short-statue. His height was 155 cm (SDS: -2.96), weight 52kg, no visual bone deformities. Hypopituitarism or any other endocrine abnormalities were excluded. Repeated tests showed low alkaline phosphatase (ALP -13 IU/l; ALP – 18IU/l reference range (40-150 IU/l) and elevated phosphate 1.76 mmol/l (0.74 - 1.52) along with all other parameters including calcium and bone remodeling markers within the reference range. On genetic evaluation we found a compound heterozygote variant *ALPL* c.1068C>A (p.Asp356Glu), c.1349G>A, (p.(Arg450His). At the moment of evaluation, short statue was the only clinical presentation of HPP, therefore no treatment was prescribed. His mother, sister, father (height 176cm) and both grandmothers (height 148cm) had low alkaline phosphatase levels. The patient's mother (age 43, height 149 cm, weight 54 kg) complained of pain in the spine and knee joints. Upon evaluation nephrocalcinosis was revealed. Her ALP levels were -19-24 IU/l (40.0-150.0) but all the other tests were within the reference range. DXA showed normal BMD at femur neck -1,1 SD, L1-L4 -0,2 SD Z-score. Exome sequencing showed the heterozygous variant in *ALPL* c.1068C>A (p.Asp356Glu). The patient's sister age 14 (height 146cm (SDS: -2.2), weight 41 kg) was diagnosed with primary hypothyroidism at the age of 6, since then she has taken Levothyroxine. The level of ALP was repeatedly low 19-24 IU/l (40.0-150.0) along with elevated phosphate 1.94- 2.1 mmol/l (0.74 - 1.52), all the other tests were within the reference range. Genetic testing revealed *ALPL* heterozygous variant c.1349G>A, (p.Arg450His). All three evaluated family members had excellent physical performance based on 6-minute walking, 10 second chair rise and grip strength tests.
Conclusion
This clinical case emphasizes a compound heterozygous variant in the ALPL gene as a plausible cause of short-statue. It is not clear if treatment with asfotase alfa would have improved this patient's height if it were given at a younger age.

JOINT1039

Case of successful management of primary hyperparathyroidism and incidentally found micro PTC during pregnancy

Samira Khalilova[1], Hyma Rachabattula[1], Sudeendra Doddi[1], Hussam Wassati[1] & Lizemarie Wium[1]
[1]Princess Royal University Hospital, Farnborough, United Kingdom

Introduction
Primary hyperparathyroidism in pregnancy is rare, with a reported incidence of 1%. Hunter and Turnbull documented the first case of hyperparathyroidism in pregnancy in 1931. Maternal and fetal/neonatal complications are estimated to occur in 67 and 80% of untreated cases respectively. Maternal complications include nephrolithiasis, pancreatitis, hyperemesis gravidarum, pre-eclampsia and hypercalcemic crises. Fetal complications include intrauterine growth restriction; preterm delivery and a three to five-fold increased risk of miscarriage, while neonatal complications include hypocalcaemia. We present a case of hyperparathyroidism successfully treated by surgery during second trimester.
Clinical case
41 y.o woman, with background of hyperparathyroidism diagnosed by combination of high adj Ca - 2.90 mmol/l(2.2-2.6), high PTH 12.6pmol/l(1.6-6.9) along with normal Vitamin D and high urine calcium/-creatinine ratio 0.035. US parathyroid and spect –CT scan confirmed diagnosis of left lower parathyroid adenoma. She found to be pregnant while awaiting surgery. During pregnancy her calcium level reached up to 2.97 mmol/l with PTH 117 ng/dl (15-65), which lead to the decision to perform surgery in second trimester. Post op histology was consistent with

parathyroid adenoma, but patient remained hypercalcaemic up to 2.91 mmmol/l despite of high fluid intake. Repeated US scan showed residual left inferior parathyroid lesion measuring 12 mm and small ill-defined subcentimetre thyroid nodule U2/U3. Subsequently, she had re-operative parathyroidectomy and left thyroid lobectomy with significant drop of PTH during surgery. Her PTH level normalised and adj Ca dropped to 2.5 and remained at this level until the end of pregnancy. Histology confirmed parathyroid adenoma tissue within scar tissue and 1 mm micro classical parathyroid carcinoma (pT1a). Had successful pregnancy without complications, apart from GDM, which ended up by elective caesarean section on time with normal baby. Her calcium level after pregnancy remains within normal limits.

Discussion

Parathyroidectomy is the definitive treatment for primary hyperparathyroidism and is recommended in pregnancy when serum calcium is greater than 2.75 mmol/l, particularly in patients with prior pregnancy loss. Retrospective data have demonstrated that patients treated with parathyroidectomy have lower rates of pre-eclampsia and preterm delivery compared to patients managed medically. Surgery is preferably performed in the second trimester due to incomplete organogenesis in the first trimester, and the risk of preterm delivery in the third trimester. Our case is also showing successful outcome of pregnancy treated with surgery, which allowed to avoid maternal and fetal complications. Concomitant finding of papillary thyroid cancer during pregnancy helped to avoid further thyroid surgery.

About a rare association: primary hyperparathyroidism and clear cell renal cell carcinoma

Hela Sakly[1], Bilel Ben Amor[1], Ghaieth Bouagga[1], Ines Bayar[1], Sana Abid[1], Héla Marmouch[1], Hanene Sayadi[1] & Inès Khochteli[1]
[1]Fattouma Bourguiba University Hospital, Endocrinology Department, Monastir, Tunisia

Introduction

The association between primary hyperparathyroidism (PHPT) and neoplasia is well described in multiple endocrine neoplasia (MEN). However, its association with malignant solid tumors remains rarely reported. We present the case of a malignant renal tumor diagnosed simultaneously with PHPT

Case Report

A 58-year-old female patient with a history of diabetes and hypertension was hospitalized for management of severe hypercalcemia due to biologically confirmed PHPT, with a parathyroid hormone (PTH) level of 205 pg/mL, hypercalcemia at 3 mmol/l, hypophosphatemia at 0.56 mmol/l and vitamin D deficiency (11.2 ng/mL). She had no family history suggestive of multiple endocrine neoplasia. A cervical ultrasound revealed a 43 mm right superior parathyroid adenoma, along with two thyroid nodules classified as EU-TIRADS 2 and 3. Additionally, physical examination revealed abdominal collateral venous circulation and a left lumbar mass corresponding, on ultrasonography, to a solid-cystic lesion in the lower pole of the left kidney, measuring 11×10×12 cm, highly suspicious for malignancy. Plasma metanephrines and PTH-related peptide (PTHrP) levels were negative. The patient underwent a left lobisthmectomy and parathyroidectomy of the left inferior and right superior glands, leading to normalization of calcium-phosphorus balance postoperatively. Histopathological analysis confirmed hyperplasia of the left inferior and right superior parathyroid glands, as well as with two left vesicular thyroid adenomas. Subsequently, she underwent a left nephrectomy, and histopathological examination revealed a 13 cm clear cell renal cell carcinoma, classed pT2bNxM0 currently under supervising.

Discussion

It is possible that this association is a coincidence. However, that there might be an interaction between the two conditions, particularly due to the production of cytokines, growth factors, or other biologically active molecules that affect both the parathyroid glands and renal tissue. In the literature, there have been a few reported cases where patients with PHPT developed renal carcinoma, often after the treatment of hyperparathyroidism. It remains to be determined whether this association is coincidental or if there is an underlying relationship that has not yet been fully elucidated.

JOINT1851

A young male patient presented with hypercalcemia due to familial hypocalceuric hypercalcemia type 1

Mohammad Salah Uddin[1] & Fathi Abourawi[1]
[1]Northern lincolnshire and goole hospitals nhs trust, Grimsby, United Kingdom

Familial hypocalciuric hypercalcemia is a genetic condition characterized by mild hypercalcemia, typically found in otherwise healthy and asymptomatic individuals. Differential diagnoses of hypercalcemia are usually based on the acuity and severity of presentation and concomitant level of serum parathyroid hormone. FHH arises from calcium-sensing receptor gene (CASR) mutations, leading to decreased receptor activity in response to serum calcium levels. This results in mild hypercalcemia, hypocalciuria, hypermagnesemia and hypophosphatemia, with normal or slightly elevated serum PTH levels. Here we describe a case of 19 yrs. old male referred by GP for having chronic fatigue for last few months. Initial investigations to find out the cause of fatigue, showed serum calcium level 2.71mmol/l (mildly higher than normal reference range) with normal phosphate of 1.14mmol/l and normal parathyroid level of 4.1 pmol/l. Subsequently, repeat blood test showed phosphate level of 0.77 mmol/l (low) with serum adjusted calcium level of 2.78 mmol/l. Family history includes father having high serum calcium level of 2.8 mmol/l which was not further investigated probably as he was asymptomatic. No other past medical history noted with no history of any current regular medications. He had low vitamin D previously which was treated with prophylactic dose of vitamin D only. His vital signs were stable with BP 118/68 mmhg, Pulse 70/min. Other systemic examination findings were unremarkable. His repeat blood test results in clinic showed Na 140 mmol/l, K 4.3 mmol/l, Creatinine 84 micromol/l, adjusted calcium level of 2.87 mmol/l, phosphate 0.86 mmol/l, 25 hydroxy vitamin D 50 nmol/l, PTH 3.6 pmol/l, TSH 1.6 mU/l, FT4 12.2 pmol/l. Urine test showed urinary calcium creatinine ratio of 0.08, with fasting urine calcium clearance of 0.0020. Considering his positive family history and presentation at an early age, genetic cause was suspected. Hence, a referral for a genetic test has been made. The genetic test results showed heterozygous for pathogenic CASR variant which can cause autosomal dominant familial hypocalciuric hypercalcemia type 1(FHH1). As he was otherwise healthy, reassurance given, and no further investigations or treatment have been offered. This case illustrates the importance of detailed history taking and appropriate clinical evaluation before deciding about further management for asymptomatic mild hypercalcemia. Appropriate clinical history and investigations including early referral for genetic test to diagnose Familial Hypocalciuric hypercalcemia will help to avoid unnecessary medical treatment or parathyroid surgery in selected cases.

Rare case of concomitant pseudohypoparathyroidism and bilateral ovarian teratoma

Tea Khurodze[1], vitali vashakidze[1], Sopo Javelidze[1], Basa Gegeshidze[1] & Ana Pruidze[1]
[1]David Tvildiani Medical University, Tbilisi, Georgia

Background

Pseudohypoparathyroidism (PHP) is a rare inherited disorder characterized by hypocalcemia and hyperphosphatemia due to end organ resistance to parathyroid hormone. This disorder is caused by mutations at the complex GNAS locus on chromosome 20 q13.3. The GNAS encodes alpha subunit of G protein stimulating the activity of adenylate cyclase, which is controlling the production of several hormones from different endocrine glands, such as: the thyroid, pituitary, ovaries, and testes. Ovarian teratomas are benign neoplasms that arise from pluripotent germ cells that differentiate into various tissues, including endocrine-related structures. Since GNAS mutations impact various tissues derived from the mesoderm and ectoderm, there could be a theoretical developmental link.

Case presentation

We present a rare case of concomitant pseudohypoparathyroidism and bilateral ovarian teratoma. A 35-year-old Caucasian female visited the clinic with complaints of carpal spasms, hand paresthesia, irritability and fatigue. Hypocalcemia detected from childhood was commenced with calcium supplements. A previous diagnosis of subclinical hypothyroidism due to thyroid hypoplasia, with negative anti-thyroid antibodies was reported and maintained on levothyroxine. At the age of 26, right ovarian cyst excision was performed (a histomorphological study confirmed a teratoma). Eight years later, a dermoid cyst was detected in the left ovary measuring 30x27x18mm, with no growth during regular follow-ups. No other clinically significant medical conditions in past medical history. She has a family history of

ovarian cancer and diabetes mellitus type 2. Physical examination was unremarkable, except for positive Chvostek and Trousseau signs, shortened 4th metacarpal and 4th metatarsal bones on both sides. Initial lab tests showed significantly low calcium level - 4.0mg/dl, increased PTH—241 pg/ml and Phosphorus- 5.2 mg/dl. DEXA scan and other laboratory results were within the reference range. A diagnosis of pseudohypoparathyroidism type 1a was made. Improvement of symptoms was achieved with combined calcitriol and calcium citrate supplementation.
Conclusion
This is a rare case of concomitant PHP and bilateral ovarian dermoid cysts. While there is no clinical evidence that these two disorders share any genetic or other pathophysiological properties, presence of both conditions in a single patient raises suspicion and remains an area of further investigations and research.

Acute hypercalcemia after immune checkpoint inhibitor therapy with pembrolizumab. A case report

Massimiliano Lazzaroni[1], Francesco Angelini[2], Rinaldo Guglielmi[3], Anjali Iadevaia[2], Aikaterini Andreadi[1] & Enrico Papini[3]
[1]University of Rome Tor Vergata, Department of Systems Medicine, Session of Endocrinology and Metabolic Diseases, Rome, Italy; [2]Regina Apostolorum Hospital, Medical Oncology Unit, Albano Laziale, Rome, Italy; [3]Regina Apostolorum Hospital, Department of Endocrine and Metabolic Diseases, Albano Laziale, Rome, Italy

Background.
Immune checkpoint inhibitors (ICIs) have dramatically changed cancer therapy by enhancing anti-tumor immunity. Their use, however, is potentially associated with a variety of immune-related adverse events (irAEs) that include rare cases of hypercalcemia. A single case of hypercalcemia induced by the programmed death-1 (PD-1) inhibitor pembrolizumab is currently reported. Severity, timing of occurrence, and pathophysiological mechanisms remain scarcely defined.
Case report
Seventy-year-old woman suffering from KRAS mutant, MSI-H colon adenocarcinoma with liver metastasis undergoing pembrolizumab as first line therapy. Shortly after its second administration, she developed severe, life-threatening, hypercalcemia (20 mg/dl) with acute kidney failure. Serum levels of intact parathyroid hormone (PTH), parathyroid hormone-related peptide (PTHrP), 25-OH vitamin D, and 1,25-OH vitamin D were suppressed, thus allowing the exclusion of primary hyperparathyroidism, ectopic PTHrP secretion and ectopic 25(OH)D-1-hydroxylase expression. Cross-sectional imaging ruled out the presence of osteolytic lesions or granulomatous disease. Immediate intravenous treatment included aggressive hydration and the infusion of zoledronic acid and high-dose glucocorticoids followed by pembrolizumab withdrawal. During the subsequent week, serum calcium levels gradually normalized and the patient's overall condition improved.
Discussion
The occurrence of hypercalcemia in cancer patients receiving ICIs requires a careful differential diagnosis between malignancy-associated and immune-mediated causes. Notably, the interference of pembrolizumab on the PD-1 pathway may enhance osteoclast differentiation and activity through a RANKL/OPG imbalance and the production of pro-inflammatory cytokines, like TNF-α and IL-6. Accordingly, experimental models of PD-1/PD-L1 inhibition have demonstrated increased bone resorption. Thus, based on the clinical and instrumental evidence, the immune-mediated PD-1 pathway disruption may be postulated as the main cause of this case of pembrolizumab-induced hypercalcemia.
Conclusions.
In patients receiving ICIs, monitoring of serum calcium and its assessment before each dose administration appear advisable. Early recognition and immediate management of hypercalcemia mitigate its morbidity and allow for the maintenance of immunotherapy. Further research into the interplay between PD-1 inhibition and bone homeostasis is warranted to improve the prevention and management of this rare but potentially critical irAE.

Hyperphosphatemic familial tumoral calcinosis in an omani child: case report

Maryam Al Badi[1,2] & Najla Najla [3]
[1]National Diabetes and Endocrine Centre, Royal Hospital, Pediatric, Muscat, Oman; [2]National Diabetes and Endocrine Centre, Pediatric, Endocrine, Muscat, Oman; [3]National Diabetes and Endocrine Centre, Royal Hospital, Pediatric, Muscat, Oman

Hyperphosphatemic familial tumoral calcinosis (HFTC) is a rare autosomal recessive disorder characterized by progressive soft tissue calcifications due to a deficiency or resistance to intact fibroblast growth factor 23 (FGF23). The condition arises from pathogenic inactivating variants in the **FGF23**, **GALNT3**, or **KL**genes. We present the case of a 10-year-old Omani girl diagnosed with HFTC. She initially presented with a gluteal mass and persistently elevated serum phosphate levels. Radiological investigations, including radiographs, computed tomography (CT), and magnetic resonance imaging (MRI), revealed a large, lobulated, calcified mass within the gluteus maximus muscle. A CT-guided biopsy of the mass demonstrated fibrous tissue with extensive dystrophic calcifications, consistent with tumoral calcinosis. Genetic testing identified a homozygous pathogenic variant in the **GALNT3**gene (c.484C>T, p.(Arg162*)), confirming the diagnosis. Despite therapeutic interventions aimed at lowering serum phosphate levels, poor compliance led to persistent hyperphosphatemia. This case underscores the challenges associated with the diagnosis and management of HFTC and highlights the importance of early detection, patient education, and adherence to treatment protocols to mitigate disease progression.

Persistent hyperparathyroidism and bilateral oncocytic adrenocortical carcinoma: interplay of endocrine and oncologic challenges

Milica Opalic Palibrk[1], Sanja Ognjanovic[1], Bojana Popovic[1], Dusan Ilic[1], Valentina Elezovic Kovacevic[1], Lena Radic[1], Katarina Krstic[1] & Djuro Macut[1]
[1]University Clinical Center of Serbia, Clinic for Endocrinology, Diabetes and Metabolic Diseases, Department for Endocrine Tumors and Hereditary Cancer Syndromes, Belgrade, Serbia

Introduction
Persistent hyperparathyroidism (PHPT) poses diagnostic and therapeutic challenges, particularly when coexisting with severe comorbidities. This case illustrates how PHPT influenced the treatment course of bilateral oncocytic adrenocortical carcinoma (ACC), underscoring the need for multidisciplinary management in addressing such complexities.
Case Description
A 60-year-old woman was diagnosed with oncocytic ACC in 2021, requiring left nephrectomy and adrenalectomy. Histopathological analysis confirmed oncocytic ACC with significant malignant potential (Ki67 18.5%, Weiss score 6). Despite initial surgical success with no evident metastases, severe hypercalcemia (>3 mmol/l) and renal impairment (eGFR 30–40 mL/min) revealed concurrent PHPT. Subtotal parathyroidectomy confirmed four-gland hyperplasia, yet hypercalcemia persisted postoperatively, delaying planned adjuvant mitotane therapy. In 2023; ^{18}F-Fluorocholine PET/CT localized an ectopic parathyroid adenoma at the sternocostal junction. A second surgery in May 2023, involving VATS exploration of the mediastinum and thymectomy, failed to locate the adenoma. A third surgery in October 2023, performed via sternotomy, successfully removed the ectopic adenoma, confirmed histopathologically. Intraoperative PTH monitoring demonstrated a significant decrease, indicating surgical success. During this period, a second ACC lesion was identified on the contralateral adrenal gland. In 2024, the patient underwent right adrenalectomy, with histopathology confirming an oncocytic ACC (Weiss score 4, Ki67 9%). Importantly, neither the initial nor the subsequent ACC exhibited functional activity at any postoperative stage. While it remains unclear whether the lesion represents a metachronous or metastatic process, delayed adjuvant therapy after the initial diagnosis likely influenced the clinical course. Postoperatively, hypoparathyroidism required intensive calcium and vitamin D supplementation. Subsequent DXA scans demonstrated improved bone mineral density, while renal function remained compromised due to solitary kidney calculosis and CKD (eGFR ~28–33 mL/min). Management of this case required close collaboration between endocrinologists, surgeons, nephrologists, and oncologists to address the overlapping challenges of PHPT and bilateral ACC. Multidisciplinary planning was crucial for integrating diagnostic imaging, surgical interventions, and long-term metabolic and oncologic care.
Conclusions
This case highlights the bidirectional impact of PHPT and ACC management, demonstrating how endocrine dysfunction may alter oncologic treatment strategies and outcomes. Advanced imaging modalities, repeated surgical

interventions, and close interdisciplinary collaboration are crucial in addressing such complex cases.

PROPEL: prospective observational registry for ENPP1 deficiency and early-onset ABCC6 deficiency

Lothar Seefried[1,2], David Weber[3], Liz Molloy[4], Christine O'Brien[4], Ruth du Moulin[5], Kurt Gunter[5] & M. Zulf Mughal[6]
[1]University Hospital at the Julius-Maximilians University, Orthopädische Klinik König-Ludwig-Haus, Würzburg, Germany; [2]University of Wuerzburg, Musculoskeletal Center, Wuerzburg, Germany; [3]Children's Hospital of Philadelphia, Philadelphia, PA, United States; [4]GACI Global, Argyle, United States; [5]Inozyme Pharma, Boston, United States; [6]Al Jalila Children's Specialty Hospital, Dubai, United States

ENPP1 Deficiency is a rare genetic disorder caused by inactivating mutations in the *ENPP1* (ectonucleotide pyrophosphatase/phosphodiesterase 1) gene (biallelic prevalence 1:64000). ENPP1 Deficiency is associated with low levels of plasma pyrophosphate (PPi) and AMP leading to ectopic (especially vascular) calcification (Generalized Arterial Calcification of Infancy [GACI] Type 1), pathologic skeletal mineralization (Autosomal Recessive Hypophosphatemic Rickets Type 2 [ARHR2]) and occlusive neo-intimal proliferation. Infants with ENPP1 Deficiency have 50% mortality in the first 6 months of life. Survivors typically develop hypophosphatemic rickets and experience bone deformities, hearing loss, impaired growth, pain and immobility leading to poor quality of life and function. Similarly, ABCC6 Deficiency, caused by biallelic mutations in the *ABCC6* (ATP-binding cassette transporter protein subfamily C member 6) gene, is a disorder of pathological mineralization and intimal proliferation manifesting in a spectrum of phenotypes, likely resulting from low PPi and adenosine due to reduced ATP, the substrate for ENPP1. The infantile-onset form (GACI Type 2) resembles ENPP1 Deficiency - infants present with widespread arterial calcification and severe cardiovascular complications. In both cases early genetic testing is key for apt treatment decision-making. Much of the current knowledge of ENPP1 and ABCC6 Deficiency is based on case reports or small retrospective studies. No targeted therapy exists for these diseases. This global, multicenter, prospective observational registry co-sponsored with GACI Global (PROPEL, NCT06302439) is designed to systematically collect clinical information to inform a comprehensive understanding of the burden of illness and progressive nature of these diseases. The key objectives are to determine the onset, variability and progression of pathological calcification and clinical complications and to assess the burden of disease on patients, including patient-reported outcomes (PROs). Except for optional PRO questionnaires, all data collected and recorded to the registry will be part of routine clinical exams. Patients will have an opportunity for optional blood draw to assess PPi levels. The registry is planned to open in 50 sites globally with the goal of recruiting up to 1,000 participants over the next 10 years, adding significant value to the existing body of evidence. Study updates and preliminary patient data will be presented.

Grading pseudofractures—the "breach – beak – bump – bridge" approach

Lothar Seefried[1], Dominik Rak[1] & Franca Genest[1]
[1]Julius-Maximilians-Universität Würzburg, Osteology Department, Würzburg, Germany

Pseudofractures are atraumatic radiolucencies resulting from compromised bone mineralization that are often associated with poor clinical outcomes in patients with metabolic bone disorders. The incidence, clinical course of healing, and risk of recurrence of pseudofractures are not well characterized, in no small part because pseudofractures and fractures are commonly reported under the general term "fractures" despite underlying pathophysiologic differences. Accordingly, this report proposes a grading scale to specifically assess pseudofractures. The grading scale was developed based on our clinical experience in treating femoral pseudofractures. The proposed circular taxonomy includes 4 radiographically distinct stages that include an unreactive initial Breach (Stage 1), appearance of a visible Beak (Stage 2) and a rounded Bump (Stage 3), and formation of a Bridge (Stage 4) across the interline. The loop closes at Stage 0, indicating absence of any radiographic hallmarks of a pseudofracture, either because a clinical suspicion does not have a radiologic correlate or because healing and remodeling are complete without residuals. These stages may correspond to a sequential transformation along the course of pseudofracture consolidation, although this requires scientific proof, and stagnation or relapse may occur at any stage. The stages should be further indicated by adding a "d" to the score for dislocation or an "s" for when the situation is clinically stable, meaning no pain and full weight-bearing because of surgical stabilization or sustainable cortical bridging (typically in Stage 4 or 0 [consolidation]). The scale may be used for any pseudofracture regardless of the anatomical site or underlying etiology. The proposed Breach–Beak–Bump–Bridge (4B) concept can be used as a tool in clinical practice to assess pseudofractures over time and to improve specificity and clarity in communication of these findings.

Radiofrequency ablation in primary hyperparathyroidism: a case study and literature review

Maria Chrysoula Tatarida Palla[1], Aspasia Drosou[2], Nikoletta Mirtsou[3], Demosthenes Mazarakis[2], Olga Tsantarlioti[2], Pyrros Gkousis[4], Victoria Kaltzidou[2], Styliani Kalaitzidou[2], EIrini Beniou[5] & Myrsini Gkeli[4,6]
[1]Metaxa Cancer Hospital Piraeus, Endocrinology, Athens, Greece; [2]Metaxa Cancer Hospital Piraeus, Endocrinology, Athens, Greece; [3]Metaxa Cancer Hospital Piraeus, Athens Greece - Department of Endocrinology, Athens, Greece; [4]Saint Savvas Oncology Hospital, Radiology, Athens, Greece; [5]Metaxa Cancer Hospital Piraeus, Athens Greece, Endocrinology, Athens, Greece; [6]Saint Savvas Oncology Hospital of Athens, Radiology, Athens, Greece

Primary Hyperparathyroidism (PHPT) is an endocrine disorder characterized by excessive production of parathyroid hormone (PTH), typically due to parathyroid adenomas, leading to hypercalcemia and its associated symptoms. Although surgery is a first-line treatment for PHPT, radiofrequency ablation (RFA) emerged as a minimally invasive alternative, especially for patients with comorbidities or those who want to avoid surgery. This poster presents a case study and a literature review of RFA in PHPT. A 78-year-old female patient with a history of breast cancer on aromatase inhibitors, type 2 diabetes mellitus, heart failure, atrial fibrillation with a pacemaker and atrophic gastritis was admitted to emergency department of our hospital with symptoms of hypercalcemia including weakness, anorexia, and nausea. Laboratory tests showed elevated serum calcium [corrected Ca^{2+}: 12.5 mg/dl (normal range: 8.4-10.5)] and PTH levels [PTH: 171.4 pg/ml (normal range: 55-65)] while imaging tests revealed a 23.5 mm parathyroid adenoma. After excluding other causes of hypercalcemia, the patient was diagnosed with PHPT. Considering the patient's comorbidities and her refusal to undergo surgery, RFA was chosen as a treatment option which was performed under ultrasound guidance and local anesthesia. The procedure involved hydro-dissection to protect surrounding structures. During the post-ablation period, patients improved clinically; subsequent follow-up confirmed a steady decline in calcium and PTH levels over 12 months and a 90% reduction in adenoma volume. A literature review was conducted for the efficacy of RFA in treatment of PHPT, based on recent studies. The RFA outcomes were promising as substantial reductions in PTH and calcium levels were noted, along with symptoms' relief and parathyroid adenoma volume rate reduction (VRR). Studies showed that the overall success rate was approximately 92%. Studies which compared RFA with parathyroidectomy found that surgery was more effective in lowering PTH levels since there is the risk of incomplete ablation in larger lesions and potential recurrence. However, RFA had lower rates of severe hypocalcemia, compared to patients undergoing parathyroidectomy, who experience a rapid drop in PTH levels and a rapid calcium influx into "the hungry bones" all resulting in decreased serum calcium levels. Other benefits of RFA are lower complication rate, faster recovery and lack of visible scarring making it an alternative option for patients with multiple comorbidities. In conclusion, RFA presents an effective alternative to parathyroidectomy for the treatment of PHPT. However, ongoing research is needed to optimize its role in clinical practice.

Hypocalciuric hypercalcemia: navigating the diagnostic challenges

Nada Ait Kassi[1], Habbadi Zineb[2], Fatima Toulali[1], Ghizlane Sabbar[1], Kaoutar Rifai[1], Hinde Iraqi[1] & Mohamed El Hassan Gharbi[1]
[1]Ibn Sina Hospital Mohamed V University, Endocrinology, Rabat, Morocco; [2]Ibn Sina Hospital Mohamed V University, Endocrinology, Rabat, Morocco

Introduction
Familial hypocalciuric hypercalcemia (FHH) is a genetic disorder that causes lifelong hypercalcemia, often mimicking primary hyperparathyroidism (PHPT). FHH is primarily due to calcium-sensing receptor (CASR) gene mutations, leading to altered calcium homeostasis. This report discusses a case of FHH in a 68-year-old patient, highlighting the diagnostic challenges and clinical management strategies.
Case Presentation
A 68-year-old woman, Mrs. F.A, with a medical history of hypertension, type 2 diabetes mellitus complicated by chronic kidney disease, and gout, was referred for the evaluation of hypercalcemia. Initial laboratory tests revealed a corrected serum calcium level of 119 mg/l, hypophosphatemia (27 pg/l), and elevated parathyroid hormone (PTH) levels (five times the normal range). The 24-hour urinary calcium excretion was markedly low (<20 mg/l), suggesting hypocalciuria, with a fractional excretion of calcium less than 0.01. The patient's clinical examination showed an overweight status (BMI 28 kg/m^2) but was otherwise unremarkable. Cardiovascular and respiratory examinations were normal. The absence of endocrinopathies and a lack of familial history of hypercalcemia were noted. Imaging studies, including cervical ultrasound, MIBI scintigraphy, and MRI, did not reveal parathyroid adenomas.
Discussion
FHH is often misdiagnosed as PHPT due to overlapping clinical and biochemical features. Both conditions present with hypercalcemia and non-suppressed PTH levels. However, FHH is characterized by hypocalciuria, a key differentiating factor. Genetic testing, although not performed in this case due to cost constraints, can confirm the diagnosis by identifying mutations in the CASR gene. Management of FHH typically involves conservative measures, as most patients are asymptomatic and do not require surgical intervention. In contrast, PHPT often necessitates parathyroidectomy. In this case, the patient was managed with hydration and regular monitoring of calcium levels.
Conclusions
This case underscores the importance of considering FHH in the differential diagnosis of hypercalcemia, particularly in the presence of hypocalciuria. Accurate diagnosis is crucial to avoid unnecessary surgical procedures and to implement appropriate management strategies. Further genetic studies could enhance our understanding and diagnosis of FHH, ensuring better patient outcomes.

Rocky road to diagnosis: uncovering primary hyperparathyroidism

Nada Ait Kassi[1], Chaimae Taleb[1], Habbadi Zineb[1], Fatima Toulali[1], Ghizlane Sabbar[1], Kaoutar Rifai[1], Hinde Iraqi[1] & Mohamed El Hassan Gharbi[1]
[1]Ibn Sina Hospital Mohamed V University, Endocrinology, Rabat, Morocco

Introduction
Recurrent nephrolithiasis is a frequent pathology often associated with significant morbidity. Among its underlying causes, primary hyperparathyroidism (PHPT) is notable for its contribution to stone formation and nephrocalcinosis. However, PHPT remains an underdiagnosed yet treatable condition, necessitating heightened awareness for timely diagnosis.
Case Presentation
We report the case of a 47-year-old male with a history of recurrent nephrolithiasis treated by extracorporeal shock wave lithotripsy in 2019. The patient was admitted for a deep vein thrombosis (DVT) of the right lower limb and initiated on anticoagulation therapy. Etiological investigations revealed PHPT with serum calcium of 107 mg/l, phosphorus of 18 mg/l, parathyroid hormone (PTH) levels 5.5 times the normal limit, and elevated 24-hour urinary calcium excretion. Renal imaging showed bilateral hydronephrosis secondary to renal calculi. Localization studies identified a 20×14 mm left inferior parathyroid nodule, confirmed as pathological on MIBI scintigraphy. A surgical referral was made for definitive management.
Discussion
PHPT is a significant cause of recurrent nephrolithiasis, responsible for up to 7% of cases. Hypercalcemia and hypercalciuria, hallmark features of PHPT, promote calcium stone formation. Evidence suggests that delayed diagnosis of PHPT, often exceeding six years from the onset of symptoms, exacerbates renal damage. Studies underline the importance of metabolic assessments in patients with recurrent urolithiasis to identify PHPT early. Surgical intervention, typically parathyroidectomy, is curative, with a marked reduction in stone recurrence postoperatively. In our case, the presence of bilateral hydronephrosis further emphasizes the burden of undiagnosed PHPT. Regular follow-up and management of residual risk factors, such as vitamin D deficiency or low urinary citrate levels, are critical for long-term outcomes.
Conclusion
This case highlights the strong association between PHPT and recurrent nephrolithiasis. Comprehensive metabolic workups in patients with urolithiasis are crucial to prevent delayed diagnoses and their complications. Early surgical management remains the cornerstone of treatment, reducing recurrence and preserving renal function.

Pregnancy and lactation-associated osteoporosis with multiple spinal fragility fractures

Jowita Halupczok-Żyła[1], Anna Brona[2], Barbara Stachowska[2], Joanna Syrycka[3], Jadwiga Szymczak[2] & Marek Bolanowski[2]
[1]Department of General and Experimental Pathology, Wroclaw Medical University, Wrocław, Poland; [2]Department and Clinic of Endocrinology and Internal Medicine, Wroclaw Medical University, Wrocław, Poland; [3]Department of Nuclear Medicine, Tadeusz Marciniak Lower Silesia Specialist Hospital-Centre for Medical Emergency, Wrocław, Poland

We present a case of a 31-year-old woman who was admitted to the Department of Endocrinology, Diabetes, and Isotope Therapy due to multiple vertebral fractures 6 months after delivery of her first child. The patient had been diagnosed with autoimmune thyroid disease with normal thyroid function before pregnancy. Treatment with levothyroxine was started in the 22nd week of gestation and continued until 6 weeks after delivery. She received vitamin D, iodine, and folic acid supplementation during pregnancy and lactation. She breastfed on demand. The patient does not smoke or abuse alcohol. Three months after delivery, the patient had a strong thoracolumbar pain while she was lifting a baby. On X-ray, scoliosis, L3-L4 discopathy, bone atrophy, and multiple vertebral fractures were depicted. Densitometry at the lumbar spine revealed osteoporosis Z-score (-) 4.8. Chest X-ray, ultrasound of breast, abdomen with pelvis, and bone scintigraphy did not reveal abnormalities. Thoracic and lumbar spine magnetic resonance imaging revealed fractures (Th4, Th7, Th9, Th12 and L1). The patient was treated with vitamin D (2000 IU a day) and calcium (1.5 g a day). A spine corset and rehabilitation were recommended but did not decrease thoracolumbar pain. On admission, the patient's BMI was 18.75 kg/m2. Osteoporosis at the lumbar spine (Z-score (-) 4.8) and femoral neck (Z-score (-) 2.9) was confirmed. During hospitalization, laboratory tests revealed normal levels of calcium, phosphates, parathormone, vitamin D, and bone turnover markers. There were no hormonal disturbances. Non-endocrine causes for secondary osteoporosis were also excluded. Finally, the patient was diagnosed with pregnancy and lactation-associated osteoporosis (PLO). Treatment with higher doses of vitamin D (4000 IU a day) and calcium (2.0 g a day) was initiated. After 8 months bone density parameters improved and the patient reported back pain relief.

Ectopic parathyroid adenoma associated with a thymoma: a case report

Amira Yanes[1], Bilel Ben Amor[1], Aycha Ghachem[1], Ines Bayar[1], Sana Abid[1], Héla Marmouch[1], Hanene Sayadi[1] & Inès Khochteli[1]
[1]Fattouma Bourguiba University Hospital, Endocrinology Department, Monastir, Tunisia

Introduction
The combination of a parathyroid adenoma and thymoma is rare, with only few cases documented in the literature. This association may be explained by the shared embryological origin of the parathyroid glands and the thymus. We present here the case of a patient with primary hyperparathyroidism who was also found to have a thymoma in the anterior mediastinum.

Case presentation
A 60-year-old female patient was diagnosed with primary hyperparathyroidism based on hypercalcemia of 3.1 mmol/l, hypophosphatemia of 0.6 mmol/l, and inappropriate PTH level of 128 pg/ml. During the initial localization workup, a SPECT-CT scan showed an ectopic, hyperfunctional parathyroid gland located behind the manubrium of sternum. A chest CT scan revealed a calcified anterior mediastinal nodule in contact with the anterior surface of the ascending aorta, measuring 21 mm and a second lesion measuring 15 mm behind the manubrium sterni, corresponding to the hyperfixation area seen on the SPECT-CT. The patient underwent surgery with resection of the two masses. The histopathological report confirmed the diagnosis of thymoma (type AB1) and ectopic parathyroid adenoma.
Discussion
Primary hyperparathyroidism is a common endocrine disorder, with parathyroid adenomas accounting for 85% of cases. In about 10% of cases, the adenoma is ectopic due to abnormal embryological migration of the parathyroid glands. Despite their distinct primary functions, the parathyroid glands and thymus share a close relationship during organogenesis, as both are derived from the third branchial pouch. The association of a parathyroid adenoma with a thymoma is a rare clinical occurrence, with only a few cases documented in the literature. Patients may only present with the clinical signs and symptoms of primary hyperparathyroidism, making it difficult to suspect the presence of a thymoma. This association can be linked to familial syndromes, such as multiple endocrine neoplasia type 1.
Conclusion
Due to the close developmental link between the parathyroid and thymus glands, it is important to investigate the presence of thymic lesions when managing patients with primary hyperparathyroidism.

JOINT3639
Assessment of bone mineral density and it's determinants in children with precocious puberty
Sara Aszkiełowicz[1], Dorota Kowalik[1], Anna Łupińska[1,2], Renata Stawerska[1,2] & Arkadiusz Zygmunt[1,3]
[1]Polish Mother's Memorial Hospital-Research Institute, Department of Endocrinology and Metabolic Diseases, Łódź, Poland; [2]Medical University of Łódź, Department of Paediatric Endocrinology, Łódź, Poland; [3]Medical University of Łódź, Department of Endocrinology and Metabolic Diseases, Łódź, Poland

Background
Precocious puberty (PP) is defined as the early onset of pubertal development, often leading to accelerated bone maturation and potential alterations in mineral metabolism. Understanding the interplay between bone mineral density (BMD) and calcium-phosphate homeostasis in this population is crucial for assessing long-term skeletal health. This study aims to evaluate factors influencing BMD and differences in calcium-phosphate metabolism among children with PP.
Methods
A cohort of 34 children (30 girls and 4 boys) diagnosed with PP underwent a comprehensive assessment, including dual-energy X-ray absorptiometry (DXA) to measure BMD at the spine (BMD Spine) and Total Body Less Head (BMD TBLH). Height-adjusted Z-scores (HAZ) were also analyzed. In addition, hormonal levels (IGF-1, androgens such as DHEAS, androstenedione, testosterone, 17-OH progesterone, and estradiol) and responses to an LHRH stimulation test at three time points were evaluated. Markers of calcium-phosphate metabolism—including total calcium, parathyroid hormone (PTH), alkaline phosphatase, inorganic phosphates, urinary calcium excretion, and vitamin D levels—were also analyzed. Statistical tests assessed correlations between these parameters and BMD.
Results
Decreased BMD was found in 10 out of 34 children, defined as HAZ $<$-1 (among which all 10 patients had reduced HAZ TBLH, and 5 of them had also reduced HAZ Spine). A significant positive correlation was observed between bone age, calendar age, body mass, PTH, and BMD Spine. Additionally, BMD TBLH showed strong positive correlations with bone age, testosterone, and IGF-1 levels. Children with reduced HAZ TBLH had higher levels of DHEAS compared to those with normal HAZ TBLH. However, no statistically significant differences were found in IGF-1, PTH, vitamin D levels, or other hormonal markers between children with reduced BMD and those with normal BMD. Furthermore, no significant impact of vitamin D insufficiency ($<$20 ng/ml) on bone mineralization parameters was observed ($P>0.05$).
Conclusion
Bone age, testosterone, and IGF-1 levels were strongly correlated with BMD in children with PP, highlighting their potential role in skeletal development. While vitamin D levels did not significantly affect BMD, distinct hormonal differences, particularly in DHEAS, were observed in children with lower BMD, indicating complex regulatory mechanisms in bone health in PP. These findings underscore the need for further longitudinal studies to assess the long-term impact of metabolic alterations on skeletal integrity.

Cystic angiomatosis. a diagnostic challenge - case report
Katarzyna Wojciechowska-Durczyńska[1,2], Marta Mikulak[2], Małgorzata Karbownik-Lewińska[1,2] & Andrzej Lewiński[1,2]
[1]Medical University of Lodz, Department of Endocrinology and Metabolic Diseases, Lodz, Poland; [2]Polish Mother's Memorial Hospital-Research Institute, Department of Endocrinology and Metabolic Diseases, Lodz, Poland

Introduction
Cystic Angiomatosis (CA) is a rare condition with several dozen cases reported in the literature. It is characterized by multifocal skeletal and visceral angiomatous lesions. The aetiology of the condition remains unclear and the exact pathological background has not been determined so far, similarly as the diagnostic and therapeutic procedures.
Case report
We report the case of a 26-year-old male patient with a 5-year history of severe bone pain located in pelvis, spine, ribs and limping. CT scan showed osteolytic lesions with osteosclerotic rim in the capitula of humerus, pelvis, spine and several lesions in the right acetabulum. It also revealed gross splenomegaly with multiple heterogenous lesions and multiple hepatic lesions. Next, PET-CT was performed showing low FDG uptake in overmentioned lesions. It was followed by bone scintigraphy that showed hyperconcentration of the tracer in the same skeletal locations. Based on the obtained results, the main suspected diagnosis was malignant sarcoma with multiple bone metastases. The US-guided biopsy of the hepatic lesion was performed showing haemangioma. Next, the patient underwent splenectomy and histological examination revealed multiple small haemangiomas. Finally, the biopsy of the left ilium was performed that revealed spaces of bone tissue replaced with fibrous tissue with multiple, thin-walled blood vessels and the absence of myeloid neoplasia, lymphoma or carcinoma. The histological features were characteristic for systemic CA.
Conclusion
Whereas CA is a condition of mostly benign course, routinely performed radiological examination usually suggests more aggressive disorders, including malignant neoplasia, which should be excluded in the differential diagnosis. Therefore, the biopsy of the bone should be performed in the early stages of the diagnostic process to prevent patients from unnecessary stress. To our knowledge this is the first report on a patient with CA in Poland.

JOINT81
A rare case of primary hyperparathyroidism caused by a giant parathyroid adenoma: a case report
Michelle Tham[1,2]
[1]Woodlands Health, Singapore, Singapore; [2]Woodlands Health, Endocrinology, Singapore, Singapore

Background
Giant parathyroid adenomas (GPAs) are a rare cause of primary hyperparathyroidism, and are characterized by adenomas that weigh $>$3.5g. The large size and higher calcium levels of GPA may mimic parathyroid carcinomas.
Clinical Case
A 43-year-old female was referred to the Endocrinology for hypercalcemia, detected after evaluation for recurrent calculi was performed. Initial laboratory findings revealed adjusted serum calcium of 3.34mmol/l, albumin of 41g/l, and phosphate 0.5 mmol/l. On systems query, she denied polyuria, polydipsia, dysuria nor loin-to-groin pain. She had no bone pain, jaw pain, abdominal pain, dyspepsia, and constipation, constitutional symptoms or mood changes. She was not on calcium supplements, lithium or thiazide. Of note, she had a history of bilateral recurrent renal calculi treated with medical expulsive therapy. On examination, she was well hydrated, and did not have neck masses, or palpable lymph nodes. Systemic examination was unremarkable. Inpatient management of severe hypercalcemia included aggressive intravenous hydration, subcutaneous calcitonin and intravenous pamidronate. A

diagnosis of primary hyperparathyroidism was made, complicated by renal calculi, low bone density, and stage 3A CKD. Parathyroid carcinoma was initially considered in view of her significantly elevated PTH levels. Due to her young age of onset, familial PHPT was considered. A screen for symptoms associated with multiple endocrine neoplasia (MEN) syndrome was negative. Neck ultrasound demonstrated a large, lobulated, hypoechoic mass posterior to the left hemi-thyroid (5.1 × 1.7 × 1.7 cm). Technetium-99m labelled sestamibi localized the left hyperfunctioning parathyroid tissue. Early definitive left parathyroidectomy was performed, and histology revealed a parathyroid adenoma with no features of malignancy. She did not have hypocalcemia post-operatively. During follow-up over 3 years, she has remained normocalcemic, with improvements in bone density.

Conclusions

GPA appears to be a genetically distinct entity compared to parathyroid adenomas and carcinoma. (1) While no malignant transformation has been noted in the literature, patients with atypical adenomas should be followed up because of the molecular resemblance to carcinomas. (2) As it is difficult to differentiate parathyroid carcinomas from giant parathyroid adenomas pre-surgically, a strong clinical index of suspicion of malignancy is important to avoid a misdiagnosis.

Renaltú, a web page to satisfy the information needs on primary tubulopathies for patients and care provider

Frank Hernández García[1,2], Helena Gil Peña[2,3], Julían Rodríguez Suárez[1,2,3], José López García[4], Pablo Martino Redondo[3] & Rocío Fuente Pérez[5]

[1]Universidad de Oviedo, Morfología y Biología funcional, Oviedo, Spain; [2]Instituto de Investigación Sanitaria del Principado de Asturias, Grupo de Investigación en Pediatría, Oviedo, Spain; [3]Hospital Universitario Central de Asturias, AGC Infancia y Adolescencia, Oviedo, Spain; [4]Universidad de Oviedo, Medicine, Oviedo, Spain; [5]Universidad Europea de Madrid, Facultad de Enfermería y Ciencias de la Salud, Madrid, Spain

Introduction

Primary tubulopathies are a group of hereditary disorders affecting renal tubular function, leading to electrolyte imbalances and mineral homeostasis alterations. Among them, X-linked hypophosphatemic rickets (XLH) is the most common hereditary form of rickets, characterized by persistent hypophosphatemia due to excessive FGF23 activity, resulting in impaired bone mineralization and growth retardation. Renaltube has established itself as a key scientific platform in the study of these disorders, while the development of RenalTú, a web page designed to satisfy the information needs of patients and care providers, represents a significant step toward improving access to specialized knowledge and resources.

Objectives

To describe the development and functionality of RenalTú as an interactive digital tool for patients with primary tubulopathies.

Methods

The development of RenalTú was structured into two key areas: technological development and educational content creation. The platform was designed as a responsive and user-friendly website, ensuring accessibility across multiple devices. Interactive features, such as structured disease information, educational videos, patient testimonials, and forums for community engagement, were integrated to enhance user experience. The educational content was developed in collaboration with nephrologists, geneticists, and patient advocacy groups to ensure accuracy and relevance. Additionally, clinical guidelines and ongoing clinical trials were included to facilitate informed decision-making by patients and healthcare providers.

Results

RenalTú (www.renaltu.com) was developed as a patient-centered digital resource, providing reliable information on primary tubulopathies in an accessible and interactive format. It enhances disease awareness, treatment adherence, and patient-provider communication.

Conclusions

RenalTú serves as an essential resource to bridge the knowledge gap for patients and caregivers dealing with primary tubulopathies, facilitating self-management and specialist interactions.

Profound hyponatremia in acute heart failure with a good outcome

Murtaza Rashid[1], Shyam Seshadri[1], Raja Nata[1], Mitra Mir Mohammad Sadeghi[1] & Jaiminkumar Patel[1]

[1]Queen Elizabeth Hospital Foundation NHS Trust, Department of Diabetes and Endocrinology, Kings Lynn, United Kingdom

We report on a male with severe hyponatremia secondary to congestive cardiac failure from dilated cardiomyopathy who was managed with fluid restriction, diuresis, and Tolvaptan before proceeding to emergency cardiac transplantation.

Case synopsis

This 54-year-old gentleman had a preceding history of the viral flu 2 months before coming in with progressive shortness of breath and swelling of his legs. He had seen a cardiologist 1 month before his attendance and an outpatient echocardiogram had revealed severely impaired left ventricular function (ejection fraction of less than 35%) he was commenced on diuretics along with Bisoprolol, spironolactone, and Ramipril. He subsequently presented to ED 2 weeks later with symptoms of progressive heart failure. Electrolyte estimation revealed severe hyponatremia (sodium of 121 mmol/l) and acute kidney injury. His serum osmolality was 262mmol/kg, urine osmolality 644mmol/kg, urine sodium of 23 mmol/l. Liver functions were deranged in keeping with hepatic congestion secondary to severe heart failure while thyroid and adrenal function were normal. Oral Bumetanide had worsened his sodium levels (sodium of 114mmol/l) and renal function with a further dropping in his urine sodium levels to 11 mmol/l, and an endocrine opinion was sought for his deteriorating sodium levels. Tolvaptan was introduced at 15 mg daily with strict monitoring of his renal function and fluid status. His sodium improved to 126 mmol/l over 2 days though he remained profoundly volume overloaded with clinical heart failure. Intravenous diuresis was commenced with stabilization of his renal function and the patient was transferred to the cardiac unit for close observation. He continued to receive regular tolvaptan with subsequent stabilization of his sodium levels to the low 120's and improvement in his renal failure proving that he had cardiorenal syndrome which responded to judicious management of his heart failure. Given persistent very poor cardiac function with an ejection fraction of under 15%, the patient was transferred to a tertiary hospital following discussion, for emergency orthoptic cardiac transplantation with a good outcome.

Discussion

This case highlights the importance of managing significant hyponatremia with a multi-disciplinary approach. Persistent low urine sodium in the setting of ongoing diuretics in our patient with severe hyponatremia suggested diuretic unresponsive heart failure and increasing risk of mortality and a poor outcome hence the key factor in management involved the judicious use of Tolvaptan and diuretics in optimizing heart failure as a bridge to eventual cardiac transplantation.

Design of 3 multicenter, phase 3, randomized trials to evaluate efficacy and safety of the enzyme replacement therapy efzimfotase alfa in patients with hypophosphatasia (HICKORY, MULBERRY, CHESTNUT)

Kathryn M. Dahir[1], Joao Dinis Freitas[2], Maria Marfa Barzano[2], Damien Simoneau[3], Emma Blasi[2], Qunming Dong[4], Wei-Jian Pan[4] & Derek Dunn[4]

[1]Vanderbilt University Medical Center, Nashville, United States; [2]Alexion, AstraZeneca Rare Disease, Barcelona, Spain; [3]Alexion, AstraZeneca Rare Disease, Baar, Switzerland; [4]Alexion, AstraZeneca Rare Disease, Boston, United States

Introduction

Hypophosphatasia (HPP) is a rare inherited, metabolic disease caused by deficient tissue-nonspecific alkaline phosphatase (ALP) activity and characterized by skeletal and nonskeletal manifestations, including rickets/osteomalacia, fracture-s/pseudofractures, muscle weakness, and pain, which significantly impact quality of life. HPP was previously classified into subtypes by age at onset; however, manifestations can change and accumulate over time, suggesting that HPP is a continuous, progressive disease. The objective of the ongoing HICKORY (NCT06079281) and MULBERRY (NCT06079359) trials is to determine the efficacy and safety of efzimfotase alfa, an investigational next-generation ALP enzyme replacement therapy (ERT) for HPP in treatment-naive patients. The objective of the ongoing CHESTNUT (NCT06079372) trial is to determine the safety and tolerability of efzimfotase alfa in patients who initiate treatment after prior treatment with asfotase alfa, a first-generation ERT.

Study Design
HICKORY, MULBERRY, and CHESTNUT are ongoing multicenter, phase 3, randomized, parallel arm trials in patients ≥2 years of age (HICKORY: ≥12 years) with HPP (**Table**). Each study includes a 24-week randomized period followed by an open-label extension of up to 2.5 years. Weight-based doses of 20, 35, or 50 mg efzimfotase alfa will be administered subcutaneously biweekly. Approximately 184 patients will be recruited globally. This clinical program is the first to evaluate a broad HPP patient population across ages, ages at onset, manifestation types (including no overt skeletal manifestations), and functional endpoints such as the 6-Minute Walk Test (6MWT) and the 30-second Sit-to-Stand Test (STS).

Table

Interest of the bone scintigraphy in the diagnosis and monitoring of enchondroma, about a case

Redhouane Longo[1] & Mourad Benrabah[1]
[1]Regional University Military Hospital, Oran, Algeria

Introduction
Enchondroma or central chondroma is a benign cartilaginous tumor with development intramedullary characterized by the proliferation of mature hyaline cartilaginous tissue. A tumour of the subject fasting (30-40 years), very common, usually discovered by chance. Solitary enchondroma accounts for nearly 3% of all bone tumors and between 12 and 24% of benign bone tumors. Generally asymptomatic. The scintigraphic aspect of enchondroma lacks specificity and may be a false positive aspect on planar images in a context of searching for secondary bone locations. Objective: The interest of bone scintigraphy in the localization and diagnostic orientation of benign bone tumors and its role in the monitoring of any malignant degeneration.
Materials and Methods
We report the case of a patient referred for an extension assessment of a mammary neoplasia. A bone scan completed with SPECT/CT was performed with a GE NM/ CT DISCOVERY 670 Gamma camera.
Results
Standard radiography showed a clear (osteolysis) of the upper end of the tibia (left tibial plate). On the planar scintigraphic imaging, there was a focal hyperfixation focus in the upper epiphyso-metaphyseal region of the left tibia. SPECT/CT slices showed a mixed osteocondensing lesion with osteolysis of the left epiphyseal cartilaginous matrix without periosteal reaction or rupture of the cortical, evoking an enchondrome of the left tibial plateau.
Discussion
The described appearance suggests enchondroma. However, a differential diagnosis with bone infarction cannot be ruled out. Interest of an MRI to establish the diagnosis and eliminate differential diagnoses (bone infarction). In addition, a subsequent scintigraphic check-up is recommended for the follow-up of any sarcomatous transformation
Conclusion
SPECT/CT has allowed a morphological characterization and the anatomical localization of enchondroma and elimination of false diagnosis of secondary bone localization. Bone scintigraphy is of interest during enchondroma where it allows to map the lesions and serves as an initial follow-up examination of any sarcomatous transformation.

Mass effect revealing a sphenoidal brown tumor: a case report

Rania Dassoufi[1], Sana Rafi[1], Ghizlane El Mghari[1] & Nawal El Ansari[1]
[1]Mohamed 6 University Hospital of Marrakech, Endocrinology-Metabolic Diseases-Nutrition Department, Marrakech, Morocco

Introduction
Brown tumour or fibrocystic osteitis is a rare benign bone lesion secondary to hyperparathyroidism. It can affect the entire bony skeleton, including the pelvis, ribs, clavicles and limbs. However some infrequent localisations are possible such as cranial and facial bone damage. we present a case of a sphenoidal brown tumour associated with tertiary hyperparathyroidism.
Case presentation
The patient was 33 years old and had been on haemodialysis for more than 8 years for chronic renal failure in a single polycystic kidney complicated by tertiary hyperparathyroidism with major hyperparathormonemia at 1398 ng/ml. The patient presented with a pituitary tumour syndrome consisting of headaches with decreased visual acuity, especially on the left side, associated with a galactorrhoea amenorrhoea syndrome that had been evolving for 1 year. Cerebral MRI revealed a 51*35*33 mm process involving the base of the skull, displacing the pituitary gland and centred on the sphenoid bone, initially suggesting a brown tumour, which was confirmed by CT scan with the presence of calcifications and a clear blowing aspect of the sphenoid cortex. Hormonally, she was complicated by anteropituitary insufficiency, which we substituted, in particular corticotropic, thyrotropic and gonadotropic insufficiency, associated with hyperprolactinaemia of probable disconnection. Finally, the patient was scheduled for neurosurgery in view of her visual prognosis.
Discussion
First described in 1891, the brown tumour is a fibrocystic bone lesion caused by hyperactivity of osteoclasts, as a result of hyperparathyroidism. It is an uncommon complication that can affect the entire bony skeleton, including pelvis, ribs, clavicles and extremities. Involvement of the sphenoidal bone is considered rare, hence the particularity of our case. The brown tumours may be completely asymptomatic or manifest as bone pain or pathological fractures, which was the case of our patient, mimicking a pituitary adenoma.

Familial hyperparathyroidism due to gcm2 gene alteration: a case report

Silvia Patricia Alonso Gallardo[1], Jose Antonio Ariza Jimenez[1] & Maria Martin Rosales[2]
[1]Hospital Universitario Costa del Sol, Endocrinology and Nutrition, Marbella (Málaga), Spain; [2]Hospital Universitario Costa del Sol, Internal Medicine, Marbella (Málaga), Spain

Introduction
Primary hyperparathyroidism (PHPT) is a common cause of hypercalcemia, often linked to parathyroid adenomas, hyperplasia, or, in rare cases, genetic mutations. Lithium therapy, frequently used in bipolar disorder, has been associated with PHPT due to its effects on calcium metabolism. However, distinguishing lithium-induced hyperparathyroidism from primary forms remains challenging. We present a case of PHPT in a lithium-treated patient with an underlying genetic mutation.
Case Report
A 48-year-old woman was referred to our clinic due to an incidental finding of hypercalcemia. She had a medical history of bipolar disorder, treated with lithium for over 10 years. Laboratory tests revealed a corrected calcium level of 11.4 mg/dL (8.3-10.6), phosphorus at 3.7 mg/dL (2.7-4.5), vitamin D at 30.3 ng/mL (20-60), parathyroid hormone (PTH) at 109.5 pg/mL (18.5-88), and 24-hour urinary calcium at 45.9 mg/24h (100-300), with a calcium/creatinine clearance ratio of 0.01. Given the suspicion of PHPT, repeat tests confirmed similar findings. Parathyroid scintigraphy indicated hyperplasia of the left superior and inferior parathyroid glands. Additional tests, including bone densitometry and renal ultrasound, showed no pathological findings. Considering these results, the mental health team evaluated

the feasibility of discontinuing lithium therapy, and genetic testing was performed for potential hereditary causes of PHPT. Despite lithium discontinuation, hypercalcemia persisted. Genetic analysis identified a heterozygous variant in the GCM2 gene, associated with familial PHPT. The patient underwent selective parathyroidectomy of the left superior and inferior glands, leading to normalization of calcium and PTH levels postoperatively.
Discussion
Between 10% and 20% of lithium-treated patients develop hypercalcemia with hypocalciuria and elevated PTH due to reduced parathyroid gland sensitivity to calcium. Typically, calcium levels normalize within months of discontinuing lithium. However, in this case, persistent hypercalcemia suggested an alternative etiology. The identification of a GCM2 gene mutation, a rare cause of familial PHPT, explained the continued hypercalcemia despite lithium cessation. This highlights the importance of genetic testing in cases where standard etiologies do not fully account for clinical findings. Few cases of GCM2-related familial PHPT have been documented, underscoring the need for further research into its pathophysiology and optimal management. This case emphasizes the necessity of a comprehensive approach in evaluating hypercalcemia, particularly in patients on long-term lithium therapy, to differentiate between drug-induced and primary hyperparathyroidism and to consider potential genetic contributions when the clinical course is atypical.

Geriatric patient presenting with severe hypercalcemia due to suspicious parathyroid carcinoma

Natia Shonia[1,2], Natia Margvelashvili[1], Spiridon Sanikidze[1] & Ketevan Chanturishvili[1]
[1]Tbilisi Institute of Medicine, David Tvildiani Medical University, Tbilisi, Georgia; [2]Tbilisi Institute of Medicine, Tbilisi, Georgia

Introduction
Primary hyperparathyroidism is a common endocrine disorder of calcium metabolism characterized by hypercalcemia and elevated or inappropriately normal concentrations of parathyroid hormone. Almost always, primary hyperparathyroidism is due to a benign overgrowth of parathyroid tissue either as a single gland (80% of cases) or as a multiple gland disorder (15–20% of cases). Most of patients with PHPT are asymptomatic, but the symptoms and signs could include nephrolithiasis, osteitis fibrosa cystica, osteoporosis, fractures, bone pain, myopathy, and neuropsychiatric impairment. Primary hyperparathyroidism can be cured by removal of the parathyroid gland or glands but identification of patients who are best advised to have surgery requires consideration of the guidelines that are regularly updated. 1.
Case Report
77 y/o female was hospitalized in our clinic. During hospitalization, performed lab tests revealed significantly elevated serum calcium (x2 ULN) and elevated PTH 20-fold. Thyroid US demonstrated parathyroid tumor suspicious for Cr measuring up to 4 cm and multinodular goiter with total thyroid volume of 25 cm3. During physical examination patient was demonstrating spasticity, lethargy, anxiety, confusion. Patient had a history of ischemic stroke – 2018, PE Arterial hypertension was diagnosed 10 years ago. Patient admitted to have increasing blood pressure findings, renal insufficiency was also diagnosed couple months ago, but no further diagnostic or treatment interventions were initiated. 10 days leading up to hospitalization patient admitted to have had lower and upper extremity tremors. She admits to having these symptoms occasionally. Decreased appetite, severe constipation were also noted. Patient had trouble moving around and was brought in by her family members. Laboratory findings also revealed sublinical hyperthyroidism, suspicious for toxic multinodular goiter. Parathyroidectomy was planned along with the total thyroidectomy. Surgery used intraoperative recurrent laryngeal nerve monitoring device, which revealed low impulse during surgical exploration of parathyroid tumor, instead of additional total thyroidectomy, only subtotal parathyreidectomy was performed considering potential risks associated with recurrent laryngeal nerve compromise.
Conclusion
High level of clinical suspicion and routine laboratory work-up for screening purposes is required for timely diagnosis of hyperparathyroidism. The evaluation and management of patients with parathyroid disease remains challenging, and surgical treatment requires experience and expertise. It's important to perform vertebral and renal imaging in addition to bone desitomety followed by corresponding treatment if required.

A case of primary hyperparathyroidism due to an oxyphil cell adenoma

Ghachem Aycha[1], Imen Halloul[1], Wiem Saafi[1], Nassim Ben Hadj Slama[1], Hamza Elfekih[1], Ach Taieb[1] & Ghada Saad[1]
[1]Farhat Hached University Hospital, Endocrinology - Diabetology Departement, Sousse, Tunisia

Introduction
Oxyphil cell parathyroid adenoma were defined as parathyroid tumours containing >75% oxyphilic. They are considered to be an uncommon cause of primary hyperparathyroidism, and were historically thought to be clinically silent cells because they were believed to involuted. Recently these adenomas present more often than previously thought and may manifest a more severe form of primary hyperparathyroidism than classical adenoma. We report the case of a parathyroid adenoma with oxyphilic cells responsible of primary hyperparathyroidism
Observation
This is a 57-year-old patient with a history of fracture of the left foot, who presented with incidentally discovered hypercalcaemia at 2.71 mmol/l. The work-up showed hypophosphaemia at 0.7 mmol/l, hypercalciuria at 7.3 mmol/24h, associated with PTH at 186 pg/ml, with no detectable repercussions. The indication for surgery was based on the presence of a fracture and hypercalciuria. The localised work-up showed a left lower parathyroid adenoma fixed on sestamibi scintigraphy, not visualised on cervical ultrasound. The patient underwent a simple post-operative course, and the patho-anatomical examination concluded that it was an oxyphilic cell adenoma of the left lower parathyroid gland. Post-operative serum calcium was 2.32 mmol/l and serum phosphorus 1 mmol/l.
Conclusion
Oxyphil cell parathyroid are an uncommon cause of primary hyperparathyroidism. Functional oxyphil adenomas occur more frequently than is usually appreciated. Their role still remains controversial, Nevertherless, they could play an important role in hormone secretion.

Imaging in X-linked hypophosphataemia (XLH)

Rui Miguel Santos[1] & Alessandra Cocca[2]
[1]Evelina London Children's Hospital, Guys and St Thomas NHS Foundation Trust, Department of Paediatric Radiology, London, United Kingdom; [2]Evelina London Children's Hospital, Guys and St Thomas NHS Foundation Trust, London, Department of Paediatric Endocrinology and Diabetes, London, United Kingdom

Summary
X-linked hypophosphataemia (XLH) is a rare metabolic bone disorder where mutations in the PHEX gene lead to increase circulation of hormone fibroblast growth factor 23 (FGFR23), causing a series of clinical manifestations including rickets, lower-limb deformity, short stature, craniosynostosis, Chiari 1 malformations, spinal stenosis, pseudo fractures and osteoarthritis, among others, with significant impact to the patient's quality of life. Imaging plays an important role in XLH from diagnosis to treatment response, early detection and management of complications. We present a comprehensive pictorial review of different imaging modalities used in our cohort of patients including x-rays, ultrasound, CT, MRI, bone scan and SPECT. We illustrate the most common findings seen at different stages of the disease and explain the advantages vs disadvantages of each imaging modality dependent on the clinical question posed for children and adults.
Methods
We searched the imaging database in our institution and found 42 patients with ages ranging from 3 to 78-years (20 under 16y) reviewed their imaging and selected the ones which best illustrate the findings seen at different stages of the disease including at diagnosis, during treatment response, and evidence of compilations. For some of the abnormalities we provide companion images depicting both normal appearances and the range of specific manifestations seen in non-XLH patients (e.g. grades of nephrocalcinosis) to facilitate a better understanding of the imaging findings.
Objectives
Know the available imaging toolbox and how to use it in XLH, from diagnosis to treatment response, including identification of complications, both in children and adults.

Primary hyperparathyroidism: from diagnosis to treatment

Rachida Bouattay[1], May Ferjani[1], Sabrina Farhani[1], Khaled Harrathi[1] & Jamel Koubaa[1]
[1]ENT and Head and Neck Department, University Hospital of Fattouma Bourguiba, Monastir, Tunisia

Introduction
Primary hyperparathyroidism (PHPT) is the leading cause of hypercalcemia. It is secondary to hypersecretion of parathyroid hormone (PTH) by the parathyroid glands. Today, PHTP is asymptomatic in 80–90% of cases. The aim of this work is to analyze the clinical, paraclinical and therapeutic profile of primary hyperparathyroidism (PHTP).
Materials and Methods
This is a retrospective study that collected 49 patient files followed for PHTP in our department, over a period of 5 years from 2016 to 2023.
Results
There were 16 men and 33 women (sex ratio = 2.3), the average age was 58 years (27 and 88 years). The circumstances of discovery were: bone pain in 83% of cases, hypercalcemia in 69% of cases and asthenia in 11% of patients. Biology showed a mean calcemia at 2.66 mmol/l (2.5 – 3.4). The mean value of parathyroid hormone was 386 pg/l. Vitamin D was measured in 16 patients; 71% of them had hypovitaminosis D. Imaging (cervical ultrasound and MIBI scintigraphy) showed a hypoechoic mass opposite the thyroid pole with a lower left location in 67% of cases. Symptomatic treatment of hypercalcemia was associated with surgical treatment in all cases. The mean value of postoperative calcemia was 2 mmol/l with a mean PTH value of 20 pg/l. The anatomopathological study concluded a parathyroid adenoma in 83%, parathyroid hyperplasia and an atypical adenoma in 10% of cases and a parathyroid carcinoma in 6% of cases.
Conclusion
Surgical management of the hyperfunctioning parathyroid gland(s) is the only curative treatment for HPTP. Medical management concerns patients for whom surgery is not indicated, who present a surgical contraindication or who refuse surgery. The diagnosis of HPTP warrants contact with an endocrinologist to ensure its management.

Demystifying an unusual culprit and analyzing implications for management: a case of lithium-induced parathyroid hyperplasia presenting as severe symptomatic hypercalcemia

Carlo Casipit[1], Bruce Casipit[1] & Maxim Barnett[1]
[1]Jefferson-Einstein Hospital, Philadelphia, United States

Background
Lithium remains one of the most effective treatments for bipolar disorder and has been associated with the development of hyperparathyroidism. Even experienced physicians can be perplexed when caring for such patients since there is a paucity of data regarding the management of lithium-induced hyperparathyroidism.
Case presentation
A 33-year-old female with bipolar disorder who is on long-term Lithium treatment presented to the hospital with a three-day history of tremors, nausea, vomiting, and constipation. She denied any fever, vision changes, hematuria, abdominal or flank pain. Vital signs were normal. Physical examination was only remarkable for fine tremors. Laboratory tests showed a serum Creatinine of 1.7mg/dL (baseline 0.5mg/dL), corrected Calcium 12.6 mg/dL (ref 8.5-10mg/dL), PTH 153 pg/mL (ref 15-65pg/mL), Phosphate 0.8 mmol/l (ref 0.8-1. 45mmol.L), 1,25 dihydroxy Vitamin D 83pg/mL (ref 18-78 pg/mL), 24-hour urinary calcium 410 mg/day (ref 100-300mg/d), Lithium level 3.1mmol/l (ref 0.5-1.2mmol/l), EKG showed a normal QTc. The endocrinology team was consulted, and the patient was started on fluids, calcitonin, cinacalcet, and pamidronate, which lowered her calcium level. Lithium was discontinued, and Valproic acid was started as an alternative. However, she had a relapse of mania during hospitalization. Psychiatry suggested restarting Lithium while continuing medical treatment for hypercalcemia. Parathyroid technetium 99m Sestamibi-CT scan showed findings of parathyroid hyperplasia and the patient deferred surgery. She was later discharged with strict outpatient Endocrinology and Psychiatry follow-up.
Discussion
Lithium alters the set point of calcium-sensing receptors in the parathyroid cells, causing increased PTH release and elevation of the calcium threshold required to suppress PTH. It affects the Wnt/B catenin pathway, causing parathyroid growth. A trial of Lithium dose reduction, discontinuation, or switching to other mood stabilizers can be attempted; however, it is associated with relapse of the mood disorder in patients on chronic lithium. Cinacalcet, which sensitizes calcium-sensing receptors, can be used while on Lithium with close monitoring of calcium levels. Parathyroidectomy can be considered for non-responders and the treatment of choice for patients who develop parathyroid adenoma.
Conclusion
Lithium-induced hyperparathyroidism is a rare complication of long-term lithium therapy. Individualized patient education regarding the risks and benefits of Lithium continuation, medical and surgical options, and the importance of a multidisciplinary follow-up with regular calcium and PTH monitoring at least every 6 months.

Two different causes of hypercalcemia

Eva Perle[1] & Iveta Dzivite-Krisane[2]
[1]Children's clinical university hospital, Riga, Latvia; [2]Riga Stradins University, Children's clinical University Hospital, Riga, Latvia

Hypercalcemia is not common among children, actual incidence in children is unknown. Although vitamin D intoxication is rare, the health effects can be serious if it is not promptly identified.

1st patient:

Blood tests	Results	Reference interval
Ca (mmol/l)	**4.43**	2.2-2.7
P (mmol/l)	1.46	0.95-1.75
25(OH)vit D (ng/ml)	**525**	30-50
PTH (pg/ml)	**1.8**	15-68
Hb (g/dl)	10.7	10.7-13.4
Creatinine umol/l	**43**	21-36

A 2 years old boy – previously healthy, presented with 2 week history of nonspecific symptoms: fatigue, poor apetite, weight gain, constipation. 1st child, 41.g.w., 3.7kg. Weight 9.4kg (-2.5SD), height 86cm (-1SD), HR 150x/min, BR 26x/min, BP 85/60 mmHg.

- Additional examination: ECG- short QTc complex, ST segment depression, Echocardiogram- normal, Kidney ultrasound – normal.
- Upon detailed questioning, the mother admitted that child receives 1000-2000 units of vitamin D daily, additionally consumes 200ml of adapted formula, as well 200-400ml of sweetened milk with added vitamin D. Total dose of vitamin D – 2600 IU/daily, long term.
- Treatment: i/v hydration + loop diuretics for 10 days, + p/o prednisolone (from 7th-10th day).

After 3 month with low calcium diet, discontinuation of vitamin D supplementation - Ca 2.38 mmol/l (N), 25(OH)D 87.3 ng/ml (N).

2nd patient:

Blood tests	Results	Reference interval
Ca (mmol/l)	**3.43**	2.2-2.7
P (mmol/l)	1.26	0.95-1.75
25(OH)vitaminD (ng/ml)	**154.2**	30-50
PTH (pg/ml)	**13.1**	15-68
Hb (g/dl)	11.2	10.7-13.4
Creatinine (umol/l)	**83**	21-36

A 2 years 2 month old boy – previously healthy, complains about ataxia, vomiting (5x), fatigue. 1st child, 41.g.w. 3.8kg. Weight 14.3 kg (+0.5SD), height 90.8cm (0SD) HR 125x/min, BR 24x/min, BP 94/58-**143/93mmHg**

- Additional examination: Fundus oculi – normal CT, MR cerebellum – normal Kidney ultrasound – **nephrocalcinosis.**ECG, echocardiogram- normal.
- Patient receives 400-800 units of vitamin D daily.
- Genetic testing: CYP24A1 gene biallelic mutation.
- Treatment: i/v hydration + loop diuretics 8 days, hydrocortison 7 days. ACE inhibitor- long-term.

The presence of CYP24A1 mutation explains the increased sensitivity to vitamin D in patients with idiopathic infantile hypercalcemia, it is genetic risk factor for development of symptomatic hypercalcemia that may be triggered by vitamin D prophylaxis in otherwise healthy infants.
Conclusions
Nonspecific symptoms like vomiting, constipation, hypertension may be sign of hypercalcemia in children. Symptomatic hypercalcemia is rare in children and requires extensive investigation.

Osteoporosis at a young age: an issue for endocrinologists – a case report

Austė Gintilaitė[1], Andra Kerševičiūtė[2], Radvilė Matukaitienė[1,2] & Birutė Žilaitienė[1,2]
[1]Lithuanian University of Health Sciences, Kaunas, Lithuania; [2]Hospital of Lithuanian University of Health Sciences Kaunas Clinics, Clinic of Endocrinology, Kaunas, Lithuania

Introduction
Bone loss in younger gynecologic cancer survivors occurs prematurely, sometimes decades before routine age-based osteoporosis screening in the general population. Data regarding bone loss management in this group of patients are generally lacking, especially in ovarian cancer survivors.
Case
A 31-year-old female was referred to an endocrinologist regarding the treatment strategy for osteoporosis. The medical history was clarified: in 2014, she was diagnosed with stage 3 ovarian cancer (G1 serous carcinoma). Laparotomy, total hysterectomy with adnexectomy, omentectomy, peritonectomy in the minor pelvic region and diaphragm, and paraaortic lymphadenectomy were performed, followed by six cycles of Paclitaxel/Carboplatin chemotherapy in the same year. Due to a BRCA2 gene mutation revealed by genetic testing, the usual choice of hormone replacement therapy (HRT) was not applied. She was monitored for oncologic recurrence and osteoporosis development. The patient was regularly followed up by the endocrinologist, with observation of Ca-P metabolism tests, bone markers (BAP, CTX), and DXA changes. DXA results presented progression from osteopenia in 2015 (spine: T-1,22; 1,033 g/cm2) to osteoporosis in 2023 (T-3,6; 0,741 g/cm2). The patient was discussed in the Reproductive Health MDT: there are no clear contraindications for prescribing HRT in the presence of a previous oncological disease and the BRCA2 gene mutation. The BRCA2 gene mutation increases the risk of breast cancer in postmenopausal women; however, there is no data indicating an increased risk at a younger age. At this stage, was recommended to prescribe HRT for at least one year, and if osteoporosis continues to progress or osteoporotic fractures occur earlier, bisphosphonates should be prescribed.
Conclusion
This case highlights the challenging management of osteoporosis in young cancer survivor and the necessity of MDT when facing a clinical situation with no strong clinical evidence and treatment guidelines.

Adrenal glands, pancreas, and urinary catheter calcifications in a 59-year-old woman with primary hyperparathyroidism

Emna Naccache[1], Elyes Kamoun[1], Feryel Belyfa[1], Chayma Bel haj Slimane[1], Mariem Yazidi[1], Fatma Chaker[1] & Melika Chihaoui[1]
[1]La Rabta Hospital, Endocrinology Department, Tunis, Tunisia

Introduction
Primary hyperparathyroidism is endocrine disease defined by increased calcium levels and excessive level of parathyroid hormone, associated with diverse systemic complications. Most common are urinary lithiasis and osteoporosis, but calcification of soft tissue are more rarely found.
Case Presentation
A 59-year-old woman, was admitted to the hospital for surgical treatment of primary hyperparathyroidism revealed by pathologic fracture. The diagnosis of primary hyperparathyroidism was confirmed based on calcium level of 3.53 mmol/l, inappropriate PTH level of3708 ng/dL, and hypercalciuria at a level of0.15 mmol/kg/24h, complicated by severe osteoporosis with a T-score of -6.6. A right 22mm parathyroid adenoma was found by neck ultrasound and parathyroid scintigraphy. Kidney scan showed calculi in the urinary tract, along with pancreatic and adrenal calcifications, which are known and uncommon soft-tissue calcification associated with hyperparathyroidism. She didn't have adrenal insufficiency, and there was no sign of tuberculosis. During her hospital stay, the patient's urinary catheter was found to have calcified deposits which was relatedwith significant hypercalciuria. This is a rare but notable manifestation of PHPT, highlighting the impact of prolonged elevated calcium levels on the urinary system.
Disscussion and conclusion
This particular case demonstrates the variety of complications that primary hyperparathyroidism can cause, some of which may be unexpected. While hypercalcemia and osteoporotic fractures are common manifestations of PHPT, calcifications in the adrenal glands, pancreas, and urinary catheter are less prevalent but nonetheless important to recognize. In some cases of PHPT, calcifications have been observed, particularly in the pancreas and adrenal glands. These calcifications are the result of the long-term impact of high calcium and PTH levels on various organs. Urinary catheter calcification is uncommon but can happen as a result of high calcium levels in the urine, particularly when hypercalciuria is present. To avoid serious problems, early surgical intervention and calcium metabolism monitoring are essential. Additionally, since PHPT can present with a variety of clinical symptoms, such as fractures and unusual calcifications, it highlights the importance of being vigilant in the diagnosis process.

An intrathyroidal parathyroid adenoma: a location not to be ignored!

Rachida Bouattay[1], Linda Misbah[1], May Ferjani[1], Khaled Harrathi[1] & Jamel Koubaa[1]
[1]ENT and Head and Neck Department, University Hospital of Fattouma Bourguiba, Monastir, Tunisia

Introduction
Primary hyperparathyroidism is a common endocrine pathology, explained in the majority of cases by the presence of a parathyroid adenoma, located in the cervical region. Intrathyroid localization of the parathyroid adenoma is rare and can be a cause of failure of surgical treatment. We report a case of intrathyroid parathyroid adenoma.
Observation
This is a 72-year-old patient, diabetic hypertensive, admitted for management of hypercalcemia discovered during the exploration of diffuse joint and bone pain. The etiological and impact assessment showed corrected calcemia at 2.8 mmol/l, hypophosphatemia, hypovitaminosis D at 14.2, and parathyroid hormone at 494 pg/ml. The cervical ultrasound showed a thyroid nodule of 33x17 mm classified EUTIRADS III. SPECT-CT objectified an intralobar nodule intensely fixing the MIBI. An *in situ* PTH dosage was performed returning 9698 pg/ml. The patient had oral hydration, and a right loboisthmectomy. The intraoperative frozen section and final histological examination confirmed the intrathyroidal localization of a parathyroid adenoma. The evolution was favorable with normalization of calcemia and PTH in the postoperative period.
Conclusion
Parathyroid ectopia is one of the causes of failure of surgical treatment of hyperparathyroidism. Intrathyroid localization must not be overlooked in order to successfully perform surgery for hyperparathyroidism. The current therapeutic strategy aims at preoperative identification of pathological parathyroid glands that combines data from cervical ultrasound, MIBI-Tc99m scintigraphy and exploratory cervicotomy.

Palopegteriparatide use for severe postoperative hypocalcemia

Mirna Hrabar[1], Ana Matijaca[1] & Vlatka Pandzic Jaksic[1]
[1]University Hospital Dubrava, Department of Endocrinology, Diabetes, Metabolic Diseases and Clinical Pharmacology, Zagreb, Croatia

Introduction
Hypocalcemia can occur as a complication of total thyroidectomy. In this context, postoperative hypoparathyroidism is due to accidental removal, damage or devascularization of the parathyroid glands. Hypocalcemia can also occur as part of hungry bone syndrome (HBS) in patients who have previously had long-standing hyperthyroidism, as it causes increased bone turnover with overall bone resorption, which then transitions to osteoblastic activity once the excess hormone is eliminated.
Case report
A 26-year-old woman underwent total thyroidectomy for long-standing Graves' disease with concomitant orbitopathy. Postoperatively, she developed hypocalcemia. She was discharged from the ENT department with calcium carbonate 6 g daily and calcitriol 3 mg daily. She did not show up for endocrinology follow-up

as scheduled. One month after surgery, she was hospitalized because of severe symptomatic hypocalcemia (paresthesias, abdominal cramps, positive Trousseau's and Chvostek's signs). Laboratory findings revealed an unmeasurably low PTH level, severe hypocalcemia (total calcium 1.3 mmol/l, ionized 0.47 mmol/l), hypomagnesemia (0.54 mmol/l) and hyperphosphatemia (2.4 mmol/l). These findings were primarily suggestive of iatrogenic (postoperative) hypoparathyroidism, but likely with concomitant HBS aggravating hypocalcemia, as the patient had severe long-standing hyperthyroidism prior to surgery. Persistent symptomatic hypocalcemia despite treatment necessitated transfer to the ICU, where she received intravenous calcium chloride as a continuous infusion, magnesium sulfate, and further dose adjustments of calcitriol, calcium carbonate and cholecalciferol were made. The targeted calcium levels could not be achieved, so teriparatide was initiated in two daily doses together with other medications. A short time later she was switched to palopegteriparatide 18 mg subcutaneously daily. Satisfactory calcium levels were maintained and the patient was discharged on the following daily doses: calcitriol 3 mg, calcium carbonate 12 g and palopegteriparatide 18 mg. Over the next few months, calcium levels were maintained with only minor adjustments to the above therapy. The patient stopped coming for regular check-ups and stopped taking the medications regularly. Inadequate adherence to therapy led to severe hypocalcemia (this time asymptomatic) and she was hospitalized. Satisfactory calcium levels were achieved and maintained by adjusting calcium and vitamin D supplementation alone, without PTH replacement therapy.

Conclusion

Palopegteriparatide can serve as a bridging therapy in patients with severe hypocalcemia due to hypoparathyroidism and HBS after total thyroidectomy for Graves' disease in the period when satisfactory serum calcium levels cannot be maintained with high doses of calcium and vitamin D supplementation.

Dermatological disorders associated with hypocalcaemia: a case report

Rania Dassoufi[1], Sidiebatt Amar[1], Sana Rafi[1], Ghizlane El Mghari[1] & Nawal El Ansari[1]
[1]Mohamed 6 University Hospital of Marrakech, Endocrinology-Metabolic Diseases-Nutrition Department, Marrakech, Morocco

Introduction

Chronic hypocalcaemia is associated with several dermatological disorders, which may take a variety of symptomatic forms. Our case report illustrates this association.

Case report

A 68 years old women who underwent thyroidectomy 10 years ago, was admitted for aetiological assessment of hyperkeratotic, scaly generalized lesions on an erythematous background evolving for 6 months in a context of altered general condition. The anamnesis reported constipation with frilosity and generalised paresthesias, with no other signs. Clinical examination revealed a fever of 38°C and the dermatological lesions described above, associated with diffuse pachyonychia, with positive schvostek more marked on the right side. The work-up revealed a neutrophil cells increase correlated with a rise in the CRP up to 300 mg/l and the sedimentation rate up to 113 mm/h, associated with severe hypocalcaemia to 54 mg/l. The suspicion of psoriasis was strongly supported on the basis of the above, and confirmed by biopsy. Patient was under levothyroxine with adjustement, associated with intravenous and oral correction of blood calcium levels. Dermatologically, a local emollient treatment was initiated. The course was marked by remarkable clinico-biological improvement.

Discussion

The acute response of the keratinocyte to calcium resembles that of the parathyroid cell. Overall, hypocalcaemia will affect keratocyte differentiation and give rise to a binding defect that can be seen in most desquamative and hyperkeratotic dermatological diseases such as psoriasis and pustulosis. As in our patient's case, it can lead to new or worsening conditions. However, what characterises the dermatological lesions associated with hypocalcaemia is their remarkable evolution after correction of the triggering or aggravating hypocalcaemia. The majority of studies note the beneficial effect of calcium and vitamin D supplementation in the healing process, even in cases of normocalcaemia.

A falsely labeled primary hyperparathyroidism: about a case report

Malak Riznat[1], Siham Malki[1] & Guerboub Ahmed Anas[1]
[1]Hopital Militaire Mohamed V Rabat, Rabat, Morocco

Introduction

Primary hyperparathyroidism is a common pathology, with diagnosis based mainly on biological parameters alone. Localization should only be performed if surgery is indicated. We report a case of MAX syndrome mistaken for primary hyperparathyroidism in the presence of a parathyroid adenoma.

Case report

A 64-year-old postmenopausal woman with 7 years' postmenopausal history, no personal or family history of lithium or thiazide diuretic use, consulted an endocrinologist for a parathyroid incidentaloma. The initial work-up revealed a biological profile of elevated calcemia (108 mg/l), elevated PTH (2 times normal) and hypophosphatemia, raising the initial suspicion of primary hyperparathyroidism without prior measurement of 24-hour calciuria. Given the presence of osteoporosis at bone mineral density, surgery was indicated. Subsequently, a 24 h calciuria was performed, which came back collapsed with a urinary calcium fraction lower than 0.01, thus rectifying the diagnosis of familial hypocalciuric hypercalcemia.

Discussion and conclusion

Marx syndrome or familial hypocalciuric hypercalcemia (FHH) is a genetic disorder caused by mutation of the calcium-sensitive receptor (CASR) gene, resulting in decreased receptor activity in response to serum calcium levels. This pathology is the first differential diagnosis to be ruled out before considering primary hyperthyroidism. The decisive biological element between these two entities is urinary calcium excretion over 24 h, with a ratio of calcium clearance to creatinine clearance of less than 0.01, indicating FHH. The coexistence of FHH and a parathyroid incidentaloma is possible, as in our case, and this is why imaging should always come last after establishing a diagnosis of primary hyperpathyroidism.

Primary hyperparathyroidism meets fibromyalgia: a crossroads of symptoms

Yesmine Elloumi[1], Fedia Boubaker[1], Houcem Elomma Mrabet[1], Najoua Lassoued[1], Baha Zantour[1], Alaya Wafa[1] & Habib Sfar[1]
[1]Taher Sfar University Hospital, Mahdia, Tunisia

Background

Fibromyalgia is a chronic diffuse pain syndrome characterized by widespread musculoskeletal pain, chronic fatigue, and sleep disturbances. These symptoms overlap with those commonly observed in hyperparathyroidism, a condition that may also present with neuropsychiatric and musculoskeletal complaints. Understanding the interplay between these two conditions could provide valuable insights into their pathophysiological mechanisms and diagnostic challenges.

Case Report

We present the case of a 49-year-old woman with a history of treated breast carcinoma, admitted to the endocrinology department for evaluation of hypercalciuria. The patient exhibited anxiety, irritability, and a focus on multiple somatic complaints, including asthenia, headaches affecting sleep quality, diffuse muscle pain, fatigue, and morning stiffness. She reported an exacerbation of pain with heat and stress, although her appetite remained intact. Symptoms persisted despite treatment with non-steroidal anti-inflammatory drugs and antidepressants. The patient underwent multiple specialist consultations, and a brain MRI revealed nonspecific white matter hyperintensities. Clinical examination identified 11 tender points out of 18 according to the American College of Rheumatology (ACR) criteria, leading to a diagnosis of fibromyalgia. Further investigations suggested a likely diagnosis of normocalcemic primary hyperparathyroidism, supported by a serum calcium level of 2.44 mmol/l, a phosphate level of 0.7 mmol/l, an inappropriately elevated parathyroid hormone (PTH) level of 166.60 pg/mL and a urinary calcium excretion of 11.22 mmol/24h. Neck ultrasound revealed a left parathyroid nodule measuring 10 × 7 × 2 mm, and bone densitometry confirmed osteoporosis. Other potential causes of hypercalciuria, such as granulomatous diseases, were ruled out.

Conclusion

The diagnosis of fibromyalgia is frequently delayed, leading to a significant socio-economic burden due to prolonged symptomatology and repeated medical consultations. In this case, the coexistence of fibromyalgia and hyperparathyroidism underscores the importance of a thorough diagnostic approach to unexplained chronic symptoms. Further research is essential to clarify the potential pathophysiological connections between these two conditions and optimize patient management.

ENT manifestations of the relapsing polychondritis (RP) in diabetic patients

Amal Chakroun[1], Nawres Bouaziz[1], May Ferjani[1], Mehdi Farjaoui[1], Rachida Bouatay[1], Nawres Kolsi[1], Amel Korbi[1], Kamel Harrathi[1] & Jamel Koubaa[1]
[1]Fattouma Bourguiba Hospital, ENT Departement, Monastir, Tunisia

Introduction
Relapsing polychondritis (RP) is a rare inflammatory systemic disease mainly affects cartilage, and describes several ENT manifestations.
Aim
To describe the clinical and evolutionary particularities, in diabetic patients with autoimmune polychondritis, and their therapeutic management.
Objectives
The patient was 80 years old, with a history of diabetes. He presented to our emergency department with a swelling of the right auricle that had been evolving for 3 days in a context of apyrexia, associated with vertiginous attacks, bilateral hypoacusis evolving for years, and chronic dysphonia. Examination revealed swelling, warmth, redness and pain over the right auricle. The external auditory canal was well calibrated, with a free mastoid region. A peripheral vestibular syndrome was noted, and the nasofibroscopy showed a laryngeal pseudomyxoma. A biological inflammatory syndrome was noted. the patient was initially put on intravenous antibiotic therapy for 15 days without any improvement, with worsening of the affected area and fistulization to the skin. A microbiological sample showed the presence of pseudomonas aeruginosa and antibiotic therapy was set according to the antibiogram. A cervicothoracic CT was performed in search of respiratory tract chondritis, which came back normal. The progression was complicated by sepsis, followed by infectious endocarditis, requiring a transfer to cardiology, for further treatment. During hospitalization in the cardiology department, The patient developed perichondritis of the contralateral ear, internal medicine was consulted to investigate a possible RP in a diabetic patient, with a series of additional exams enabling us to confirm RP.
Conclusion
It's important to know how to recognize RP, because a delay can lead to severe complications. Diagnosis is clinical and may be supported by biopsy and response to treatment.

The phantom hormone: decoding bone loss in a breast cancer patient

Ioana Armasu[1], Ioana Adumitresei[2], Ioana Vasiliu[3], Letitia Leustean[1], Maria Christina Ungureanu[1] & Cristina Preda[1]
[1]University of Medicine and Pharmacy "Grigore T Popa", Endocrinology, Iasi, Romania; [2]University of Medicine and Pharmacy "Grigore T Popa", Iasi, Romania; [3]University of Medicine and Pharmacy "Grigore T Popa", Physiology, Iasi, Romania

Background
Women who have had breast cancer treatment may have an increased risk of osteoporosis and fracture. Moreover, breast cancer might have complications like distant metastases accompanied by hypercalcemia and high alkaline phosphatase levels, but hyperparathyroidism is not commonly considered in the differential diagnosis.
Case Presentation
We present the case of a 62-year-old female, with medical history of breast cancer (2013, right breast conservatory surgery, subsequent radiotherapy and 5 years of hormonal treatment with Tamoxifen), with no tumor recurrence detectable at yearly oncology assessments, is referred to an endocrinology consult due to persistent elevated alkaline phosphatase and severe osteoporosis with lowest bone mineral density (BMD) at distal radius level (T-score of -4 SD), compared to lumbar spine (T-score L1-L4 of -2.7 SD) and hip (T-score femoral neck of -2.7 SD). Causes of secondary osteoporosis were investigated detecting elevated PTH (104 pg/ml, N:10-69), normal 25-OH-vitamin D (64.1 ng/ml, N > 30, under adequate vitamin D supplementation 4000-5000IU/day), mild hypercalcemia (10.33mg/dl, N:8.5-10.3), hypercalciuria (398.4 mg/24h, N < 250), normal phosphatemia (3.67 mg/dl, N:2.6-4.5). Considering vitamin D was above 40-50ng/ml, and PTH is its end-activator (by renal hydroxylation) potentially increasing hypercalcemia, we decided to stop vitamin D supplementation until investigations were completed. Cervical ultrasound identified normal thyroid gland, but a small hypochoic nodule 6.3 mm localized in the lower pole of the left thyroid lobe confirmed a parathyroid adenoma by parathyroid scintigraphy. The functional and imaging data confirmed the diagnosis of primary hyperparathyroidism, and a 3-month biological follow-up spontaneous improvement was observed: PTH of 83.32 pg/ml, 25-OH-vitamin D maintained within normal range 31.56 ng/ml, normal calcium levels (total calcium of 9.8mg/dl), normal phosphatemia.
Conclusions
We presented the case of a woman diagnosed with severe osteoporosis seven years after a breast cancer diagnosis, associating persistent elevated alkaline phosphatase levels in the absence of detectable local or distal tumor recurrence, which proved to be in the context of primary hyperparathyroidism.

Pseudohypoparathyroidism 1b diagnosed in middle adulthood with an atypical presentation: a case report

Guillermo SErra Soler[1], Alicia Sanmartín Sánchez[1], Andreu Campos Peris[1], Ramón Zafra Jiménez[1], Santiago Tofé Povedano[1] & Iñaki Argüelles Jiménez[1]
[1]Universitary Son Espases Hospital, Endocrinology, Palma De Mallorca, Spain

Introduction
Pseudohypoparathyroidism (PHP) refers to a group of heterogeneous disorders defined by targeted organ unresponsiveness to PTH characterized by endocrine abnormalities (hypocalcemia, hyperphosphatemia and elevated PTH concentrations), abnormal physical characteristics and neurocognitive deficits. The are several types: type 1 PHP (1a, 1b, 1c), type 2, pseudo-pseudohypoparathyroidism, and other forms (acrodysostosis)
Case report
A 45-year-old man was referred to the endocrinology department from orthopaedic department due to an elevated PTH concentration in the blood test (1,385 pg/mL) with normocalcaemia, normophosphatemia, normal creatinine, and low 25-(OH) vitamin D after a fall with damage in the right forearm.. The x-ray showed a lytic lesion in the epiphysis of radius, another in the metacarpus of the third finger and brachydactyly. The biospy showed a benign lesion with giant cells (giant cell granuloma). A bone gammagraphy showed other lesions in the knees, shinbone and tarsus suggestive of brown tumors. A bone densitometry showed a Z-score -2.8 at the spine and -2 at the hip. The 24-hour urine calcium was normal. He had hypothyroidism diagnosed ten years ago and suffered a fracture of his left ankle fifteen years ago. He was taking levothyroxine and 25-(OH) vitamin D supplements. His height was 173 cm and his weight 82 Kg. He had peculiar facial features and hands. He did not have children. Therefore, we suspected a PHP and we requested a genetic test, a complete hormonal test and started treatment with calcitriol. The genetic test was compatible with PHP type 1b, with a loss of methylation in GNAS A/B located within the differentially methylated region (DMR1) in the GNAS complex locus. No other hormonal abnormalities were found A bone densitometry performed nine months later showed an improvement in the Z-score: Z-score -1 at the spine and -1.7 at the hip. The dose of calcitriol was increased up to two micrograms/day to maintained the PTH levels (111 pg/mL) at the upper level of normal range (28-115 pg/mL)
Conclusions
It is important an early diagnose and treatment in patients with PHP to avoid long-term bone damage and perform genetic counseling Calcitriol is an effective and safe treatment in normocalcaemic patients with PHP like ours

Hypercalcemia as the initial manifestation of sarcoidosis: a case series

Lina Eltayieb[1], Edward Lau[1], Roshan Shrestha[1], Bashir Mahamud[1], Ayesha Awan[1], Furhana Hussein[1], Naing myoaung[1], Dalya Sadulah[1], Sumaiya Khalil[1], Mariana Dram[1], Min Sun[1], Belayet Hossain[1] & Gideon Mlawa[1]
[1]Barking, Havering And Redbridge University Hospitals Nhs Trust, Endocrinology and Diabetes, London, United Kingdom

Introduction
Sarcoidosis is a multi-system granulomatous disorder that can present with hypercalcemia, renal impairment, and other systemic manifestations. Hypercalcemia in sarcoidosis results from the overproduction of 1,25-dihydroxyvitamin D by activated macrophages within the granulomas. Here we present a case series on three patients diagnosed with sarcoidosis over the past 10 years in our trust.
Case Presentations
Case 1:A 37-year-old male presented with weight loss, fatigue, nausea, polyuria. Initial investigations revealed hypercalcemia (4.06mmol/l) and acute kidney injury (AKI) with elevated creatinine (315µmol/l). Computer tomography (CT) imaging was suggestive of sarcoidosis, and an elevated ACE level (220 IU/l) supported the diagnosis. Biopsy of left inguinal lymph nodes confirmed non-necrotizing granulomas. The patient was treated with intravenous fluids, bisphosphonates, and prednisolone, leading to improvement in hypercalcemia (2.45mmol/l) and renal function (creatinine 105µmol/l). **Case 2:**A 38-year-old male with sarcoidosis presented with hypercalcemia (3.4mmol/l) and AKI while on long-term prednisolone. Whilst CT-imaging showed bilateral mediastinal and hilar lymphadenopathy consistent with sarcoidosis, biopsies of these did not show granulomatous changes. ACE levels (92.8 IU/l) were elevated, supporting the diagnosis of sarcoidosis, despite the lack of granuloma formation on biopsy. Treatment with intravenous fluids and pamidronate, followed by prednisolone therapy, resulted in clinical and biochemical improvement. **Case 3:**A 63-year-old female with a 19-year history of sarcoidosis presented with persistent hypercalcemia (3.46mmol/l), muscle weakness, and polyuria, despite ongoing steroid therapy. CT-imaging showed no active granulomatous disease or malignancy, and the patient's complex medical history, including chronic kidney disease and atrial fibrillation, complicated the management. The patient's recurrent hypercalcemia was managed with bisphosphonates, which showed slight improvement in calcium levels.
Discussion
Sarcoidosis remains an important differential for hypercalcaemia and all patients should receive full body CT-imaging to guide further investigations and management including site for tissue biopsy. Whilst corticosteroids remain the cornerstone of treatment for sarcoidosis, these cases highlight the role of adjunct therapy including bisphosphonates in the management of the hypercalcaemia. These were sufficient to resolve associated complications including impaired renal function secondary to nephrocalcinosis and interstitial nephritis.
Conclusion
This case series highlights the complexities in diagnosing and managing sarcoidosis-related hypercalcemia. Clinicians should maintain a high index of suspicion for sarcoidosis in patients presenting with unexplained hypercalcemia and renal dysfunction, particularly when other causes such as malignancy have been excluded. It also reinforces the importance of early recognition and a multidisciplinary approach involving nephrology, endocrinology, and respiratory medicine to optimize patient outcomes.

A case report: COL1A1 mutation with albright hereditary osteodystrophy (AHO) features

Ratikorn Chaisiwamongkol[1], Pattata Wiromrat[1] & Khunton Wichajarn[1]
[1]Khon Kaen University, Pediatric, Khon Kaen, Thailand

This case report outlines the clinical presentation, diagnostic journey, and treatment response of a 21-year-old female initially referred at age 6 with recurrent fractures. Genetic testing confirmed a COL1A1 mutation commonly associated with osteogenesis imperfecta (OI), but the patient also exhibited features suggestive of Albright Hereditary Osteodystrophy (AHO). Whole genome sequencing ruled out GNAS mutation, prompting a discussion on the phenotypic spectrum of COL1A1 mutations.

Waddling gait and parathyroid adenoma: what to have in mind for a quick diagnosis?

Merita Emini Sadiku[1,2,3], Zana Vela Gaxha[1,2], Granit Xhiha[4], Adem Rama[1], Nadije Morina Kuci[2] & Ardiana Perjuci Begolli[2]
[1]University of Prishtina "Hasan Prishtina", Medical Faculty, Clinic of Endocrinology, Prishtina, Kosovo, Prishtina, Kosovo; [2]University Clinical Center of Kosova, Clinic of Endocrinology, Prishtina, Kosovo; [3]Policlinics "endoCLINIC medical & laboratory", Prishtina, Kosovo; [4]Regional Hospital of Gjakova, Department of Neurology, Gjakova, Kosovo

Parathyroid adenoma often remains undiagnosed for a relatively long time, due to the fact that bone pains and disorders of the osteomuscular system, patients seek to be resolved in other non-endocrinological problems. Case presentation: The case describes a primary thyroid adenoma in a 46-year-old patient with a two-year history of upper and lower limb pain, treated by a rheumatologist as polyathralgia without signs of improvement from therapy! In the meantime, the patient is also diagnosed with severe osteoporosis. The neurologist who was consulted for a headache during the neck examination noticed a mass in the lower part of the neck and in the ultrasound a nodule was seen for which he was referred to the endocrinologist (Figure 1). After the corresponding laboratory and imaging examinations, the patient is diagnosed with very high PTH, high calcium(Table 1) bilateral nephrocalcinosis (Figure 2), marked osteoporosis (Figure 3), fractures of the lumbar vertebrae (Figure 4), bones with diffuse osteolytic foci (Figure 5) and parathyroid adenoma, together with the expressed and characteristic clinical waddling gait from lumbar fractures and myopathy lead to primary hyperparathyroidism from parathyroid adenoma. The patient is referred for surgery and for a short time he was being fully recovered and normal gait of walking.

Key Words
Parathyroid adenoma, parathyroid hormone, hypercalcemia, bone pain

Extremely rare association of primary hyperparathyroidism and familial hypocalciuric hypercalcemia

Salsabil Haouach[1], Sara Ijdda[1], Sana Rafi[1], El Mghari Tabib Ghizlane[1] & Nawal Elansari[1]
[1]CHU Mohamed VI Marrakech, Marrakech, Morocco

Introduction
Familial hypocalciuric hypercalcemia (FHH) is a rare benign hypercalcemia that is sometimes difficult to distinguish from moderate primary hyperparathyroidism (HPT1). Familial hypocalciuric hypercalcemia (FHH) is an autosomal dominantly inherited disorder of calcium metabolism. Its main feature is mild to moderate hypercalcemia, mostly persistent and non-progressive, hypocalciuria, with normal or slightly elevated serum PTH levels. It is typically found in otherwise healthy and asymptomatic individuals. The coexistence of familial hypocalciuric hypercalcemia (FHH) and primary hyperparathyroidism (PHPT) is extremely rare.
Case Report
We report the case of a 56-year-old female patient with hypercalcaemia associated with hyperparathyroidism. The corrected calcaemia was elevated to 109 mg/l (reference values [RV] 86-100) with a PTH 1-84 at 240 pg/ml (RV 9.20-44.6) and a low calciuria at 75 mg/24h (RV 100-320), associated with a scintigraphy showing a 12*9 mm parathyroid adenoma on the lower left parathyroid, the patient did not adhere to the criteria for surgery of a HPT1. Strict monitoring of blood calcium levels and urinary and bone clinical signs was indicated. The hypocalciuria was controlled two times, then a diagnosis of an association of a HHF and a HPT1 was suspected.

Discussion
The diagnostic usually includes family history, clinical assessment, laboratory studies, 24-hour urine calcium excretion measurement. Genetic testing for *CASR* mutations is recommended in ambiguous cases revealing a heterozygous mutation in exon 4 of the calcium sensor gene. In our case it was not yet tested. Treatment mainly involves patient education and reassurance, with calcimimetic medications like Cinacalcet-HCL used in more symptomatic cases, despite not being FDA-approved for FHH.
Conclusion
Diagnosing FHH can be challenging due to its overlap with primary hyperparathyroidism (PHPT). The association of the two pathologies is rare. The possibility of Marx syndrome was raised by the hypocalciuria.

Sjögren's syndrome revealing familial hypocalciuric hypercalcemia: a case report

Kouloud Boujelben[1], Mariam Akacka[1], Mouna Elleuch[1], Mohamed Khairi Arous[1], Mouna Mnif[1], Faten Haj Kacem Akid[1], Mohamed Abid[1], Nadia Charfi[1], Dhoha Ben Salah[1] & Nabila Rekik Majdoub[1]
[1]Hedi Chaker University Hospital, Endocrinology Department, Sfax, Tunisia

Introduction
Familial hypocalciuric hypercalcemia (FHH), also known as Marx syndrome, is a benign hereditary condition with autosomal dominant transmission. Here, we describe a case of FHH diagnosed in the context of the management of Sjögren's syndrome.
Case Report
A 41-year-old female patient with no significant medical history presented with ocular and oral dryness. The diagnosis of Sjögren's syndrome was confirmed based on a Grade 4 Chisholm lymphocytic sialadenitis found on labial biopsy and the presence of positive anti-SSA antibodies. A phosphocalcium assessment repeatedly showed hypercalcemia (2.7–2.83 mmol/l) with normal phosphatemia and alkaline phosphatases, along with hypocalciuria confirmed on multiple occasions (0.45–1.3 mmol/24h). Given this moderate and asymptomatic hypercalcemia, an etiological investigation was conducted, ruling out:Primary hyperparathyroidism (normal PTH, unremarkable ultrasound), Multiple myeloma (normal serum immunoelectrophoresis), Sarcoidosis (normal angiotensin-converting enzyme levels), Drug-induced hypercalcemia (no relevant medication history) The presence of hypocalciuria further supported the diagnosis of familial hypocalciuric hypercalcemia (FHH).
Discussion
Renal involvement in Sjögren's syndrome can lead to hypercalciuria due to tubular dysfunction. The uniqueness of this case lies in the unexpected finding of hypocalciuria, which, after an extensive workup, was attributed to FHH. FHH is associated with an inactivating mutation of the calcium-sensing receptor (CaSR) gene, located on chromosome 3, necessitating screening of other family members

Congenital Hypogonadotropic Hypogonadism is caused by conditions affecting the hypothalamus or pituitary gland, leading to altered or absent secretion of *GnRH* (gonadotropin-releasing hormone) or inadequate biosynthesis of pituitary gonadotropins (*FSH* and *LH*). The disease can be categorized into two groups: two-thirds of patients present with hypogonadotropic hypogonadism associated with anosmia, defined as "Kallmann syndrome," while the remaining one-third exhibit congenital hypogonadotropic hypogonadism with normal olfactory function, termed "idiopathic." An alteration in the prokineticin system (*PROK1* and *PROK2*) is among the various causes of hypogonadotropic hypogonadism. Specifically, PROK2 is predominantly expressed in the central nervous system, where it prompts the migration of *GnRH*-secreting neurons. Loss-of-function mutations in this protein or its receptor (*PROKR2*) have been associated in literature with the onset of hypogonadotropic hypogonadism, even in the absence of olfactory dysfunction. A 44-year-old male patient was referred to our outpatient clinic following recent pathological rib fractures, without a family history of fragility fractures or osteoporosis. Blood tests revealed normal phosphate-calcium metabolism, however the gonadal profile showed low levels of testosterone and gonadotropins, documenting hypogonadotropic hypogonadism. The patient reported no symptoms commonly associated with hypogonadism such as difficulties with ejaculation or nocturnal/morning erections). Despite this, a scrotal ultrasound revealed testicles smaller than expected for his age and a physical examination detected mild gynecomastia. The patient reported no change in his sense of smell. The densitometry scan revealed the presence of osteoporosis at the radial site (Z-score -2.4) and reduced bone mass at the lumbar vertebral site (Z-score -1.7). The Trabecular Bone Score (TBS) showed a markedly reduced value (TBS L1-L4: 1.012). X-rays of the dorsal and lumbar spine revealed osteoporotic fractures in the D11 and D12 vertebrae. An MRI of the pituitary gland with contrast showed no abnormalities. Genetic analysis identified a heterozygous mutation in exon 3 of the *PROKR2* gene, classified as a variant of uncertain significance for hypogonadotropic hypogonadism. After confirming normal haematocrit and PSA levels, therapy with testosterone gel was initiated for hypogonadotropic hypogonadism resulting in a progressive normalization of testosterone levels. For osteoporosis associated with fragility fractures, intravenous infusion of zoledronic acid was administered and vitamin D supplementation therapy was started. In conclusion, hypogonadism should be considered in the evaluation of male patients presenting with osteoporosis, especially at a young age, to ensure accurate diagnosis and management of the condition and its associated complications.

Pitfalls and challenges in the management of secondary hyperparathyroidism and mineral and bone disorders associated with CKD

Nada Akad[1,2], Mihaela Florea[2], Teodora Nastasa[2] & Stefana Bilha[2,3]
[1]"Grigore T Popa" University of Medicine and Pharmacy, Nephrology, Iasi, Romania; [2]Saint Spiridon County Hospital, Endocrinology, Iasi, Romania; [3]"Grigore T Popa" University of Medicine and Pharmacy, Endocrinology, Iasi, Romania

Mineral and bone disorders (MBD) associated with chronic kidney disease (CKD), known as CKD-MBD, involve key alterations including hyperphosphatemia, low vitamin D levels, hypocalcemia, and secondary hyperparathyroidism (SHPT). These changes disrupt bone and mineral metabolism, leading to renal osteodystrophy and increased fracture risk. The management of CKD-MBD and associated osteoporosis is often a challenge in current practice. We report the challenges encountered in managing a series of dialysis patients under the care of our Endocrinology Department. The first case involves a 75-year-old male undergoing peritoneal dialysis with SHPT and osteoporosis (forearm T-score of -5.8). His parathyroid hormone (PTH) level was 1063 pg/mL, prompting a 99mTc-MIBI scintigraphy, which revealed a right inferior parathyroid adenoma and left inferior hyperplastic parathyroid gland. Treatment with cinacalcet was initiated but proved inadequate, as PTH levels increased to 1138 pg/mL two years later, with a corrected calcium level of 11.1 mg/dL. Parathyroidectomy (PTx) was advised but deferred due to his fragility, opting for conservative treatment. The second case involves a 55-year-old woman on hemodialysis (HD) with a history of subtotal PTx, with persistent SPTH (levels of 1655 pg/mL), with a corrected calcium level of 9 mg/dL. Post-PTx 99mTc-MIBI scintigraphy identified a left inferior parathyroid adenoma, and she subsequently underwent total PTx. Postoperatively, her PTH level decreased to 300.9 pg/mL, while her corrected calcium level dropped to 7.8 mg/dL despite supplementation with 1800 mg of calcium and 1.5 µg of alfacalcidol daily. Osteoporosis (forearm T-score of -4.5) treatment with denosumab was postponed due to hypocalcemia risks. The third case pertains to a 47-year-old woman on HD with SHPT (PTH levels of 2544 pg/mL) who underwent total PTx. However, PTH remained elevated at 2891 pg/mL, with a corrected calcium level of 7.7 mg/dL. A subsequent 99mTc-MIBI scintigraphy identified two additional hyperplastic parathyroid glands, indicating a total of six parathyroid glands. Due to marked improvement in her general symptoms and bone mineral density after the first PTx, conservative management was decided until further evaluations. The final case concerns a 74-year-old woman on HD with osteoporosis (femoral neck T-score of -3.5). She presented

with a PTH level of 434 pg/mL and a corrected calcium level of 9.5 mg/dL. Treatment with denosumab, in combination with alfacalcidol, was initiated, resulting in a significant and prolonged drop in calcium levels to 6.86 mg/dL one month after denosumab administration. These cases highlight the complexity of managing CKD-MBD in dialysis patients.

Giant parathyroid adenoma revealed by severe hypercalcemia and disabling bone pain: case report

Ftouh Wiam[1], El Azzouzi Wiame[1], El Bernichi Ouassima[1], Aziouaz Fatima[1] & Benkacem Mariem[1]
[1]University Hospital Center Mohamed VI, Faculty of Medicine and Pharmacy of Tangier, Department of Endocrinology and Diabetology, Tangier, Morocco

Parathyroid adenomas are a common cause of primary hyperparathyroidism; however, giant parathyroid adenomas (GPA), defined as weighing more than 3.5 grams, are rare.

Case Presentation

We report the case of a 53-year-old woman who presented with severe, disabling bone pain, prompting medical evaluation. Laboratory tests revealed severe malignant hypercalcemia (146 mg/l), hypophosphatemia (24 mg/l), and markedly elevated parathyroid hormone (PTH) levels (1898 pg/mL). Initial management consisted of intravenous hydration (2–4 L/24h). Due to persistent hypercalcemia, treatment with zoledronic acid (4 mg) was initiated. Electrocardiography showed a bundle branch block without QT interval shortening. Neck ultrasound identified a large, well-defined, hypoechoic, hypervascularized parathyroid adenoma at the inferior pole of the right thyroid lobe, measuring 2.67 $\times$ 2.02 $\times$ 4 cm. Once calcium levels were stabilized, the patient underwent a successful parathyroidectomy. The excised adenoma weighed 6 g, and histopathological examination confirmed a benign parathyroid adenoma. Postoperatively, PTH levels significantly decreased (100 pg/mL), with notable clinical and biochemical improvement.

Discussion/ Conclusion

This case highlights the importance of recognizing severe hypercalcemia as a potential indicator of GPA and underscores the essential role of surgical intervention in achieving favorable patient outcomes.

Method for increasing the ultrasonic conductivity of skull bone tissue in patients who are planned to be treated with magnetic resonance imaging-guided focused ultrasonic imaging

Liliya Kuzina[1]
[1]Central City Hospital, Chystiakove, Ukraine

The invention relates to medicine, namely to endocrinology and neurosurgery, and can be used to treat patients with altered ultrasound conductivity of bone tissue who are planned to be treated with magnetic resonance imaging-guided focused ultrasound (MR-FUS) The MR-FUS method is most often used to treat movement disorders such as Parkinson's disease, dystonia, and essential tremor. The method is based on two technologies – high-intensity focused ultrasound (HIFU) and MRI. Using heating or cavitation at a variable distance from the sensor, HIFU can cause selective thermal coagulation in a clearly defined volume. The error in the destruction of brain tissue with this method is extremely small and averages 0.50–0.75 mm, varying depending on the technical characteristics of the selected equipment. The arsenal of solutions to the problem associated with low CUPT is very limited, which in turn leads to numerous refusals to perform operations using focused ultrasound. The objective of the invention is to develop a method for increasing the ultrasound conductivity of the bone tissue of the skull for further surgical interventions in patients using MR-FUS in a short time and with a safer method. The technical result of using the invention is a significant increase in the skull UCCT in patients with an initial UCCT of less than 0.35, achieving the threshold value necessary for thalamotomy with MR-FUS. The proposed method for increasing the ultrasound conductivity of the cranial bone tissue is carried out as follows. The patient for whom MR-FUS is planned undergoes CT of the cranial bones to determine the UPCCT, as well as laboratory tests for ionized calcium and vitamin D. If the coefficient is less than 0.35, the patient is administered Bonviva (Ibandronic acid) 3 mg intravenously by bolus over 15-30 seconds once every 3 months, Aquadetrim (Cholecalciferol) at a dose of 1500-5500 IU per day and Calcium D3 Nycomed (Calcium carbonate + Cholecalciferol) at a dose of 500 mg + 200 IU 2 times a day. The course of treatment is 3-6 months. After 3 months, the patient undergoes a repeat CT of the cranial bones on the same device and with the same program to assess the ultrasound conductivity coefficient of bone tissue, and laboratory tests for vitamin D and ionized calcium. If the cranial CUPCT increases by more than 0.35, the patient is referred for surgery using focused ultrasound. If there is no effect after 3 months.

Blood sugar profiles in children receiving high doses of systemic glucocorticoids

Mari Lukka[1,2], Vallo Tillmann[1,2] & Aleksandr Peet[1,2]
[1]Children's Clinic of Tartu University Hospital, 51014 Tartu, Estonia, General Paediatrics, Tartu, Estonia; [2]University of Tartu, Institute of Clinical Medicine, Department of Paediatrics, Tartu 50405, Estonia

Backround

Glucocorticoids (GC) are still the first-line treatment of many autoimmune, inflammatory and allergic conditions. The prevalence of glucocorticoid induced hyperglycemia is not well known in the paediatric population. Specific recommendations for timing and frequency of blood glucose monitoring are lacking in children receiving high doses of glucocorticoids.

Objective

To describe the blood sugar profiles measured with continuous glucose monitoring (CGM) in children receiving systemic glucocorticoid treatment.

Methods

Children who received glucocorticoid treatment due to an underlying condition at a dose of at least 1 mg/kg/day prednisolone-equivalent were monitored with a iPro 2 or a Guardian 4 continuos glucose monitor during their GC treatment course. CGM data and blood sugar profiles were analyzed retrospectively. Time above range and time in range (TAR - percentage of glucose values above 10 mmol/l, TIR - precentage of glucose values in the range 3.9- 10 mmol/l) were measured and diurnal glucose variations were analyzed.

Results

Blood sugar profiles were measured in 10 patients (2 boys, 8 girls) aged 4 to 17 years (mean age 10,5 years $\pm$ 0.7 years) over the mean period of 5 days. Six patients received oral prednisolone and 4 received intravenous methylprednisolone. Seven patients experienced episodes of hyperglycemia. The average TIR of the partcipants during the GC treartment was 93.0 $\pm$ 36.9%, the average recorded TAR was 6.1 $\pm$ 9.1%. The average sensor glucose (SG) at 08:00 AM was 5.0 $\pm$ 1.6 mmol/l, at 08:00 PM 8.3 $\pm$ 3.0 mmol/l and at midnight 7.6 $\pm$ 2.6 mmol/l. Hyperglycemic episodes occured predomonitatly between 18:00-21:00PM and presented mainly as a single prolonged postprandial episode after dinner or late evening snack.

Discussion and conclusion

Two thirds of the investigated subjects experienced GC-induced hyperglycemia. Participants experienced episodes of hyperglycemia regardless of the route of GC administration. Higher SG measurements were registered during evening hours compared to early morning and this should be taken into account, when screening for GC-induced hyperglycemia.

The role of muscular fitness on bone mineral content and areal bone mineral density in children and adolescents with type 1 diabetes: a 2-year longitudinal analysis of the diactive-1 cohort study

Maria J. Chueca Guindulain[1], Sara Berrade Zubiri[1], Carlos Andres Sesma[1], Ignacio Hormazábal-Aguayo[2], NIdia Huerta-Uribe[2], Jacinto Muñoz-Pardeza[2] & Antonio García-Hermoso[2]

[1]University Hospital Navarra, Pediatrics, Pamplona, Spain; [2]Navarrabiomed, Universidad Pública de Navarra (UPNA), IdiSNA, Pamplona, Spain

Background
The incidence of type 1 diabetes (T1D) among youth is on the rise. Poor glycemic control can contribute to comorbidities, including compromised bone health. In growing populations, muscular fitness has been associated with improved bone health.
Aim
To explore the relationship between muscular fitness and bone health in children and adolescents living with T1D.
Methods
A total of 83 youth with T1D (ages 6–18 years; 44.6% girls; mean glycosylated hemoglobin [HbA1c]: 7.5 ± 1.0%) from the Diactive-1 Cohort Study were monitored over two years. Bone mineral content (BMC) and areal bone mineral density (aBMD) were assessed using dual-energy X-ray absorptiometry (DXA) whole-body scans for the total body less head (TBLH), arms, legs, pelvis, and spine. Muscular fitness metrics, including handgrip strength, one-repetition maximum (RM), and muscle power, were evaluated with a dynamometer and eGYM devices. Handgrip strength and TBLH bone parameters were standardized for age and sex using reference data from the BMD Childhood Study and the FitBack Project. The statistical analyses were computed via R studio program.
Results
Generalized linear mixed models showed longitudinal associations of handgrip strength with TBLH-BMC (unstandardized beta coefficient [B]= 17.18, 95% confidence interval [CI] 12.47–21.90) and TBLH-aBMD (B= 0.004, 95%CI 0.002–0.006); RM with TBLH-BMC (B= 20.09, 95%CI 10.88–29.31) and TBLH-aBMD (B= 0.007, 95%CI 0.004–0.011); and power with TBLH-BMC (B= 26.80, 95%CI: 17.31–36.28) and TBLH-aBMD (B= 0.009, 95%CI 0.005–0.012). Comparable results were observed across the other regions ($p<0.05$). Additionally, analyses with standardized data confirmed the relationships of handgrip z-scores with TBLH-BMC z-scores (B= 0.19, 95%CI 0.08–0.30) and TBLH-aBMD z-scores (B= 0.350, 95%CI: 0.210–0.490).
Conclusions
Strengthening programs aimed at improving muscle strength could play a crucial role in preventing bone health complications in youth with T1D. These findings emphasize the importance of incorporating muscular fitness into therapeutic strategies for this population.

Impact of emergency admission on glycemic control in hospitalized diabetic patients

Mohamed Khairi Arous[1], Houcem Elomma Mrabet[2], Mouna Mnif[1], Younes Derbel[1], Mariam Akacka[2], Najoua Lassoued[2], Zantour Baha[2], Nadia Charfi[1], Dhoha Ben Salah[1], Alaya Wafa[2] & Nabila Rekik Majdoub[1]
[1]Hedi Chaker University Hospital, Department of Endocrinology, Sfax, Tunisia; [2]University Hospital Tahar Sfar, Department of Endocrinology, Mahdia, Tunisia

Introduction
Emergency admissions are stressful situations that can disrupt glycemic control in diabetic patients. These disruptions are often caused by multiple factors, such as the severity of the underlying condition, the physiological stress response involving cortisol and adrenaline secretion, and sometimes inadequate therapeutic adjustments in the hospital setting. Few studies have explored the impact of emergency admissions on glycemic control in diabetic patients, despite their potential implications for management and prevention of acute complications. This study aims to evaluate the impact of emergency admissions on glycemic control in hospitalized diabetic patients.
Patients and methods
We conducted a multicenter cross-sectional study between February and March 2024 in three Tunisian university hospitals: Hedi Chaker University Hospital in Sfax, Habib Bourguiba University Hospital in Sfax, and Taher Sfar University Hospital in Mahdia. The study included diabetic patients hospitalized in cardiology, pneumology, urology, general surgery, and orthopedic departments. Data collected included the reason for admission (emergency or elective), the occurrence of acute hyperglycemic complicaton or hypoglycemia, and the evaluation of glycemic control. Glycemic control was classified as insufficient if less than 50% of blood glucose readings (BGR) were within the intra-hospital glycemic target (defined by the ADA as 1–1.8 g/l), moderate if 50–70% of BGR were within the target, and satisfactory if more than 70% of BGR met the target.
Results
A total of 315 patients were included, two-thirds of whom were men. The median age was 65 years, and the median diabetes duration was 8 years. The majority (87%) had type 2 diabetes. Most patients (75.9%) were admitted via emergency departments. Acute hyperglycemic decompensation was diagnosed in 21% of patients, and hypoglycemia was observed in 20.6%. Among patients who underwent glycemic monitoring, 50.7% had insufficient glycemic control, while only 21.6% achieved satisfactory control. Emergency admissions did not significantly increase the risk of hyperglycemic decompensation (P = 0.631), although 78.5% of patients with decompensation had been admitted through emergency departments. The frequency of hypoglycemia was also comparable between emergency and elective admissions (P = 0.211). Similarly, emergency admission was not significantly associated with insufficient glycemic control (P=0.396).
Conclusion
This study demonstrates that while the majority of hospitalized diabetic patients were admitted through emergency departments, these admissions did not significantly influence the risk of hyperglycemic decompensation, hypoglycemia, or insufficient glycemic control.

Screening for prenatal depression in women with gestational diabetes: the relationship with self-esteem and social support

Dorra Ben Salem[1], Yosra Htira[2], Chaima Jemai[2], Olfa Laajili[2], Imene Hedfi[2], Zohra Hadj Ali[2] & Faika Ben Mami[2]
[1]National Institute of Nutrition and Food Technology, Department of Nutritional Diseases C, Tunis, Tunisia; [2]National Institute of Nutrition and Food Technology, Department of Nutritional Diseases C, Tunis, Tunisia

Introduction
Pregnancy is a period of particular vulnerability, with prenatal depression being the most commonly observed psychopathological disorder. This study aims to assess the presence of depressive symptoms and associated psychosocial disorders in a sample of pregnant women followed for gestational diabetes.
Patients and Method
A cross-sectional study was conducted over a seven-month period in the National Institute of Nutrition. Prenatal depression, self-esteem, and social support were assessed using the Edinburgh Depression Scale (EPDS), Rosenberg Self-Esteem scale, and Social Support Questionnaire (SSQ6), respectively. An EPDS score greater than 12/30 indicates the presence of depressive symptoms.
Results
One hundred sixty-three women took part in the study, with a mean age of 33.21 ± 4.82 years, ranging from 22 to 48 years. Half of the participants were beyond 28 weeks of gestation at the time of the interview. The median Edinburgh depression score was 10 ± [6; 14] and depressive symptoms were observed in 61 participants, representing 37.4% of the sample. The mean Rosenberg self-esteem score was 32.94 ± 5 and a low to very low self-esteem level was detected in 26.4% of the women. The SSQ6 perceived social support scale revealed two scores: availability of support (12 ± [9; 16]) and patient satisfaction with the received support (28 ± [20; 31]). The presence of depressive symptoms was significantly associated with low to very low self-esteem levels (47.5% vs. 13.7%, $P< 10^{-3}$), lower availability scores (10 ± [8; 13.5] vs. 13 ± [10; 17], P = 0.001), and lower satisfaction scores (26 ± [18; 30] vs. 29 ± [21.75; 32], P = 0.02). Similarly, significant correlations were found between a decrease in the depression score and an increase in self-esteem (r = -0.55; $P< 10^{-3}$), availability, and satisfaction scores (r = -0.28; $P<10^{-3}$).
Conclusion
Early screening and appropriate management of psychosocial difficulties during pregnancy, particularly low self-esteem and lack of social support, could play a crucial role in reducing depressive symptoms in this population.

Identification of cardiometabolic phenotypes and key indicators in patients with arterial hypertension, type 2 diabetes mellitus, and obesity

Inna Dunaeva[1] & Nonna Kravchun[1]
[1]Kharkiv National Medical University, Kharkiv, Ukraine

Cardiovascular diseases (CVDs) remain a major global health concern, contributing to one-third of global mortality. Recent research highlights the role of cardiometabolic phenotypes in determining cardiovascular risk, particularly in patients with arterial hypertension (AH), type 2 diabetes mellitus (T2DM), and obesity (OB). The interplay between these conditions results in complex pathophysiological mechanisms that require further investigation to optimize risk stratification and management strategies.
The study **aimed**to identify specific cardiometabolic phenotypes in patients with AH, T2DM, and OB and to determine early markers of cardiovascular and renal dysfunction. The study further sought to explore correlations between these conditions and biomarkers, including cardiotrophin-1 (CTF-1), neutrophil gelatinase-associated lipocalin (NGAL), N-terminal pro-brain natriuretic peptide (NT-proBNP), leptin, and cystatin C.
Materials and methods
A total of 211 patients were included in the study, divided into four groups based on comorbid conditions: 1. Group 1 (AH only) – 49 patients. 2. Group 2 (AH and OB) – 54 patients. 3. Group 3 (AH and T2DM) – 57 patients. 4. Group 4 (AH, OB, and T2DM) – 51 patients. Clinical, laboratory, and instrumental assessments were conducted, including lipid and carbohydrate profiles, renal function tests, and echocardiography. Biomarkers such as NGAL, NT-proBNP, and CTF-1 were measured using enzyme-linked immunosorbent assays (ELISA).
Results
The study identified three distinct cardiometabolic phenotypes: phenotype 1 (AH and OB, $n = 54$): Characterized by progressive cardiac remodeling, increased leptin levels, and a moderate risk of renal impairment. Phenotype 2 (AH and T2DM, $n = 57$): Associated with significant renal dysfunction, as evidenced by elevated NGAL and cystatin C levels, indicating early nephropathy. Phenotype 3 (AH, OB, and T2DM, $n = 51$): Displayed the most severe metabolic disturbances, with high NT-proBNP levels reflecting heart failure progression and increased NGAL levels predicting renal complications. Lipid metabolism disturbances were more pronounced in groups with OB and T2DM, with significantly higher total cholesterol and triglycerides. Carbohydrate metabolism markers (insulin and HbA1c) were significantly elevated in patients with T2DM. Echocardiographic data showed increased left ventricular mass and reduced ejection fraction in patients with multiple comorbidities.
Conclusions
The findings highlight the importance of early detection of cardiometabolic phenotypes to prevent cardiovascular and renal complications. NGAL emerges as a strong predictor of nephropathy, while NT-proBNP serves as a marker for heart failure progression. The combination of AH, OB, and T2DM significantly worsens cardiometabolic status, necessitating personalized therapeutic strategies.
Key words
type 2 diabetes mellitus, obesity, arterial hypertension, cardiometabolic phenotypes.

Correlation of hypoglycemic episodes and cognitive functions in people with diabetes mellitus

Afroditi Tsalkitzi[1], Anastasia Ntikoudi[1], Despoina Rizikou[1,2] & Eugenia Vlachou[1]
[1]University of West Attica, Athens, Greece; [2]University of West Attica, Nursing, General hospital of Piraeus Tzaneio, Athens, Greece

Introduction
People with Diabetes Mellitus (DM) often face episodes of hypoglycemia with a serious impact on their daily life. Newer data suggests that severe episodes of hypoglycemia, experienced either recently or throughout life, cause cognitive decline.
Aim
To investigate the relationship between hypoglycemic episodes and cognitive functions among people with DM.
Material – Methods
A quantitative non-randomized cross-sectional study was performed with a sample of 104 individuals with type 1 and type 2 DM aged between 18 and 65 years. Subjects included were experiencing episodes of hypoglycemia and had not been diagnosed with any disease causing cognitive impairment. The study was conducted in two public hospitals of Athens within one year. A demographic questionnaire, the Hypoglycemia Patient Questionnaire and the Clarke's Hypoglycemia Awareness Questionnaire were administered while the Montreal Cognitive Assessment (MoCA) was also conducted. For the statistical analysis of the data, the t-test criterion for independent samples, the analysis of variance for one factor (One-way ANOVA) and the multiple regression analysis were applied.
Results
At the MoCA test the mean score was 26.16 ± 2.69 while the lowest score was 18 and the highest was 30. More than half of the participants had a normal score (equal to or higher than 26) (59.6%) while the 40.4% presented possible mental impairment. Participants who showed reduced awareness of hypoglycemia had a lower MoCA test score than those with high awareness to a statistically significant degree ($P = 0.01$). A statistically significant main effect of severe hypoglycemic episodes on cognitive function score was observed ($P = 0.002$). Participants who had never experienced severe episodes of hypoglycemia scored higher on cognitive function than those who reported more than one severe episode ($P = 0.03$) with a high effect rate ($d = 0.82$). Multiple regression analysis showed that the occurrence of a severe hypoglycemic episode 2 to 12 times ($b = -0.15$, $P < 0.05$) and age ($b = -0.31$, $P < 0.001$) were negative predictors of the score of the cognitive assessment.
Conclusions
Severe episodes of hypoglycemia were associated with cognitive decline in people with DM. Age was also a predictor of cognitive deficit. Further research studies are needed to clarify the relationship between hypoglycemia and cognitive function in order to improve the quality of life of people with DM.
Key words
Diabetes Mellitus, hypoglycemia, cognitive function

The evaluation of arterial stiffness indices in children and adolescents with type 1 diabetes mellitus or excess weight

Eirini Kostopoulou[1], Marios Papasotiriou[2], Konstantinos Miliordos[2], Evangelos Papachristou[1], Dimitrios Goumenos[1] & Dionysios Chrysis[2]
[1]University Hospital of Patras, Pediatric Endocrinology, Patras, Greece; [2]University Hospital of Patras, Department of Nephrology and Kidney Transplantation, Patras, Greece

Purpose
The relationship between pediatric obesity or Type 1 Diabetes Mellitus and cardiovascular disease in adulthood is well established, with the pathophysiological mechanisms being already present in childhood. Arterial stiffness is a strong, independent predictor of cardiovascular disease in adulthood and the most widely accepted method for its evaluation is Pulse Wave Velocity (PWV). We evaluated PWV in children and adolescents with T1DM or excess weight, in order to detect subclinical vascular alterations at a very early stage.
Methods
A total of 199 children and adolescents aged 2-18 years participated in the study, including 96 with T1DM, 49 with overweight or obesity, and 54 healthy controls. PWV was measured using the automated oscillometric device Mobil-O-Graph.
Results
Systolic BP (SBP) and central SBP (cSBP) were significantly increased in both patients with overweight/obesity and those with T1DM compared to controls. Furthermore, overweight/obesity patients had higher SBP, cSBP and cDBP compared to T1DM patients, whereas DBP was significantly increased only in overweight/-obesity patients compared to controls. Pulse wave velocity values were also significantly increased in both overweight/obesity patients and those with T1DM compared to controls, while overweight/obesity patients had higher PWV when compared to patients with T1DM.
Conclusion
Impaired arterial elasticity, expressed as increased pBP, cBP, and PWV, was found in children and adolescents with T1DM and overweight/obesity, particularly in the latter. PWV could potentially serve as a screening and diagnostic tool for impaired vascular health and, perhaps, as a prognostic tool for future cardiovascular disease in children and adolescents with T1DM or overweight/obesity.

Profile of chronic diabetes complications in hospitalized patients: A multicenter tunisian study

Mohamed Khairi Arous[1], Houcem Elomma Mrabet[2], Mouna Mnif[1], Younes Ayadi[1], Yesmine Elloumi[1], Faten Haj Kacem Akid[1], Zantour Baha[2], Sfar Mohamed Habib[2], Mouna Elleuch[1], Alaya Wafa[2] & Nabila Rekik Majdoub[1]

[1]Hedi Chaker University Hospital, Department of Endocrinology, Sfax, Tunisia; [2]University Hospital Tahar Sfar, Department of Endocrinology, Mahdia, Tunisia

Introduction
Diabetes, a chronic disease with a steadily increasing prevalence, is a significant public health issue in Tunisia and globally. Its chronic complications, both microvascular and macrovascular, are the leading causes of morbidity and mortality. While acute complications are well documented in hospital settings, data on chronic complications remain limited. This study aims to describe the profile of chronic diabetes complications in hospitalized patients.
Patients and methods
A descriptive cross-sectional study was conducted between February and March 2024 in three Tunisian university hospital centers: CHU Hedi Chaker in Sfax, CHU Habib Bourguiba in Sfax, and CHU Taher Sfar in Mahdia. The study included hospitalized diabetic patients from cardiology, pulmonology, urology, general surgery, and orthopedic departments. Data collected included diabetic retinopathy, chronic renal failure (defined by a glomerular filtration rate below 60 ml/min), stroke, coronary insufficiency, heart failure, and peripheral artery disease.
Results
A total of 315 patients were included with a male-to-female ratio of 2. The median age was 65 years, and the median duration of diabetes was 8 years. 87% ($n = 272$) had type 2 diabetes, 6% ($n = 19$) had type 1 diabetes, and 5.4% ($n = 17$) were newly diagnosed during hospitalization. 60.6% of patients ($n = 191$) had associated hypertension. Diabetic retinopathy was present in 26.5% of patients, and chronic renal failure was observed in 20.6% ($n = 65$), with 2.6% ($n = 8$) in the terminal stage. Twenty-four patients (7.6%) had a history of stroke before admission. Coronary artery disease was diagnosed before hospitalization in 65 patients, and peripheral artery disease was diagnosed in 29 patients (9%). Additionally, 24 patients (7.6%) were being followed for heart failure at the time of their inclusion.
Conclusion
This study highlights the high prevalence of chronic complications among hospitalized diabetic patients. These findings underscore the importance of systematic screening and early management of chronic diabetes complications in hospital settings, regardless of the admission reason, to reduce the morbidity associated with this condition.

Impact of surgical interventions on glycemic control in hospitalized diabetic patients

Mohamed Khairi Arous[1], Houcem Elomma Mrabet[2], Mouna Mnif[1], Hamdi Frikha[1], Mariam Akacka[2], Najoua Lassoued[2], Zantour Baha[2], Mohamed Abid[1], Mouna Elleuch[1], Alaya Wafa[2] & Nabila Rekik Majdoub[1]
[1]Hedi Chaker University Hospital, Department of Endocrinology, Sfax, Tunisia; [2]University Hospital Tahar Sfar, Department of Endocrinology, Mahdia, Tunisia

Introduction
Surgical interventions are high-risk situations for diabetic patients due to the metabolic disturbances induced by surgical stress and the resulting hormonal changes. These disturbances and sometimes inadequate therapeutic adjustments can impair glycemic control and increase the risk of acute complications. Despite its clinical significance, few studies have explored the impact of surgical interventions on the glycemic control of hospitalized diabetic patients. This study aims to assess the repercussions of surgical interventions on glycemic control.
Patients and methods
This multicenter cross-sectional study was conducted between February and March 2024 in three Tunisian university hospital centers: Hedi Chaker and Habib Bourguiba University Hospitals in Sfax, and Taher Sfar University Hospital in Mahdia. The study included diabetic patients hospitalized in medical and surgical departments. The collected data included the reason for admission, whether a surgical intervention was performed during hospitalization, the occurrence of acute hyperglycemic decompensation or hypoglycemia, and the assessment of glycemic control. Glycemic control was considered insufficient if less than 50% of measured capillary blood glucose levels (CBG) were below the intra-hospital target range (defined by the ADA between 1 and 1.8 g/l), moderate if 50 to 70% of CBG values were within the target range, and satisfactory if more than 70% of CBG values achieved this target.
Results
Among the 315 patients included, 102 (32%) underwent surgical intervention during their hospitalization. Diabetes was newly diagnosed in one patient following surgery. Acute hyperglycemic decompensation occurred in 21 patients (20.6%), while hypoglycemia was observed in 23 patients (22.5%). Poor glycemic control was noted in 41 patients (40.2%), and glycemic monitoring was not performed in 17 patients (16.7%). Insulin therapy was discontinued in 21 of the 49 insulin-treated patients who underwent surgery. Surgical interventions were not significantly associated with acute hyperglycemic decompensation ($P = 0.519$) or hypoglycemia ($P = 0.434$). Similarly, surgical interventions were not significantly associated with poor glycemic control ($P = 0.585$).
Conclusion
Contrary to expectations, surgical interventions were not systematically associated with acute decompensations or poor glycemic control in hospitalized diabetic patients. However, this study highlights the importance of optimized perioperative management to maintain adequate glycemic control and prevent associated complications.

The transition from pediatric to adult care in type 1 diabetes: A real challenge

Yesmine Jallouli[1], Marwa Chiboub[1], Syrine Trabelsi[1], Meriem Adel[1], Manel Jemel[1] & Kammoun Ines[1]
[1]National Institute of Nutrition of Tunisia, Department B, Tunis, Tunisia

Introduction
The transition of type 1 diabetic patients from pediatric to adult care represents a real challenge in diabetes consultations, highlighting the importance of effectively 'bridging the gap. The aim of our work was to evaluate the impact of this transition on glycemic control.
Methods
A retrospective observational study including type 1 diabetic patients who were followed in the department C of the children's hospital and then referred to the transition consultations organized within department B of the National Institute of Nutrition between 2018 and 2023. Each transition consultation involved an endocrinologist, a nutritionist, and a nurse.
Results
The study included 28 type 1 diabetic patients. Fifty-three percent of the patients were male. The average age at the time of transition was 16 years $\pm$ 2 [11-21 years]. The average duration of diabetes was 10 years $\pm$ 4 [1-15 years]. Half of the diabetic patients were not on a complete basal-bolus regimen. Sixty-one percent of the patients were overdosed on basal insulin (with an average dose of 0.59 IU/kg), and 23% experienced frequent hypoglycemia. The average HbA1c at the time of transition was 10.2% $\pm$ 1.5 [8.2; 13.5]. Eighty-eight percent of patients consulted regularly after the transition. Half of the patients experienced a significant improvement in HbA1c after 6 months, with an average decrease of 1.7%. Additionally, 27% of patients continued to improve after 12 months, with an average HbA1c improvement of 2% compared to the baseline.
Conclusion
The care transition for diabetic patients faces the complexity of managing the disease during a phase characterized by multiple physical, psychological, and social changes. A structured approach, including therapeutic education and psychological support, must be implemented to prevent interruptions in care (care gap), ensure continuity, and successfully manage this transition.

Association of AGES and obstructive sleep apnea in patients with diabetes

Deimante Paskeviciene[1], Rasa Verkauskiene[1], Lina Radzeviciene[1], Diana Simoniene[1] & Erika Jurkute[2]
[1]Lithuanian University of Health Sciences, Institute of Endocrinology, Kaunas, Lithuania; [2]The Kaunas Hospital of Lithuanian University of Health Sciences, Department of Endocrinology, Kaunas, Lithuania

Background.
Obstructive sleep apnea (OSA) is a chronic sleep disorder characterized by repeated episodes of the upper airway obstruction during sleep, resulting in hypoxemia, hypercapnia, sleep fragmentation. Individuals with sleep apnea are often unaware of their breathing difficulties during sleep, leading to frequent underdiagnosis of the condition. If left untreated, OSA can lead to hypertension, cardiovascular diseases, neurocognitive impairments, and metabolic dysfunction.

OSA is frequently associated with type 2 diabetes (T2D), with prevalence reaching up to 86%, particularly among obese diabetic patients. OSA increases cardiovascular risk and is associated with high oxidative stress levels and inflammation. Under conditions of increased oxidative stress, the accumulation of advanced glycation end-products (AGEs) is accelerated. Higher AGEs levels are associated with metabolic syndrome, cardiovascular disease, and diabetes-related complications. This study aimed to analyze the relationship between AGEs levels and the presence of OSA in patients with diabetes.
Materials and methods
AGEs concentration in the skin was non-invasively measured using AGE Reader in 117 patients with type 1 diabetes (T1D, $n = 61$) and T2D ($n = 56$), with low ($n = 39$), intermediate ($n = 42$) and high ($n = 36$) risk of OSA. The STOP-BANG questionnaire, validated and adapted for Lithuanian patients, was used. High risk for OSA was defined by as any of the following: a total score of 5-8 points; positive responses to ≥ 2 of 4 questions plus male gender or plus BMI > 35 kg/m^2 or plus neck circumference ≥ 40 cm. Intermediate risk was defined by 3-4, low risk by 0-2 positive answers. Data on patients' clinical characteristics were collected from medical records.
Results
The median diabetes duration was 16 years (range1-60), age – 56 years (range 20-81). The study cohort consisted of 67 (57.3%) women and 50 (42.7%) men. The risk of developing OSA significantly depended on gender ($P < 0.001$) and type of diabetes ($P < 0.001$). Men and patients with T2D have higher risk of developing OSA compared with woman and patients with T1D. There were no significant associations between OSA and HbA1c or the duration of diabetes ($P = 0.602$ and $P = 0.267$, respectively). However, we revealed a progressive increase in AGE median values as OSA risk increases ($P < 0.05$).
Conclusions
Patients with T2D, particularly males, demonstrate a higher risk of developing OSA. Our findings suggest that non-invasive measurement of skin AGEs could be useful additional tool for OSA risk evaluation as the association between higher AGEs levels and OSA risk shows the potential role of oxidative stress in the pathophysiology of both conditions.

Uncovering underlying causes: a crucial step in managing diabetic ketoacidosis

Nada Ait Kassi[1], Ikram Qasdi[1], Habbadi Zineb[1], Fatima Toulali[1], Ghizlane Sabbar[1], Kaoutar Rifai[1], Hinde Iraqi[1] & Mohamed El Hassan Gharbi[1]
[1]Ibn Sina Hospital Mohamed V University, Endocrinology, Rabat, Morocco

Introduction
Diabetic ketoacidosis (DKA) is a serious complication of diabetes that can occur in type 2 diabetes mellitus, particularly with poor glycemic control and concurrent illnesses. This report details the presentation, management, and clinical outcomes of a patient admitted with DKA.
Case Presentation
A 62-year-old female with a history of type 2 diabetes managed with metformin, complicated by poor adherence, presented with gastrointestinal symptoms of nausea and vomiting. Her condition worsened, prompting an emergency visit where severe hyperglycemia (capillary blood glucose of 5 g/l), significant ketonuria (2+ acetone), and a raised anion gap (RA at 15) were identified, confirming DKA. On admission, she exhibited general weakness, abdominal tenderness, and an altered general condition. Laboratory findings included a white blood cell count of 10,600, elevated C-reactive protein (CRP) initially at 214 mg/l (decreasing to 66 mg/l), and negative infectious screenings (thoracic radiography and renal ultrasound). A thoraco-abdominopelvic CT scan revealed a perforated mucocele complicated by pseudomyxoma peritonei.
Discussion
Patients with mucinous neoplasms of the appendix present a clinically challenging spectrum of pathologic processes. Incidental discovery of an appendiceal mucocele is common. Pseudomyxoma peritonei (PMP), although more severe, frequently has a slow-growing course with non-specific symptoms, requiring high suspicion, especially with probable previous appendiceal pathology. Mucinous neoplasms of the appendix range from benign mucoceles to malignant cystadenocarcinomas. Accurate diagnosis and management are crucial, particularly in specialist centers focusing on preventing locoregional recurrence.
Conclusions
This case underscores the importance of recognizing and promptly treating DKA in type 2 diabetic patients, especially with poor glycemic control and additional conditions. Comprehensive management addressing underlying causes and complications is essential for optimal outcomes. Regular follow-up with thorough assessments is crucial for preventing recurrence and managing long-term complications.

Relationship between polymorphic markers rs7903146 variant of TCF7L2 gene, rs10830963 variant of mtnr1b gene and rs1801282 variant of pparg (pro12ala) gene and various subtypes of gestational diabetes mellitus

Natalya Volkova[1] & Ilya Davidenko[1]
[1]Rostov State Medical University, Rostov-on-Don, Russian Federation

Introduction
Nowadays various pathogenetic subtypes of gestational diabetes mellitus (GDM) are distinguished: with predominant β-cell dysfunction and with prevailing insulin resistance (IR). Currently, many works are devoted to the study of polymorphisms of various genes that can influence the development of GDM. However, no attempt has yet been made to study the genetic markers of various subtypes of GDM, which could make a significant contribution to both the diagnosis and probable prevention of carbohydrate metabolism disorders during pregnancy.
Objective
To study the association of polymorphic markers rs7903146 of the TCF7L2 gene, rs10830963 of the MTNR1B gene and rs1801282 of the PPARG Pro12Ala gene with the presence of various subtypes of GDM in pregnant patients.
Materials and methods
130 pregnant women were divided according to the results of the Matsuda index: group I-45 pregnant women with GDM and β-cell dysfunction, group II-43 pregnant women with GDM and IR, group III-42 pregnant women without GDM (control). Single nucleotide polymorphisms rs7903146, rs10830963, rs1801282 were determined by allele-specific PCR. The differences were recognized as statistically significant at the level of $P < 0.05$. Calculations were performed in R (version 3.2, R Foundation for Statistical Computing, Vienna, Austria).
Results and discussion
In the course of this study, it was found that some polymorphic markers were associated with a reduced risk of having different subtypes of GDM. Thus, the genotype of T/T polymorphic markers rs7903146 of the TCF7L2 gene is associated with low risk and GDM with predominant IR (OR = 0.06, 95% CI: 0.004–1.18, $P = 0.045$), and with β-cell dysfunction (OR = 0.06, 95% CI: 0.003–1.13, $P = 0.04$). At the same time, the genotype of C/C polymorphic markers rs10830963 of the MTNR1B gene was associated with a reduced risk of only the GDM subtype with β-cell dysfunction (OR = 0.41, 95% CI: 0.174–0.98, $P = 0.049$). On the other hand, we found polymorphic markers that, on the contrary, were associated with an increased risk of having GDM with predominant IR. It turned out to be the genotype of T/C polymorphic markers rs7903146 of the TCF7L2 gene (OR = 2.53, 95% CI: 01.048–6.09, $P = 0.049$).
Conclusion
The results obtained indicate the potential role of the T/C genotype of polymorphic markers rs7903146 of the TCF7L2 gene in the development of the GDM subtype with predominant IR. The presented data certainly require further study to determine, first, the criteria for the diagnosis of various subtypes of GDM, depending on the mechanisms underlying the pathogenesis of carbohydrate metabolism disorders.

Effect of vitamin D supplementation on metabolic and psychopathological disorders in patients with type 2 diabetes mellitus in chronic stress conditions

Maryna Bobryk[1], Viktoriia Yerokhovych[1], Dmytro Malyi[2] & Iuliia Komisarenko[1]
[1]Bogomoletz National Medical University, Kyiv, Ukraine; [2]Dentistry, Institute of Postgraduate Education of Bogomoletz National Medical University, Kyiv, Ukraine

According to the IDF Diabetes Atlas 2021, there were 2,325,000 adult patients with diabetes aged 20-79 years in Ukraine, as well as 920,100 undiagnosed cases. The prevalence of depression in Ukraine civilians reached 30% in 2020 and has been growing since then. Patients with type 2 diabetes mellitus (T2DM) are more sensitive to the stress factor of war, which is added to traditionally common psychopathological disorders. They have a 20% higher prevalence of anxiety compared to those without diabetes. A mutual negative effect between the state of depression and the course of T2DM is well known. According to the results of assessing the vitamin D status of Ukrainian population, an unsatisfactory level was found in 47% of people. The aim of the study was to assess the effect of vitamin D supplementation on metabolic and psychopathological manifestations in patients with T2DM. 164 patients with T2DM aged 19-75 years, in D-deficit status, glycated hemoglobin of 7-8.5%, BMI 30-39 kg/m2 were included in the study. Exclusion criteria: CKD, pregnancy, BMI $\geq$ 40 kg/m2, vit D intake 3 months before, insulin therapy, antidepressants, tranquilizers, sedatives usage. Patients were randomized into 2 groups of 82 people in each, comparable by age and gender. Patients received oral antidiabetic agents. Additionally, vitamin D supplementation was used in the main group: 3 months 10,000 IU daily, then 3 months 4000 IU daily; in the control group: 3 months no vitamin D treatment, then 3 months 4000 IU daily. Depression, anxiety and stress grades were evaluated using DASS21 scale.

Results

Patients in the main group showed a statistically significant decrease of salivary cortisol levels, glycated hemoglobin A1c, HOMA index, BMI and levels of depression, anxiety and stress after 3 months of taking vitamin D. The effect was prolonged to 6 months. Among patients in the control group, the levels of glycated hemoglobin A1c and BMI did not significantly improve, psychopathological disorders have been worsened.

Conclusion

Vitamin D supplementation is recommended for patients with type 2 diabetes in chronic stress condition. Vitamin D supplementation for 3 months at a dose of 10,000 IU daily in T2DM patients in D-deficit status improved carbohydrate metabolism, contributed to the normalization of saliva cortisol levels, reduced the levels of depression, anxiety and stress.

Prevalence of sarcopenia and dinapenia in young population with type 1 diabetes mellitus

Nuria Birruezo Hernández[1], Yael Giner Esteban[1], MARÍA DEL CARMEN ANDREO-LOPEZ[1,2], Maria Teresa Martínez Zarco[1], Elena Martínez Silla[1], Raúl Rodríguez Juárez[1], Juan Luis Delgado Montoya[1], Laura Cánovas Noguera[1] & Pablo José López Ibarra[1]
[1]Hospital Universitario Clínico San Cecilio, Granada, Spain; [2]Instituto de Investigación Biosanitaria de Granada, Granada, Spain

Background

Sarcopenia is proposed as a complication of type 1 diabetes (T1D1). However, there are few studies on its prevalence and related clinical outcomes in TD1. Our aim was to analyze whether sarcopenia and dynapenia are more common in people with TD1, as well as to determine if there are associations with disease-related factors.

Methods

A cross-sectional study of young subjects with DT1 and healthy controls matched for age, sex and body mass index (BMI). The following variables were collected: DT1-related clinical and metabolic data, muscle strength measured with the Jamar dynamometer and quadriceps rectus femoris muscle mass (Y-axis, X-axis, area and circumference) measured with ultrasound. The appendicular skeletal mass index (ASMI) was assessed by calf circumference to define myopenia. Regarding dynapenia, a cut-off point at p10 was used according to the Spanish population percentile table. Statistical analysis was performed with IBM SPSS v.25.

Results

34 patients with DT1 (40 $\pm$ 14 years; 54.4 % female and BMI 24.4 $\pm$ 4.09 kg/m^2) were analyzed. In the case group, the mean HbA1c was 6.85 $\pm$ 1.84%, the frequency of microvascular complications was 32.4% (8.8% presented nephropathy, 23.5% retinopathy, 17.6% polyneuropathy). There were no patients with macrovascular complications. Regarding the strength measured by dynamometry was 31.2 $\pm$ 10.9 kg in cases vs. 34.2 $\pm$ 12.9 kg in controls (P= 0.313). Calf circumference values were significantly lower in the DT1 group (35.2 $\pm$ 2.7 cm vs. 37.8 $\pm$ 2.9 cm; P = 0.00). The ASMI value was 6.57 $\pm$ 1.21 kg/m2 in cases and 7.25 $\pm$ 1.31 kg/m2 in controls (P = 0.31). Patients with myopenia accounted for 29.4% of cases and 12.1% of controls (P = 0.082). The prevalence of dinapenia did not show statistically significant differences between groups (26.5% in cases vs. 18.8% in controls; P = 0.454). Finally, sarcopenia was observed in 2 cases and 1 control (5.9% vs. 2.9% respectively; P = 0.55).

Conclusions

Deterioration of muscle strength in DT1 and muscle mass was observed. However, the prevalence of dynapenia and sarcopenia was not significantly higher in DT1, at least, in this young population. Further studies are needed in this and other groups with larger sample to confirm these results.

JOINT2617

Relationship between severe hypoglycemia and time in range in type 1 and type 2 diabetes patients

Víctor Siles-Guerrero[1], Victor SIMON FRAPOLLI[2], Rosa Natalia GARCÍA PÉREZ[1], Juan Manuel Guardia-Baena[1] & Araceli Munoz-Garach[1]
[1]Hospital Universitario Virgen de las Nieves, Granada, Spain; [2]Hospital Universitario Virgen de la Victoria, Málaga, Spain

Introduction

Time in Range (TIR) has emerged as a key therapeutic target in the management of diabetes, reflecting the proportion of time a patient's glucose levels remain within the recommended range (70–180 mg/dL). Maintaining an adequate TIR is associated with better glycemic control and a lower risk of diabetes-related complications. However, the relationship between TIR and the incidence of severe hypoglycemia remains unclear. Severe hypoglycemia, defined as an event requiring external assistance for recovery, represents a major concern in diabetes management due to its potential to cause cognitive impairment, cardiovascular complications, and increased morbidity. This study examines whether a lower TIR is associated with an increased likelihood of experiencing severe hypoglycemic episodes in patients with type 1 and type 2 diabetes.

Objective

To assess the impact of TIR on the probability of experiencing severe hypoglycemia and to evaluate its potential as a predictor of metabolic safety in diabetes patients.

Methods

A retrospective analysis was conducted using continuous glucose monitoring (CGM) data from a cohort of 70 patients with type 1 and type 2 diabetes treated at a hospital in southern Spain. TIR values, time spent in hypoglycemia ($<$70 mg/dL and $<$54 mg/dL), and the occurrence of severe hypoglycemia were compared between patients using non-parametric statistical tests. The primary outcome was the incidence of severe hypoglycemia in relation to different TIR thresholds.

Results

Patients who experienced severe hypoglycemia did not exhibit significantly lower TIR values compared to those without severe episodes. However, a subgroup analysis revealed that individuals with TIR below 60% tended to have a higher incidence of severe hypoglycemia. Although this difference did not reach statistical significance (P = 0.16), a clinically relevant trend was observed. Additionally, a greater percentage of time spent in hypoglycemia was noted in patients with severe episodes, reinforcing the importance of minimizing glucose variability.

Conclusions

While reduced TIR has been linked to poorer overall glycemic control and increased glucose variability, its specific role in predicting severe hypoglycemia remains uncertain. The findings suggest that TIR may be a useful indicator of metabolic instability, but its predictive capacity for severe hypoglycemia requires further validation. Larger prospective studies are needed to establish TIR as a reliable risk stratification tool and to optimize diabetes management strategies aimed at minimizing hypoglycemic events while maintaining optimal glycemic control.

Impact of corticosteroid therapy on glycemic control in hospitalized diabetic patients

Mohamed Khairi Arous[1], Houcem Elomma Mrabet[2], Mouna Mnif[1], Yassmine Abdelkafi[1], Kouloud Boujelben[1], Boubaker Fadia[2], Zantour Baha[2], Nadia Charfi[1], Sfar Mohamed Habib[2], Alaya Wafa[2] & Nabila Rekik Majdoub[1]
[1]Hedi Chaker University Hospital, Department of Endocrinology, Sfax, Tunisia; [2]University Hospital Tahar Sfar, Department of Endocrinology, Mahdia, Tunisia

Introduction

Corticosteroid therapy, widely used in hospital settings for its anti-inflammatory and immunosuppressive effects, is known for its hyperglycemic effects. Despite its frequent use, its impact on glycemic control in hospitalized diabetic patients remains underexplored. This study aims to evaluate the influence of corticosteroid therapy on glycemic control in hospitalized diabetic patients.

Patients and methods

We conducted a multicenter, cross-sectional study over three months in three Tunisian university hospitals: Hedi Chaker University Hospital in Sfax, Habib Bourguiba University Hospital in Sfax, and Taher Sfar University Hospital in Mahdia. The study included diabetic patients hospitalized in medical and surgical departments. Data collected included corticosteroid prescription during hospitalization, the dose of corticosteroid prescribed in prednisone-equivalent milligrams, the occurrence of acute hyperglycemic complication or hypoglycemia, and glycemic control evaluation. Glycemic control was classified as insufficient if less than 50% of capillary blood glucose (CBG) readings were below the in-hospital glycemic target (defined by the ADA as 1–1.8 g/l), moderate if 50–70% of CBG readings were within the target, and satisfactory if more than 70% of CBG readings met the target.

Results

The total number of patients included was 315, of whom 65% were men. Twenty-seven patients (8.5%) received corticosteroid therapy during their hospitalization. The median corticosteroid dose administered was 53 mg [50–75] of prednisone equivalent per day. Diabetes was newly diagnosed in three patients during corticosteroid therapy. Among patients treated with corticosteroids, glycemic monitoring was not performed in three cases, while four patients experienced acute hyperglycemic decompensation, one patient developed hypoglycemia, and 14 patients (51.9%) had poor glycemic control during hospitalization. Insulin therapy was used to manage hyperglycemia in 80% of corticosteroid-treated patients ($n = 21$), with sliding scale insulin being the most commonly prescribed regimen (16 patients, 59.3%). Corticosteroid therapy was not significantly associated with acute hyperglycemic decompensation ($P = 0.416$) or poor glycemic control ($P = 0.435$). However, corticosteroid therapy was associated with a significantly lower risk of hypoglycemia ($P = 0.027$).

Conclusion

This study demonstrates that corticosteroid therapy in hospitalized settings did not significantly influence the risk of acute hyperglycemic decompensation or overall glycemic control in diabetic patients. However, its use was associated with a significantly reduced risk of hypoglycemia.

What fears do women with gestational diabetes face?

Takoua Moussa[1], Chaima Jemai[1], Yesmine Guerbouj[1], Insaf Jameleddine[1], Zohra Hadj Ali[1], Olfa Laajili[1], Imen Hedfi[1], Yosra Htira[1] & Faika Ben Mami[1]
[1]Institute of Nutrition of Tunis, C Department, C Department, Tunisia

Introduction

Gestational diabetes (GD) is a condition that can make pregnancy emotionally challenging and filled with concerns, requiring significant lifestyle adjustments to manage stress. The objective of our study was to identify the different fears experienced by pregnant women in order to find solutions for managing them.

Methods

This descriptive study was conducted on 53 women diagnosed with GD, followed up in our GD unit at Service C of the Tunis Institute of Nutrition. Data were collected through direct interviews.

Results

The average age of the patients was 33.79 $\pm$ 4.8 years. Regarding medical history, 7.5% had hypertension, 3.8% had dyslipidemia, and 7.5% had hypothyroidism. The prevalence of anemia during pregnancy was 24.5%. Most patients had normal blood pressure (BP), with an average systolic BP of 11.43 $\pm$ 1.08 cmHg and an average diastolic BP of 6.7 $\pm$ 0.91 cmHg. Similarly, their diabetes was generally well-controlled, with an average HbA1c of 5.55 $\pm$ 0.67%, although 24.5% required insulin therapy. Regarding pregnancy progression, 28.3% of women were in the first trimester (T1), 47.2% in the second (T2), and 24.5% in the third (T3). Insulin therapy raised several concerns: 54.7% of patients feared injections, 50.9% had unfounded concerns about insulin's effects on the fetus, and 35.8% worried about hypoglycemia. Additionally, 58.5% of women found blood glucose monitoring through GAD to be restrictive. Fears related to GD complications were widespread: 77.4% of patients unjustifiably feared fetal malformations, 75.5% were concerned about the risk of diabetes in the newborn, and 71.7% worried about congenital infections. Furthermore, 30.2% were apprehensive about cesarean delivery, and 77.4% feared the persistence of diabetes in the postpartum period. However, no statistically significant association was found between pregnancy term and the various fears expressed by the patients (P = NS).

Conclusion

Our study highlights the importance of a comprehensive approach to GD management, addressing not only the medical aspect but also providing psychological and educational support to patients. Identifying and addressing their fears, while correcting misconceptions, could enhance treatment adherence and promote an optimal pregnancy outcome. A more personalized and empathetic approach could help build patient confidence and contribute to better maternal-fetal care.

Spontaneous pneumomediastinum: a rare complication of diabetic ketoacidosis

Karoui Sarra[1], Rihab Laamouri[1], Ibtissem Ben Nacef[1], Sabrine Mekni[1], Sawsen Essayeh[1], Imen Rojbi[1] & Khiari Karima[1]
[1]University of Tunis El Manar, Faculty of Medecine of Tunis, 1007, Tunisia, Charles Nicolle Hospital Tunis, Endocrinology Department, Tunis, Tunisia

Introduction

Pneumomediastinum is an entity defined with presence of free air in the mediastinum cavity. It is usually due to a trauma but it can occur spontaneously. Association with diabetic ketoacidosis (DKA) has been reported in few cases. Herein, we present the case of a patient who was diagnosed with DKA accompanied with spontaneous pneumomediastinum.

Case presentation

A 17-year-old male patient, with no medical history was admitted in our hospital in January 2025 for acute vomiting and general fatigue. He didn't report any history of trauma. Respiratory rate was 33 breaths/minute, heart rate was 121 beats/minute, blood pressure was 116/81mmHg. The patient was apyretic. Subcutaneous crepitus on chest and neck was found. Blood glucose was 5.3 g/l. Arterial gas showed pH of 6.85, HCO3- of 2.6, pCO2 of 15.1, pO2 of 128.8. The chest abdomen and pelvis scan demonstrated pneumomediastinum, subcutaneous emphysema and pneumoperitoneum. Severe DKA was confirmed. The patient received hydration with normal saline and intravenous rapid insulin infusion with relay to subcutaneous insulin. The pneumomediastinum was treated conservatively. The evolution was favorable. There was no dyspnea neither chest pain. Respiratoy rate was normal. A good glycemic control was obtained with basal-bolus insulin. A chest X-ray of control 13 days after the DKA was normal.

Comments and Conclusions

Spontaneous pneumomediastinum is a rare condition, first reported by Hamman in 1939. Pathophysiology was decribed by Maklin as an increase in intralveolar pressure, followed by alveolar rupture. This barotrauma can be the result of severe vomiting and Kussmaul breathing in DKA. Air dissects through the bronchovascular sheath into the mediastinum. It can also dissect through other serous structures, subcutaneous tissue and peritoneal cavity. It is generally a benign entity with a good prognosis. Spontaneous resolution of the pneumomediastinum was found in most reported cases. Careful attention to this particular condition is needed espacially by emergency physicians to avoid under-diagnosis.

A case of HAIRAN syndrome in a teenage girl with hirsutism and secondary amenorrhea

Zeynep Donbaloglu[1]
[1]Antalya City Hospital, Pediatric Endocrinology Department, Antalya, Türkiye

Introduction
HAIRAN syndrome (Hyperandrogenism, Insulin resistance, Acanthosis nigricans) is a rare and severe subphenotype of polycystic ovary syndrome (PCOS), marked by hyperandrogenism, insulin resistance, and dermatologic manifestations, including acanthosis nigricans. This syndrome primarily affects young females and presents with symptoms like hirsutism, menstrual irregularities, and obesity. HAIRAN syndrome is distinct from typical PCOS due to the significant severity of insulin resistance and the associated metabolic disturbances. The clinical management of HAIRAN syndrome requires a comprehensive approach involving hormonal regulation, insulin-sensitizing agents, and supportive interventions to address both physical and psychological aspects of the condition.
Case Description
We present a 16-year-old female patient diagnosed with HAIRAN syndrome. The patient has a long history of obesity since childhood and presented with complaints of weight gain, excessive facial and body hair, and menstrual irregularities. She had menarche at age 12, but over the past 9 months, she experienced secondary amenorrhea with no menstruation. Her family history is significant for obesity and type 2 diabetes in her mother, and a sibling diagnosed with PCOS. On physical examination, the patient was found to be hypertensive and had severe acanthosis nigricans on the neck, axillae, and cubital fossae. Anthropometric measurements revealed a BMI of 43.7 kg/m^2, categorizing her as severely obese, with significant signs of insulin resistance. Laboratory investigations revealed elevated androgen levels, including total testosterone of 55 ng/dl (normal range $<$48 ng/dl), free testosterone of 85 pmol/l (normal range 10-45 pmol/l), and androstenedione levels of 8 nmol/l (normal range 0.8–6.1 nmol/l). Additionally, a low SHBG level of 13 nmol/l (normal range 40–90 nmol/l) was noted, further confirming the presence of hyperandrogenism and contributing to the diagnosis of HAIRAN syndrome.
Conclusion
This case highlights the clinical complexity of HAIRAN syndrome, emphasizing the importance of early diagnosis and comprehensive management. The patient's treatment regimen included insulin-sensitizing agents (metformin), anti-androgen therapy (spironolactone), and oral contraceptives (ethinylestradiol and cyproterone) for menstrual regulation and reduction of hirsutism. Amlodipine was prescribed to manage hypertension, and the patient was referred for psychological support to address self-esteem and quality of life concerns. Given the rare and multifactorial nature of HAIRAN syndrome, a multidisciplinary approach involving endocrinologists, gynecologists, dermatologists, and psychologists is essential for optimal patient care. Ongoing follow-up is necessary to monitor the patient's response to treatment and ensure the proper development of menstrual cycles and overall health.

PAX4 mody - a novel variant

João Menino[1,2], Patricia Ferreira[1,2], Inês Meira[1,2], Ana Leite[1,2], Jorge Pedro[1,2] & Joana Queirós[1]
[1]ULS São João, Serviço de Endocrinologia, Diabetes e Metabolismo, Porto, Portugal; [2]Faculdade de Medicina da Universidade do Porto, Porto, Portugal

Introduction
The Paired Box Gene 4 (PAX4) encodes a transcription factor crucial for pancreatic beta-cell development and maintenance in a differentiated state. PAX4 mutations have been identified as a cause of maturity-onset diabetes of the young (MODY), and also in ketosis prone diabetes. MODY diagnosis requires a high clinical suspicion, encompassing a group of rare monogenic forms of diabetes. We report a novel variant of PAX4 in a 29-year-old female which appears to be pathogenic.
Case report
A 29-year-old female was referred to Endocrinology for diabetes. At diagnosis, four years ago, our patient had a BMI 31.1kg/m2 and was asymptomatic. Several random glucose tests were above 200mg/dL, and her HbA1c was 7.1%. Metformin 2000mg/day was started. She had no other significant medical history or medications. Her family history was notable for diabetes (DM), including both her parents, who were treated with oral antidiabetics, one of her sisters diagnosed at 30 years, and the other sister diagnosed at 18 years during pregnancy, who was treated with insulin due to chronic kidney disease. Additionally, all of her grandparents had DM, as did seven out of nine of her father 's siblings, and two out of five of her mother's siblings. On presentation to our clinic, she had no symptoms, no physical examination alterations, including acanthosis nigricans or other skin abnormalities, and no DM-related complications. Following lifestyle modification, her BMI reduced to 23.3kg/m2 and her A1c improved to 5.3%. Further testing revealed a normal C-peptide (2.69ng/mL, reference 1.10-4.40) paired with a normal glucose of 76mg/dL, negative auto-antibodies (anti-insulin, anti-ICA, anti-IA2 and anti-GAD). Exeter Diabetes Calculator ® revealed a 75.5% chance of having MODY. Next-generation sequencing for MODY identified a heterozygous mutation (NM_001366110.1(PAX4):c.1022G$>$A, p.(Trp341*)) in the PAX4 gene, resulting in a stop codon in the 341st position, classified as a variant of uncertain significance. Metformin was suspended and her A1c remained at 5.3%. Her family members were referred for genetic testing.
Conclusions
PAX4 variants are rare, and individuals affected have had clinical presentations and diagnoses ranging from ketosis-prone DM, to T1DM, T2DM and PAX4-MODY. Given our patient's family history and early onset of diabetes, PAX4-MODY is highly suspected. Genetic testing is increasingly available and should be done to allow for a better understanding of atypical types of DM and to improve patient management.

Sodium-glucose cotransporter 2 inhibitors in type 1 diabetes mellitus: prohibited?

Javier García Sánchez[1], Sara León Utrero[1], Juan Luis Delgado Montoya[1], Enrique Redondo[1], Miguel Quesada Charneco[1] & Pablo J López- Ibarra Lozano[1]
[1]Hospital Universitario Clínico San Cecilio, Granada, Spain

Introduction and objectives
Sodium-glucose cotransporter 2 (iSGLT2) inhibitors in type 2 diabetes (DM2) have demonstrated clear metabolic and cardio-renal benefits. Cardio-renal complications are also very common in patients with type 1 diabetes (DM1). However, the risk of developing diabetic ketoacidosis (DKA) has limited the use of these agents in DM1 and especially in certain DM1 subgroups where they would be beneficial. The aim of this study was to evaluate the renal and metabolic evolution of patients with DM1 and high cardiovascular risk at 6 and 12 months after the use of iSGLT2.
Material and methods
Prospective descriptive observational study analysing 22 patients with DM1 who were indicated to start treatment with iSGLT-2 in the Endocrinology outpatient clinic of the San Cecilio Hospital in Granada, Spain. Clinical and analytical variables were measured. The analysis was performed with SPSS 25.0.
Results
Twenty-two patients with DM1 aged between 18 and 65 years old (mean 49.4$\pm$11,5 years) were included, half of whom were male. The mean time of evolution of DM1 was 28.9$\pm$13.7 years. Thirteen were iSCI users and nine were MDI users. After initiation of iSGLT2 a mean weight loss of 1.8 and 2.8 kg was observed at 6 months and 12 months respectively. HbA1c decreased from a baseline mean of 7.8% to 7.5 and 7.3% at 6 and 12 months respectively. Renal profile: 45.45% of patients had diabetic nephropathy (3 macroalbuminuria and 5 microalbuminuria). From a mean baseline albuminuria of 232.4 mg/g, a decrease of 53 and 87.5mg/g was observed at 6 and 12 months respectively. No episodes of diabetic ketoacidosis (DKA) were observed during follow-up.
Conclusions
The use of iSGLT2 in a DM1 population at high cardiovascular risk resulted in improvement in terms of weight and metabolic control and, above all, a marked decrease in albuminuria without worsening of renal function and without significant DKA or other complications. Therefore, patients with DM1 at high cardiovascular risk and especially with established nephropathy may benefit from the use of iSGLT2.

Efficacy on functionality and perceived quality of life of a nutritional support programme with specific supplementation for people with type 2 diabetes at risk of malnutrition

Ana María Moyano-Sánchez[1], Concepción Muñoz Jiménez[1], Soraya León Idougourram[1] & María José Molina Puerta[1]
[1]UGC Endocrinología y Nutrición. Hospital Universitario Reina Sofía, Department of Endocrinology and nutrition, Córdoba, Spain

Introduction and Objectives
Diabetes mellitus is a highly prevalent disease that can affect nutritional status, as well as quality of life and functioning. The present study aims to evaluate the differences in nutritional status, by analysing functionality parameters and quality of life scales, in patients with diabetes and disease-related malnutrition (DRE) or high nutritional risk, at baseline and 3 months after starting specific nutritional supplementation.
Material and Methods
We selected 15 patients assessed in nutritional prehabilitation consultations, with a diagnosis of type 2 diabetes mellitus and digestive cancer, with DRE or high nutritional risk according to GLIM criteria, in active oncological treatment (chemotherapy, surgery). A nutritional support programme was initiated with dietary recommendations, exercise and specific supplementation for people with type 2 diabetes. Anthropometric assessments, functional tests (number of squats performed in 10 seconds, up and go test) and scales (diabetes stress scale, EQ-5D-5L) were performed at the first consultation and at a 3-month review. Differences were analysed using SSPS v.24 statistical software. A value of $P<0.05$ was considered statistically significant and trend to statistical significance $P<0.1$.
Results
Mean age 71.3 years (SDS 8.2). Antidiabetic treatment received by patients: 69% metformin, 31% iDPP4, 23% iSGLT2, 15% slow insulin, 8% rapid insulin, 8% sulphonylureas. Subjective global assessment at baseline was 61.5% moderate and 15.4% severe malnutrition. At 3 months, 46.2% were moderately malnourished and 53.8% were normonnourished. At 3 months after the start of nutritional supplementation, calf diameter had increased from baseline by a statistically significant 34.4cm vs 35.2cm ($P<0.05$). Diabetes stress scale scores 7.6 vs 4.2 points (NS) and EQ-5D-5L 7 vs 7.6 (NS) also improved. Functional tests of squats and TUG improved modestly 8.8 vs 10.1 squats (NS) and 10.9 vs 10 seconds ($P<0.05$). There was no change in dynamometry results 29.5 vs 29.1 kg (NS).
Conclusions
The implementation of a nutritional support programme in routine medical practice, based on dietary recommendations, exercise and specific supplementation for people with type 2 diabetes with malnutrition or high nutritional risk, improved functional outcomes and subjective assessment in our cohort of oncology patients.

JOINT897

Vitamin D and glycemic control in type 1 diabetes

Nour Hentati[1], Faten Mahjoub[1], Maryam Naifar[1], Rim Rachdi[1], Ramla Mizouri[1], Rim Ben Othman[1], Nadia Ben Amor[1] & Henda Jamoussi[1]
[1]National Institute of Nutrition of Tunis, Tunis, Tunisia

Background
Type 1 diabetes (T1D) is a chronic autoimmune disorder that requires ongoing management of blood glucose levels to prevent long-term complications. Recent studies have suggested a potential link between vitamin D status and glycemic control in individuals with diabetes.
Purpuse
The aim was to study the relationship between 25-hydroxy vitamin D (25(OH)D) levels and glycemic control in patients with type 1 diabetes.
Methods
We conducted a cross-sectional study, including 50 type 1 diabetic patients. All participants underwent a thorough assessment, including the measurement of 25-hydroxyvitamin D, as well as the assessment of fasting blood glucose and hemoglobin A1c levels.
Results
The median age of the participants was 26 years [21.00 - 31.75], with a sex ratio (F/M) of 1.4. The median duration of diabetes was 13.00 years [9.25 - 17.75]. The average level of 25(OH)D was 11.14 $\pm$ 6.49 and 56% of patients had a severe deficiency ($\leq$10 ng/ml). The assessment of glycemic control showed that 78% of patients had a fasting blood glucose level above the therapeutic target (7.2 mmol/l), and 66% had an HbA1c $\geq$ 9%. The analysis of the association between glycemic control and 25(OH)D levels revealed that patients with elevated fasting blood glucose levels had a lower median 25(OH)D level compared to those with fasting blood glucose within therapeutic targets but without a statistically significant difference (8.93 ng/ml [7.57 – 13.89] versus 11.42 ng/ml [6.88 – 15.42]; $P = 0.61$). Furthermore, patients with an HbA1c $\geq$ 9% had a lower median 25(OH)D level compared to those with an HbA1c $<$ 9% (11.39 ng/ml [8.44 – 14.44] versus 8.74 ng/ml [7.08 – 13.25]; $P = 0.14$).
Conclusion
Although patients with elevated blood glucose levels tended to have lower median 25(OH)D levels compared to those with glycemic control within target ranges, these differences were not statistically significant. Further research with larger sample sizes may be needed to better understand the relationship between vitamin D levels and glycemic control in type 1 diabetic patients.

Fighting with a double-edged sword: a case of pancreatic transplant failure with resurgence of autoimmune diabetes in a patient with metastatic colon cancer treated with pembrolizumab

Carlo Casipit[1], Bruce Casipit[1], Maxim Barnett[1] & Justin Riley Lam[1]
[1]Jefferson-Einstein Hospital, Philadelphia, United States

Background
Pembrolizumab is a monoclonal antibody that inhibits PD-1 activity, enhancing cell-mediated cancer cell killing. However, it inadvertently increases the risk of autoimmunity and, in transplant patients, the incidence of graft failure.
Case presentation
A 50-year-old male presented to the hospital due to worsening hyperglycemia over 4 months. He had a past medical history of Type 1 Diabetes Mellitus, End Stage Renal Disease status post Kidney and Pancreatic transplant in 2007, reportedly compliant with Tacrolimus and Prednisone, recently diagnosed with Colon Cancer with metastasis to the transplanted kidney resulting in resection and reinitiation of hemodialysis, he is currently on Pembrolizumab which was started 4 months ago. He denied any fever, rash, polyuria, or diarrhea but reported abdominal pain. He has been off insulin since his transplant but was restarted on a basal-bolus insulin regimen 4 months ago for progressively elevated glucose levels uncontrolled by an insulin sliding scale. Vital signs were normal. Physical examination was unremarkable. Diagnostic tests showed Glucose 400 mg/dL, Beta-Hydroxybutyrate 1.8 mmol/l (ref $<$0.5 mmol/l), blood gas pH 7.43, HCO3 23, CO2 36, HbA1C 7%, C-peptide $<$0.10 ng/mL (ref 0.5-2 ng/mL), Lipase 20 IU/l, TSH and cortisol were normal. Abdominal ultrasound showed normal size and vasculature of the transplanted pancreas. The patient opted for an outpatient pancreatic biopsy. Endocrinology, Oncology, and Transplant teams were consulted, Pembrolizumab was discontinued, his basal-bolus insulin regimen was adjusted, and immunosuppressants were continued. His glucose control improved, and he was discharged with a close outpatient follow-up for further work-up.
Discussion
Our patient's worsening hyperglycemia is likely secondary to pancreatic transplant failure with concerns for the recurrence of autoimmune diabetes from Pembrolizumab. Pembrolizumab works by enhancing the cell-mediated killing of malignant cells. However, it can inadvertently attack donor alloantigens in the transplanted kidneys causing graft failure. Although, the recurrence of autoimmune diabetes in a transplanted pancreas is rare since immunosuppressants effectively control autoimmunity, the concomitant use of Pembrolizumab can inhibit immunosuppression and cause a resurgence of autoimmunity.
Conclusion
Pembrolizumab remains central in the management of multiple malignancies. However, its use is associated with risks for autoimmune endocrinopathies and organ transplant rejection. Therefore, all physicians should properly educate patients regarding the risks and benefits of treatment and ensure close multidisciplinary follow-up.

When karyotype is necessary in hyperinsulinemic hypoglycemia:a case report in mosaic turner syndrome

Samkhwan Thongsukkaeo[1], Vichit Supornsilchai[2], Khomsak Srilanchakorn[2], Nattakarn Numsriskulrat[2] & Suphab Aroonparkmongkol[2]
[1]King Chulalongkorn Memorial Hospital, Bangkok, Thailand; [2]King Chulalongkorn Memorial Hospital, Pediatric endocrinologist, Bangkok, Thailand

Background
Hyperinsulinemic hypoglycemia is a common cause of hypoglycemia in neonates and infants, with several etiologies including syndromic disorders such as Turner syndrome. Turner syndrome linked to glycaemic dysregulation, including diabetes mellitus and, less typically, neonatal hyperinsulinemic hypoglycemia. Turner syndrome and hyperinsulinism are linked by an unknown aetiology.
Case Presentation
We report the case of a 4.5-year-old girl who developed a seizure at the age of 3 months as a result of hypoglecemia. She was born at term, weighing 3,120 g, with AGA. At a blood glucose level of 34 mg/dL, the critical blood sample revealed insulin 3.0 uIU/mL, serum ketones $<$ 0.3 mmol/l, growth hormone (GH) 9.81 ng/mL, and cortisol 16.6 ng/dL. As a result, hyperinsulinemic hypoglycemia is diagnosed, and she has now begun therapy with Diazoxide at a dose of 10 mg/kg/day. The Diazoxide dose has been titrated based on blood sugar, and the most current dose is 3.5 mg/kg/day, which is well managed. A whole genome sequencing investigation for common hyperinsulinism target genes yielded no results. Height velocity has diverged from the 3rd percentile from the age of two, with an average annual height gain of 3.3 cm. At the age of 4.5 years, her height was 91 cm (-3.4 SDS), her BW was 13.5 kg (-1.7 SDS). The paternal and maternal height are 178 and 160 cm, respectively and mid-parental height is 162.5 cm. The normal workup for short stature was completed, including a karyotype analysis. Mild dysmorphic characteristics, such as a bilateral epicanthal fold, clinodactyly in both hands, and hyperconvex nails, were discovered, but otherwise are unremarkable. A film X-ray of the hand reveals slight shortening of the 4th metacarpal bone. A karyotype examination of 50 metaphases found mosaic Turner syndrome with a marker chromosome (46,X,dup(X)(q22q28)/45,X(1)/46,X,+mar(1)).
Discussion
Unlike usual cases of congenital hyperinsulinism, which are linked with increased height and weight, this individual had short stature and borderline low weight, indicating Turner syndrome. Reports from case series and case reports in the literature suggest a link between Turner syndrome and hyperinsulinism, albeit the mechanism is unknown. Some instances have been associated with islet cell nucleomegaly and *KDM6A* haploinsufficiency.
Conclusion
This report emphasizes the significance of examining Turner syndrome in females who appear with unexplained hyperinsulinemic hypoglycemia, especially when coupled with growth failure. More study is needed to understand the processes driving hyperinsulinism in Turner syndrome.

Incidence and survival implications of diabetic nephropathy in post-heart transplant patients

Tasigan Chaemchoi[1], Ai-lada Intrarakamhang[2], Kanokwan Thammanatsakul[2], Supanee Sinphurmsukskul[2], Sarawut Siwamogsatham[3], Sarinya Puwanant[4], Aekarach Ariyachaipanich[4] & Thiti Snabboon[5]
[1]King Chulalongkorn Memorial Hospital, The Thai Red Cross Society, Department of Pharmacy, Bangkok, Thailand; [2]King Chulalongkorn Memorial Hospital, The Thai Red Cross Society, Excellent Center for Organ Transplantation, Bangkok, Thailand; [3]Chulalongkorn University, Chula Clinical Research Center, Faculty of Medicine, Bangkok, Thailand; [4]Chulalongkorn University, Division of Cardiovascular Medicine, Department of Medicine, Faculty of Medicine, Bangkok, Thailand; [5]Chulalongkorn University, Division of Endocrinology and Metabolism, Department of Medicine, Faculty of Medicine, Bangkok, Thailand

Background
Evidence of diabetic nephropathy (DN) following heart transplantation (HTx) in Asian populations remains scarce. This study aimed to assess the incidence, risk factors of post-HTx DN and evaluate its impact on patient survival.
Methods
A retrospective cohort study was conducted on consecutive adult patients who underwent their first HTx at a single center between 2019 and 2023 and survived to hospital discharge. These patients were prospectively followed until December 31, 2024. Post-HTx DN was defined as the concurrent presence of new-onset diabetes mellitus (demonstrated by $\geq$2 consecutive HbA1c $\geq$6.5% or fasting plasma glucose $\geq$126 mg/dL) and albuminuria (urine albumin-to-creatinine ratio $\geq$30 mg/g) in patients without pre-existing diabetes, assessed from three months after heart transplantation onward. Patient survival was assessed using the Kaplan-Meier method, with group comparisons performed using the log-rank test. Cox proportional hazards models were employed for multivariate analysis. Statistical analyses were conducted using STATA version 16 (StataCorp, Texas, USA).
Results
Among 52 patients (85% male, mean age 47.2$\pm$11.8 years, mean BMI 21.7$\pm$3.3 kg/m^2), 10 (19%) had pre-existing diabetes mellitus (DM) before HTx. During a median follow-up of 36 months, 11 patients (21%) developed post-HTx DM, with 2 (4%) progressing to DN. Among patients without pre-existing DM before HTX, new-onset post-HTx DN showed no significant associations with patient characteristics, choice of immunosuppressant regimens, or the occurrence of at least one episode of grade $\geq$2R allograft rejection requiring steroid pulse therapy. Post-HTx DN was independently associated with a sustained decline in kidney function (hazard ratio [HR] 17.4, $P = 0.001$), defined by the persistence of one of the following criteria for at least 4 weeks: $\geq$ 40% decline in eGFR, eGFR $<$ 15 ml/min/1.73 m^2, doubling of serum creatinine, or initiation of dialysis. During the follow-up period, four deaths were recorded, with causes including hemorrhagic stroke, cardiac arrest, sepsis with multiple organ failure, and an unknown cause. Both post-HTx DN (HR, 47.3; $P = 0.007$) and post-HTx dialysis (HR, 45.4; $P = 0.002$) were identified as significant independent risk predictors of all-cause mortality.
Conclusions
Approximately 4% of HTx patients developed post-HTx DN, which may serve as one of the prognostic indicators for their survival outcomes. Further studies on a larger sample size are needed to identify risk predictor of post-HTx DN, enabling the implementation of effective preventive measures.

Prediabetes and systemic inflammation

Valentina Soldat Stankovic[1], Sinisa Stankovic[1], Gabrijela Malesevic[1], Snjezana Popovic Pejicic[1] & Djuro Macut[2]
[1]University of Banja Luka, Medical Faculty, Banja Luka, Bosnia and Herzegovina; [2]University of Belgrade, Medical Faculty, Belgrade, Serbia

Introduction
Systemic inflammation may play a central role in the pathogenesis of diabetes and atherosclerosis. C-reactive protein (CRP), a marker of systemic inflammation, is an independent risk factor for cardiovascular disease. Elevated CRP levels are also present in patients with glucose intolerance (IGT). and diabetes. Several prospective studies have shown that an elevated CRP level is an independent risk factor for the development of diabetes. Although these findings indicate that peripheral blood CRP levels are closely related to glucose levels, it remains unclear whether this relationship exists at glycemic levels in the prediabetic range.
Methods
The study included 106 patients with angiographically diagnosed coronary artery disease, who, based on the oral glucose tolerance test (OGTT), were classified into a group with type 2 diabetes (T2D, $n = 34$), a group with impaired glycemia and glucose intolerance (IFG /IGT, $n = 38$) and a group with normal glucose tolerance (NGT, $n = 34$). The control group consisted of subjects with normal glucose tolerance and no coronary disease ($n = 100$), individually matched by age and body mass index (BMI) with coronary patients included in the study. The circulating level of lipids, insulin, hsCRP, the albumin level in the morning urine sample, and the insulin resistance index HOMA were determined in all of them.
Results
The level of hsCRP was elevated in the group of coronary patients with diabetes ($P<0.05$), as well as in the group of patients with prediabetes

($P<0.05$), compared to the control group. hsCRP values were not significantly different in coronary patients, regardless of glycemic status ($P>0.05$). There is a higher BMI in the group of coronary patients with diabetes and prediabetes ($P<0.05$). A significant correlation of hsCRP with glycemia in 120 min OGTT test was found. ($P<0.05$), independent of existing obesity.

Conclusion

Patients with coronary disease and prediabetes and new onset T2D did not differ significantly in the level of systemic inflammation. Chronic subclinical inflammation, detected by an elevated level of C-reactive protein, is more strongly associated with post load glycemia than with fasting glycemia.

Key words

C-reactive protein, prediabetes, coronary disease

Hypogonadism - is it more frequent in males with type 1 diabetes mellitus?

Maria Ilieva-Gerova[1,2], Maria Orbetzova[1] & Ralitsa Raycheva[3]

[1]Medical University Plovdiv, Clinic of Endocrinology and Metabolic Diseases, Plovdiv, Bulgaria; [2]UMHAT "Sv. Georgy" University General Hospital, Clinic of Endocrinology and metabolic diseases, Plovdiv, Bulgaria; [3]Medical University Plovdiv, Social Medicine and Public Health, Plovdiv, Bulgaria

Introduction

Diabetes mellitus is a chronic metabolic disease, well known for its systemic effects. Type 1 diabetes mellitus (T1DM) is an autoimmune disease with leading insulinopenia and hyperglycaemia but also been linked to the influence of the hypothalamic-pituitary-gonadal axis (HPG) and fertility issues in both men and women, including development of hypogonadism. The aim of the study was to investigate the serum androgen levels in men with T1DM and age- and BMI- matched clinically healthy men of active reproductive age to determine the presence of hypogonadism.

Materials and methods

The study included 71 individuals – 30 men with T1DM and 41 clinically healthy men serving as a control group. A detailed medical history related to disease duration, type of insulin administered, total daily insulin dose (TDI), insulin dose per kilogram (dose/kg) was taken. Anthropometric measurements of weight (kg), height (cm), were performed on all participants, body mass index (kg/m2) (BMI) was calculated. Basal levels of luteinizing hormone (LH), follicle-stimulating hormone (FSH), estradiol (E2), testosterone (T), sex hormone binding globulin (SHBG), dehydroepiandrosterone sulfate (DHEA-S), thyroid stimulating hormone (TSH), serum prolactin (Prl), were studied. Free androgen index (FAI), calculated free testosterone (cFT) and bioavailable testosterone (BioT) were calculated. Biochemical studies included levels of total protein (TPROT), albumin (ALB) and creatinine (CREA), fasting blood glucose (FBG), glycated hemoglobin (HbA1C) and microalbuminuria (U-ALB)

Results

The mean age of the studied men was 31.72 ± 6.05 years and the mean BMI was 24.87 ± 6.03 kg/m2 and no statistically significant difference was found between the groups ($P = 0.944$, $P = 0.537$ respectively). All participants had normal levels of total protein and albumin in the absence of statistically significant differences between the examined men ($P = 0.188$, $P = 0.600$, respectively). As expected, HbA1C and fasting blood glucose levels were higher in men with T1DM compared to healthy controls ($P = 0{,}000$, respectively). Men with T1DM had statistically significantly higher SHBG levels ($P = 0.000$) and lower FAI levels compared to controls ($P = 0.004$). Lower levels of BioT compared to the control group were detected in the DM1 group, but without reaching a statistically significant difference ($P = 0.071$). There were no significant differences in the levels of LH, FSH, LH / FSH, E2, T and cFT in the two groups of men ($P = 0.126$, $P = 0.553$, $P = 0.284$, $P = 0.900$, $P = 0.101$, $P = 0.465$, respectively). All participants had euthyroid function and normoprolactinaemia.

Conclusions

Men with T1DM of active reproductive age had comparable with healthy controls levels of androgens and no presence of hypogondism.

Fear of hypoglycemia: a significant challenge for pregnant women with type 1 diabetes

Narjisse Ouazzani[1], Salma Bensbaa[1], Nassim Essabah Haraj[1], Siham Elaziz[1] & Asma Chadli[1]

[1]Endocrinology and Metabolic Diseases Department Ibn Rochd Hospital Casablanca, Clinical Neurosciences and Mental Health Laboratory Faculty of Medicine and Pharmacy, Hassan II University - Casablanca, Morocco, Endocrinology and Metabolic Diseases Departement, Casablanca, Morocco

Introduction

Pregnant women with type 1 diabetes face an increased risk of maternal and neonatal complications. While tight glycemic control is beneficial in reducing these risks, it can also increase the risk of hypoglycemia, leading to recurrent episodes and potentially severe hypoglycemia, which may culminate in an excessive and pathological fear of hypoglycemia

Objective

This study aims to assess the link between severe hypoglycemia and pathological fear of hypoglycemia in pregnant women with type 1 diabetes, considering factors like diabetes characteristics and mental health.

Methods

A prospective study enrolled 70 pregnant women with type 1 diabetes between March 2022 and December 2024. Fear of hypoglycemia was assessed using the HFS-II scale. Severe hypoglycemia was defined as an event requiring assistance due to altered mental or physical status, regardless of blood glucose level. Data analysis was performed using Tibco Spotfire, with Chi-square tests for categorical variables and Kruskal-Wallis tests for numerical and categorical comparisons.

Results

The frequency of severe hypoglycemia was 47 %, and the mean HFS II score was 31 in this group (G1). In the second group (G2), 53 % of patients had no episodes of severe hypoglycemia, and the mean HFS II score was 7. Group 1 demonstrated poorer glycemic control, evidenced by a higher frequency of severe hypoglycemia, lower hypoglycemia awareness, and higher HbA1c levels. This group also exhibited a higher prevalence of diabetes-related complications, including retinopathy and nephropathy. Furthermore, Group 1 demonstrated less SMBG and fewer adjustments to their diabetes management regimen. In contrast, Group 2 exhibited better glycemic control, lower complication rates, and improved self-care practices. Potential contributing factors are the longer duration of diabetes and the presence of autoimmune diseases in Group 1. The factors that were found to be significantly correlated with a high HFSII score were anxiety ($P = 0.0007$), depression ($P = 0.0009$), the perception of receiving inadequate care and emotional support ($P = 0.0065$), and the presence of diabetic retinopathy ($P = 0.005$). Severe hypoglycemia was associated with anxiety ($P = 0.0009$), depression ($P = 0.0006$), perceived inadequate care and support ($P = 0.0011$), recurrent hypoglycemia ($P = 0.0001$), hypoglycemia unawareness ($P = 0.0001$), poor glycemic control ($P = 0.0008$), and diabetic retinopathy ($P = 0.034$). Lipodystrophy areas demonstrated a strong association, although it did not reach statistical significance ($P = 0.0672$).

Conclusion

Severe hypoglycemia affected 47 % of pregnant women with type 1 diabetes, raising concerns due to its association with fear of hypoglycemia and its link to factors like anxiety and inadequate care.

Dysglycemias in HNF1-b-associated disease: phenotype-genotype correlations

Mariana Gomes Porras[1,2], Luis Salamanca Fresno[3], Isabel González Casado[3] & Ángel Campos Barros[4]

[1]Regional University Hospital of Malaga, Endocrinology and Nutrition, Málaga, Spain; [2]PhD student at the University of Malaga., Málaga, Spain; [3]La Paz University Hospital, Pediatric Endocrinology, Madrid, Spain; [4]Institute of Medical and Molecular Genetics (INGEMM), IdiPAZ, La Paz University Hospital and CIBERER on Rare Diseases (CIBERER U753), ISCIII., Madrid, Spain

Introduction

Hepatocyte nuclear factor 1-b (*HNF1-β*)-associated disease is a multisystem entity.

Objective
To describe the degree of dysglycemia in patients with *HNF1-β* variants diagnosed at *INGEMM* between 2009 and 2024.
Methods
Multicenter retrospective observational study including 67 patients (33 pediatric and 34 adult, 29 cases were family cases) with *HNF1-β* variants identified by MLPA and a custom NGS panel (including 473 genes associated with dysglycemia). Variant filtering, classification and prioritization was performed with VarSeqV2.6.2 and Alamut Visual Plus V1.12, using confidence and quality criteria, (depth >100x; % bp 20x >95%) allele frequency <1% (gnomAD V2.1.1 controls) and *in silico* prediction of pathogenicity (CADD V1.6 score > 20).
Results
45/67 patients (67.2%) presented heterozygous SNV in *HNF1-β* (88.9% missense, 6.7% frameshift, 4.4% nonsense), 46.6% classified as VUS and 26.7% as probably pathogenic or pathogenic. 22/67 patients (32.8%) presented a heterozygous deletion in 17q12 including all *HNF1-β* exons. 13 variants were *de novo*, of which, 69.2% were 17q12 deletions. In the group with *HNF1-β* SNVs, diabetes mellitus (DM) was predominant (62.2%, 28/45 patients), with mean diabetic debut at 32.8 years (11-59 yrs), mean current HbA1c 7.2±0.9%; 20/28 (74%) had microvascular (17/20 nephropathy, 5/20 retinopathy, 3/20 neuropathy) , and 4/28 (14.8%) macrovascular (3/4 ischemic heart disease, 1/4 peripheral arterial disease) complications. 18/28 (66.6%) are on insulin therapy (50% in combination with other hypoglycemic agents- OHAs). Normoglycemia and prediabetes were present in 22.2% and 15.6%, respectively. In 17q12 recurrent deletion syndrome (17q12RDS) cases, normoglycemia predominated (45.4%, 10/22), followed by prediabetes (36.4%, 8/22) and DM (18.2%, 4/22), with mean diabetic debut at 32.9 years (12-33 yrs), mean current HbA1c 6.9±0.7%, 1 patient presented microvascular complications (retinopathy and nephropathy), everyone under insulin therapy (75% in combination with OHAs). Among the prediabetes cases, there was 1 case with transient neonatal DM. In both groups, the most frequent comorbidities were urinary abnormalities (73.2% vs 100% mostly with neonatal diagnosis) and liver disease (56.1% vs. 59.1%). In the group with SNV, hyperuricemia/gout (32.5%), hypomagnesemia (30.8%) and pancreatic atrophy/agenesis (29.3%) stood out. In the group with 17q12RDS, hypomagnesemia (70%), neuropsychiatric disorders (36.4%), and genital abnormalities (22.7%) were the most frequent findings.
Conclusions
The clinical expression of *HNF1-β*-associated disease is highly variable, even within families, requiring a specialized multidisciplinary approach. Sporadic cases are frequent, especially in 17q12RDS, in which neonatally diagnosed genitourinary abnormalities, hepatopathy, hypomagnesemia and neuropsychiatric alterations predominate. Most cases with SNVs develop mainly insulin-dependent DM due to advanced nephropathy and pancreatic dysgenesis.

Study of the clinical profile of diabetics followed up in front-line structures

Ramla Mizouri[1], Hana Ben Younes[2], Rym Ben Othman[1], Rim Rachdi[3], Faten Mahjoub[3], Olfa Berriche[1], Nadia Ben Amor[1] & Jamoussi Henda[1]
[1]Institut National de Nutrition de Tunis, Service A, Tunis, Tunisia; [2]Hôpital régional Yasminette de Ben Arous, Tunis, Tunisia; [3]Institut National de Nutrition de Tunis, Tunis, Tunisia

Introduction
Diabetes is a major public health problem, responsible for life-threatening complications. Maintaining therapeutic control in diabetics is a challenge for all primary care physicians. We aimed to study the clinico-biological profile of diabetics followed up in primary care centers, to identify factors predictive of metabolic control and to evaluate the quality of management of these patients in these centers.
Methods
It was observational, descriptive, cross-sectional and retrospective study, conducted in three primary care facilities: Mhamdia, Megrine and Megrine Chaker. Recruitment took place from February 1 to July 31, 2023. We collected the clinical and biological data of the included patients from the medical files and by interrogation carried out by the investigator.
Results
We collected 221 type 2 diabetics with a mean age of 64.67 ± 11.04 years, predominantly female (sex ratio = 0.38). The mean duration of diabetes was 11.8 ± 8.79 years. Glycemic, blood pressure and lipid control were attained in respectively 38.7%, 27.2% and 12.4% of patients. The multivariate study showed poor glycemic control in diabetics who were elderly ($P = 0.05$); on insulin therapy ($P = 0.001$); had a frequent consumption of sweets ($P = 0.009$) and consumed bread excessively ($P = 0.010$). Better blood pressure control was found among those on antihypertensive treatment ($P < 0.0001$) and non-smokers ($P = 0.037$). Better lipid balance was noted in patients at low to moderate cardiovascular risk ($P < 0.0001$). Hypoglycemia was observed in 37.1% of patients. Risk factors independently associated with the occurrence of hypoglycemia were overweight ($P = 0.004$), insulin therapy ($P = 0.006$) and the presence of macroangiopathy ($P = 0.038$). At least one microangiopathic and macroangiopathic complication was noted in 37.1% and 19% of diabetics respectively. Protective factors against the onset of microangiopathy were dietary reminders at each consultation ($P = 0.006$), metformin intake ($P = 0.027$) and target blood pressure ($P = 0.037$). The development of macroangiopathy was significantly associated with insulin therapy ($P = 0.008$). Glycated hemoglobin was tested as recommended in 63.8% of patients.
Conclusion
The present study showed a discrepancy between the recommendations and our results. The management of diabetics needs to be improved in primary-care center.

JOINT2831
Retrospective evaluation of clinical and metabolic differences in the course of diabetic ketoacidos in patients with diabetes mellitus using SGLT-2 inhibitors: a single center study

Büşra Arslan[1], İsmail Kırlı[1], Gulhan Akbaba[2] & Nese Cinar[2]
[1]Faculty of Medicine, Mugla Sitki Kocman University, Department of Internal Medicine, Mugla, Türkiye; [2]Faculty of Medicine, Mugla Sitki Kocman University, Mugla, Türkiye

Objective
There is increasing data that sodium glucose cotransporter 2 inhibitors (SGLT-2i) may increase the risk of euglycemic diabetic ketoacidosis (DKA). This study aims to retrospectively evaluate clinical and metabolic differences observed during the course of DKA among type 2 diabetic patients (T2DM) using or not using SGLT-2i and type 1 diabetic patients (T1DM). The differences in treatment modalities and intensive care processes among the groups were also assesed.
Materials and Methods
Demographic data, treatment modalities, laboratory results (plasma glucose, HbA1c, C-peptide, blood gas analysis, electrolytes, inflammation markers), clinical parameters [Glasgow Coma Scale (GCS), vital signs], micro- and macrovascular complications and DKA management parameters (ICU admissions, time to resolution of ketosis, the duration of insulin infusion, the amount of HCO3 and saline requirement) were obtained by reviewing electronic medical records and patient files.
Results
Among included 124 patients (61F, 63M), 30,6% were diagnosed with T1DM (n:38), while 69.4% had T2DM (n:86). Among patients with T2DM, 37.2% (n:32) of them were receiving SGLT-2i. The average diabetes duration was similiar among the groups (13.5 years in SGLT-2i users vs. 13.6 years in non-SGLT-2i users vs.12.2 years in T1DM; $P > 0.05$). Infection was the main precipitating factor for DKA in (13 out of 32) SGLT-2i users. There was no statistically significant difference among the groups regarding GCS, other vital signs, or ICU admission rates. Initial glucose levels, HbA1c, C-peptide, lipid profile, blood gas ph, lactate, electrolyte levels were similiar among the groups. But, all patients with euglycemic DKA with plasma glucose < 300 mg/dL ($n = 9$, 7.2%) were found in the SGLT-2i users group. On the otherhand, SGLT-2i users had higher degree of ketosis compared to patients non-SGLT-2i users (keton 3 positivity, 65.6% vs. 35.2%, $P < 0.05$). Moreover, ketonemia resolution time and insulin infusion duration were significantly higher in patients using SGLT-2i compared to other groups ($P < 0.05$ for all). In addition, more amount of HCO3 (6.59±8.68 mmol/l in SGLT-2i users vs. 2.41±4.67 mmol/l in non-SGLT-2i users vs. 3.11±5.71 mmol/l in T1DM; $P < 0.05$) and saline infusion (6078.1±1739.9 mL in SGLT-2i users vs. 3894.4±965.3 mL in non-SGLT-2i users vs. 4894.7±1732.3 mL in T1DM; $P < 0.05$) was required in SGLT-2i users compared to other groups during the treatment.
Conclusion
Considering the association of SGLT-2i use with prolonged ketone negativity and insulin infusion time and increased HCO3 and fluid requirements, intensive care

treatment protocols should be personalized and more stringent control and follow-up protocols should be developed for these patients.

Trends in diabetic foot infections in albania: a decade of insights into etiology and risk factors

Eni Celo[1], Sokol Hasho[2] & Leonard Deda[3]
[1]Trauma University Hospital, Tirana, Albania; [2]Shefqet Ndroqi University Hospital, Tirana, Albania; [3]Mother Theresa University Hospital, Tirana, Albania

Diabetic foot infections (DFIs) are a leading cause of morbidity and amputation in patients with diabetes, yet, the etiology and risk factors are not fully understood. This study analyzes temporal trends in DFI causes, microbiological profiles, and clinical outcomes over a 10-year period, using data from three different cohorts (2013, 2019, and 2024) of 400 patients treated at Reha Diabetic foot clinic. Our results show that there is an important change in the microbiological profile of DFIs with increasing incidence of multidrug-resistent organisms (MDRO), especially MRSA. Between 2013 and 2024, the proportion of MDRO-related infections rose significantly and correlated with previous antibiotic treatment and longer hospitalization. In 2013, Pseudomonas aeruginosa was the most common microorganism, whereas in 2024, Staphylococcus aureus became the dominant species. Additionally, we identified key risk factors for severe DFIs, including peripheral arterial disease (PAD), poor glycemic control (HbA1c $>$ 9%), and late admission to specialized care. Patients with PAD had an increased risk for the development of osteomyelitis ($P<$ 0.01), while those with HbA1c $>$ 9% had a 40% higher risk of amputation ($P<$ 0.05). Our study highlights the changing nature of DFIs and the importance of early treatment to improve patient outcomes. Using broad-spectrum antibiotics alongside a multidisciplinary approach can help manage infections more effectively. By identifying and addressing the factors that contribute to these infections and staying aware of evolving microbial patterns, we can take important steps toward reducing the risk of severe complications, including disability and death from diabetic foot disease.

The importance of interleukin 6 in the detection of silent myocardial ischemia in patients with tipe 2 diabetes

Gabrijela Malesevic[1], Snjezana Popovic Pejicic[1], Valentina Soldat Stankovic[1], Tamara Kovacevic Preradovic[1], Bojan Stanetic[1], Ljiljana Kos[1], Bojana Caric[1] & Ivona Risovic[1]
[1]University Clinical Centre of the Republic of Srpska, Medical Faculty, University of Banja Luka, Bosnia and Herzegovina, Department of Endocrinology, Banja Luka, Bosnia and Herzegovina

Introduction and aim
A special feature of Coronary Heart Disease (CHD) in patients with type 2 diabetes (T2D) is that it is often asymptomatic and occurs as a consecuence of cardiovascular auotonomic neuropathy. Predicting the risk of cardiovascular events occurrence and progression of atherosclerosis and correlation of inflammatory agents in its progression has increasingly been the focus of research. Increased levels of interleukin 6 (IL-6) accelerates atherosclerosis and occurrence of cardiovascular complications in patients with T2D. Therefore, the determination of IL 6 in these patients would be significant in stratifying the risk of CHD. The aim of the study was to evaluate the importance of determining inflammatory cardiovascular risk markers IL-6 in screening for the presence of CHD in asymptomatic patients with T2D.
Methods
The cross-sectional study included 159 patients with T2D, without any symptoms and signs of CHD and no previous history CHD. Ergometric testing proved or ruled out the presence of silent CHD. The levels of IL-6 were determined by ELISA.
Results
IL6 values were significantly higher in patients with positive ergometric test (5.83 ± 1.99 pg/mL) compared to patients with negative ergometric test (2.04 ± 1.39 pg/mL) ($P<0.001$). The patients with higher IL-6 values were 1.457 more likely to have positive ergometric tests than those with lower IL-6 ($P<0.05$). The combination of IL-6, glycoregulation parameters (HbA1c) and duration of diabetes are significant predictors of silent ischemia. With their increase, the probability of a positive ergometric test also increases ($P<0.01$).
Conclusion
It was proven that there was a greater possibility of the presence of silent CHD in asymptomatic patients with T2D with higher values IL-6 and their determination could be recommended in improving cardiovascular risk stratification in asymptomatic patients with T2D.

Key words
diabetes mellitus, coronary heart disease, interleukin 6.

Gennimatas' General Hospital of Athens, Department of Pathology, Athens, Greece; [5]'G. Gennimatas' General Hospital of Athens, First Departmennt of Surgery, Athens, Greece

Background
Insulinomas are functioning neuroendocrine neoplasms (NENs) characterized by autonomous secretion of insulin. The incidence of insulinomas is 1-4 people per million per year which peaks in the fifth decade of life with a female preponderance. The vast majority (90%) of insulinomas are solitary, benign, pancreatic lesions with a diameter of <2 cm. Ectopic insulinomas are extremely rare ($<2\%$), most frequently arising in peri-pancreatic or peri-duodenal regions. Extra-pancreatic NENs secreting insulin have also been described in the liver, the cervix, the kidney and the pelvis.
Case presentation
A 29-year-old woman was referred to Endocrinology Department with features of Whipple's triad during recurrent episodes of hypoglycemia. Symptomatic hypoglycemia (glu 39mg/dl), developed twelve hours after the initiation of a 72-hour fast, with increased insulin and c-peptide levels (insulin$=$ 60.4μIU/ml, c-peptide$=$4.3ng/ml). Insulin antibodies were undetectable and insulin-like growth factor 2-mediated hypoglycemia was excluded. An abdominal MRI was performed which showed a 3 cm mass at the anatomic site between the spleen, the left kidney and behind the pancreatic tail, but failed to reveal any pancreatic lesions. Further imaging with ^{68}Ga-DOTATATE PET/CT was in accordance with the MRI findings and showed increased radiotracer uptake (SUVmax 29.6) by the aforementioned tumor. However, on endoscopic ultrasound, a small lesion (<1 cm) in the tail of pancreas was localized in addition to the primary lesion. Ultrasound-guided fine needle aspiration was performed on both lesions and the presence of neuroendocrine neoplasmatic cells was confirmed in both the pancreatic tumor and the peri-pancreatic one. Distal pancreatectomy, splenectomy and resection of the extra-pancreatic lesion were performed. Histopathology revealed two well-differentiated, neuroendocrine neoplasms grade 2 (NEN-G2) of intermediate malignancy with a Ki-67 of 3%. Immunostaining was positive for insulin, glucagon, NSE, CD-56, synaptophysin and chromogranin. The pancreatic insulinoma measured 0.6 cm and the peri-pancreatic one 4 cm. Given that multiple insulinomas are characteristic of MEN-1 syndrome, genetic testing for *menin* variants was performed which was negative. Post-operative period was uneventful and during a 6-month follow-up period the patient has remained asymptomatic and euglycemic.
Conclusions
To our knowledge, this is the first report of sporadic multifocal insulinoma with both intra-pancreatic and peri-pancreatic lesions. In addition, our case emphasizes the importance of successful pre-operative insulinoma localization in order to ensure definite curative treatment.

[1]Hong Kong Children's Hospital, Hong Kong, Hong Kong; [2]Pamela Youde Nethersole Eastern Hospital, Hong Kong, Hong Kong; [3]Queen Elizabeth Hospital, Hong Kong, Hong Kong; [4]The University of Hong Kong, Hong Kong, Hong Kong; [5]Queen Mary Hospital, Hong Kong, Hong Kong; [6]Prince of Wales Hospital, Hong Kong, Hong Kong; [7]Tuen Mun Hospital, Hong Kong, Hong Kong; [8]Princess Margaret Hospital, Hong Kong, Hong Kong; [9]United Christian Hospital, Hong Kong, Hong Kong; [10]Kwong Wah Hospital, Hong Kong, Hong Kong; [11]Alice Ho Miu Ling Nethersole Hospital, Hong Kong, Hong Kong; [12]Caritas Medical Centre, Hong Kong, Hong Kong; [13]Tseung Kwan O Hospital, Hong Kong, Hong Kong

Background
New technological devices are increasingly used in the management of children with type 1 diabetes (T1D) worldwide and has been shown to improve glycaemic control and reduce risk of hypoglycaemia. In the past, there was considerable barrier in accessing these technologies locally. Territory-wide funding programme for CGMS and limited sponsorship for insulin pump have rolled out in the past few years. However, there is limited data on whether this has impacted glycaemic outcomes.
Method
This retrospective study assessed the use of CGMS and insulin pump in Hong Kong from 2017 to 2023. Data were retrieved from the Hong Kong Childhood Diabetes Registry. HbA1c over time, rates of DKA and severe hypogylcaemia (requiring glucagon injection/hospitalization) were evaluated. Additionally, HbA1c was compared between users versus non-users of CGMS and insulin pump in 2023.
Results
Table 1 showed an expansion of both regular CGMS and insulin pump use from 0% to 41.7% and 3.1% to 9.6% respectively from 2017 to 2023. There was significant improvement in HbA1c levels ($P < 0.05$) over the same period. No change in rates of DKA or severe hypogylcaemia was found. In 2023, regular CGM users demonstrated lower HbA1c levels compared to non-users (7.6 ± 1.2 vs 8.4 ± 1.8, $P < 0.05$). HbA1c was also lower among insulin pump users (7.5 ± 1.4 vs 8.0 ± 1.4, $P < 0.05$), with more achieving the target HbA1c $< 7\%$ (44.7% vs 19.8%, $P < 0.05$).
Conclusion
While coverage of diabetes technologies remained much lower than that of many developed countries, utilization has expanded in the past 8 years in Hong Kong. Those who used these technologies had better glycaemic control. With this, policy change to allow broader coverage in children with T1D should be enforced.

Table 1.

Year	No of children with T1D	Regular CGM use (>80% time) (%)	Insulin pump (%)	Average HbA1c (%)	DKA	Severe hypoglycaemia
2017	325	0	3.1%	8.2 ± 1.7	8.3%	1.2%
2018	365	10.4%	5.5%	8.3 ± 1.8	2.5%	0.8%
2019	389	9.5%	6.4%	8.2 ± 1.8	3.1%	2.3%
2020	375	12.8%	7.2%	8.0 ± 1.6	2.4%	2.9%
2021	367	27.7%	6.8%	7.9 ± 1.5	3.0%	0.8%
2022	382	34.6%	7.9%	8.0 ± 1.6	2.9%	1.3%
2023	396	41.7%	9.6%	8.0 ± 1.5	2.8%	2.3%

Early diagnosis of acromegaly in patient with with type 1 diabetes based on glycemic data measured using an advanced hybrid closed loop system

Csaba Sumanszki[1], Peter Reismann[2] & Gyozo Kocsis[1]
[1]Semmelweis University, Internal Medicine and Oncology, Budapest, Hungary; [2]Semmelweis University, Budapest, Hungary

Introduction
A spectrum of metabolic alterations in acromegaly predisposes patients to diabetes mellitus, with chronic overproduction of growth hormone (GH) induced insulin resistance representing the most significant underlying mechanism.
Aim
We present a comprehensive case report detailing the clinical findings and advanced hybrid closed-loop (AHCL) system data of a female patient with Type 1 diabetes mellitus diagnosed with GH-secreting pituitary adenoma.
Case description
41-year-old female patient with Type 1 diabetes mellitus diagnosed at the age of 13, treated previously with intensified conventional therapy (ICT), was initiated continuous glucose monitor at the age 39 due to poor glycemic control (HbA1C 9.1%), despite adequate dietary compliance and close to normal weight (BMI 25.7 kg/m2). Initially, small improvement in her glycemic control was achieved (insulin need decreased from 0.93 to 0.73 U/kg/day). Throughout one-year glycemic control worsened (insulin need increased to 0.9 U/kg/day, time in range (TIR) decreased from 59 to 40%), and the patient was diagnosed with hypertension. The decision to transition to AHCL system was made, which despite improving glycemic control (TIR:68%), could not decrease insulin need (0.81 U/kg/day). The suspicion of GH-induced insulin resistance, raised based on slight clinical features, was confirmed by elevated level of IGF-1 (784.00 mg/l). Hormonal panel showed intact adrenal, thyroid and gonadal axes and normal prolactin level. GH suppression test using glucose was omitted, instead, GH profiling in an euglycemic state was performed with 2-hour interval measurements for 8 hours that revealed an elevated average GH level of 56,6 mg/l. A pituitary MRI showed a macroadenoma (16x15x14 mm), with a slight protrusion in the left sinus cavernosus (Knosp grade 2). Echocardiography, abdominal ultrasound and colonoscopy revealed no abnormalities. The patient was started on somatostatin analogue therapy and successful pituitary surgery was performed. Pathological examination showed mammosomatotroph pituitary neuroendocrine adenoma with elevated proliferation rate (Ki-67 index 5%). Postoperative GH and IGF-1 levels decreased and glycemic control improved (insulin need decreased: 0,55 U/kg/day, TIR: 73% and HbA1C: 7,5%).
Conclusion
The diagnosis of acromegaly in patients with Type 1 diabetes can often be challenging, early recognition of decreased insulin sensitivity in a previously well-controlled patient and characteristic clinical features are essential for accurate and timely diagnosis.

[1]IRCCS Policlinico S. Orsola, Endocrinology and Diabetes Prevention and Care Unit, Bologna, Italy; [2]University of Bologna, Department of Medical and Surgical Sciences (DIMEC), Bologna, Italy; [3]IRCCS Policlinico S. Orsola, Nephrology, Dialysis and Transplantation Department, Bologna, Italy

Background and Aims
Diabetic Kidney Disease (DKD) is one of the most common complications of diabetes mellitus (DM) and the leading cause of dialysis worldwide. Previous multidisciplinary approaches have been attempted with varying success. This study aims to assess the results of a three-year diabetes-nephrology outpatient program established at an Italian Research Hospital.
Materials and Methods
A single-centre, retrospective, observational study involving 306 patients with type 2 DM and CKD, who received at least two evaluations in the multidisciplinary service, consisting in simultaneous joint medical visits conducted by a diabetologist and a nephrologist. Anthropometric and biochemical parameters, as well as therapies, were compared between first evaluation (V0) and latest

follow-up visit (V1). Estimated glomerular filtration rate (eGFR) slope was calculated as *(eGFR V1- eGFR V0)/(time of follow-up).*

Results

Of the 306 patients evaluated, 60,5 % had stage G3a-G3b CKD and 58,7% had stage A3 albuminuria according to KDIGO classification. Mean time of follow-up was 27 ± 12 months. Significant improvements between V0 and V1 were seen in BMI (mean BMI at V0 30,5 ± 7,4 vs 29,4 ± 5,4 kg/m^2 at V1, $P<0{,}001$), waist circumference, systolic and diastolic blood pressure, total and LDL-cholesterol (LDL-c V0 93,8 ± 41,2 vs LDL-c V1 70,2 ±34,2 mg/dl, $P<0{,}001$), triglycerides (170,5 ± 124,1 vs 143,1 ± 65,9 mg/dl, $P<0{,}001$), uric acid and HbA1c (mean HbA1c 55,8 ± 12,8 at V0 vs 52,2 ± 11,5 mmol/mol at V1, $P<0{,}001$). In the multivariate regression analysis, greater reduction in HbA1c was associated with higher baseline HbA1c and treatment with glucagon-like peptide-1 receptor agonists (GLP-1 RA). The eGFR showed a significant decline between V0 and V1 (52,3 ± 22,6 at V0 vs 48,6 ± 22,9 ml/min at V1, $P<0{,}001$), with a mean eGFR slope of -2,1 ±7,0 mL/min/1,73m^2/year. Moreover, a significant reduction in urine albumin-creatinine ratio (uACR) was observed from V0 to V1 (median uACR at V0 138,5 [23-554] mg/g vs. 83,5 [20 - 501] mg/g at V1, $P = 0{,}002$). In a multivariate regression analysis, a slower eGFR decline was linked to treatment with sodium glucose co-transporter 2 inhibitors (SGLT2i), while a higher baseline eGFR, greater baseline 24-hour proteinuria and older age were associated with faster eGFR decline.

Conclusions

This study suggests an effective and simply viable model of care for the integrated management of co-morbid type 2 DM and CKD and confirms the central role of SGLT2i and GLP-1 RA in this context.

Evaluation of clinical, laboratory and immunological characteristics in the early onset (diagnosed age

Tae Keun Oh[1], Dong-Hwa Lee[1], Hyun Jeong Jeon[1] & Jung Sue Kim[2]
[1]Chungbuk National University College of medicine, Internal Medicine, Cheongju, South Korea; [2]St. Mary's Hospital, Pediatrics, Cheongju, South Korea

Aims

The classification of early onset (< 30 years old) patients with diabetes mellitus (DM) as either type 1 diabetes (T1D) or type 2 diabetes (T2D) can be a challenge due to their similar overlapping phenotypes. In our present study, we attempted to utilize various clinical and laboratory characteristics in combination with immunological factors in the blood to determine whether it would be possible to distinguish and more accurately characterize our patients as T2D.

Methods

Electronic medical records were evaluated to obtain information categorized as either early onset patients with DM ($n = 102$) and patients with T1D ($n = 89$). Using the stored serum from these patients, autoantibodies of anti-IA2, anti-ZnT8 and anti-GAD were measured

Results

In the clinical characteristics, early onset patients with DM ($n = 102$) were younger (31.7 ± 7.0 years old, $P< 0.01$), more overweight (28.1 ± 5.5 kg/m^2, $P< 0.05$), shorter duration of diabetes (10.4 ± 7.3 years, $P< 0.01$) and a more prevalent family history of diabetes (81%, $P< 0.0$) than patients with T1D. The laboratory values from early onset patients with DM exhibited lower HbA1c (8.0 ± 2.1%, $P< 0.01$) and glucose levels (165 ± 73 mg/dL, $P< 0.01$) with conversely higher C-peptide levels (2.2 ± 1.2 ng/ml, $P< 0.01$). Measurements of immunological factors, demonstrated that the prevalence of anti-ZnT8 (2%) and anti-GAD antibody (2%) in early onset patients with DM was significantly lower ($P<0.01$) compared to patients with T1D (13% for anti-ZnT8 and 38% for anti-GAD). The prevalence of anti-IA2 was not significantly different between early onset patients with DM (13%) versus patients with T1D (11%). In the multivariate logistic regression analysis, C-peptide level (B 4.453, S.E 0.844, Wald 27.808, $P< 0.001$) was the strongest independent factor to distinguish early onset patients with DM as T2D. After adjusting C-peptide level, family history of diabetes (B 0.830, S.E 0.420, Wald 3.909, $P = 0.048$), BMI (B 0.111, S.E 0.039, Wald 8.167, $P = 0.004$) and the relative negative status of anti-GAD (B -2.041, S.E 0.597, Wald 11.670, $P< 0.001$) were determining factors in our analyses.

Conclusions

In this study, our findings suggested that early onset patients with DM may be more accurately diagnosed as T2D if they have a compilation of elevated C-peptide levels, higher BMI, more prevalent history of familial diabetes and the absence of detecting anti-GAD antibodies.

New technologies counteracting genetic errors: a case report

Selena Rodríguez Fernández[1], Óliver Quintero Rodríguez[1], Kevin Díaz Gorrín[1], Javier Panizo Fra[1], Ana León Ocando[1], Laura Mesa Suárez[1], Elena Rodríguez Sosa[1] & Macarena Sánchez-Gallego Alonso[1]
[1]Hospital Universitario de Canarias, Endocrinology and Nutrition, Santa Cruz de Tenerife, Spain

Introduction

Among the diagnostic criteria for Diabetes Mellitus (DM) is the determination of glycated hemoglobin levels. In addition, it plays a crucial role in the long-term monitoring of diabetic patients, as it has been identified as a significant predictor of chronic complications of the disease. Hemoglobin is a hemoprotein found in red blood cells. Several pathologies can affect this protein, including hemolytic anemias (which may be intrinsic, such as hemoglobinopathies, enzyme defects, membrane disorders, or extrinsic, such as immune/non-immune causes). Thus, the glycated hemoglobin values used for DM monitoring may be altered in the presence of any of these hematological diseases.

Clinical Case

A 46-year-old male was referred from the Primary Care consultation after being diagnosed with type 2 DM. The diagnosis was made incidentally due to elevated fasting blood glucose levels during pre-anesthetic laboratory studies. The reason for referral was the presence of abnormally low glycated hemoglobin levels in relation to the blood glucose levels usually presented by the patient. The patient's personal medical history includes grade 2 obesity, cholelithiasis, hepatic steatosis, and monoclonal gammopathy of uncertain significance. Upon the first evaluation, it was found that the patient's son is being studied for chronic hemolytic anemia and type 1 DM. Given the characteristics of the patient and his offspring, it was decided to rule out any erythrocyte abnormalities in both individuals and to conduct a genetic panel study.

Results

The following analytical results were obtained during the next evaluation:

- Fasting blood glucose of 140 mg/dL, glycated hemoglobin of 4.20%.
- Hemoglobinopathies and enzyme defects were ruled out. A heterozygous mutation in the PIEZO1 gene, c.7367G > A (p. Arg245His), was detected in both the father and the son. This mutation is responsible for the membrane disorder known as hereditary dehydrated stomatocytosis or hereditary xerocytosis. Hereditary xerocytosis arises due to alterations in erythrocyte permeability. It is characterized by chronic hemolytic anemia, primarily due to a slight increase in erythrocyte potassium permeability, leading to dehydration, rigidity, and hemolysis of red blood cells.

Conclusion

In some cases, such as hereditary xerocytosis and other hemolytic anemias, glycated hemoglobin is not useful for routine chronic monitoring of diabetic patients, as its values may be altered. In these cases, as demonstrated in this patient, glucose monitoring systems play a crucial role and serve as an excellent tool for improving the control of diabetic patients.

Blood sugar peaks and valleys: visualizing glucose patterns through world's highest mountains

Annina Althaus[1], Maria Mathiopoulou[2] & Maria Iris Romay Ogando[1]

[1]University Hospital Zurich, Department of Endocrinology, Diabetology and Clinical Nutrition, Zurich, Switzerland; [2]Hospital of Uster, Department of Endocrinology and Diabetology, Uster, Switzerland

Background and aims
Continuous Glucose monitoring (CGM) has become a standard practice in diabetes diagnostic. The resulting daily blood glucose profiles often resemble mountain landscapes, leading to the use of metaphors such as a "mountain and valley" to describe sharp rises and falls in blood sugar levels. These fluctuations are primarily influenced by dietary choices, activity levels, insulin balance and individual insulin sensitivity or treatment. In our clinical practice, we have observed that visual analogies, such as mountain comparisons, facilitate patients' comprehension of CGM patterns. Notably, terms like "Matterhorn" and "Kilimanjaro" were recalled and referenced by patients in following consultations.
Materials and methods
We analyzed CGM curves, including basic glucose metrics (e.g., glucose variability), daily and meal-related patterns (e.g., fasting, postprandial, and nighttime trends), insulin effects, the influence of physical activity, and the occurrence of hypoglycemia, to identify patterns.
Results
Inspired by the Swiss mountains, our article visualizes the most common blood glucose profile patterns by comparisons with the world's highest and most iconic peaks, which can empower patients to make informed lifestyle and treatment decisions.
Conclusion
This approach underscores the role of CGM as a pivotal tool, transforming abstract data into actionable insights for personalized care. Visual representations can help simplify the complexity of blood glucose patterns, making them more accessible and easier for patients to understand.

Mountain	Description of glucose	Possible causes
 Mount Everest or Matterhorn	Rising throughout the day, especially evening-time and declining at night	Carbohydrate/fast acting insulin imbalance
 Kilimanjaro or Zugspitze	Elevated blood glucose levels persisting throughout the day (plateau-shape)	Carbohydrate-rich diet with insulin imbalance or non-adherence to insulin treatment (e.g. fear of hypoglycemia)
 Mount Watzmann	Elevated blood glucose levels after the evening meal, persisting throughout the night (U-shape)	Carbohydrate/insulin imbalance during the night, e.g. fear of nocturnal hypoglycemia or Intense physical activity during the day
 Three Peaks (of Lavaredo)	Alternating increase and decrease (peak-valley pattern)	Carbohydrate-rich meals, often followed by a rapid decline in blood glucose level
 Mount Fitz Roy or Mount Whitney	No clear pattern or consistency in blood glucose levels	Inconsistent diet or incorrect carbohydrate estimation
 a small hill nearby, e.g. Uetliberg for people from Zurich	stable blood glucose levels	Good diabetes management

18p deletion syndrome associated with type 1 diabetes and hashimoto's thyroiditis: a case report on autoimmune disorders and genetic factors

Mehmet Ali Oktay[1], Elif Tuğçe Tunca Küçükali[1], Aylin Kılınç Uğurlu [1], Esra Döğer[1], Gülsüm Kayhan[2], Mahmut Orhun Çamurdan[1] & Aysun Bideci[1]
[1]Gazi University Faculty of Medicine Hospital, Department of Pediatric Endocrinology, Ankara, Türkiye; [2]Gazi University Faculty of Medicine Hospital, Department of Medical Genetics, Ankara, Türkiye

Introduction
18p deletion, first described by Jean de Grouchy in 1963, is a rare chromosomal anomaly caused by the partial or complete loss of genetic material on the short arm of chromosome 18. This syndrome occurs in approximately 1 in 50,000 live births and exhibits various phenotypic features, including mild to moderate intellectual disability, short stature, speech delay, and facial dysmorphisms. Additionally, this syndrome has been associated with autoimmune diseases such as autoimmune thyroid disorders, rheumatoid arthritis, celiac disease, lupus, and alopecia. However, the molecular mechanisms explaining the connection between 18p deletion syndrome and autoimmunity remain unclear.
Case Report
A 3-year-8-month-old girl presented with complaints of polydipsia and polyuria. Physical examination revealed dysmorphic features, including a round face, broad nasal bridge, long philtrum, hypertelorism, and a short neck. Cardiovascular evaluation detected a 3/6 systolic murmur. Laboratory investigations showed glucose 339 mg/dL, insulin 11.43 mU/l, C-peptide 1.26 ng/mL, HbA1c 9.4%, and positive Anti-GAD and Anti-insulin antibodies. The patient was diagnosed with Type 1 Diabetes Mellitus (T1DM) and insulin therapy was initiated. Further evaluations revealed bilateral sensorineural hearing loss, myopia, IgA deficiency, and subaortic stenosis. At the age of five, epilepsy developed, and antiepileptic therapy was started. Array CGH analysis revealed a 13.7 Mb deletion in the 18p11.32-p11.21 region (arr[hg19] 18p11.32p11.21(148963-13875138)x1). During follow-up, elevated Anti-TPO and Anti-TG antibodies led to the diagnosis of Hashimoto's thyroiditis, and levothyroxine therapy was initiated.
Discussion
18p deletion syndrome is a rare genetic condition with a broad spectrum of clinical features. Common findings include short stature, facial dysmorphisms, intellectual disability, skeletal deformities, and ophthalmologic problems. 18p deletion syndrome is associated with early-onset autoimmune thyroid diseases, T1DM, and other immune system disorders. Genetic analysis highlighted the loss of *PTPN2, PTPRM, ADCYAP1, USP14,* and *LPIN2* genes. *PTPN2* plays a critical role in regulating immune responses, increasing the risk of T1DM and autoimmune diseases. *PTPRM* negatively regulates STAT3 phosphorylation; its loss may lead to increased Th17 cell fractions and accelerated autoimmune processes. *ADCYAP1* protects beta cells from cytokine-induced apoptosis, while *USP14* maintains cellular homeostasis by preventing beta-cell apoptosis. *LPIN2* regulates lipid metabolism and inflammatory responses; its deficiency may cause immune system hyperactivity, triggering T1DM. The loss of these genes has been highlighted as potential mechanisms underlying autoimmunity and diabetes pathogenesis.

Key words
18p deletion syndrome, Type 1 Diabetes Mellitus, Hashimoto's thyroiditis, Autoimmune diseases

JOINT3446

Two rare monogenic diabetes cases due to CEL mutations: one with MODY 8 phenotype, one presenting as type 1 diabetes

Ceren Tufan[1], Ersen Karakilic[1], Canan Ceylan Köse[1], Emre Sedar Saygili[1], Hayri Bostan[2] & Fatma Sılan[1]
[1]Canakkale Onsekiz Mart University Faculty of Medicine, Endocrinology and Metabolism, Canakkale, Türkiye; [2]Canakkale Mehmet Akif Ersoy State Hospital, Endocrinology and Metabolism, Çanakkale, Türkiye

Introduction
Monogenic diabetes accounts for approximately 1-5% of all diabetes cases. Carboxyl-Ester Lipase(CEL) gene mutation-associated diabetes is extremely rare, accounting for less than 1% of all monogenetic diabetes. It is usually associated with MODY-8 but can cause different clinical presentations. CEL mutations can lead to islet cell loss due to defective protein accumulation in the pancreas. While insulin deficiency is expected, the coexistence of T1DM with autoimmune markers is notable. **Case 1:**A 52-year-old male with a 15-year history of diabetes mellitus(DM) and 13 years on insulin therapy presented for blood glucose regulation. His BMI was 23 kg/m^2, and his physical examination was unremarkable. He was on insulin glargine (28 U, OD), insulin aspart (14 U, TID), vildagliptin/metformin (BID), and dapagliflozin(OD). HbA1c was 8.7%, C-peptide 0.77 ng/mL, and Anti-GAD was negative. Other laboratory tests, including hemogram, renal function, and liver function tests, were within normal limits, with no albuminuria. Non-proliferative diabetic retinopathy was detected. His father and six siblings had been diagnosed with DM at a young age. Genetic

analysis revealed a heterozygous CEL(c.1966G>C, p.A656P) mutation(Table 1).
Case 2:A 28-year-old female with T1DM since age two presented for follow-up. Her BMI was 22 kg/m^2, and her physical examination was normal. She was on insulin aspart/degludec(30 U, BID) and insulin aspart(8 U, OD). HbA1c was 9.4%, C-peptide<0.1 ng/mL, and Anti-GAD was elevated(47.5 U/mL), while other diabetes-related autoantibodies were negative. Renal and liver function tests were normal, and the albumin-to-creatinine ratio was 76 mg/day, leading to ramipril(2.5 mg, OD) initiation. No diabetic retinopathy was found. She had no family history of DM. Genetic analysis identified a homozygous frameshift mutation in CEL (c.1876_2039del, p.V626fs*6). The 3D structures of wild-type and mutant proteins were predicted using SWISS-MODEL(Table 2).
Conclusion
Cases of diabetes associated with CEL gene mutations are extremely rare and typically present as a form of diabetes requiring insulin therapy. While these mutations can lead to monogenic diabetes cases associated with MODY-8, their potential association with T1DM, as observed in our second case, suggests a broader clinical spectrum. Increased reporting of monogenic diabetes forms will enhance the recognition of diabetes-associated genes and contribute to a better understanding of its etiopathogenesis.

Frequency of cardiovascular autonomic neuropathy and its association with microvascular complications in states of glucose tolerance abnormalities

Meva Dogan[1], Fatma Dilek Dellal Kahramanca[2], Zeliha Yazar[3], Osman Inan[1] & Bekir Cakir[2,4]
[1]Ankara City Hospital, Internal Medicine, Ankara, Türkiye; [2]Ankara City Hospital, Endocrinology and Metabolism, Ankara, Türkiye; [3]Ankara City Hospital, Ophthalmology, Ankara, Türkiye; [4]Yildirim Beyazit University, Endocrinology and Metabolism, Ankara, Türkiye

Introduction
Cardiovascular autonomic neuropathy (CAN) is significant cause of mortality and morbidity in diabetic individuals. Postprandial hypotension (PPH) is one of the clinical manifestation of CAN. The aim of study was to explore the frequency of CAN and spesifically PPH in different glucose tolerance abnormality states meeting prediabetes criteria, besides the relationship between CAN, PPH, and diabetic microvascular complications.
Methods
A total of 82 patients who met the criteria for prediabetes according to fasting, random blood glucose or HbA1c levels included in the study. During OGTT, blood pressure and heart rate were evaluated in 0, 10, 20, 30, 45, 60, 75, 90, 105 ve 120. minutes. Resting heart rate and heart rate after inspiration, orthostatic hypotension assessment, ECG recording following Valsalva maneuver, handgrip test were performed for evaluating CAN. One test positivity was accepted possible CAN, while 2 or more test positivity were considered confirmed CAN according to Toronto Consensus Criteria. Microvascular complications were evaluated in all patients.
Results
At least one positive test result was found in all 70 patients performed CAN tests. Of these patients, 8 (11.4%) were diagnosed with possible CAN, while 62 (88.6%) were detected confirmed CAN. Confirmed CAN were detected in 14 (87%) patients with IFG, 25 (96%) patients with IGT, 29 (91 %) patients had both IFG and IGT. Possibly CAN were detected in 2 (13 %) patients with IFG, 1 (4%) patients with IGT, 1 (9 %) patients had both IFG and IGT. The remaining patients were diagnosed with prediabetes based on HbA1c levels. PPH was detected in 27 patients (33.3%) during one or more measurement points of OGTT. This rate was 30%(n =21) among patients who underwent CAN testing. Of patients with PPH, 19 (27%) had confirmed CAN, and 2 (0.2%) had possible CAN. No cases of orthostatic hypotension were observed. Rates of microalbuminuria and peripheral neuropathy were 7.5% and 68.1% in prediabetic patients. The rates were 12.5% and 57% in possible CAN patients, while they were 6.7% and 71% in patients with confirmed CAN. No cases of diabetic retinopathy were observed.
Conclusions
Microvascular complications can develop in prediabetic state. CAN and PPH can be frequently observed in different glucose tolerance abnormalities. As part of routine evaluation in prediabetic patients, screening for CAN, PPH, and microvascular complications should be implemented.

	Possibly CAN n =8		Confirmed CAN n =62	
	n	%	n	%
IFG (n =16)	2	13%	14	87 %
IGT (n =26)	1	4 %	25	96 %
IFG & IGT (n =11)	1	9 %	10	91 %

Type 2 diabetes was linked to asthma: a meta-analysis

Nhat Nam Nguyen[1], Dung Si Ho[2], Manh Truong Nguyen[1], Trung Dinh Nhat Nguyen[3], Tai Quoc Tran[4] & Yang-Ching Chen[5]
[1]Hanh Phuc International Hospital, Binh Duong, Viet Nam; [2]Pham Ngoc Thach University of Medicine, Ho Chi Minh City, Viet Nam; [3]University of Medicine and Pharmacy at Ho Chi Minh City, Ho Chi Minh City, Viet Nam; [4]University Medical Center, Ho Chi Minh City, Viet Nam; [5]Taipei Medical University, Taipei, Taiwan

Background and Objectives
Asthma and diabetes pose major global health concerns. While the link between asthma and type 1 diabetes is well-documented, the connection between asthma and type 2 diabetes (T2DM) remains less explored. Recent findings suggest that this relationship is more intricate than previously believed, extending beyond the conventional T-helper 1/2 paradigm. This systematic review and meta-analysis aimed to examine the association between asthma and T2DM, as well as to explore potential contributing factors and mechanisms.
Methods
A comprehensive literature search was performed across four databases up to October 31, 2013, to identify studies investigating the relationship between asthma and T2DM. Studies that did not specify the type of diabetes were excluded. Data on disease risk, including event counts and odds ratios (ORs), were extracted and analyzed using meta-analysis techniques. Pre-specified analyses included subgroup analysis, meta-regression, sensitivity analysis, and dose-response analysis.
Results
Fourteen studies, encompassing a total of 17 million participants, were included in the analysis. A bidirectional association between asthma and T2DM was observed ($P<$ 0.01), suggesting potential shared pathological mechanisms. The presence of hypertension and dyslipidemia may partially mediate this relationship. Additionally, asthma severity, rather than disease duration, was linked to an increased risk of T2DM (P = 0.01) in a dose-dependent manner. Sensitivity analyses confirmed the robustness of these findings.
Conclusions
This study identifies a reciprocal association between asthma and T2DM, emphasizing the need for early screening and preventive interventions for one condition when the other is diagnosed.

Treatment of hyperuricemia as an option for slowing the progression of diabetic nephropathy

Zheni Gjergji[1], Ergita Nelaj[2], Hergi Gjergji[3] & Margarita Gjata[2]
[1]Hospital Center "Dr. Xhafer Kongoli", Internal Medicine, Elbasan, Albania; [2]University Hospital Center "Mother Teresa", Internal Medicine, Tirana, Albania; [3]Universitary Hospital of Augsburg, Internal Medicine, Augsburg, Germany

Introduction
Diabetic nephropathy is the main cause leading to end-stage renal disease. Uric acid may play a role as the underlying cause of diabetic nephropathy. The serum level of uric acid is also a risk factor for cardiovascular disease and atherosclerosis. It's a complex interplay among hyperuricemia, diabetes melitus and the progression of diabetic nephropathy. Our aim is to evaluate allopurinol effects on proteinuria in diabetic patients with nephropathy.
Material and methods.
80 patients with type 2 diabetes mellitus and incipient diabetic nephropathy were included. 40 patients were randomized to receive allopurinol (100 mg/d) and 40 were randomized to receive placebo. Administration of antihypertensive and renoprotective drugs (angiotensin-converting enzyme inhibitors and angiotensin receptor blockers) continued for both groups, without changes in dosage. Proteinuria was compared at baseline, 2 and 4 months among the two groups.
Results
Each group consisted of 19 men and 21 women. After four months of treatment, serum levels of uric acid ($P = .02$) and 24-hour urine protein ($P = .049$) were significantly lower in the patients on allopurinol treatment, compared with the control group.
Conclusions
Treatment with hyperuricemia can reduce severity of proteinuria. So, it's important to use them as an adjuvants cost-effective therapy for patients with diabetic nephropathy.

Main epidemiological indicators of diabetes mellitus among the urban population on the example of Minsk (2014–2024)

Alena Yurenia[1], Tatsiana Mokhort[2], Natallia Seliazniova[1] & Alena Kislaya[3]
[1]Minsk City Clinical Endocrinology Center, Minsk, Belarus; [2]Belarusian State medical University, Endocrinology, Minsk, Belarus; [3]2nd City Children's Clinical Hospital", City Children's Endocrinology Center, Minsk, Belarus

Aim
To assess the dynamics of the prevalence of DM among the Belarusian urban population in the period 2014-2024.
Materials and methods
Data from the official statistics of the Ministry of Health of Belarus and demographic indicators were the subject of the study.
Results
The prevalence of diabetes increased from 2296.4 cases in 2014 to 4588.6 cases per 100,000 population in 2024. The average annual increase in DM prevalence was 7.6% (type 1 DM - 4.1%, type 2 DM - 7.9%). The primary incidence of diabetes was 202.7 - 416.0 cases per 100,000 population, of which T1DM: 9.0 - 11.0, T2DM: 196.4 - 405.0 cases per 100,000 population. The average annual increase in the primary incidence of diabetes was 8.3% (T1DM - 2.9%, T2DM - 8.4%). The increase is the result of active measures to diagnose T2DM in at-risk groups. Gender characteristics: T2DM is 1.9 times more common in women than in men, in people with T1DM was the same for both sexes, other types of diabetes are 2.7 times more common in men. Diabetes affects 5.6% of the adult population of Minsk, a figure in line with WHO projections. The proportion of working-age people was on average 87% among those with T1DM, 21% among those with T2DM, and 75% among those with other types of diabetes. On average, 3.7% of people with DM die each year, and 92.3% of these deaths occur in people over working age. The leading cause of death was cardiovascular disease: DM1 - 49.0% of deaths, DM2 - 67.9%. Malignant neoplasms came second: 5.5% of deaths in T1DM and 14.9% in T2DM. The proportion of deaths due to complications of DM, including emergencies, was less than 0.1%.
Conclusions
The above data indicate that the quality of medical care, availability of antihyperglycaemic drugs, including insulin, and means of self-control ensure a low mortality rate from diabetes mellitus, but at the same time emphasise the need for management decisions on the prevention of cardiovascular pathology and early detection of malignant neoplasms.

The transition phase and glycemic control: insights from 100 patients study

Chaimaa Er-Ragh[1], Nassim Essabah Haraj[1], Siham El Aziz[1] & Asma Chadli[1]
[1]CHU Ibn Rochd, Clinical Neuroscience and Mental Health Laboratory, Endocrinology, Diabetology, Metabolic Diseases, and Nutrition Department, Casablanca, Morocco

Introduction
The transition period from pediatric to adult diabetology is particularly critical. Transferring care to adult services is often associated with a deterioration in glycemic control. We aimed to assess glycemic control among type 1 diabetics during this transition phase.
Patients and Methods
This was a retrospective descriptive study involving 100 type 1 diabetic patients initially followed in pediatrics before transitioning to the endocrinology-diabetology department at CHU Ibn Rochd. Data were collected on glycemic balance, follow-up regularity, and treatment adherence at the time of transition and afterward, from January 2021 to September 2024. Statistical analysis was performed using IBM SPSS software.
Results
The average age of our patients was 16 years (range: 14 to 18), with a female predominance (56%). The duration of diabetes was approximately 5 years, and the transition occurred at an average age of 14 years. Transition announcements were made by pediatricians for all our patients. The interval between referral and the first consultation was less than three weeks. Patients attended an average of 3.3 consultations per year at the start of the transition, and 2.1 consultations per year afterward. All patients were on a basal-bolus insulin regimen, with 14% using human insulin and 86% using insulin analogs, and performed approximately four capillary blood glucose tests per day. the average Hba1c was 10.1% before the transition and 9.23% afterward ($P < 0.001$). Nine patients were hospitalized for diabetic ketoacidosis due to treatment discontinuation after the transition. Regarding degenerative complications, 11 patients exhibited diabetic retinopathy at the time of transition.
Conclusion
The transition from pediatric to adult diabetology is a critical phase for type 1 diabetic patients. Our study highlights a decline in medical follow-up. However, the observed reduction in HbA1C levels demonstrates the potential for modest improvement. These findings underline the need to strengthen support and coordination between pediatric and adult services to improve clinical outcomes and the quality of life of young patients.

JOINT3740 Glycemic control in type 1 diabetes patients transitioning from pediatric to adult care

Juan Luis Delgado Montoya[1], Javier García Sánchez[1], Enrique Redondo[1], Sara León Utrero[1], Elena Martínez Silla[1], Raúl Rodriguez Juárez[1] & Pablo J López- Ibarra Lozano[1]
[1]Hospital Universitario Clínico San Cecilio, Granada, Spain

Introduction and Objective
The transition of adolescents with Type 1 Diabetes Mellitus (T1DM) to adult Endocrinology services coincides with significant personal changes. Interstitial glucose monitoring is a key tool for diabetes management. This study aims to evaluate metabolic control in adolescents after transitioning to adult endocrinology follow-up.
Materials and Methods
A descriptive observational study was conducted on patients aged 14–18 years who had at least one data download in 2024 while under follow-up at the General Endocrinology outpatient clinic of Hospital Universitario Clínico San Cecilio (Granada). Anthropometric variables, treatment characteristics, and disease control parameters (glucometry and HbA1c) were analyzed. Statistical analysis was performed using SPSS v.15.

Results
A total of 35 patients with T1DM were included, 54.3% male, with a mean age of 16.2 ± 1.4 years. All were on basal-bolus insulin therapy (1 ± 0.4 U/kg), with a mean disease duration of 7 ± 4.2 years. The mean follow-up period was 9.7 ± 8.2 months. Mean BMI was 22 ± 3.4 kg/m^2, and mean HbA1c was 7.9 ± 1.6%. The average insulin sensitivity factor was 33 ± 20.6. The mean time in range (TIR) was 51%, time above range (TAR) 44%, and time below range (TBR) 5%. The mean coefficient of variation was 40.2 ± 7.5%, with a Glucose Management Indicator (GMI) of 7.5 ± 1%. The mean number of daily sensor readings was 10 ± 2, with an average sensor activity rate of 76 ± 20%. Three patients experienced one or more episodes of severe diabetic ketoacidosis requiring hospitalization and intensive care unit (ICU) admission since starting follow-up.
Conclusions
This study highlights suboptimal metabolic control in T1DM patients transitioning from pediatric to adult care. The creation of specialized transition units could improve metabolic outcomes and prevent complications in this population.

Early-onset diabetic neuropathy in a teenager with brittle type 1 diabetes: a case report

Rihab Khochtali[1], Sana Abid[1], Ines Bayar[1], Chanez Kalboussi[1], Bilel Ben Amor[1], Ekram Hajii[1], Héla Marmouch[1], Hanene Sayadi[1] & Inès Khochteli[1]
[1]Department of Endocrinology and Internal Medicine, Fattouma Bourguiba University Hospital, Monastir, Tunisia

Introduction
Diabetic neuropathy (DN) is one of the most common complications of diabetes, affecting approximately 50% of patients, typically after 5 years of type 1 diabetes (T1DM). DN is associated with increased risks of falls, fractures, amputations, high economic costs, and a significant reduction in quality of life.
Case Presentation
We report the case of a 17-year-old male diagnosed with brittle T1DM 4 years ago. His diabetes has been poorly controlled, with frequent hospitalizations due to diabetic ketoacidosis and recurrent severe hypoglycemic episodes. Contributing factors include recurrent infections, lipodystrophy at insulin injection sites, and psychological factors such as denial of the disease and treatment non-adherence. His HbA1c was 17%. The patient presented with paresthesia in all four limbs, scoring 4/10 on the Douleur Neuropathique 4 (DN4) questionnaire. Neurological examination revealed errors on the monofilament test, indicating neuropathy, though there were no significant sensory or motor deficits. Electromyography (EMG) confirmed early-stage sensory-motor axonal neuropathy with conduction blocks and bilateral carpal tunnel syndrome. No other diabetes-related complications, such as retinopathy, were detected. Other causes of neuropathy, including vitamin B12 deficiency, thyroid dysfunction, and renal failure with electrolyte imbalance, were excluded. Symptoms significantly improved with optimized glycemic control and the initiation of amitriptyline (10 mg/day).
Discussion
According to Yoon Hi Cho *et al*., approximately 16% of patients with newly diagnosed T1DM within 2 to 5 years develop diabetic neuropathy. Hyperglycemia is the primary risk factor for DN, and both the duration of diabetes and poor glycemic control contribute significantly to nerve damage. Additionally, the neurotrophic action of insulin is deficient even in the early stages of T1DM, contributing to the development of neuropathy. Maintaining rigorous glycemic control from the onset of diabetes is essential to prevent or delay the development of neuropathic complications.
Conclusion
Early screening for diabetic neuropathy should be considered even in patients with recent-onset T1DM, as early intervention with glycemic optimization and symptomatic treatment can improve outcomes and prevent further complications.

Ultrasound monitoring for chemotherapy complications in diabetic patients

Rostyslav Bubnov[1], Iryna Chaykovska[2] & Roman Kotsyuba[2]
[1]Zabolotny Institute of Microbiology and Virology, NAS of Ukraine, Interferon, Kyiv, Ukraine; [2]Drohobych city hospital #1, Drohobych, Ukraine

Background and Aims
Chemotherapy often induces complications in multiple organs, necessitating early detection to optimize therapy and improve patient outcomes. However, assessing the structural and functional conditions of organs like the pancreas, kidneys, thyroid, nerves, and colon remains challenging. Multiparameter ultrasound (US) shows promise in providing precise information during cancer diagnosis and treatment. This study aimed to assess US utility in detecting complications early among diabetic patients undergoing chemotherapy.
Methods
We included 12 diabetic and 10 non-diabetic patients undergoing chemotherapy. Routine clinical and laboratory tests, along with multiparameter abdominal US, were performed weekly. Assessments included colonic wall thickness, peristaltic waves, Doppler spectral analysis of mesenteric blood flow, bile duct measurements, and evaluations of the liver, kidneys, pancreas, thyroid, and nerves.
Results
Key observations included:

1. **Pancreas**: Six patients showed increased pancreas size and two developed hypoechoic lesions within the first week. Pancreatic size decreased later (after 3 weeks), with one patient diagnosed with pancreatitis.
2. **Kidneys**: Early signs included elevated resistive index (RI) and increased parenchymal thickness, though velocities remained normal.
3. **Thyroid**: Three patients exhibited hypoechoic heterogeneous textures, while two showed reduced thyroid size by weeks 2-3.
4. **Colon**: Diabetic patients showed less colonic wall thickening (3-6 mm) versus controls (7-8 mm) and reduced peristalsis. Mesenteric Doppler revealed higher peak systolic velocities (up to 200 cm/sec) in diabetics compared to controls (140-170 cm/sec).
5. **Neuropathy**: Three patients presented with numbness in limbs. US revealed increased fascicle diameters (1.5-2.5 mm).

Conclusions
Multiparameter US markers provide critical insights into early chemotherapy-related complications across various organs, enabling timely therapy adjustments and improved prognosis. Monitoring with US is particularly effective for diabetic patients, revealing distinct changes and enhancing clinical care.

A rare case of MODY12 (ABCC8 Mutation) presenting with both congenital hyperinsulinism and maturity onset diabetes of the young

Emma Badalyan[1], Irina Muradyan[2], Azatuhi Ashotyan[3], Maria Badalyan[4] & Lusine Navasardyan[5]
[1]Clinical Researcher, Associated with the Yerevan State Medical University Endocrine Department, Yerevan, Armenia; [2]"Muratsan" University Hospital Complex, Yerevan, Armenia; [3]Wigmore Women's and Children's Hospital, Yerevan, Armenia; [4]"Izmirlyan" Medical Center, Yerevan, Armenia; [5]Yerevan State Medical University, "Arabkir" Medical Center, Yerevan, Armenia

Background and Aim
MODY 12 (Maturity-Onset Diabetes of the Young, type 12) is a rare form of monogenic diabetes caused by mutations in the ABCC8 gene. The current report describes the case of a young patient diagnosed with Type 1 Diabetes, who experienced prolonged intervals of hyperglycemia alternating with episodes of hypoglycemia and vice versa. Further investigation through genetic testing identified a heterozygous (HG38, chr11:17394379C>T, c.4432G>A) mutation in exon 37 of the ABCC8 gene, leading to the p.(Gly1478Arg) variant. The aim of the report is to show the difficulties and uncertainty of the management and treatment of patients with such clinical presentations.
Case Presentation
A 13-year-old Caucasian male, presented to the Emergency Department, with complaints of polyuria, polydipsia, and nocturia last 30 days. He also reported a weight loss of about 10 kg, current weight was 57kg (SDS = +0,96). HbA1c was 8.2%, fasting glucose was 19mmol/l, C-peptide was 1.48ng/ml (normal = 1.1-4.4), antidiabetic antibodies were negative. The patient was initially diagnosed with type 1 diabetes with ketosis and subcutaneous insulin-therapy started with total of 0.105 units/kg of rapid-acting insulin. During next several years he stopped insulin-therapy and initiated again 2-3 times per year due to ketosis. After approximately four years the patient began experiencing frequent episodes of

hypoglycemia, with blood glucose levels dropping as low as 2.0mmol/l without insulin injections, alternating with periods of hyperglycemia. Continuous alternation between hyperglycemia and hypoglycemia, prompted a genetic test. Since opportunities for genetic testing are limited in our country, the patient underwent testing abroad, in Moscow. In the ABCC8 gene (NM_000352.6), a heterozygous variant HG38, chr11:17394379C>T, c.4432G>AHG38, chr11:17394379C>T, c.4432G>AHG38, chr11:17394379C>T, c.4432G>A was identified in exon 37, resulting in the amino acid substitution p.(Gly1478Arg) p.(Gly1478Arg)p.(Gly1478Arg), with a sequencing depth of 225x (rs72559715rs72559715rs72559715). This variant has been previously reported as pathogenic in patients with autosomal dominant congenital hyperinsulinism and autosoma ldominant ABCC8-associated diabetes (MODY 12) (PMID: 19475716, 30098243, 30977832, 32928245). Now, the patient is 21 years old and experiences hypoglycemic episodes approximately 7–8 times per year without receiving any specific treatment.

Discussion

Current case highlights the diagnostic and clinical challenges associated with rare conditions, particularly in countries like Armenia, where access to genetic testing is limited. On the other hand, due to the lack of precise guidelines for the treatment and management of such patients, they could be misdiagnosed with other types of diabetes and receive inappropriate management.

From group to individual: how paediatric diabetes education is changing in the era of technology

Jasmin Dorothée von Zezschwitz[1,2], Dörte Hilgard[2], Angela Galler[3], Christof Klinkert[4], Bernhard Kulzer[5], Heike Saßmann[6] & Reinhard Holl[7]
[1]University of Copenhagen, Department of Nutrition, Exercise and Sports (NEXS), Copenhagen, Denmark; [2]Paediatric Endocrinology and Diabetology - Paediatric Practice Dr. med. Hilgard, Witten, Germany; [3]Charité - Universitätsmedizin Berlin, Free University of Berlin, and Humboldt University of Berlin, Social Pediatric Center, Pediatric Diabetology, Berlin, Germany; [4]Paediatric Endocrinology and Diabetology - Kinder- und Jugendmedizin Radewig, Herford, Germany; [5]Research Institute of the Diabetes Academy Mergentheim (FIDAM GmbH), Bad Mergentheim, Germany; [6]Hannover Medical School (MHH), Research and Teaching Unit for Medical Psychology, Hannover, Germany; [7]Institute of Epidemiology and Medical Biometry, ZIBMT, University of Ulm, German Center for Diabetes Research (DZD) - For the DPV Study Group of the DGPAED and the German Center for Diabetes Research (DZD), Ulm, Munich, Germany

Objective

Has the focus on technology in diabetes care influenced the type and frequency of diabetes education programs for children and adolescents with type 1 diabetes (T1D) in Germany and do we see general differences in age and sex regarding the participation of educational programs over the last years?

Methods

This analysis is based on data from the German DPV registry (status of 03/2024), including 42,975 paediatric patients with T1D aged 0–18 years from 364 centres in Germany. Patients with a diabetes duration of <6 months and those from centres without documented education were excluded (<1%). The frequency and type of education for multiple age groups and sexes were analysed for 2010–2023 using multivariable regression models to assess temporal trends (SAS 9.4, SAS Institute Inc., USA).

Results

International guidelines recommend regular education every 2 years. However, only 54.7% of patients attended structured diabetes re-education programs within five years after diagnosis. Those with belated re-education showed higher HbA1c levels across all groups. While the frequency of individual education remained relatively stable over time, with a temporary decrease during the pandemic, the group education programs significantly declined from 46.4% (2015) to 28.9% (2020) and could only slightly recovery to 31.3% in 2023 ($P<$ 0.0001 respectively). Adolescents >12 years (46.3%) were less likely to receive education than families of younger children <6 years (56%, $P<0.0001$). Girls (56.8%) participated in educational programs more frequently than boys (52.8%, $P<0.0001$). Their attendance in group education was also significantly higher ($P<0.0001$). The share of patients receiving individual insulin pump training increased from 36.6% (2015) to 51.0% (2023), reflecting the growing role of technology in diabetes management and need for resources in clinics and doctors' offices.

Conclusion

Diabetes education for children and adolescents with T1D has undergone visible changes in recent years. There is a shift towards more individual and technology-focused education, requiring more personnel and neglecting the essential understanding of basics and personal development with T1D. Later re-education showed associations with higher HbA1c. Where younger children and girls received more structured diabetes education, adolescents and boys participated less frequently. Additionally, with the substantial decline in group education children lose secondary benefits like peer contact. These disparities highlight the need for targeted strategies to ensure adequate education for all. Innovative approaches, such as the "GaDiaKi" program for group education and telemedicine-based interventions, may help address these gaps and improve long-term diabetes care.

Donohue syndrome: three case studies illustrating clinical heterogeneity and management challenges

Meirav Oren[1], Ronit Parikman[2], Noah Gruber[3] & Shoshana Gal[4]
[1]Pediatric department, Unit of pediatric Endocrinology, Galile Medical Center, Nahariya, Israel, Azrieli Faculty of Medicine, Bar-llan University, Safed, Israel, Nahariya, Israel; [2]Pediatric Endocrine and Diabetes Unit, Edmond and Lili Safra Children's Hospital, Sheba Medical Center, Ramat-Gan, Israel, Ramat Gan, Israel; [3]Pediatric Endocrine and Diabetes Unit, Edmond and Lili Safra Children's Hospital, Sheba Medical Center, Ramat-Gan, Israel, School of Medicine, Faculty of Medical and Health Sciences, Tel aviv University, Tel Aviv, Israel, Ramat Gan, Israel; [4]Pediatric Department, Bnai-Zion Medical Center, Haifa, Isreal, Bruce Rappaport Facuity of Medicine, Technion, Israel, Haifa, Israel

Three cases of Donohue syndrome, a rare disorder of severe congenital insulin resistance due to INSR gene mutations, are presented. All patients exhibited severe intrauterine growth restriction (IUGR), failure to thrive (FTT), dysmorphic features, extremely high insulin and C-peptide levels at birth.

Case 1

A 7-month-old male infant had metformin initiated at 50 mg/kg/day at three weeks. He developed severe hypertrophic cardiomyopathy, requiring beta-blocker therapy, and was treated with ursodiol for cholestatic liver disease. Frequent enteral feedings enriched with polycose via gastrostomy were provided to prevent hypoglycemia. Continuous glucose monitoring (CGM) indicated 80% time in range (55-180 mg/dL), 18% above range (>180 mg/dL), and 2% below 55 mg/dL. Last measured length and weight SDS were -5.0 and -4.0, respectively. Despite treatment, he died at seven months, with a hypoglycemia episode near the time of death.

Case 2

A 13-month-old female infant had metformin initiated at 50 mg/kg/day at one month, along with continuous PZ feedings and MCT oil due to recurrent hypoglycemia. The CGM was unreliable, and metformin did not improve HbA1c or C-peptide levels, leading to its discontinuation. Liver dysfunction with cholestasis and synthetic impairment was treated with ursodiol, vitamin K, and ADEK. She experienced ovarian torsion at six months, hyperandrogenism, respiratory distress managed with Vapotherm, nephrocalcinosis, and difficulty to mange central hypothyroidism. Current length SDS is -5.0, weight SDS is -4.5.

Case 3

A 21-month-old female infant had metformin started at 40 mg/kg/day at one month, with recombinant IGF-1 (0.2 mg/kg/day) added at 11 months. Glycemic control improved: 84% time in range 55-180 mg/dL, yet growth parameters remained poor (weight -9.8 SDS, length -5.5 SDS). Current IGF-1 levels are measurable, and C-peptide levels have decreased, but insulin levels remain extremely high. She presented with enlarged ovaries, hyperandrogenism, cardiomyopathy (beta-blocker treated), restrictive lung disease requiring ventilation, and well-managed central hypothyroidism.

Differences

While all patients exhibited significant challenges, the specific manifestations and responses to treatment varied. Case 1 presented cardiac complications earlier and had a fatal outcome. Case 2 involved significant liver dysfunction. Case 3 demonstrated some improvement in glucose control using multiple treatments, but persistent growth failure, and respiratory difficulty.

Conclusion

Donohue syndrome presents significant diagnostic and therapeutic challenges. The variability in presentation and treatment response underscores the need for individualized management, close monitoring, and multidisciplinary care. Further research into this rare syndrome is crucial for improving outcomes and understanding its pathophysiology.

Impact of smoking and physical activity on cardiovascular outcomes in type 2 diabetes with metabolic dysfunction-associated steatotic liver disease: a nationwide study

So Hyun Cho[1], Gyuri Kim[1], Kyu-na Lee[2], Rosa Oh[1], Ji Yoon Kim[1], Myunghwa Jang[1], You-Bin Lee[1], Sang-Man Jin[1], Kyu Yeon Hur[1], Kyungdo Han[3] & Jae Hyeon Kim[1]
[1]Samsung Medical Center, Sungkyunkwan University School of Medicine, Department of Medicine, Seoul, South Korea; [2]The Catholic University of Korea, Department of Biomedicine & Health Sciences, College of Medicine, Seoul, South Korea; [3]Soongsil University, Department of Statistics and Actuarial Science, Seoul, South Korea

Background
This study investigated the effects of smoking and regular physical activity (PA) on the risk of composite cardiovascular disease (CVD) outcomes in type 2 diabetes mellitus (T2DM) patients across different steatotic liver disease (SLD) categories.
Methods
We used a health examination database from 2015 to 2016, with follow-up data for 1,921,310 patients aged 20 years and older with T2DM. Participants were categorized based on SLD status where hepatic steatosis was defined as a fatty liver index (FLI) $\geq$ 30. Cox analyses were used to analyze the association between smoking, regular PA and the risk of composite CVD event, myocardial infarction (MI), ischemic stroke, and cardiovascular mortality.
Results
Among current smokers in each SLD group, the adjusted hazard ratios (HR) for composite CVD events significantly increased from no steatosis to metabolic dysfunction-associated steatotic liver disease (MASLD), metabolic dysfunction and alcohol-related steatotic liver disease (MetALD), and alcohol-related liver disease (ALD), with the highest HR observed in ALD (aHR, 2.14; 95% CI, 2.04–2.24). The ALD group without regular PA had the highest risk of composite CVD event (aHR, 1.33; 95% CI, 1.28–1.38). The highest risk of composite CVD event was found among current smokers without regular PA, with the aHR increasing in a stepwise manner from no steatosis to MASLD, MetALD, and ALD, the latter showing the highest (aHR, 2.67; 95% CI, 2.53–2.82).
Conclusion
Smoking and physical inactivity significantly increase CVD risk in T2DM patients, with the highest risk observed in the ALD group, underscoring the need for targeted lifestyle modifications, including smoking cessation, regular PA, and alcohol abstinence, to reduce CVD risk in this high-risk population.

Yellowish appearance - an unusual presentation of type 1 diabetes mellitus in children

Cheng Guangan[1], Mohd. Fahmi Mohd. Hani[1], Shu Ching Ee[1] & Nisah Abdullah[1]
[1]Hospital Sultanah Aminah, Paediatric, Johor Bahru, Malaysia

Type 1 diabetes mellitus (T1DM) in children is commonly associated with other autoimmune diseases, especially coeliac disease and autoimmune thyroiditis. Autoimmune hepatitis (AIH) is rare among patients with type 1 diabetes with a reported prevalence of 3.8%. However, none has been reported to present with acute liver failure with hyperglycaemia prior to diagnosis. We describe a case of 9-year-old girl developed icterus with acute liver failure and incidental finding of asymptomatic hyperglycaemia (lab glucose 20 mmol/l and ketone of 0.1 mmol/l) at presentation. Her initial laboratory investigations revealed hyperbilirubinaemia (179μmol/l) which consisted mainly of conjugated bilirubin (156μmol/l) with raised liver enzymes (aspartate aminotransferase (212IU/l), alanine aminotransaminase (248IU/l) and gamma-glutamyl transferase (132IU/l)). Furthermore, coagulation profile was found to be deranged with a prothrombin time of 34.2s and INR of 2.71, fulfilling the Paediatric Acute Liver Failure (PALF) study group definition of acute liver failure. Concurrently, her HbA1C was raised at 6.8% with positive T1DM autoantibodies for Anti Glutamic Acid Decarboxylase (> 280,000IU/ml), Anti Islet Cell (75.31 IU/ml) and Anti Insulinoma Associated Antigen 2 (5.801IU/ml) confirming a diagnosis of T1DM. Interestingly, she has a normal random C-peptide (703pmol/l) and insulin (301pmol/l) at presentation prior to the initiation of insulin therapy. However, a repeated c-peptide showing a rapid drop to a low level after 6 weeks. Her subsequent investigations fulfilling the scoring list for autoimmune hepatitis issued by the International Autoimmune Hepatitis Group (IAIHG), leading to a definite diagnosis of AIH. She responded well to prednisolone (2mg/kg/day) and azathioprine, leading to a normalisation of her co-agulation profile. However, she required a daily insulin dose up to 2.8unit/kg/day to achieve a good glycemic control during her treatment period. This leads to an improvement of her HbA1C down to 5.8% after 6 weeks. Screening of other associated autoimmune diseases were negative (Normal thyroid function tests with negative thyroid peroxidase antibodies, anti-endomysium and anti-tissue transglutaminase antibodies) In summary, we have presented the case of a 9-year-old girl developed T1DM and AIH at the same time. Although patients with T1DM commonly present with polyosmolar symptoms or diabetic ketoacidosis at diagnosis, our case illustrate that severe AIH can occurs at presentation of T1DM in children. Therefore, there should be a high index of suspicion for other rare forms of autoimmunity in children with T1DM.

Neonatal diabetes mellitus in a boy with wolfram-like syndrome

Stephanie Vermeulen[1], Mirjam van Albada[1] & Annemieke Boot[1]
[1]Beatrix Children's Hospital, University Medical Center Groningen, Groningen, Netherlands

Introduction
Wolfram syndrome is a rare progressive neurodegenerative disorder caused by a recessive mutation in the WFS1 or WFS2 gene, typically characterized by diabetes mellitus and optic atrophy. Other symptoms include AVP deficiency and hearing loss. Wolfram-like syndrome is caused by an autosomal dominant mutation in the WFS1 gene and characterized by congenital hearing loss, optic atrophy and diabetes mellitus. We describe a case of a boy with Wolfram-like syndrome.
Case report
The boy was born after 38 weeks and 5 days gestation, weighing 2270grams (< -2SD) with multiple dysmorphic features. He had hearing loss and vision impairment. Genetic testing (5GPM) revealed a heterozygous pathological variant c.2425G>A/p.Glu809Lys located in exon 8 of the WFS1 gene. This mutation has been previously reported in 5 different children who developed diabetes mellitus at a very young age; ranging from the age of 3 months to 3 years. At the age of 4 months, after correction of clubfeet, a high glucose of 23mmol/l was measured without ketoacidosis or other symptoms of hyperglycemia. He started on a low dose of insulin detemir with a glucose sensor and after a few days the treatment was changed to subcutaneous insulin via a pump at a dose of 0.4U/kg/day, allowing for his discharge. After 14 days the glucose suddenly increased and remained high continuously. Despite receiving extra insulin glucose levels could not be controlled. He was restless and readmitted again. A few days later he experienced a general convulsion. Despite the administration of anti-epileptic drugs he continued to show epileptic activity on EEG. He was switched to intravenous insulin and the dose had to be increased to about 2U/kg/day to control his glucose levels. Unfortunately, at the age of 5 months the boy died due to severe epileptic encephalopathy following therapy resistant epileptic activity.
Conclusion
Patients with Wolfram-like syndrome can develop diabetes mellitus before the age of 6 months. Glucose levels should be evaluated regularly.

JOINT2563

Type 1 diabetes, SARS-CoV-2 and vitamin D3

Agnieszka Zubkiewicz-Kucharska[1], Monika Seifert[1], Joanna Chrzanowska[1] & Robert Śmigiel[1]
[1]Wrocław Medical University, Department of Pediatric Endocrinology, Diabetology and Metabolic Diseases, Wrocław, Poland

The aim of the study was to assess the relationship between vitamin D3 concentration and the titer of anti-SARS-CoV-2 IgG antibodies in type 1 diabetes children (T1D).
Methods
Between June 1, 2021 and June 1, 2024, a cross-sectional study was conducted among T1D children. The control group consisted of children without carbohydrate metabolism disorders and autoimmune diseases. The titer of anti-SARS-CoV-2 IgG antibodies, the concentration of 25(OH) vitamin D3 and

HbA1c were determined. Vitamin D3 deficiency was diagnosed if <30 ng/ml, and anti-SARS-CoV-2 IgG seropositivity if ≥ 7.1 BAU/ml.
Results
The study group included 232 children (122 boys), 196 people with diabetes, aged 12.5 $\pm$ 4.0 years, in whom a total of 289 tests were performed (in 51 T1D children test was performed $\geq$twice). The median 25(OH)D3 concentration was 26.6 [IQR = 15.6] ng/ml and did not differ depending on gender, diagnosis of T1D or co-occurrence of other diseases ($P > 0.05$). Vitamin D3 deficiency was diagnosed in 178 children (61.6%). The concentration of 25(OH)D3 was lower in the group of children with new T1D (Me = 21.8 [IQR = 9.5] ng/ml), compared to long-lasting T1D (Me = 27.75 [IQR = 17, 2] ng/ml) and in the controls (Me = 28.3 [IQR = 18.6] ng/ml), $P = 0.0093$. Anti-SARS-CoV-2 IgG Ab seropositivity reached 95.5%, median titer was 307.2 [IQR = 624.8] BAU/ml, did not differ depending on gender, vitamin D3 supplementation and vaccination ($P > 0.05$), as well on the co-occurrence of other diseases ($P > 0.05$). In T1D, the anti-SARS-CoV-2 IgG Ab titer was higher than in the controls (Me = 328.7 [IQR = 677.4] BAU/ml vs. Me = 169.4 [IQR = 402.6] BAU/ml), $P = 0.0130$. The Ab titer in new T1D (Me = 122.0 [IQR = 559.4] BAU/ml) was lower compared to the long-lasting T1D (Me = 359.7 [IQR = 678.6] BAU /ml) and controls, $P < 0.0001$. There was a correlation between anti-SARS-CoV-2 IgG Ab and age (R = 0.3359, $P < 0.0001$) and HbA1c and 25(OH)D3 (R = -0.3267, $P < 0$, 0001). Children seronegative for SARS-CoV-2 ($n = 13$, 5.6%) were younger (7.4 $\pm$ 5.4 years vs. 12.6 $\pm$ 3.9 years), $P = 0.0241$, 25 (OH)D3 (Me = 25.9 [IQR = 114.7] ng/ml vs. Me = 26.6 [IQR = 16.2] ng/ml) and HbA1c (Me = 8.0 [IQR = 6).6] % vs. Me = 7.3 [IQR = 2.5] %) were comparable to AntiSARS-Cov2(+).
Conclusions
In children with type 1 diabetes, the titer of anti-SARS-CoV-2 IgG antibodies did not depend on the concentration of vitamin D3, however, in the group of children with the lowest 25(OH)D3 concentration, the titer of IgG anti-SARS-CoV-2 antibodies was also lowest. Lower titers of these antibodies in younger children indicate a weaker immune response in this group. Vitamin D3 deficiency occurring in the majority of respondents indicates the need for its systematic supplementation.

JOINT1171

Technological implementation and evolution of metabolic control in pediatric T1D patients: "real life experience"

Nancy Portillo Najera[1,2], Amaia Sanchez Arlegui[1,2], Claudia Cifuentes Zamalloa[1,2], Gema Grau Bolado[1,2], Amaya Vela Desojo[1,2] & Itxaso Rica[1,2]
[1]Cruces University Hospital., Pediatric Endocrinology, Barakaldo, Spain; [2]BioBizkaia. Health Research Institute, Pediatric Endocrinology, Barakaldo, Spain

The technological advances in the treatment of pediatric patients with Type 1 Diabetes (T1D) facilitate metabolic control. The ISPAD in 2018 and the ADA in 2020, proposed reaching an HbA1c $<7\%$ as a goal. Basque Country (November 2017), the first autonomous community at Spain to approve continuous glucose monitoring (CGM) systems for pediatric T1D patients.
Objective
To know the evolution of metabolic control in T1D patients in a tertiary hospital and its possible relationship with the implementation of technologies. To compare two samples exploiting data exported in 2019 and 2023 from the SWEET registry(*) and the mean Hba1c with that published in our department prior to technological implementation (AvDiabetol.2014;30:82).
Patients and methodology
$n = 170$ patients in 2023. Variables: age, sex, age at T1D onset, time of evolution, insulin therapy regimen, use of CGM systems, DKA at onset, HbA1c, time in range(TR) and associated comorbidity. Results were compared with another cohort controlled in 2019 ($n = 141$) and the mean HbA1c with that previously published in 2000 ($n = 82$), 2008 ($n = 76$) and 2013 ($n = 106$).
Results
2023 cohort $n = 170$, data in Table 1. Subgroup with AID system ($n = 49$) are younger, younger age at onset and better HbA1c (7.04% $\pm$ 0.6 vs 7.4% $\pm$ 0.9). The subgroup with DKA at onset ($n = 87$) has a longer time of evolution and worse metabolic control (7.47% $\pm$ 0.98 vs 7.12% $\pm$ 0.76). **Comparison cohort 2023 and 2019**: The proportion of CGM and AID systems use is higher in 2023, no change in the rest of the variables (Table 1).
HbA1c evolution Mean HbA1c at years 2019 and 2023 is lower than reported in the 3 cohorts studied (8.2% vs 7.9% vs 7.8%; years 2000, 2008 and 2013).
Conclusions
The use of AID system is associated with improved metabolic control, being the DKA at onset a risk factor for not achieving it. Technological implementation is associated with an improvement in HbA1c. Metabolic control is acceptable at present, can still be optimized.

Table 1. Student's t-test for quantitative variables, chi-square for qualitative variables. Statistical significance level $P < 0.05$.

Descriptive	2019($n = 141$)	2023($n = 170$)	p
Age at onset(years)	6.9 $\pm$ 3.9	6.5 $\pm$ 3.7	ns
Age at the consultation(years)	12.8 $\pm$ 4.5	12.1 $\pm$ 4.2	ns
Evolution time(years)	5.8 $\pm$ 4.3	5.5 $\pm$ 3.9	ns
HbA1c(%)	7.4 $\pm$ 1.03	7.3 $\pm$ 0.8	ns
Insulin dosage(UI/kg/día)	0.83 $\pm$ 0.3	0.75 $\pm$ 0.26	$P = 0.006$
Sex(% female)	44.7	45.3	ns
DKA at onset (severe) (%)	49(7.8)	51(7.6)	ns
Proportion using AID systems(%)	14	29	$P = 0.002$
Proportion using CGM systems(%)	77	91	$P < 0.001$

Lada diabetes in older patients: clinical diagnostic implications of imaging and laboratory biomarkers

Iryna Chaykovska[1] & Rostyslav Bubnov[2]
[1]Drohobych city hospital #1, Drohobych, Ukraine; [2]Zabolotny Institute of Microbiology and Virology, NAS of Ukraine, Interferon, Kyiv, Ukraine

Introduction
Latent autoimmune diabetes in adults (LADA) is a hybrid form of diabetes often misdiagnosed as type 2 diabetes mellitus (T2DM) in older adults. Early and accurate diagnosis of LADA is critical for effective management and prevention of complications. Ultrasound (US) has emerged as a valuable tool for stratifying patients with LADA by assessing metabolic and structural changes in associated organs [1-4].
Materials and Methods
We evaluated 10 cases of LADA treated at an endocrinology clinic (age 56–70 years, 6 females). Clinical and laboratory assessments included:
- Measurement of glutamic acid decarboxylase antibodies (GAD-Ab) and islet cell antibodies (ICA-Ab).
- Abdominal ultrasound (2–10 MHz convex probe) to assess multiparameter features of the kidneys, pancreas, and liver.
- Doppler ultrasound, shear wave elastography (SWE), and quantification of visceral fat (VF) and subcutaneous fat (SF) thickness and areas.

Results
- All patients had increased antibody levels, with positive GAD-Ab and ICA-Ab confirming LADA.
- Treatment with anti-inflammatory agents led to improved glycemic control and normalization of laboratory parameters.
- US findings included:
  - Pancreatic hypoechoic loci in all patients.
  - Signs of autoimmune thyroiditis in 6 patients, with corresponding US changes.
  - Altered liver parenchyma attenuation and abnormal renal Doppler flow in a subset of patients.
- Body composition analysis revealed overweight in most cases, one patient was underweight, and visceral fat accumulation was prominent.

Conclusion
A comprehensive diagnostic approach integrating imaging and laboratory biomarkers is essential for stratifying LADA in older patients. Ultrasound techniques such as SWE and Doppler imaging provide valuable insights into metabolic and structural organ changes, supporting tailored therapeutic strategies to optimize glycemic control and manage comorbidities.

Evaluating the reach of hellotype1: a digital innovative educational platform in regional languages for diabetes education in southeast asia

May Ng[1,2], Muhammad Yazid Jalaludin[3], Sovutha Sun[4], Phat Tung Ma[5], Sirimon Reutrakul[6], Satha Sum[7], Candy Gan[8], Fiona Ooi[9] & Anne-Charlotte Ficheroulle[9]

[1]Faculty of Health, Social Care and Medicine, Edge Hill University, Ormskirk, United Kingdom; [2]Paediatric Department, Mersey and West Lancashire Teaching Hospitals, Southport, United Kingdom; [3]University of Malaya, Kuala Lumpur, Malaysia; [4]National Pediatric Hospital, Phnom Penh, Cambodia; [5]University Medical Center, Ho Chi Minh City, Viet Nam; [6]University of Illinois Thai Association of Diabetes Educators, Bangkok, Thailand; [7]Calmette Hospital, Phnom Penh, Cambodia; [8]typeOne.sg, Singapore, Singapore; [9]Action4Diabetes, Taunton, United Kingdom

Background
Amidst the pandemic in 2021, HelloType1.com was developed by Action4Diabetes (A4D), a non-governmental organization collaborating with local healthcare professionals in Southeast Asia, as an innovative digital educational platform for Type 1 diabetes (T1D) in regional local languages. HelloType1 was launched in Cambodia, Vietnam, Thailand, and Malaysia from 2021 to 2023, with Memorandums of Understandings (MOUs) signed between A4D and each country. HelloType1 Facebook page was also created for each country in their local languages for sign-posting to the HelloType1 website.
Aims
This study aims to investigate the usability and internet data analytics of HelloType1 within each participating country from 2021-2023
Methods
Data analytics utilised Google Analytics (GA4) with tracking data from the website *hellotype1.com,* and Facebook analytics were analysed from the Facebook online metrics
Results
The total number of users of the HelloType1.com digital platform grew by 382% between 2021 and 2022 with the launch of the programme in Vietnam (March 2022) and in Thailand (November 2022) and by 47% between 2022 and 2023 with the launch of the programme in Malaysia (May 2023). In 2023, 20% of the total users of the programme are Facebook followers and 80% are website users. The average pages per sessions increased from 2 pages to more than 3 pages in 2023 showing the interest of the user to browse for more content. More than half of the traffic of HelloType1.com originated from search engines (56% in 2023). On the Facebook sites, the organic page reach has increased by 120% between 2022 and 2023 with an increased engagement rate from 8% to 14% in 2023 which demonstrate the high interest from the followers and their willingness to interact and share the HelloType1 Facebook content with their community.
Conclusions
These internet analytics offer valuable insights into the delivery of an innovative diabetes educational resource in local languages, particularly in low-middle income countries with limited resources. Future plans are underway to use the platform to create a local community support and a peer-to-peer networks with online workshops for patients and caregivers, where the community can ask their questions via cha forums on the Facebook site that can be moderated by patients and caregivers. In addition, we hope that the programmes will be supported by local governments for example in Malaysia, the Hellotype1 in the local language is endorsed by the Ministry of Health.

Association of metformin use and vitamin b intake with dementia risk in non-diabetic people: insights from the UK biobank

Sun Jae Jung[1]

[1]Yonsei University College of Medicine, Preventive Medicine, Seoul, South Korea

Background
The relationship between metformin and dementia remains complex and controversial. Previous epidemiological studies have presented conflicting evidence regarding potential neuroprotective effects or cognitive risks associated with metformin use. This study aimed to comprehensively examine the association between metformin use, vitamin B12 intake, and dementia risk, considering both diabetic and non-diabetic populations.
Methods
A retrospective cohort study was conducted using data from 499,804 participants in the UK Biobank, selected from an initial cohort of 502,422 after excluding incomplete data. The research employed multivariate logistic regression models stratified by type 2 diabetes status and categorized vitamin B12 intake across quartiles to assess dementia risk factors and potential interactions.
Results
Of the 499,804 participants, 6,893 were diagnosed with dementia. The analysis revealed significant findings across different population subgroups. Non-diabetic males showed a marked association between metformin use and increased dementia risk (Odds Ratio 3.83, 95% Confidence Interval 1.15–12.75). Among non-diabetic females, metformin use combined with vitamin B12 deficiency was linked to elevated dementia odds (OR 1.63, 95% CI 1.04–2.55). Notably, no statistically significant associations emerged for participants with type 2 diabetes.
Conclusion
The study demonstrates that metformin use in non-diabetic individuals, particularly with vitamin B12 deficiency, may increase dementia risk. These findings warrant further investigation into the mechanisms linking metformin, vitamin B12, and cognitive health, and emphasize the importance of monitoring vitamin B12 levels in non-diabetic metformin users.

In the heat of the moment: burns uncover the silent diabetes

Nada Ait Kassi[1], Habbadi Zineb[1], Fatima Toulali[1], Ghizlane Sabbar[1], Kaoutar Rifai[1], Hinde Iraqi[1] & Mohamed El Hassan Gharbi[1]

[1]Ibn Sina Hospital Mohamed V University, Endocrinology, Rabat, Morocco

Introduction
Diabetic patients with peripheral neuropathy are particularly vulnerable to foot burns, which are often complicated by infections, delayed wound healing, and severe outcomes such as amputations. Although rare, these cases highlight the importance of early and adequate care.
Case Presentation
We present the case of a 41-year-old male admitted for a severe inaugural decompensation of diabetes associated with bilateral thermal foot burns. The burns, neglected for 10 days, were severely infected. Despite hospitalization involving daily wound care, strict glycemic control, and antibiotic therapy, healing was suboptimal. The progression to deep infections and osteomyelitis resulted in bilateral amputations to control septic complications.
Discussion
This case highlights the critical nature of foot burns in diabetic patients, exacerbated by peripheral neuropathy and delayed medical attention. Consistent with findings, these injuries are associated with high infection rates, severe complications, and frequent surgical interventions, including amputations. Preventive education and prompt care are vital in mitigating these adverse outcomes.
Conclusion
Diabetic foot burns constitute a medical emergency with potentially devastating consequences. This case underscores the necessity of early, intensive, and multidisciplinary management. Enhanced strategies for prevention and care are essential to reduce morbidity and improve outcomes.

Prevalence and clinical impact of obesity in patients living with type 1 diabetes

Nora Boutatss[1], Nassim Essabah Haraj[1], Siham El Aziz[1] & Asma Chadli[1]

[1]UHC Ibn Rochd, Department of Endocrinology and Metabolic Diseases Ibn Rochd University Hospital - Casablanca, Morocco Laboratory of Clinical Neurosciences and Mental Health Faculty of Medicine and Pharmacy - Hassan II University - Casablanca, Morocco

Introduction
Although traditionally linked to type 2 diabetes, obesity is becoming increasingly prevalent among patients living with type 1 diabetes.
Objective
To assess the prevalence of obesity in T1D patients and identify associated factors, guiding prevention and management strategies.
Materials and Methods
A retrospective descriptive study was conducted on 755 T1D patients followed in the our department. Obesity was defined as a body mass index (BMI) greater than 30 kg/m^2. The data are analyzed using the IBM SPSS Statistics 27.0 software
Results
The study included 755 patients with a mean age of 25.7 $\pm$ 9.5 years and an average HbA1c of 12.48 $\pm$ 2.6%. The prevalence of overweight and obesity was 20.2% and 8.1%, respectively. Women accounted for 67% of obese patients, with a male-to-female ratio of 0.3 among obese individuals ($P = 0.02$). Hypertension (HTN) prevalence was significantly higher in obese patients (44.5%) compared to normal-weight individuals (18.9%, $P < 0.01$). Dyslipidemia was more frequent in obese patients (32.7%) than in non-obese patients (12.3%, $P = 0.02$). Retinopathy was observed in 26% of obese patients compared to 17.3% in normal-weight patients. Furthermore, 66% of obese patients were using human insulin.
Conclusion
Our study highlights specific and modifiable risk factors in obese T1D patients, including associations with cardiovascular and microvascular comorbidities. A proactive approach, incorporating lifestyle interventions and personalized management, is essential for optimal care.

JOINT1471

Effect of subcutaneous semaglutide in patients with type 2 diabetes mellitus on the degree of systemic inflammation

Rosa Natalia García Pérez[1], Víctor Siles-Guerrero[1], Elena Isidora Tena Sánchez[1], José Manuel Romero-Márquez[1] & Araceli Munoz-Garach[1]
[1]HOSPITAL VIRGEN DE LAS NIEVES, GRANADA, Spain

Introduction
Type 2 diabetes mellitus (T2DM) is a chronic disease that combines insulin resistance and metabolic alterations, being one of the leading causes of global morbidity and mortality. Its management includes improving glycemic control, reducing body weight, and optimizing the lipid profile. Additionally, controlling systemic inflammation is key to reducing cardiovascular and hepatic complications. New therapies, such as GLP-1 receptor agonists, have been shown to be effective in the comprehensive treatment of this condition.
Objective
To evaluate the effect of semaglutide on anthropometric, metabolic parameters and the systemic inflammation index (SII) after six months of treatment in patients with T2DM.
Materials and Methods
A retrospective study was conducted on 250 patients with T2DM treated at the Endocrinology and Nutrition Department of the Virgen de las Nieves Hospital in Granada, who started subcutaneous semaglutide treatment. Follow-up was carried out over approximately six months. Anthropometric (weight) and analytical data were collected, including glucose, cholesterol, neutrophils, lymphocytes, and SII. The following SII grades were defined: normal range (<381), low-grade inflammation (381 - 525), and severe inflammation (>525). Data obtained at baseline and after six months were analyzed using the statistical software Jamovi, applying the paired sample T-test with a per-protocol approach.
Results
From the total number of patients, comparable SII values before and after the intervention were obtained for 171 individuals. Of these, 48% were women, with a mean population age of 58 years at the beginning of semaglutide treatment. A significant reduction in weight ($P < 0.001$), glucose ($P < 0.001$), and total cholesterol ($P = 0.004$) was observed, indicating improvements in weight, metabolic, and lipid control (Table 1). No significant changes were recorded in neutrophils ($P = 0.485$), lymphocytes ($P = 0.582$), or the systemic inflammation index (SII; $P = 0.773$), which remained stable, suggesting the preservation of immune balance after the intervention.

Table 1 Baseline and post-intervention effects of semaglutide

Variable	Pre-treatment	Post-treatment	p-value
Weight (kg)	108.39 $\pm$ 26.62	102.45 $\pm$ 25.13	< 0,001
Glucose (mg/dL)	156.62 $\pm$ 65.11	127.60 $\pm$ 50.19	< 0,001
Total cholesterol (mg/dL)	174.55 $\pm$ 46.98	164.46 $\pm$ 46.82	0,004
Neutrophils (x10^3/µL)	4.99 $\pm$ 1.75	5.24 $\pm$ 1.75	0,485
Lymphocytes (x10^3/µL)	2.47 $\pm$ 0.95	2.49 $\pm$ 0.92	0,582
SII ratio	581.45 $\pm$ 355.26	593.23 $\pm$ 487.66	0,773

Conclusion
Treatment with semaglutide in patients with T2DM significantly improved weight, metabolic, and lipid control after six months, while the SII and immunological parameters remained stable, without significant changes.

JOINT3440

Effect of subcutaneous semaglutide on liver fibrosis degree in patients with type 2 diabetes mellitus measured by the FIB-4 index

Rosa Natalia García Pérez[1], Víctor Siles-Guerrero[1], Elena Isidora Tena Sánchez[1], Gonzalo Piédrola Maroto[1] & Martín López de la Torre Casares[1]
[1]Hospital Virgen De Las Nieves, Granada, Spain

Introduction
The incidence of non-alcoholic fatty liver disease (NAFLD) has reached approximately 20-30% in recent years, with obesity, insulin resistance, and lipid metabolism disorders being the main risk factors. NAFLD can present in various stages, ranging from simple steatosis to fibrosis. In most cases, assessing fibrosis requires a liver biopsy. The FIB-4 index is a recently developed non-invasive tool that helps identify patients with significant fibrosis using age, AST, ALT, and blood platelet count, improving accessibility for diagnosing liver fibrosis.
Objective
To determine the degree of liver fibrosis measured by the FIB-4 index in patients with Type 2 Diabetes Mellitus (T2DM) at the start of subcutaneous semaglutide treatment and compare it six months after initiation.
MaterialS and Methods
A retrospective study was conducted on 250 patients with T2DM treated at the Endocrinology and Nutrition Department of Virgen de las Nieves Hospital in Granada, who started subcutaneous semaglutide treatment. Follow-up was carried out for approximately six months. Anthropometric (BMI) and laboratory data were collected, including HbA1c (%), triglycerides (mg/dL), ALT (U/l), AST (U/l), and FIB-4 score. The FIB-4 score was classified into three risk categories: low (<1.36), intermediate or gray zone (1.36-2.67), and high (>2.67). Data obtained at baseline and six months later were analyzed using the Jamovi statistical software, applying the paired t-test with a per-protocol approach.
Results
Of the total patients, comparable FIB-4 values before and after the intervention were obtained in 64 patients, with a mean age of 58 years and a female representation of 43%. As shown in Table 1, a significant reduction was observed in BMI ($P = 0.03$), HbA1c ($P < 0.001$), triglycerides ($P = 0.001$), ALT ($P < 0.001$), and AST ($P = 0.003$). The FIB-4 score showed a trend towards reduction, but it did not reach statistical significance ($P = 0.155$) after six months of semaglutide treatment.
Conclusion
Subcutaneous semaglutide as a treatment for T2DM significantly reduced several metabolic and hepatic parameters after six months; however, the decrease in the FIB-4 index was not statistically significant.

Table 1. Baseline and post-intervention effects of semaglutid

Variable	Pre	Post	p-value
BMI (kg/m^2)	37.0 $\pm$ 8.2	35.6 $\pm$ 6.8	0.03
HbA1c (%)	8.3 $\pm$ 1.5	7.1 $\pm$ 1.2	0.001
Triglycerides (mg/dL)	239.9 $\pm$ 236.6	169.9 $\pm$ 93.9	0.001
ALT (U/l)	32.4 $\pm$ 23.8	25.4 $\pm$ 14.4	0.001
AST (U/l)	28.9 $\pm$ 18.3	23.6 $\pm$ 9.9	0.003
FIB-4 score	1.2 $\pm$ 0.6	1.1 $\pm$ 0.5	0.155

Biological changes in new-onset diabetic ketoacidosis (DKA) before and during covid-19

Fatma Ben Abdessalem[1], Taieb Ach[1], Gorchene Asma[1], Jihene Sahli[2], Imen Halloul[1], Wiem Saafi[1], Hamza Elfekih[1], Ghada Saad[1] & Yosra Hasni[2]
[1]University of Sousse, Faculty of Medicine of Sousse, Farhat Hached University Hospital, Endocrinology Diabetology Department, 4000, Sousse, Tunisia; [2]University of Sousse, Faculty of Medicine of Sousse, Farhat Hached University Hospital, Preventive Medicine Department, 4000, Sousse, Tunisia

Introduction
DKA is a serious life-threatening complication of diabetes mellitus, with its incidence increasing over the past decades. Recent evidence suggests that COVID-19 may play a role in the pathophysiology of new-onset diabetes mellitus

by triggering islet autoimmunity. The aim of this work is to compare the biological characteristics of new onset DKA before COVID-19 with those during the pandemic.
Patients & Methods
This is a cross-sectional analytical study carried out in the Diabetology & Endocrinology department of Farhat Hached University Hospital of Sousse. The study population included all the patients who had been hospitalized for new onset DKA between the year 2018 and 2022, divided in two groups: Group1(G1) :patients hospitalized before COVID-19 since the first of March of 2018 until first of March 2020 and Group2(G2):patients hospitalized during COVID-19 since second of March 2020 until 28thFebruary 2022. A metabolic, renal, hormonal, and immunological assessment has been requested.
Results
A total of 340 patients were evaluated:137 were registered in G1, while 203 were registered in G2. There was no significant difference in WBC count, hemoglobin or platelets between G1 and G2. Creatinine levels were significantly higher in G2 compared with G1 with a median of 52 [Q1–Q3]=[41.5–63] µmol/l and 56.6 [Q1–Q3]=[46–69] µmol/l respectively (***P* = 0.006**). Urea levels did not differ significantly between the two groups ($P = 0.262$). CRP was comparable between the two groups with a mean of 5 [Q1–Q3]=[2–14.5]mg/l in G1 and 6 [Q1–Q3]=[2–11.5] mg/l in G2 ($P = 0.791$). No significant difference was detected regarding Triglycerides, HDL-cholesterol, TC or LDL-cholesterol levels between G1 and G2. Hypertriglyceridemia was present in 32% patients in G1 vs 33% in G2 ($P = 0.470$). LDL-cholesterol was outside objective range according to cardiovascular risk in 56% of patients in G1 vs 65% patients in G2 ($P = 0.214$). Anti-GAD antibodies titers significantly increased during the pandemic period compared with the pre-pandemic period with a median value of 92.5 [Q1–Q3]=[22.5–1074] in G1 vs 330 [Q1–Q3]=[58.5–1795] in G2 (***P* = 0.021**). Anti-IA2 antibodies titers significantly increased as well during the pandemic period compared with the pre-pandemic period with a median value of 0 [Q1–Q3]=[0–104.75] in G1 vs 93 [Q1–Q3]=[0–3571] in G2(***P* = 0.009**). No significant difference was found regarding anti-ZNT8 titers between the two groups ($P = 0.475$)
Conclusions
Our study suggests a potential link between COVID-19 and increased islet autoimmunity, as evidenced by higher anti-GAD and anti-IA2 antibody titers in post-pandemic patients.

Study on insulin gene rs689 polymorphism in patients with diabetic neuropathy

Talat Saatov[1], Sunnatilla Abdurakhimov[1], Zafar Ibragimov[1], Elvira Ibragimova[1], Zulaykho Shamansurova[2], Gulnora Artykbaeva[1], Tokhir Ishankhodjaev[1] & Abdunabi Tashtemirov[1]
[1]Institute of biophysics and biochemistry under Mirzo Ulugbek National University of Uzbekistan, lab of metabolomics, Tashkent, Uzbekistan; [2]2. Central Asian University Medical School Endocrinology, Tashkent, Uzbekistan

Diabetic neuropathy (DN) is one of the most common complications affecting more than 67% of patients with diabetes. In this regard, identifying genetic markers of the risk of developing DN is of great importance for the early diagnosis of this disease. The relationship between the rs689 polymorphism of the insulin gene and the development of diabetic neuropathy was studied.
Materials and Methods
The study included 2 groups: the main group was patients with DN and the control group - people without signs of DN. To study the rs689 polymorphism of the INS gene, we used a modified allele-specific PCR method. Genotyping was carried out using a programmable thermal cycler Applied Biosistems-2720 (USA).
Results and Discussion
Our findings demonstrated that the genotype distribution for rs 689 polymorphic locus of the INS gene in DN and control complied with Hardy -Weiberg equilibrim. The frequency of occurrence of the wild A allele of the INS gene in the main and control groups was 72.7% and 83.3%, respectively. The unfavorable T allele was less common in the population sample compared to the main group (16.7% and 27.3%, respectively). An analysis of the distribution of genotypes revealed that the most common genotype among the examined groups was the homozygous genotype AA (51.5% in the group with DN and 69.2% in the control group). The frequency of the heterozygous AT genotype in the sample of patients and in the control group was 42.4% and 28.2%, respectively. The distribution frequencies of the TT genotype in patients with DN are 6.1%, in the control group 2.6%, respectively. The ratio of allele frequencies and genotypes by polymorphic variant for patients with DN showed a statistically significant increase in the risk of developing this disease in carriers of the T allele (RR=1.64; 95% CI: 1.05–2.56, $\chi2=4.76$; $P = 0.029$), AT genotypes (RR= 1.56; 95% CI: 1.0–2.44, $\chi2=3.89$; $P = 0.049$), TT (RR= 2.95; 95% CI: 0.57–15.3, $\chi2=1.85$; $P = 0.18$). From the results obtained, it follows that carriers of the T allele and AT genotypes have an increased risk of developing DN, while carriers of the A allele and A/A genotype have a reduced risk of developing the disease. The findings may have important clinical implications for predicting the risk of developing diabetic neuropathy.

Treatment of 1182 early type I DM with a combination of 3 immune modulatory drugs Eight years of experience

Kiumars Pirkalani[1,2]
[1]Mehr Medical Group, Tehran, Iran; [2]Mehr Medical Group, Internal Medicien, Tehran, Iran

Background and Aims
Immune modulation of type I diabetes has failed in the last 90 years ago. Increase of C-Peptide has never been seen. Based on experience with harmless immune modulatory drugs in other disease such as alopecia areata, multiple sclerosis, and …. we tried to treat type I DM in the last 7 years ago. The treatments were changed gradually and the most effective protocol is presented.
Materials and Methods
Eleven hundred eighty-two patients were treated with Azithromycin 250mg, Vit A 25000IU twice weekly, and Atorvastatin 10-40mg every night as the immune modulatory block. Dapagliflozin (or Empagliflozin), Glucophage and Pioglutazone were used to reduce the need for insulin. In refining and defining response rate, serum fasting and 2hpp Insulin and C-Peptide, HbA1C, anti-Gad and anti-Islet cell Ab were measured at beginning and every 3 months.
Results
Hundred percent of the patients responded to at least one of the seven parameters with a reduction of HbA1c at 1.4-9.4 percent. Patients could omit their short acting insulin at evening, morning and noon in 100, 87 and 69% respectively. Reduction of anti-GAD and Anti Islet cell AB were encountered in 96 and 92 percent from a high of up to 2000 and 150 down to below 5 and 1.2. Fasting and 2hpp Insulin, fasting and 2hpp C-Peptide were increased in 86%, 88%, 68% and 82% from a low of 0.2, 0.4, 0.001, 0.001 to a high of 4.2, 16.2, 0.3 and 7.6 respectively. Three hundred eighty-eight (32.8%) patients discontinued their insulin completely and 198 (16.7%) awaits this.
Discussion
The astonishing results of increased C-Peptide with declaration of 2hpp C-Peptide as a novel response marker denotes that either increased secretion of insulin or increased beta cell proliferation (like DYRK-1 pathway) is possible *in vivo*. More sophisticated techniques are needed.

JOINT1448

Superimposition of increased beta oxidation due to insulin deficiency is the principal molecular mechanism of diabetic ketoacidosis: a proportional hazard model

Kiumars Pirkalani[1]
[1]Mehr Medical Group, Tehran, Iran

Relative insulin deficiency and high Glucagon level are the hallmark of DKA. What is the exact mechanism? When does exactly the cascade begin? How we can prevent it? Is there a cascade of events that begins days before overt clinical presentation and can we stop it?
Aim
Finding molecular pathogenesis of ketoacidosis
Methods
In a 6 years research we used immune modulatory drugs to stop type I DM. Cox multivariate analysis on 1700 patients was done. Many combinations were used and those without response were omitted. Earlier combinations included Nicotinic acid but our triumphant combination with significant c-Peptide increase did not.
Results
Although socioeconomic status, omission of Insulin and infection were the three strongest risk factors, patients (763) on Nicotinic acid showed almost no case of DKA in the first year and only 6 in the second year that was later found to be due to Nicotinic acid discontinuation. The protocol without Nicotinic acid showed 26 cases of DKA in almost 650 patients. A proportional hazard study showed very

indirectly that the DKA process begins at least 2 weeks before overt clinical presentation and can be prevented by pharmacological intervention. Some patients showed deterioration of well being with urinary ketone of 1+ that seemed not to need treatment.

Conclusion

Increased activity of ATGL, HSL augmented by loss of inhibition of Perilipin-1 causes high load of Acetyl-CoA within the mitochondria that overrides its clearing potential. Acids leak out of it and the cytoplasm has no enzymatic weapon to counteract it. Extrusion of acid into the circulation re-established cytoplasmic milieu at the expense of generalized acidity. This can be blocked by anti-lipolysis agents such as Nicotinic acid or Acipimox. Increased incidence of DKA coincident with DDP-4 or SGLT-2 inhibitors is not a per se phenomenon but due to less insulin use and lower energy expenditure. Many data shows that Insulin concentrations less than 72ng/dl in mice can cause ketoacidosis.

Association between body composition parameters, disease duration, and glycemic control in adult patients with type 1 diabetes: a cross-sectional study

Stella Pigni[1,2], Valentina Antoniotti[3], Jessica Baima[3], Sabrina Tini[3], Rosa Pitino[2], Sara Sturnia[2], Tommaso Daffara[2], Simonetta Bellone[3], Gianluca Aimaretti[2] & Flavia Prodam[3]

[1]Humanitas University, Department of Biomedical Sciences, Pieve Emanuele (MI), Italy; [2]University of Eastern Piedmont, Department of Translational Medicine, Novara, Italy; [3]University of Eastern Piedmont, Department of Health Sciences, Novara, Italy

Introduction

Alterations in body composition, such as reduced lean mass and increased adiposity, may negatively influence insulin sensitivity, glycemic control, and contribute to cardio-metabolic risk in patients with type 1 diabetes (T1D). These changes may result from insulin therapy, inadequate eating patterns, physical inactivity, or inflammatory processes associated with the disease. Understanding the interplay between T1D, body composition and metabolic parameters may help optimizing patient care. This study aimed to investigate the relationships between body composition parameters, clinical characteristics and glycemic control in a cohort of Italian adult patients with T1D.

Methods

This cross-sectional study included 94 patients with T1D (mean age $\pm$ standard deviation 43 $\pm$ 15 years); 58.5/41.5% males/females) with mean disease duration of 16 years (range 10-27), mean body mass index 24.6 kg/m^2 (21.8-27.7). Body composition was assessed using bioelectrical impedance analysis, measuring fat mass (FM), fat-free mass (FFM), skeletal muscle mass (SMM), sarcopenic index (SI), and phase angle (PA). Glycemic control was evaluated using continuous or flash glucose monitoring systems-derived metrics. Clinical data included diabetes-related complications, and patients' comorbidities and concomitant medications. Daily insulin requirements were also calculated.

Results

Correlation analysis showed significant associations between disease duration and FFM (r = -0.21, P = 0.0382), SMM (r = -0.31, P = 0.0024), and SI (r = -0.28, P = 0.0064). Daily insulin requirements positively correlated with FM (r = 0.29, P = 0.0047). PA was inversely associated with glucose management indicator (GMI r = -0.22, P = 0.0482), while positively correlated with time in range (TIR r = 0.22, P = 0.0436). Gender analysis revealed that females had significantly higher FM, and lower of FFM, SMM, SI, and PA values compared with males.

Conclusions

These finding suggests that long-standing T1D negatively affects muscle-mass measures. Moreover, poor glycemic control can negatively influence PA, a marker of cellular health, which has been associated with adverse clinical outcomes in several pathological conditions, including cancer, infections, and metabolic diseases. Furthermore, the positive relationship between FM and daily insulin requirements emphasizes the role of body fat in insulin resistance. Therefore, our study suggests the importance of monitoring and optimizing body composition as part of the comprehensive management of T1D. Significant gender-specific differences in body composition also highlight the need for personalized therapeutic strategies. Further research is needed to clarify the mechanisms underlying these relationships and their implications for clinical care in T1D patients.

Demographic and clinical characteristics of patients with LADA diabetes at hospital universitario de canarias, spain

Selena Rodríguez Fernández[1], Óliver Quintero Rodríguez[1], Kevin Díaz Gorrín[1], Javier Panizo Fra[1], Ana León Ocando[1], Laura Mesa Suárez[1], Elena Rodríguez Sosa[1], Itiziar Aznar Ondoño[1] & Macarena Sánchez-Gallego Alonso[1]

[1]Hospital Universitario de Canarias, Endocrinology and Nutrition, Santa Cruz de Tenerife, Spain

Introduction

The diagnosis of diabetes between the ages of 25 and 45 can be complicated, as the less common subtypes of diabetes sometimes overlap with characteristics typical of type 1 and type 2 diabetes mellitus (DM). Latent Autoimmune Diabetes in Adults (LADA) shares an autoimmune component with DM1, and therefore, there is an early progression towards insulinopenia compared to DM2. However, in most cases, patients initially present good control using only non-insulin antidiabetic drugs, similar to DM2. For this reason, patients are often initially misdiagnosed with DM2. In patients with clinically compatible characteristics, it is essential to determine autoantibodies against pancreatic beta-cell structures to establish the correct diagnosis. The literature indicates that the most frequently present and sensitive antibodies are anti-glutamic acid decarboxylase antibodies (anti-GAD). However, other autoantibodies may also be present.

Material and Methods

A descriptive and cross-sectional study was conducted to assess the clinical and demographic characteristics of patients with LADA. A sample of 44 patients aged between 38 and 72 years (mean age of 50.9 years), 56.8% of whom were women, was evaluated between 2022 and 2023 in the Endocrinology Department of "Hospital Universitario de Canarias", Spain.

Results

A retrospective assessment was made regarding the following: diagnosis change, diagnostic delay, presence of autoantibodies (anti-GAD and anti-IA2), initial glycated hemoglobin, final glycated hemoglobin, C-peptide levels, time treated only with non-insulin antidiabetic drugs, time treated only with basal insulin, time to the initiation of basal-bolus regimen, and the use of continuous glucose monitoring (CGM) systems.

- Mean time of diagnostic delay (years): 6.5
- Mean initial HbA1c: 8.7%
- Mean final HbA1c: 7.4%
- Mean treatment time with non-insulin antidiabetic drugs (years): 2.65
- Mean time treated with only basal insulin (months): 9
- Mean time until the initiation of basal-bolus regimen (years): 3.7
- **Diagnosis change:**81.8% of patients
- **Use of CGM:**88.6% of patients
- **Autoantibodies:**Only anti-GAD positive: 48.7%; Only anti-IA2 positive: 15.38%; Both positive: 35.89%
- **C-peptide levels (ng/mL):** $<$0.5: 38.7%; 0.5-2: 54.83%; $>$2: 10.52%

Conclusion

Although LADA is a recognized form of diabetes, no specific guidelines have been established for its management, and it is often confirmed years after an initial diagnosis of DM. An individualized approach should be taken, considering the metabolic characteristics as well as the signs and symptoms of insulinopenia (emphasizing the importance of determining C-peptide levels in diagnosis and follow-up).

Characteristics of patients with diabetes mellitus evaluated by hospital interconsultations at the canarias university hospital (HUC)

Óliver Quintero Rodríguez[1], Selena Rodriguez Fernandez[1], Kevin David Díaz Gorrín[1], Javier Panizo Fra[1], Ana Paola León Ocando[1], Laura Mesa Suárez[1], Elena Rodríguez Sosa[1], Patricia León González[1], Macarena Sánchez-Gallego Alonso[1] & Patricia Cabrera García[1]

[1]Hospital Universitario de Canarias, Endocrinology and Nutrition, San Cristóbal de La Laguna, Spain

Introduction

A significant proportion of hospitalized patients have some form of diabetes mellitus (DM). Achieving optimal glycemic control in hospitalized patients requires consideration of multiple factors, including food intake, fasting for tests/procedures, clinical deterioration, and corticosteroid use. Blood glucose levels outside the safe range (140 mg/dL–180 mg/dL) increase the risk of complications during hospitalization.

Objectives
To describe the characteristics of diabetic patients evaluated in the Endocrinology and Nutrition consultations at the Hospital Universitario de Canarias (HUC).
Materials and Methods
A descriptive observational study was conducted on a sample of 118 diabetic patients monitored through Endocrinology and Nutrition consultations at HUC from October to December 2024. The variables analyzed included age, sex, type of diabetes, referring hospital department, blood glucose levels at initial and final evaluations, HbA1c, treatment, associated comorbidities, and follow-up plan.
Results
A total of 53 women and 65 men were studied, with most patients aged 70–80 years (31%) and an average age of 65 years. Among them, 90 patients (76%) had type 2 diabetes (T2DM), 25 (21%) had type 1 diabetes (T1DM), and 3 (3%) had latent autoimmune diabetes in adults (LADA). The hospital department requesting the most consultations was Vascular Surgery (14%), followed by Gastroenterology (13%) and Nephrology (11%). At the initial evaluation, 29% of patients had blood glucose levels between 250–300 mg/dL, while 16% had levels exceeding 400 mg/dL. Before the endocrinology assessment, 44% of patients were on a sliding-scale insulin regimen, but 74% required an immediate transition to a basal-bolus insulin regimen. When analyzing blood glucose levels, it was noted that 31% of patients were receiving corticosteroids. Regarding HbA1c levels, 27% of patients had values between 7% and 8% (mean: 8.28%), while 14% had HbA1c levels $>10\%$. Among the associated comorbidities, 37% had diabetic retinopathy, 43% had nephropathy, and 24% had polyneuropathy. For follow-up after discharge: 28% were referred to primary care physicians. 52% were scheduled for endocrinology outpatient follow-up. The remaining 20% included deceased patients, patients discharged without notification, voluntary discharges, and those followed up outside the island.
Conclusions
The limited effectiveness of sliding-scale insulin regimens in hospitalized patients is demonstrated. Maintaining blood glucose levels between 140 and 180 mg/dL is a safe target for hospitalized patients. Strengthening adherence to glycemic control protocols in hospitalized patients is essential. Additionally, hospitalization provides an opportunity to reinforce diabetes education, optimize home treatment, and assess follow-up needs upon discharge.

JOINT2869

A diagnosis of MODY 2 following MIS-C

Sare Kaygusuz[1,2], Fuat Bugrul[3] & Mustafa Gokoglu[4]
[4]Istanbul Medeniyet University, School of Medicine, Department of Pediatric Endocrinology and Diabetes, Istanbul University, Aziz Sancar Institute of Experimental Medicine, Department of Genetics, Istanbul, Türkiye; [2]Istanbul University, Aziz Sancar Institute of Experimental Medicine, Department of Genetics, Istanbul, Türkiye; [3]Selcuk University, School of Medicine, Department of Pediatric Endocrinology and Diabetes, Konya, Türkiye; [4]Kahramanmaras Necip Fazil City Hospital, Department of Genetics, Kahramanmaras, Türkiye

Background
Maturity-Onset Diabetes of the Young (MODY) due to *GCK* mutations is a form of monogenic diabetes characterized by mild fasting hyperglycemia. Here, we present a pediatric case of GCK-MODY diagnosed after Multisystem Inflammatory Syndrome in Children (MIS-C).
Case
A 4-year-old girl, born at term with a birth weight of 3,200 g, was referred for persistent hyperglycemia. She had been hospitalized for three weeks due to MIS-C, before her visit. Family history revealed diabetes in her maternal grandfather, aunt and mother necessitating the use of antidiabetic medications, which raised concerns for MODY. Initial labs showed fasting glucose of 120 mg/dL and HbA1c of 5.4%. An OGTT revealed 0-minute glucose of 136 mg/dL and 120-minute glucose of 151 mg/dL, with an insulin response suggesting preserved beta-cell function. Genetic testing identified a heterozygous pathogenic variant in GCK (c.214G$>$A, p.Gly72Arg, rs193922289), confirming GCK-MODY. However during follow-up after MIS-C, postprandial hyperglycemia and an HbA1c of 8% raised concerns for insulinopenic diabetes. Further rise of blood glucose levels necessitated use of insulin. Autoimmune diabetes markers (IAA, ICA, GADA) were negative. The patient was also screened for other antibodies related to autoimmune thyroiditis and celiac disease, which were negative. After 6 months of treatment, insulin was discontinued.Duringthelast 2.5 years of follow-up,the patient remained stable, with anHbA1c of 5.9%at her last visit.
Discussion
Recent studies suggest COVID-19 may increase diabetes risk, but its exact role is unclear. The mechanisms likely involve systemic inflammation, glucocorticoid use, endothelial dysfunction, and persistent viral presence affecting pancreatic β-cell function and insulin sensitivity. Some propose classifying post-COVID diabetes as a distinct syndrome. In this case, initial postprandial hyperglycemia and an HbA1c of 8% raised concerns for insulinopenic diabetes, leading to autoantibody testing. However, negative autoantibodies, stable glucose after insulin withdrawal, and the presence of a GCK variant suggest transient hyperglycemia was MIS-C-induced. The exact mechanism remains unknown, highlighting the need for long-term follow-up. This case also underscores the importance of considering MODY in pediatric patients with persistent hyperglycemia with strong family history. Dynamic follow-up and a tailored approach are crucial to avoiding unnecessary treatments.

Melatonin levels across patients with type 2 diabetes mellitus with and without sleep disorders

Solomiia Shykula[1] & Alina Urbanovych[1]
[1]Danylo Halytsky Lviv National Medical University, Lviv, Ukraine

Melatonin is a hormone that significantly impacts our sleep and circadian rhythms. It also influences glucose metabolism, but how exactly it happens is still unclear. Due to the Timing Model, low melatonin levels during the night may limit β-cell recovery, while high levels with food intake may lead to an increased risk of diabetes. Nowadays, the number of sleep disorders has increased, and a lot of people, including patients with type 2 diabetes, choose to take melatonin pills as these are available over the counter without a prescription. The purpose of this study was to determine the relationship between levels of melatonin, diabetes mellitus, and sleep disorders.
Methods
This was a quantitative research study with 77 patients included. Participants' ages ranged from 32 to 69 years (M = 54,3, SD = 8,27), with 41 (53%) identified as female. Avarage HbA1c was $9,28 \pm 2,14$. As for years from the beginning of diabetes - 7[5; 10,25]. All patients have confirmed diabetes mellitus type 2 and were screened for sleep disorders with the Pittsburgh Sleep Quality Index (PSQI) questionnaire. Melatonin levels were indicated in the salvia, which was collected at night. We use the colorimetric method to test samples with the Melatonin Elisa kit (ab283258) supply. Statistical analysis was provided in Microsoft Office Excel.
Results
The study found that 45 patients (58%) had normal melatonin levels, 17 patients (22%) had elevated levels, and 15 patients (20%) had reduced levels. Among women, 12 patients (29%) had high levels, 7 patients (17%) had low levels, and 22 patients (54%) had normal levels. Among men, 5 patients (14%) had high levels, 8 patients (22%) had low levels, and 23 patients (64%) had normal levels. Furthermore, 25 participants (32.4%) scored above 5 on the PSQI, indicating poor sleep quality. Within this group, 3 patients (12%) had high melatonin levels, 7 patients (28%) had low levels, and 15 patients (60%) had normal levels. The correlation between melatonin levels and sleep disturbances was 0.11.
Conclusions
Melatonin levels have a weak correlation with sleep disorders, which means this hormone is not the leading cause of this problem. It is essential to check the level of melatonin before administering it to patients with diabetes to provide personalized treatment and avoid harming someone who has a normal or elevated level of melatonin.

Fibrocalculous pancreatic diabetes (SPINK 1 mutation) in klinefelter syndrome: first case report

Md Ejaz Alam[1,2], Mohammad Hayat Bhat[1] & Mohd Salem Baba[1]
[1]Government Medical College, Endocrinology and Metabolism, Srinagar, India; [2]Government Medical College, Srinagar, Endocrinology, Srinagar, India

Background
Klinefelter Syndrome (KFS) is the most common sex chromosome disorder in males, typically characterized by a 47, XXY karyotype, hypergonadotropic hypogonadism, infertility, and metabolic complications such as insulin resistance and type 2 diabetes. Fibrocalculous Pancreatic Diabetes (FCPD), a unique form of diabetes prevalent in tropical regions, is associated with pancreatic calcification, exocrine insufficiency, and insulin dependence. The coexistence of KFS and FCPD is exceedingly rare, presenting significant challenges in diagnosis and management due to overlapping endocrine and metabolic dysfunctions.
Case Presentation
We report a case of a 48-year-old male with KFS and FCPD. The patient was diagnosed with diabetes mellitus four years prior to hospital admission and presented with progressive weight loss, steatorrhea, and intermittent abdominal pain. Despite intermittent insulin use, he experienced poor glycemic control with an HbA1c of

17.7% and random blood glucose of 500 mg/dL at admission. Clinical evaluation revealed primary infertility, decreased libido, and small, firm testes. Imaging confirmed pancreatic calcifications and ductal dilation, while genetic testing identified a pathogenic SPINK1 gene mutation (N34S 101 A>G). Karyotype analysis established a 47, XXY diagnosis, consistent with KFS. Further investigations revealed primary hypogonadism, osteoporosis, vitamin D deficiency, and low lipid levels. The patient was managed with a basal-bolus insulin regimen, pancreatic enzyme replacement, vitamin supplementation, zoledronic acid for osteoporosis, and testosterone replacement therapy.

Discussion

This case highlights the complex interplay of metabolic and endocrine dysfunction in the rare coexistence of KFS and FCPD. KFS contributes to insulin resistance via increased adiposity and reduced muscle mass, while FCPD adds challenges of pancreatic exocrine insufficiency and insulin dependence. Additionally, hypogonadism in KFS exacerbates metabolic derangements, with testosterone deficiency linked to increased insulin resistance and bone loss. Multidisciplinary management is essential, addressing glycemic control, pancreatic insufficiency, and hormonal replacement.

Conclusions

The coexistence of KFS and FCPD underscores the need for comprehensive evaluation and personalized management of patients with overlapping metabolic and endocrine disorders. This case emphasizes the importance of a multidisciplinary approach integrating insulin therapy, enzyme and vitamin replacement, and testosterone therapy to optimize metabolic outcomes and quality of life.

Localized scleroderma in a type 1 diabetic patient : a case report

Mariam Mabrouk[1], Chedia Zouaoui[1], Kahena Jaber[2], Ines Bani[1], Bchir Najla[1], Annam Benchhida[1], Dorra Dorraelguiche[1] & Haroun Ouertani[1]

[1]Military Hospital of Tunis, Endocrinology Department, Tunis, Tunisia; [2]Military Hospital of Tunis, Dermatology Department, Tunis, Tunisia

Introduction

Morphea or localized scleroderma is a rare disease characterized by excessive collagen fiber production in the dermis, leading to the appearance of indurated subcutaneous areas. The association of systemic scleroderma and type 1 diabetes has been reported but not morphea. We report the case of a 16-year-old girl who consulted for diabetes type 1 with extensive lipodystrophic areas.

Observation

A 16-year-old girl presented to the Endocrinology Department for uncontrolled diabetes. Her medical history included an auto-immune hypothyroidism treated with 75 mg/day of levothyroxine. She has been diabetic since the age of 8, diagnosed following a biological screening due to a cardinal syndrome. Anti-GAD65, IAA, ICA and anti-ZNT8 antibodies were negative. She was treated with insulin analogs: insulin detemir and aspart. Initially, she developed large indurated subcutaneous areas and atrophic zones in insulin injection sites (abdomen, arms, and thighs), despite right injection techniques and rotation. Progressively, new indurated subcutaneous areas appeared outside of the injection sites. The diagnosis of morphea was suspected and confirmed by a skin biopsy showing a homogenized reticular dermis, with collagen bundles that were more or less thick and dense, and either horizontal or parallel to the surface. Dot sclerosis was negative. The patient was started on methotrexate at 12.5 mg/week, and an insulin pump was proposed to obtain a better control of diabetes with reduced the number of injections.

Conclusion

The identification of localized scleroderma in a patient initially thought to have lipodystrophy highlights the importance of considering rare and atypical diagnoses in patients with diabetes as they can have a significant impact on diabetic control.

Predictors of diabetes in tropical calcific pancreatitis - a cross sectional, observational study

Subhash Yadav[1], Smriti Panda[2] & Monika Yadav[2]

[1]Sanjay Gandhi Post Graduate Institute of Medical Sciences, Endocrinology, Lucknow UP, India; [2]Sanjay Gandhi Postgraduate Institute of Medical Sciences, Endocrinology, Lucknow UP, India

Introduction

Diabetes in tropical calcific pancreatitis is a common complication with prevalence ranging from 5-10% in western population and 15-20% in southeast Asian population. Compared to type 2 diabetes, these patients need insulin earlier, have higher risk of hypoglycemia. Knowledge about risk factors would help early intervention and delay development of diabetes. In this study we have assessed the risk factors for the development of diabetes among the TCP patients.

Aim

To identify the risk factor of development of diabetes in subjects with tropical calcific pancreatitis (TCP)

Methodology

The study is a cross-sectional study conducted in a tertiary care hospital. All the patients above 18 years of age attending the Endocrinology or Gastroenterology OPD with a diagnosis of idiopathic chronic pancreatitis were included in the study. Relevant clinical history, examination and were done. Imaging details of patients were taken. For patients without diabetes OGTT was done.

Results

Total 219 patients have been enrolled whom 143 (65%) are diabetic and 76 (35%) are non-diabetic. Diabetes has a mean age of 34.7 ± 12.7 years which is significantly higher than non- diabetics 28 ± 10.8 years ($P = 0.00$). A greater number of diabetes patients had a history of surgery (15% vs 5%) and exocrine insufficiency (80.4% vs 67%) compared to non- diabetes. There is no significant difference in BMI, history of acute pancreatitis, family history of diabetes or chronic calcific pancreatitis in the two groups. Biochemical parameters showed a significantly lower C-peptide, amylase and lipase levels in diabetics compared to non-diabetics. On pancreatic imaging it is found that significantly higher number of patients with diabetes have pancreatic atrophy (95% vs 86%), parenchymal calcifications (65% vs 51%) and a larger duct size of 7 (4.2-9) vs 5 (3.8-7) mm. Multivariate logistic regression showed pancreatic parenchymal atrophy OR- 14.3 (CI-1.1-179), exocrine insufficiency (steatorrhea) OR-5.1 (CI-1.3-20), older age OR-1.05 (CI-1.0-1.1) and lower C-peptide OR- 0.05 (CI- 0.005-0.6) as risk factors for diabetes in TCP patients.

Conclusion

Among patients with TCP, those with older age, history of surgery, exocrine insufficiency and lower C-peptide levels have higher risk of diabetes mellitus. In pancreatic imaging, parenchymal calcifications, atrophy and ductal dilatation were found to be risk factors for diabetes mellitus.

The importance of cardiovascular implementation tests in diagnostic of the diabetic cardiovascular autonomic neuropathy

Snjezana Popovic Pejicic[1,2,3], Valentina Soldat Stankovic[1,2], Gabrijela Malesevic[1,2] & Nina Pejicic[1,2]

[1]The University of Banja Luka, the Faculty of Medicine, Banja Luka, Bosnia and Herzegovina; [2]The University Clinical Centre of the Republic of Srpska, Banja Luka, Bosnia and Herzegovina; [3]Academy of Science and Arts of the Republic of Srpska, Banja Luka, Bosnia and Herzegovina

Introduction

The chronic vascular complications are the most common cause of death and invalidity of diabetic patients, and cardiovascular chronic complications are the most affected. The diabetic cardiovascular autonomic neuropathy (CAN) is chronic complication of diabetes mellitus, frequently without any symptoms, and with high mortality which demands early detection.

Aim

Aim of this work was to establish: possibility of CAN early detection with the implementation of cardiovascular dynamic tests and diagnostic value each of those cardiovascular tests.

Methods

During this research we have evaluated 90 examinees: 30 of them with diabetes type 1, 30 with diabetes type 2 and 30 healthy examinees – without primary cardiac disease and diabetes. The autonomic nervous system function was examined by 5 tests for cardiovascular reflexes, with those tests we have evaluated cardiac rate reaction on various stimuli (Valsalve maneuver, deep breathing test, stand-up after lying position test) or blood pressure (orthostatic hypotension test and Hand grip test). In performing of these tests, we have used: sphygmomanometer, ECG machine, aneroid manometer and manual manometer.

Results

Results have showed that the most common pathological test in diabetes type 1 (71,4%, $P < 0.001$) and type 2 (83,3%, $P > 0.001$) was stand-up from lying position test, and afterwards deep breathing test – in diabetes type 1 (66,7%, $P < 0.001$) and

type 2 (80,0%, $P < 0.001$). Valsalve maneuver, orthostatic hypotension test and Hand grip test were pathological in 33,3% of the patients with autonomic neuropathy in type 1 of diabetes, and in type 2 (46,7%, 13,3% and 20,0%).
Conclusions
The cardiovascular tests enable early detection of the presence of CAN and objective assessment of the cardiovascular function, and have great prognostic, diagnostic and therapeutic significance. Stand-up test from lying position and deep breathing test were the most often pathological in CAN patients, and therefore having the greatest diagnostic value. Cardiovascular tests should be accepted as golden standard in CAN diagnostic and put it in everyday clinical practice. Correct interpretations of these tests enable categorization of damage degree of autonomic nerve system, which has great importance in further treatment and management of these patients.

JOINT2133

Prevalence of obesity and diabetes in reproductive age (20–44 years) in the bulgarian population

Anna-Maria Borissova[1], Boyana Trifonova[2], Lilia Dakovska[1], Eugenia Michaylova[1], Neriman Topchieva[1] & Mircho Vukov[1]
[1]University Hospital Sofiamed, Sofia, Bulgaria, Faculty of Medicine, Sofia University "Saint Kliment Ohridski", Sofia, Bulgaria, Clinic of Endocrinology, Department of Internal Diseases, Sofia, Bulgaria; [2]University Hospital Sofiamed, Sofia, Bulgaria Faculty of Medicine, Sofia University "Saint Kliment Ohridski", Sofia, Bulgaria, Sofia, Bulgaria

Obesity and overweight (BMI >25 kg/m^2), affecting all age groups, are considered major risk factor for the onset of diabetes/prediabetes outside of pregnancy and for hyperglycemia during pregnancy.
Aim
To investigate the relationship between BMI >25 kg/m^2 in the young reproductive age group (20–44 years) and the development of diabetes/prediabetes.
Materials and Methods
A total of 931 individuals (20–79 years) were studied, divided into three age groups: 20–44 years (n-340, 36.5%), 45–59 years (n-300, 32.2%), and 60–79 years (n-291, 31.3%). The analysis focused on 340 individuals from the reproductive age group (20–44 years), consisting of 158 women (46.5%) and 182 men (53.5%). Height and weight were measured, and BMI was calculated.
Results
The current diabetes prevalence in Bulgaria is 16.55%, distributed across the age groups as follows: 4.1% (14/342) in 20–44 years, 18.3% (55/301) in 45–59 years, and 29.55% (86/291) in 60–79 years. In the young group, BMI >25 kg/m^2 was observed in 56.2% (191/340), distributed between women (30.4%, 58/191) and men (69.6%, 133/191), with a significant gender difference ($P<0.001$). Among this group, diabetes was present in 4.1% (14/340), prediabetes in 10.3% (35/340), and no carbohydrate metabolism disorders in the remaining 85.6% (291/340). In this young group obesity was identified in 57.1% (8/14)* of individuals with diabetes, 45.7% (16/35) of those with prediabetes, and 19.9% (58/291)* of individuals without carbohydrate metabolism disorders (*$P<0.05$). In our earlier study on pregnant Bulgarian women, hyperglycemia was identified in 14.4% (79/547), with 7.5% (29/386) occurring before 24 gestational weeks and 31% (50/161) after 24 gestational weeks ($P<0.01$)[1]. A significant relationship with pre-pregnancy weight was also observed: women with hyperglycemia (n-79) had an average BMI of 26.10 ± 6.65 kg/m^2 compared to 22.89 ± 4.57 kg/m^2 in those with normoglycemia ($P<0.001$).
Conclusion
Over 56% of individuals in the young reproductive age group (20-44 y) have a BMI >25 kg/m^2, a strong risk factor for the development of diabetes/prediabetes and a risk factor for hyperglycemia during pregnancy. Upon the onset of pregnancy, screening for glucose tolerance disorders is essential, particularly in women with obesity or overweight at the time of conception.

New-onset autoimmune diabetes mellitus concomitantly with myositis secondary to pembrolizumab treatment in a patient with squamous lung cancer: a case report

Fotis Mermigkas[1], Vasiliki Daraki[1], Evangelia Pissadaki[1], Panagiotis-Nikolaos Tsakalomatis[1], Vasiliki Venetsanaki[1], Michael Papadakis[2], Maria Sfakiotaki[1], Grigoria Betsi[1], Sofia Agelaki[2] & Paraskevi Xekouki[1]
[1]University General Hospital of Heraklion, Department of Endocrinology Diabetes and Metabolic Diseases, Crete, Greece; [2]University General Hospital of Heraklion, Department of Medical Oncology, Crete, Greece

Background
Immunotherapy displays a prominent role in the current treatment of many malignancies. However, several adverse events of immune checkpoint inhibitors (ICIs) have been described so far. We present a rare case report of pembrolizumab–induced autoimmune diabetes mellitus (DM) concomitantly with myositis.
Case presentation
A 65-year-old Caucasian male, with no personal or family history of DM, was treated with pembrolizumab for squamous lung cancer. Two months after the 1st dose of treatment, he presented to the emergency department due to muscle weakness, fatigue and high plasma glucose levels (>500mg/dl). The patient also reported polyuria, polydipsia, mouth dryness, weight loss and abdominal pain over the last three days. Physical examination revealed tachycardia, tachypnea, dehydration, numbness of the lower extremities and left eyelid ptosis. The patient did not experience any cardiac symptoms and the electrocardiogram was normal. Laboratory tests were indicative of diabetic ketoacidosis concomitantly with myositis. Further investigation, for DM, revealed low c-peptide (0,55 ng/dl), and insulin concentration ($<1,6$ μUI/ml). Immediate treatment was initiated, including hydration, intravenous insulin infusion and high-dose intravenous methylprednisolone of 1gr daily with significant clinical and biochemical improvement. He was subsequently switched to subcutaneous insulin therapy and to 1mg/kg methylprednisolone orally which was slowly tapered over the next two months. The patient tested positive for autoantibodies against glutamic acid decarboxylase (anti-GAD) and islet cell autoantibodies (ICA). These data established the diagnosis of new-onset autoimmune DM. The antibodies for myasthenia Gravis were negative. Six months later, the patient presented within glycemic targets along with a significant improvement of the left eyelid movement and fatigue.
Discussion
Pembrolizumab is an ICI, widely used in cancer treatment. Its main action is to inhibit lymphocytes' PD-1 receptors and elicit an immune response. This allows the immune system to target and destroy cancer cells, but also, leads to immune-related adverse events (irAEs) in various organ systems. Immune-mediated destruction of pancreatic β-cells and myositis by pembrolizumab are rare disorders. This is the first case report of pembrolizumab-induced autoimmune DM concomitantly with myositis, described so far. Monitoring of early signs of these adverse events and medical professional awareness are crucial, as some of these could be life-threatening. The exact mechanisms are yet to be elucidated.

Type 2 diabetes and quality of life in relation to perceived psychological stress

Lina Radzeviciene[1] & Lina Lašaitė[1]
[1]Institute of Endocrinology, Lithuanian University of Health Sciences, Kaunas, Lithuania

Aim
To investigate quality of life (QoL) in patients with type 2 diabetes (T2DM) experiencing low perceived psychological stress level and high perceived psychological stress level.
Methods
Perceived psychological stress level and QoL were assessed in 146 patients with T2DM (57 men, 89 women, age 56.7 ± 12.6 years, T2DM duration 7.4 ± 6.9 years, body mass index (BMI) 33.6 ± 5.7 kg/m^2, HbA1c level 7.7 ± 1.6%), using Perceived Stress Scale (a higher score denotes a higher level of stress) and WHO Bref Quality of Life questionnaire (a higher score denotes better QoL).
Results.
Patients with high perceived stress level had lower scores in physical health (10.9 ± 1.6 vs. 13.9 ± 2.4, $P<0.001$), psychological health (11.4 ± 2.8 vs. 13.7 ± 2.1, $P=0.018$), and social relations domains (12.3 ± 1.9 vs. 13.6 ± 2.6, $P=0.038$) than those with low perceived stress level. No significant differences were found in QoL environmental domain as well as in age, T2DM duration, BMI, HbA1c level between patients experiencing low and high perceived stress. Perceived stress level in patients with T2DM correlated negatively with QoL physical health score ($r=-0.255$, $P=0.015$).
In conclusion.
Patients with type 2 diabetes experiencing high perceived psychological stress level have worse quality of life in terms of physical health, psychological health and social relations than those with low level of perceived psychological stress.Perceived stress level in patients with type 2 diabetes is related to physical health.

Hypoglycemia in an insulin-treated diabetic: when causes pile up

Mohamed Khairi Arous[1], Houcem Elomma Mrabet[1], Najoua Lassoued[1], Matiem Souissi[2], Zantour Baha[1], Alaya Wafa[1] & Sfar Mohamed Habib[1]
[1]University Hospital Tahar Sfar, Department of Endocrinology, Mahdia, Tunisia; [2]Hedi Chaker University Hospital, Department of Endocrinology, Sfax, Tunisia

Introduction
Hypoglycemia is a frequent and potentially severe complication in insulin-treated diabetics, requiring meticulous management to prevent instability and adverse outcomes. While its primary etiology often stems from insulin mismanagement, hypoglycemia can also have multifactorial origins. Here, we present the case of an adult with recurrent hypoglycemia due to a combination of complex, overlapping factors.
Case Report
A 56-year-old male, diabetic for 36 years, presented with recurrent unrecognized hypoglycemic episodes, occasionally resulting in loss of consciousness. His medical history included combined spinal sclerosis and bipolar disorder, managed with sodium valproate and risperidone. The patient was on a basal-bolus regimen of human insulin (1.25 IU/kg), administered exclusively postprandially. Clinical examination revealed severe malnutrition (BMI: 13.8 kg/m^2), depressive syndrome, edentulism, and prominent lipodystrophies at the arms, the sole injection sites. An extensive evaluation for malnutrition, including biological tests, tumor markers, tuberculosis screening, and imaging, yielded negative results, and hormonal profiles revealed no deficiencies. Initial management involved correcting therapeutic errors, transitioning to insulin analogs with appropriate dose adjustments, and implementing gradual nutritional repletion. While these interventions led to partial improvement, recurrent hypoglycemia persisted. Hypoglycemic episodes confirmed exogenous hyperinsulinism. The persistence of hypoglycemia prompted suspicion of iatrogenic factors. Sodium valproate and risperidone were reviewed, and their potential contributions to hypoglycemia were explored. Discontinuation of risperidone and dose reduction of sodium valproate (guided by elevated serum levels) resulted in resolution of hypoglycemia and progressive weight gain.
Discussion and Conclusion
Severe hypoglycemia in insulin-treated diabetics often originates from improper insulin administration, as seen in our patient's use of restricted injection sites with associated lipodystrophy. Insulin overdose, although common, is frequently underestimated. The multifactorial malnutrition in this case required a multidisciplinary approach, particularly collaboration with the treating psychiatrist to optimize nutritional status. Sodium valproate-induced hypoglycemia, though rare, is attributed to impaired hepatic gluconeogenesis mediated by decreased L-carnitine levels. Similarly, risperidone has been implicated in hyperinsulinism through pancreatic alpha-2 receptor antagonism, although this mechanism remains debated. The absence of hypoglycemia awareness in this patient likely resulted from autonomic neuropathy compounded by recurrent episodes and vitamin B12 deficiency. This case underscores the importance of a comprehensive evaluation in patients with insulin-treated diabetes and recurrent hypoglycemia. Identifying and addressing multifactorial causes, including drug-induced hypoglycemia, is essential. Long-term follow-up is critical to ensure sustainable therapeutic success and to mitigate the risk of recurrence.

Evolution of glycemic profile of diabetic women after childbirth

Haifa Abdesselem[1], Chaima Sdiri[1], Kamilia Ounaissa[1], Emna Bornaz[1], Fatma Boukhayatia[1], Asma Ben Brahim[1], Rym Yahyaoui[1] & Chiraz Amrouche[1]
[1]National Institute of Nutrition and Food Technology, Department of Nutritional Diseases (D), Tunis, Tunisia

Background
Pregnancy represents a critical period in the life of a woman with diabetes, as it leads to weight gain and alters glycemic control as well as lipid profile. The aim of our study was to determine the evolution of glycemic profile of a group of diabetic women after childbirth.
Methods
We conducted a prospective descriptive study in pregnant women treated for pregestational diabetes and followed at the Department of Nutritional Diseases «D» of the National Institute of Nutrition of Tunis. Glycemic profile was monitored during pregnancy and six months postpartum.
Results
We collected 30 diabetic patients with a mean age of 32.2 ± 4 years [ext :23-39]. Most patients had type 2 diabetes (80%). The mean duration of diabetes was 3.6 ± 2.9 years in patients with type 2 diabetes and 13.6 ± 7.3 years in patients with type 1 diabetes. During pregnancy: The mean glycated hemoglobin (A1C) was 7.8 ± 1.6% with a range from 5.9% to 12%. The occurrence of a hypoglycemic episode was reported in 22% of the patients. After six months of childbirth, only 10% of babies were exclusively breastfed, while half were formula-fed. The mean fasting blood glucose level was 10,11 ± 4,5 mmol/l, and the mean A1C was 8,19 ± 2,05%. Only 3 patients reported experiencing hypoglycemic episodes. We observed a lower mean A1C level in cases of exclusive breastfeeding ($P = 0.035$).
Conclusion
Six months after childbirth, we observed an increase in the glycated hemoglobin level and a decrease in the number of hypoglycemic episodes. Further studies on a larger scale might be needed.

A case of insulin antibody-mediated insulin resistance in type 2 diabetes treated by glucocorticoid

Dhoha Ben Salah[1], Yassmine Abdelkafi[1], Khouloud Boujelben[1], Hamdi Frikha[1], Mouna Mnif[1], Faten Haj Kacem Akid[1], Nadia Charfi[1], Mohamed Abid[1], Mouna Elleuch[1] & Nabila Rekik Majdoub[1]
[1]Hedi Chaker University Hospital, Endocrinology Department, Sfax, Tunisia

Introduction
Severe insulin resistance (IR), although rare, is clinically significant as it leads to deterioration of glycemic control despite very high insulin doses. One of the rarest etiologies is autoimmunity, particularly the production of insulin autoantibodies (IAA), which can result in extreme insulin resistance and unpredictable glycemic variations.
Observation
We report the case of a 61-year-old woman with a history of type 2 diabetes treated with human insulin for 10 years. She developed insulin resistance and was admitted to our hospital. She has reported a deterioration of her glycemic control despite an increase in the dose of insulin up to 200 U/day. Clinical examination was unremarkable, with no history of drug intake. A high titer of insulin antibodies was detected in the serum (77.6%). Prednisolone was administered with a dose of 0.5 mg/kg/day for one month. The dosage was tapered by 5 mg at 15-day intervals until reaching 5 mg/day. Insulin requirement decreased by 66% and glycemic control was reached."
Discussion and Conclusion
Insulin resistance is defined as a state (of a cell, tissue, or organism) in which there is a decrease of the biological response to insulin. Clinically, it manifests as a deregulation of glycemic homeostasis. IAA-mediated IR is a rare autoimmune disorder characterized by high titers of insulin autoantibodies, leading to excessive insulin binding and sequestration, resulting in postprandial hyperglycemia and nocturnal hypoglycemia. The treatment of antibody-mediated IR is not standardized; corticosteroid therapy often gives good results. Immunosuppressive therapy, insulin analogs, and plasmapheresis have been proposed in refractory cases. Although uncommon, this condition can cause significant metabolic disturbances and increased morbidity. However, if the diagnosis is early recognized and the treatment is well-conducted, the prognosis can be improved.

Diabetes as a major risk factor for pharyngostoma: influence of comorbidities on postoperative outcomes

Houas Jihene[1], Monia Ghammam[1], Jawaher Kechiche[1], Habiba Ben Sghaier[1], Malika El Omri[1], Mouna Bellakhdher[1], Abir Meherzi[1], Wassim Kermani[1] & Mohamed Abdelkefi[1]
[1]University of Sousse Faculty of Medicine of Sousse, Sousse, Tunisia

Introduction
Diabetes is a major risk factor for the development of pharyngostoma, a severe postoperative complication that significantly impairs healing. Other contributing factors include poor nutritional status, radiotherapy history, and infection, all of which further compromise tissue regeneration and wound closure.

Objective
This study aims to evaluate the impact of diabetes and other associated risk factors on the incidence, progression, and management of pharyngostoma.
Methods
A retrospective analysis was conducted on patients who developed pharyngostoma, comparing diabetic and non-diabetic cases while considering additional risk factors such as malnutrition, prior radiotherapy, and infections. Data on healing time, complication rates, and clinical outcomes were analyzed.
Results
The average age of our patients was 60 years. The sex ratio was 19.5. 95.1% of patients were smokers, and 51.2% were alcoholics. Some patients had associated comorbidities; diabetes was noted in 7.3% of cases, hypertension in 8.9% of cases, heart disease in 0.8%, and chronic obstructive pulmonary disease in 2.4% of cases. Ten (8.1%) patients had a history of laryngeal cancer. In 3 cases (2.4%), partial laryngeal surgery was performed, and in 7 cases (5.7%), initial non-surgical treatment included radiotherapy. Radiotherapy was exclusive in two cases and combined with chemotherapy as part of a laryngeal preservation protocol in the remaining 5 cases. For locoregional and distant staging, all patients underwent panendoscopy and cervical thoracic CT scan. Total laryngectomy was performed in all patients, extended to neighboring structures in 35.8% of cases. Postoperatively, pharyngostoma occurred in 11 (8.9%) of our patients. Univariate analysis found a statistically significant relationship between the occurrence of pharyngostomy and a history of diabetes ($P = 0.034$), preoperative radiotherapy ($P = 0.016$), total laryngectomies extended to the hypopharynx ($P = 0.017$), and postoperative parietal infection ($P = 0.000$). Preoperative albumin and hemoglobin levels, initial tracheostomy, advanced tumor stage, and suture type were not associated with an increased risk of pharyngostomy in our series.
Conclusion
Diabetes significantly increases the risk of pharyngostoma, particularly when combined with other risk factors. Optimized glycemic control, along with appropriate nutritional support, infection prevention, and careful surgical planning, is essential to improving postoperative outcomes in high-risk patients.

An unusual cause of hypoglycemia: insulin autoimmune syndrome

Gökhan Rıza Baykal[1], Aslı Altınbezer[1], Abbas Ali Tam[2], Didem Ozdemir[2], Oya Topaloglu[2], Reyhan Ersoy[2] & Bekir Cakir[2]
[1]Ankara Bilkent City Hospital, Department of Endocrinology and Metabolism, Ankara, Türkiye; [2]Ankara Yıldırım Beyazıt University Faculty of Medicine, Ankara Bilkent City Hospital, Department of Endocrinology and Metabolism, Ankara, Türkiye

Introduction
Insulin autoimmune syndrome (IAS) is a rare cause of hypoglycemia characterized by elevated serum insulin levels and autoantibodies against endogenous insulin that cause spontaneous hypoglycemic episodes. The aim of this case is to emphasize the significance of evaluating IAS in individuals with recurrent hypoglycemia.
Case
A 64-year-old man who had hypoglycemia episodes for 2 months was referred to our endocrine clinic with a suspicion of insulinoma. The patient has no known disease other than choledocholithiasis. In blood tests performed due to hypoglycemia, fasting serum glucose (FSG) was 42 mg/dL, insulin level was 1523.5 mU/l, c-peptide was 6.11 µg/l, and HbA1c was 6.3%. We conducted a 72-hour fasting test to confirm the diagnosis of endogenous hyperinsulinemia. After 14 hours, hypoglycemic symptoms emerged, and FSG was 40 mg/dL, insulin was 212.9 mU/l, and C-peptide was 4.9 µg/l. There was no blood glucose response after glucagon administration. MRI of the abdomen, Gallium-68 Dotatate scintigraphy, and endoscopic ultrasonography (EUS) failed to detect the tumor. The anti-insulin antibody was 91.5% (<8.2). Autoimmune hypoglycemia was considered in the patient. We reviewed the patient's recent prescriptions to determine the triggering factor, as he had been describing hypoglycemia for the last few months. We saw prescriptions for dexketoprofen, paracetamol, and erdosteine. We adjusted the patient's diet regimen and performed close blood sugar monitoring. All of the patient's medications were discontinued, and agents that could trigger hypoglycemia were avoided. During follow-up, the patient's episode frequency decreased, and hypoglycemia was not at a level that would affect his daily life.
Conclusion
Insulin autoimmune syndrome is a rare syndrome that causes episodes of hypoglycemia. This case highlights the importance of considering IAS as a differential diagnosis in patients presenting with recurrent hypoglycemia secondary to hyperinsulinemia. The standard diagnostic test for IAS is the measurement of insulin autoantibodies. Clinicians should keep in mind patients with atypical hypoglycemia, which enables timely diagnosis and eliminates the necessity for expensive imaging methods or invasive surgical interventions. The primary treatment for IAS is a diet consisting of low glycemic index foods. Additionally, steroids may be utilized as an adjunctive therapy.

On the evaluation of the significance of hyperuricemia from the position of belonging to the metabolic syndrome

Anna Chernyayeva[1], Myroslava Mykytyk[1] & Oksana Khyzhnyak[1]
[1]V. Danilevsky Institute for endocrine pathology problems NAMS of Ukraine, Department of Clinical Endocrinology, Kharkiv, Ukraine

Metabolic syndrome (MS) is cluster of risk factors for cardiovascular diseases. None of the available versions of recommendations for the diagnosis of MS hyperuricemia (HU) is not recognized as a criterion of MS, although some MS and HU are quite common.
The aim Analysis of the relationship of HU with the components of the MS in a random population sample.
Materials and Methods
The group of subjects ($n = 727$) was formed according to the generally accepted epidemiological approaches by the method of random sampling from among the workers and employees of the industrial enterprise (average age (38.13 ± 5.1) years). Statistical processing of the results was performed using Package for Social Sciences v.16.0 (SPSS Inc, Chicago, Il, USA).
Results And Discussion.
HU was diagnosed in 16.2% of people. It has been established that in people with HU the probability of diagnosis of impaired of glucose homeostasis (IGH) increases by 5.1 times, type 2 DM by 3.7 times, obesity by 2.9 times, arterial hepertension (AG) by 2.3 times and dyslipidemia by 1.7 times, respectively. It is determined that almost every second case of HU in a random population sample is associated with at least two more components of MS (AG + obesity), in every fourth case – with three components (AG + obesity + dyslipidemia), in every eighth case – with four components (AG + obesity + dyslipidemia + IGH). It was found that in every fourth representative of the random population sample, who was diagnosed with impaired of glucose tolerance and type 2 DM, has a "complete" MS; the probability of diagnosing MS in people with IGH increases 10 times compared with the population.
Conclusions
If the verification of "complete" MS is not limited to the mandatory inclusion of HU, the frequency of diagnosis in one member of a random population sample of the quartet of symptoms (obesity + AG + dyslipidemia + hyperinsulinemia) doubles and is already 4.0% of the total random population sample. Under this condition, every second representative of the random population sample of IGH is diagnosed with "complete" MS.

Diabetes mellitus in acute exacerbation of chronic obstructive pulmonary disease. retrospective study

Elona Xhardo Hysenbelli[1,2], Bledar Hysenbelli[3], Elira Myrtaj[4] & Dorina Ylli[5]
[1]University Hospital "Shefqet Ndroqi"., Internal Medicine, Tirana, Albania; [2]University Hospital "Shefqet Ndroqi", Internal Medicine, Endocrinology, Tirana, Albania; [3]University Hospital "Mother Tereza", Emergency Care, Tirana, Albania; [4]Regional Hospital, Internal Medicine, Gjirokaster, Albania; [5]University Hospital "Mother Tereza", Tirana, Albania

Background
The relationship between Type 2 Diabetes Mellitus(T2DM) and Chronic Obstructive Pulmonary Disease (COPD) is known to be bidirectional. Diabetes Mellitus (DM) and hyperglycemia are important risk factors for poor outcomes in hospitalized patients with acute exacerbation of COPD (AECOPD). There is limited data regarding specific outcomes in diabetic patients with AECOPD and still many issues need to be clarified about the impact of T2DM in this patient population.

Objective
This study aimed to evaluate the impact of previously known and newly diagnosed DM, on outcomes of hospitalised patients with AECOPD.
Methods
A total of 100 hospitalized patients diagnosed with AECOPD, during the interval January-March 2024, in e tertiary Hospital Center in Albania, were included in the present study. Outcomes of diabetic- AECOPD patients were compared with non-diabetic AECOPD patients. Markers associated with development of type 2 DM were identified. At the same time we analysed how glycemic control during the hospitalization period could influence final outcomes regarding in-hospital case fatality and in-hospital adverse events.
Results
Of the 100 patients enrolled in this study, the overall prevalence of T2DM was 31%, with average glucose values X = 245 mg/dl (min 93mg/dl —max 556 mg/dl). The T2DM group had higher inflammatory marker levels and a longer hospital stay versus the non-diabetic group. Age, increased inflammatory markers, elevated blood glucose on admission and inhospital were all risk factors for complications like need for assisted ventilation and mortality in hospitalized AECOPD patients.
Conclusions
AECOPD patients had a higher prevalence of T2DM than the general population; T2DM comorbidity caused longer hospital stays, and increased risc of inhospital complications in AECOPD hospitalised patients. Poor blood glucose control may increase the risk of mortality in AECOPD patients.

JOINT1266
Post-surgical biliary pancreatitis and GAD positive diabetes: a rare case of type 3c DM with autoimmune features
Tinatin Kutchukidze[1] & Edward Amdur[2]
[1]New vision University, New Anglia University, UK, Endocrinology, Tbilisi, Georgia; [2]New vision University, Endocrinology, Tbilisi, Georgia

Background
Diabetes mellitus is primarily classified as Type 1(autoimmune origin, mainly by GAD antibodies), and Type 2 (insulin resistance with B-cell dysfunction); however, a clinically significant subtype, Type 3c diabetes, develops due to chronic pancreatitis, pancreatic surgery, or trauma. While type 3c DM typically results from exocrine damage, the presence of GAD antibodies raises the possibility of distant autoimmune mechanisms contributing to B cell loss. Disguising between T3cDM and autoimmune diabetes is crucial in determining optimal treatment strategies.
Case Report
A previously healthy 22-year-old male with a family history of diabetes and autoimmune disease underwent elective laparoscopic fundoplication for a hiatus hernia, with post-operative complications of severe abdominal pain with steatorrhea, nausea, shortness of breath, insomnia, and fatigue. Pain control due to opioid intolerance (hallucinations on morphine and nausea with oxycodone) required PCA fentanyl 20 mg bolus, paracetamol, and diclofenac supplement. Imaging and laboratory findings confirmed biliary pancreatitis with peri-pancreatic inflammatory changes - Amylase 768U/l (n 25-125U/l) and Lipase 1234U/l(n < 150U/l), surgical emphysema, mediastinal gas without pancreatic necrosis. MRCP revealed multiple tiny gallstones and a distal common bile duct calculus. Persistent hyperglycemia ranging from 16-22 mmol/l, HbA1c - 78 (n - 7.5%), and autoimmune screening confirmed for GAD antibodies < 200 IU/ml (n < 5 IU/ml) and lower C peptide at 0.3mg/ml (n 0.9-4 ng/ml), which raised suspicion of surgical type 3c induced diabetes consistent with exocrine-derived. The patient was managed with basal-bolus insulin (Lantus 28 units nightly, Novorapid 8-14 units per meal) and sliding scale correction for blood glucose 10 mmol/l. The patient was discharged with a management plan of Creon 250,000 units and Humalog 12-20 units with a meal. Tresiba long-acting double strength 84 units at night. The patient claims the symptoms of fatigue, night sweats, diarrhea, and severe unknown origin left upper quadrant radiating to left shoulder abdominal pain.
Conclusion
This is an atypical instance of type 3c diabetes accompanied by post-surgical pancreatitis, biliary blockage, and a rapid onset of GAD-positive diabetes. Acute pancreatitis has been known to elevate GAD-antibody levels, which can result in insulin-dependent diabetes. The presented case is rare as GAD antibody levels are typically lower in autoimmune diabetes (less than 100 U/ML). We suggest that post-surgical pancreatitis caused by gallstones triggered an increase in autoimmune cells, resulting in damage to the islet cells and insulin deficiency. This complex case underscores the necessity of a collaborative approach in both diagnosis and treatment.

JOINT1087
Working time and metabolic syndrome- analysis of indian data
Bhavin Vasavada[1] & Aayush Vasavada[2]
[1]Shalby Hospitals, Ahmedabad, India; [2]NHL Medical College, Ahmedabad, India

Introduction
There has been a recent debate on the relation between work time and metabolic syndrome. The aim of this study is to see whether there is any association between state-wise work time and state-wise prevalence of diabetes and hypertension.
Methods
We compared published data of average working minutes/day in India state-wise from 2019 Time Use Survey, with diabetes, hypertension and dyslipidemia prevalence state-wise, and looked for a correlation with diabetes, and hypertension data state-wise. We collected data from the ICMR-INDIAB study and the latest published literature. We used the Shapiro-Wilk test, skewness and kurtosis to check for the normality of data. We used the Pearson r correlation test for parametric and the Spearmen rho test for nonparametric data to check for correlation between state-wise working time, state-wise diabetes, hypertension and dyslipidemia prevalence. We also evaluated rural and urban data separately whenever available. Statistical analysis was done using JASP (University of Amsterdam).
Results
In our findings, the Average time spent on paid activities by individuals per state positively correlated with state-wise Diabetes mellitus prevalence rate. (Spearman rho 0.412, $P = 0.024$). This relationship was sustained in the urban/rural divide. Average time spent on paid activities in the urban region positively correlated with urban diabetes prevalence state-wise. (Pearson r 0.5, $P = 0.05$). Similarly, rural work time is also correlated positively with the rural prevalence of diabetes mellitus. (Pearson r= 0.595, $P = 0.019$). Average time spent on paid activities was not significantly correlated with diagnosed hypertension at the time of the survey ($P = 0.812$), but it was positively correlated with undiagnosed hypertension at the time of the survey. (Spearman rho 0.358, $P = 0.041$). Work time also correlated positively with cholesterol levels > 200 (spearman rho 0.372, $P = 0.047$), Ldl > 130, (spearmen rho 0.367, $P = 0.05$). However, no significant correlation was found between triglyceride levels > 150 and HDL levels < 40.
Conclusion
In India, the state-wise prevalence of metabolic syndrome components like diabetes, hypertension and dyslipidemias correlated positively with average working minutes/ day, suggesting the need to define optimal working time to find a balance between economic growth and health.

Durability of glycemic response with FDC of sitagliptin and metformin in treatment naive T2DM indian patients from a real-world retrospective EMR based study
Pranav Sheth[1], Parag Shah[2], Prachi Ahire[3], Bharadwaja Pendurthi[1], Shruti Dharmadhikari[1], Chintan Khandhedia[1], Neeraj Markandeywar[1], Amey Mane[1] & Suyog Mehta[1]
[1]Sun Pharma Laboratories Ltd, Mumbai, India; [2]Gujarat Endocrine Centre, Ahmedabad, India; [3]Sun Pharmaceutical Industries Ltd, Mumbai, India

Background and aims
We conducted a real-world, retrospective, observational, electronic medical records (EMR) based study to understand the effectiveness of sitagliptin and sitagliptin + metformin fixed-dose combination (FDC) in Indian patients with type 2 diabetes mellitus (T2DM). The data here presents a subgroup analysis of treatment naïve T2DM patients who received sitagliptin + metformin FDC.
Materials and methods
Aggregated and anonymised EMR data of adult (age ≥18 years) male and female patients having T2DM, who were prescribed with sitagliptin or sitagliptin + metformin FDC, with or without other oral anti-diabetic medicines and had data

available for baseline and follow-up visits from 2017 to 2023 was retrieved. Patients who were on insulin or any other injectable antidiabetic medication like Glucagon-like peptide-1 agonists were excluded. This subgroup analysis assessed the effectiveness of sitagliptin + metformin FDC on glycosylated haemoglobin (HbA1c) levels of naïve patients from baseline to 3 months and 9 months. The study was registered on Clinical Trial Registry – India (CTRI/2023/10/058366)
Results
EMR data was available for 986treatment-naive patients with HbA1c $\geq$7%, who received sitagliptin + metformin FDC. The follow up data for 315 patients was available at 3 months and for 118 patients at 9 months. Mean HbA1c at baseline was 8.94 $\pm$ 1.78 in patients with 3 months' data (n =315) and it was 8.71 $\pm$1.60 in patients with 9 months' data (n =118). Mean change from baseline (CFB) in HbA1c at 3 months (8.94 $\pm$ 1.78 to 7.33 $\pm$ 1.05; CFB: -1.61 $\pm$ 1.83, P<0.0001) was statistically significant. Mean CFB in HbA1c at 9 months (8.71$\pm$ 1.60 to 7.45 $\pm$ 1.29; CFB: -1.26 $\pm$ 1.90, P<0.001) was also statistically significant. Proportion of patients achieving HbA1c <7% in sitagliptin + metformin FDC arm was 40.32% at 3 $\pm$ 1 month and 44.07% at 9 $\pm$ 1 month.
Conclusion
This subgroup analysis of EMR based study in India demonstrated effectiveness of sitagliptin and metformin FDC, in significantly improving HbA1c and providing durable control over 9 months in treatment-naïve T2DM patients in a real-world setting with more proportion of patients achieving HbA1c <7% over time.

Hybrid closed loop in a residential setting: it takes a village but it is worth it

Georgina Doyle[1], Ciara O'Brien[1], Catherine mgarry[1], Michelle McCormack[1], Lorraine Kelly[2], Niamh Cullinane[2] & Ma Pyeh Kyithar[1,3]
[1]Midland Regional Hospital Portlaoise, Diabetes Department, Portlaoise, Ireland; [2]Midland Regional Hospital Portlaoise, Department of Nutrition & Dietetics, Portlaoise, Ireland; [3]School of Medicine, Trinity College Dublin, Dublin, Ireland

Hybrid closed loop (HCL) insulin pumps represent a significant advancement in diabetes management and has shown to improve glycaemic outcomes, reduce diabetes-related distress, and improve quality of life. However, its application in residential environments is not well studied. This case study explores the effectiveness of using a HCL insulin pump in a residential setting in a 27-year old woman with Type 1 diabetes (T1D) who is unable to self-care diabetes. She has Trisomy 21, T1D for five years, total hypoglycaemia unawareness, primary hypothyroidism, coeliac disease, and oesophageal achalasia. She lives in residential care and has very limited vocabulary and sensory issues with insulin injections. Oesophageal achalasia deteriorated over the years despite pneumatic dilatations, and only minimal oral food intake became possible. Therefore, percutaneous endoscopic gastrostomy (PEG) tube was inserted to administer the nutrition. Despite being on basal bolus regimen with insulin aspart and detemir and wearing real-time continuous glucose monitoring, her glycaemic ranges were suboptimal (average sensor glucose 14.5mmol/l, GMI 9.6%, Time-in-Range 15%, Very High-Above-Range 57%, High-Above-Range 28%, HbA1c 61mmol/mol). She required multiple hospital admissions due to hyperglycaemic and hypoglycaemic episodes and her quality of life was affected due to recurrent and prolonged hospital admissions. There was also a significant weight gain with BMI 43 kg/m^2. Considering all above, the diabetes MDT explored the option of Metronic MiniMed^{TM} 780G HCL insulin pump with the patient's family and caregivers. Initially, 22 residential staff were trained using a virtual insulin pump platform to familiarize them with pump functions. This was followed by practical, in-person sessions, where staff learned to perform tasks such as set insertions and changes. Smartguard technology was integrated into the training to enhance the staff's ability to manage glucose levels effectively. The diabetes MDT followed up very closely with the patient and caregivers in-person and virtually to adjust the PEG feeding plan and HCL system. The patient has been on HCL system for the past eight months and glycaemic ranges have improved significantly (average sensor glucose 9.3mmol/l, GMI 7.3%, Time-in-Range 55%-67%, Time-below-Range 0-1%, HbA1c 53mmol/mol). Since HCL system, the patient had only two short hospital admissions, is energetic, participating in daily activities and her weight has reduced by 5 kg. Our case suggests that HCL system together with a skilled diabetes MDT support offers promising benefits for residential use. Continued research is necessary to optimise the functionality of HCL system for this cohort.

Role of pre-pregnancy weight and weight gain during pregnancy on maternal and fetal outcomes: real word data from an italian centre

Eleonora Ciocca[1], Sara Dajci[2], Giuseppe Pugliese[3], Chiara Giuliani[4] & jonida haxhi[3]
[1]Department of Experimental Medicine, Sapienza University of Rome, Rome, Italy, rome, Italy; [2]Sapienza university of Rome, rome, Italy; [3]Department of clinical and molecular medicine, Sapienza University of Rome, Rome, Italy; [4]UOC medicina specialistica endocrino-metabolica, Sant'Andrea University Hospital, Rome, Italy., rome, Italy

Gestational diabetes mellitus (GDM) refers to glucose intolerance of variable severity that begins or is diagnosed for the first time during pregnancy and resolves immediately after birth. Although this condition often resolves after giving birth, it can increase the risk of developing type 2 diabetes in the future. The primary aim of our study was to evaluate the possible determinants of maternal-neonatal outcomes in women diagnosed with GDM, in our center between 2021 and 2024.A secondary objective was to evaluate whether the type of birth, spontaneous, or induced, could determine a different risk of neonatal complications or a different category of neonatal weight, classified as adequate weight for gestational age (AGA), small for gestational age (SGA) or large for gestational age (LGA). We initially evaluated 150 women attending our outpatient clinic. Only those who had at least one follow-up visit after birth were included, for a total of 59 women included in the study. We used multivariable regression models to identify clinical predictors of materno-fetal outcomes, namely post-pregnancy maternal weight and glycemia, and offspring birthweight and perinatal complications. Maternal baseline weight, weight gain during pregnancy, treatment for GDM, breastfeeding, assisted fertilization were included as possible predictors. The correlations between postpartum fetal complications, offspring birth weight and weight category, and type of delivery were also evaluated.A total of 59 women were included in the analysis (age 34$\pm$ 5,3 years, BMI 25$\pm$7,2 kg*m$^-$2). Higher pre-pregnancy weight (β 0.850 P = 0.000) and greater weight gain during pregnancy (β 0.889 P = 0.016) were the best predictors of post-pregnancy weight. Similarly, regarding neonatal weight, the determinants that emerged were the mother's pre-pregnancy weight (β 16.88 P = 0.035) and maternal weight gain during pregnancy (β 58.18 P = 0.019); lastly, earlier diagnosis of GDM (β -0.37, P = 0.057) and insulin treatment during pregnancy (β -5.677, P = 0.061), were associated with a tendency to have higher post-partum fasting glycemia When comparing different birthing methods, these appeared to have no influence on fetal perinatal complications or weight. Our study highlights how the mother's pre-pregnancy weight is a fundamental determinant of weight gain during pregnancy, post-pregnancy weight and fetal weight. This calls for public health interventions aimed at avoiding overweight in childbearing age. Women with an early diagnosis of GDM and the use of insulin during pregnancy might be at a greater risk of postpartum impaired fasting glucose. Routinely inducing labor at 39 weeks of pregnancy is not supported by our data but this needs to be confirmed in larger samples.

Nephroprotective treatment with dapagliflozin in patients with diabetic kidney disease

Olimkhon Sharapov[1,2] & Sherzod Abdullaev[1,3]
[1]Tashkent Pediatric Medical Institute, Internal diseases, nephrology and hemodialysis, Tashkent, Uzbekistan; [2]Republican Specialized Scientific Practical Medical Center of Nephrology and Kidney transplantation, Adult and Pediatric Nephrology, Tashkent, Uzbekistan; [3]Republican Specialized Scientific Practical Medical Center of Nephrology and Kidney transplantation, Immunogenetics, Tashkent, Uzbekistan

Background and Aims
Albuminuria in patients with diabetes presents a higher risk for adverse renal and cardiovascular (CV) outcomes. Sodium glucose co-transporter 2 (SGLT2) inhibitors demonstrate improved albuminuria and reduces the risk of end-stage renal disease in patients with chronic kidney disease. The study aim was the impact of the SGLT2 inhibitor dapagliflozin on urine albumin-to-creatinine ratio (UACR) and GFR decline.
Method
In the single center trial, total 132 participants with CKD and type 2 diabetes (T2D) were randomly assigned to dapagliflozin (n = 78) 10 mg once daily or placebo (n = 54). Kidney inclusion criteria were eGFR 30–-60ml/min/1.73 m2 and any UACR. The primary end point was a composite of sustained decline in

eGFR >50%, end-stage renal disease, or kidney or cardiovascular death. Percentage treatment difference was estimated by geometric mean ratio for the overall cohort and by eGFR and UACR subgroups. Progression/regression of UACR were assessed. Hazard ratios, 95% confidence intervals (CI), and p-values were estimated by Cox proportional hazards model.
Results
Median baseline eGFR was 42.3ml/min/1.73 m2, with 5% at <30ml/min/1.73 m2. At baseline, median UACR was 103 mg/g, and 1/4 of patients had normoalbuminuria, 2/4 had micro, and 1/4 had macroalbuminuria. Median follow up was 18 months. The UACR difference for dapagliflozin vs placebo was -25.1% (95% CI -27.5, -23.2; $P < 0.001$). Reductions were similar across eGFRs. In UACR 30-299mg/g and >300mg/g, reductions were significant in dapagliflozin ($P < 0.001$). Progression risk was lower and regression risk higher in dapagliflozin vs placebo ($P < 0.001$).
Conclusion
Dapagliflozin significantly slowed long-term eGFR decline in patients with CKD with T2D compared with placebo, and significantly reduced UACR and had favorable effects on UACR progression and regression.

Predictive factors for the use of insulin therapy in gestational diabetes

Zineb Dhaimi[1], Bensbaa Salma[1], Nassim Essabah Haraj[1], Siham El Aziz[1] & Asma Chadli[1]
[1]CHU Ibn Rochd, Laboratory of Neuroscience and Mental Health Faculty of Medicine and Pharmacy, Hassan II University – Casablanca, Morocco, Department of Endocrinology, Diabetology, and Metabolic Diseases, Casablanca, Morocco

Introduction
In diabetic patients, planning conception is essential to prevent embryofetopathy and the progression of diabetes complications in the mother.
Study Objective
The aim of our study is to analyze the clinical and metabolic profile of a group of pregnant women with Gestational Diabetes (GD) and to determine the predictive factors for the use of insulin therapy.
Materials and Methods
This is a retrospective study conducted in our Department, including 368 patients with gestational diabetes. Statistical analysis was performed using SPSS software.
Results
The average age of the patients was 32 years. The average term for diagnosing gestational diabetes was 25.2 weeks of amenorrhea. 22% had a history of GD. Insulin therapy was required in 27% of cases. The average total insulin dose required was 0.5 units/kg/day at the end of third trimester. A regimen with three rapid insulin injections was prescribed for 20 pregnant women. For the remaining patients, a basal-bolus regimen was necessary to achieve targets. The need for insulin therapy was more frequent when GD was diagnosed earlier (<24 weeks) ($P = 0.02$), in patients older than 35 years ($P = 0.02$), and with higher fasting blood glucose levels and average glycated hemoglobin levels ($P = 0.01$).
Conclusion
This study demonstrated that earlier diagnosis of GD, advanced maternal age, and elevated fasting blood glucose levels are predictive factors for insulin therapy, consistent with previous studies. However, a history of macrosomia, recurrence of GD, and diabetic heredity were frequently associated with patients treated with insulin but without statistically significant results.

JOINT1477

The use of hybrid closed-loop systems in a pediatric population with type 1 diabetes mellitus- a real-world retrospective study

Irina Bojoga[1,2], Sorin Ioacara[1,2] & Simona Fica[1,2]
[1]"Elias" University Emergency Hospital, Bucharest, Romania; [2]"Carol Davila" University of Medicine and Pharmacy, Bucharest, Romania

Introduction
Hybrid closed-loop (HCL) systems consist of three essential components: a continuous glucose monitoring (CGM) sensor, an algorithm that analyzes data from the CGM, and an insulin pump capable of delivering varying doses of insulin based on this information, alongside doses administered by the user. These technologies aim to improve metabolic control and reduce hypoglycemia risk, enhancing patients' quality of life.
Material and methods
We conducted a retrospective study involving children with type 1 diabetes (T1D) who were admitted to our department to initiate HCL insulin pump therapy. We evaluated the patients at two key points: at baseline, when the insulin pump was first initiated, and during a follow-up visit at least six months later. We assessed glycated hemoglobin (HbA1c) levels at both time points and downloaded CGM reports documenting the previous 90 days. These reports included various parameters: time in range (TIR: 70-180 mg/dL), time in tight range (TITR: 70-140 mg/dL), time below range (TBR) categorized as <70 mg/dL, 54-70 mg/dL, and <54 mg/dL, time above range (TAR) categorized as >180 mg/dL, 180-250 mg/dL, and >250 mg/dL, and the coefficient of variation (CV). This research aimed to assess the effectiveness of HCL therapy in improving glycemic control in children with T1D.
Results
Thirty-two children (68.8% female) participated in the study. Participants had an average age of 11.5 years ($\pm$2.8) and a mean diabetes duration of 5.8 years ($\pm$3.7), with an average follow-up time of 11.9 months ($\pm$4). At follow-up, HbA1c decreased significantly (7$\pm$1% vs 6.6$\pm$0.6%, $P = 0.01$). CGM reports were available at baseline and follow-up for 27 patients. The results revealed a significant increase in TIR (69.2$\pm$15.7% to 79.4$\pm$7.9%, $P<0.001$). Additionally, TITR rose from 48.4$\pm$16.9% to 57.9$\pm$10.1% ($P<0.001$). TBR <70 mg/dL and between 54-70 mg/dL significantly decreased: TBR <70 decreased from 5.4$\pm$3.6% to 3.2$\pm$2.3% ($P = 0.008$), and TBR 54-70 decreased from 4.2$\pm$2.2% to 2.7$\pm$1.9% ($P = 0.007$). TBR <54 mg/dL decreased also, but this change was not statistically significant (1.2% vs. 0.5%, $P = 0.06$). Furthermore, TAR and its subintervals showed significant reductions: TAR >180 mg/dL dropped from 25.3$\pm$16.2% to 17.2$\pm$8.1% ($P = 0.02$), TAR 180-250 mg/dL decreased from 18.1$\pm$9.3% to 13.8$\pm$5% ($P = 0.003$), and TAR >250 mg/dL fell from 7.2% to 3.3% ($P = 0.006$). The CV also significantly decreased, changing from 37.4$\pm$7.3% to 34.3$\pm$5.3% ($P<0.001$).
Conclusions
HCL systems enhance metabolic control in children with T1D, helping them achieve targets for glucose variability and increasing time spent in normoglycemia, thus reducing the risk of short-term and long-term complications.

Congenital hyperinsulinism: same parents, different genetics. regarding two cases

Ana-Belen Ariza-Jimenez[1], Jose Antonio Ariza Jimenez[2], Maria Martin-Rosales[3] & Isabel Leiva-Gea[4]
[1]Hospital Universitario Reina Sofia, Instituto Maimonides de Investigación Biomédica de Cordoba. Cordoba University., Pediatric Endocrinology, Cordoba, Spain; [2]Hospital Universitario Costa del Sol, Endocrinology and Nutrition, Marbella (Málaga), Spain; [3]Hospital Universitario Costa del Sol, Internal Medicine, Marbella (Málaga), Spain; [4]Hospital Materno infantil Malaga, Pediatric endocrinology, Malaga, Spain

Introduction
Congenital hyperinsulinism is the most common cause of recurrent hypoglycemia in children <2 years of age.
Aim
To show two cases of brothers with consanguineous parents in order to spread the disease and its evolution and management
Case 1
Girl who showed at 24 hours of age febrile seizure, hypoglycemia (21 mg/dl), and subependymal hemorrhage. She required glucose intake (21mg/kg/day), antic-onvulsant, IV calcium, vitamin D, phenylbutyrate, benzoate, arginine, lactulose, carnitine, glycosade (150ml/kg/day), dextrinomaltose, cornstarch and feeding by NGT. Two critical samples were carried out. Lactic acid (5.6), cholesterol (217), ammonium (287), CK (2689), GOT (377), GGT 342), insulin (40 and 48.57), acids fatty (5), were elevated, while acylcarnitine 6 (C6), C-peptide (7 and 7.76), calcium (8.8), and vitamin D were decreased. Ketone bodies were negatives. She was diagnosed with congenital hyperinsulinism, and PET was performed, finding a diffuse pattern with doubtful focality in the pancreatic tail. Normal genetic panel for hyperinsulinism and K-ATP channels. In expanded exome she was carrier of ABCC8, POMC and TNNI3 mutations. She started treatment with diazoxide without response. She was treated with octreotide (27mg/kg/day), sirolimus (3mg/m2/day) and hydrocortisone. She showed hypertriglyceridemia and swallowing disorders. Currently being treated with Lanreotide 60mg sc every 2 months. Diagnosed with dilated cardiomyopathy with EF 30% and thrombosis at 2 years, requiring EMO and heart transplant. After transplant, lanreotide was withdrawn due to hyperglycemia, and reintroduced a few months later.

Case 2
Male who at birth showed severe non-ketotic hypoglycemia that required glucose intake (>8mg/kg/minute). Critical sample compatible with hyperinsulinism (C peptide >0.6, glucose 25 mg/dl), treated with diazoxide, dextrinomaltose, and more glucose, with hypoglycemia persisting, so he started octreotide 60 mg/dose + glycosade and raw starch (cornstarch), controlling himself. Genetics detected SUR1 DEFICIENCY. At 1.5 years of age he was diagnosed with dilated cardiomyopathy. He developed severe left ventricular dysfunction and moderate/severe mitral insufficiency. After 2 years, the ejection fraction worsened and produced decompensated heart failure, requiring external ventricular assistance. He showed instability and continuous febrile processes that only improved after hydrocortisone. In brain MRI, marked diffuse cerebral atrophy and established infarcts. He progressively worsened, evolving to cardiorespiratory arrest and death
Conclusions
- In case of negative genetics and high suspicion, complete exome may be a diagnostic possibility.
- In case of no response to diazoxide, the next therapeutic steps would be both oral and subcutaneous somatostatins, in that order.
- Hypertriglyceridemia and swallowing disorders are reported side effects of somatostatins and sirolimus.

Role of dedicated DSN: improving outcomes through intervention and support
Anna Hawkins[1], Melissa Hill[1], Hanne Caserta[1] & Aneliya Sirkova[1]
[1]Barking, Havering and Redbridge University Hospitals NHS Trust, Essex, United Kingdom

Presentation
We report a case of a 40-year-old male admitted in April 2023 with left foot infection and an ulcer on lateral aspect of 5th toe. Past medical history of Type 2 Diabetes Mellitus diagnosed age 25, Hypertension and Hypercholesterolaemia. Current medication Metformin 1g BD, Gliclazide 160mg BD, Canagliflozin 100mg OD, Ramipril 10mg OD and Atorvastatin 20mg OD. On admission HbA1c was found to be 138mmol/mol, patient was therefore referred to the in-patient diabetes nurses. Medication compliance was noted as an issue, considering foot infection insulin was commenced. Basic education and diet advice was given, patient was referred for additional support in the community. Patient declined insulin following discharge stating he would improve his diet and oral medication compliance to achieve better glucose control. At 12 weeks post discharge review in diabetic foot clinic and having been on oral antibiotics the foot infection had settled, and the ulcer was improving. HbA1c had reduced to 90mmol/mol. Patient advised to re-consider insulin but declined. At 18 weeks review, HbA1c rose to 110mmol/mol, patient admitted poor compliance with both diet and medication. Plan to start insulin at next clinic visit in 6 weeks as no Diabetes specialist nurse (DSN) available at the time. At 24 weeks review by DSN in diabetic foot clinic he had very limited blood glucose readings, patient still refusing insulin but agreed to a freestyle libre trial and close DSN phone follow-up. Patient again reported poor compliant with medication, high carbohydrate, sugar, and fat diet. Education was given regarding diabetes complications, diet and exercise impacts on blood glucose levels and the importance of medication compliance. At 25 weeks review we had further detailed discussion regarding glucose results, diet and lifestyle considering freestyle libre data in relation to post meal peaks and subsequent review with DSN 1 week later showed glucose to be 78% within target (4-10mmol/mol). Therefore, no changes to medication, patient to continue to work on improvements with lifestyle modifications. Further weekly phone support with DSN was scheduled. At 31 weeks review in joint foot clinic revealed foot infection fully resolved; foot wound completely healed with an HbA1c of 54mmol/mol.
Conclusions
Dedicated intensive input from DSN with freestyle libre improved challenging compliance issues. Thus, achieved significant improvement in glucose control, leading to complete wound healing while avoiding the need for insulin.

JOINT3745
Two cases of wolfram syndrome in bulgarian children from pleven region
Stanimira Elkina[1], Irina Halvadzhiyan[1], Venetsiya Bozhanova[1] & Chayka Petrova[1]
[1]Medical University - Pleven, Department of Pediatrics, Pleven, Bulgaria

Wolfram syndrome (WS) is a rare autosomal recessive disorder (ORPHA:3463, OMIM# 222300) caused by mutations in the WFS1 genes (Wolfram syndrome type 1 = WS1) or CISD2 genes (Wolfram syndrome type 2 = WS2), with a global prevalence of less than 1 in 1 000 000. These patients often present with diabetes mellitus, diabetes insipidus, optic atrophy, and sensorineural deafness (DIDMOAD). In addition, abnormal urinary tract function or neuropsychiatric disorders could be observed. An Autosomal Dominant Wolfram-like syndrome with similar clinical features, caused by heterozygous mutations of the WFS1 gene, is also reported. We report two patients with Wolfram syndrome, diagnosed more than 10 years after the onset of diabetes mellitus. First patient is a 14-year old boy with diabetes mellitus, bronchial asthma and optic atrophy, genetically proven for WS1. Second patient is 16-year old girl with diabetes mellitus, diabetes insipidus, epilepsy and severe urological abnormalities, suspected for WS. Multiple systemic organ involvement with different and highly heterogeneous clinical features makes WS a diagnostic challenge. Early genetic testing could confirm the diagnosis and improve individual therapeutic approach and outcomes for patients.

A favorable factors influencing glycemic control in pediatric type 1 diabetes patients
Hae Sang Lee[1], Young Suk Shim[1] & Min Hyung Cho[1]
[1]Ajou University Hospital, Suwon, South Korea

Backgrounds
To prevent short-term and long-term complications in pediatric type 1 diabetes patients, optimal glycemic control in essential. However, there is a lack of information about the factors that can predict future blood sugar level control among the patients. Through this article, we aim to investigate predictive factors for optimal blood sugar regulation and identify adverse prognostic factors.
Methods
Retrospective chart analysis was conducted on 92 pediatric and adolescent patients with type 1 diabetes mellitus who visited the Department of Pediatrics at Ajou University Hospital from 2000 to the present. The patients were divided into two groups based on their average HbA1c levels over the past year: the well-controlled group (WC, HbA1c < 7.5) and the poorly controlled group (PC, HbA1c ≥ 7.5). Data collection included all possible factors that may be associated with glycemic control of type 1 diabetes.
Results
Out of the total 92 patients, there were 41 patients in the Well-Controlled (WC) group and 51 patients in the Poorly-Controlled (PC) group, with average HbA1c levels of 6.23 ± 0.41 and 8.62 ± 1.53, respectively. The PC group tended to have a higher current age compared to the WC group (156.85 ± 44.834 vs 175.86 ± 36.718 months, $P = 0.035$). The HbA1c measured after starting insulin treatment was lower in the WC group ($6.587 \pm 0.872\%$ vs $7.259 \pm 1.242\%$, $P=0.003$). When using continuous glucose monitoring(CGM) or insulin pump, the chance of being in the PC group was lower (CGM: Odds ratio 0.396, $P = 0.036$; Insulin Pump: Odds ratio 0.197, $P = 0.009$). No significant differences in sex, BMI, diabetes duration, initial HbA1c and C-peptide level, and DKA history were noted between WC and PC groups.
Conclusions
Older age and higher HbA1c levels after starting treatment suggest a higher likelihood of poor blood sugar control, requiring intensified care. Furthermore, since the use of CGM and insulin pumps aids in blood glucose control, we should encourage patients to use these.

Trends and outcomes in pediatric diabetes management after universal coverage expansion: a single tertiary care experience in Thailand
Kulpatra Paisansukanant[1,2], Samkhwan Thongsukkaeo[1,2], Narisa Pramojaney[1], Suphab Arunyaparkmongkol[2], Nattakarn Numsriskulrat[2,3] & Taninee Sahakitrungruang[2]
[1]Department of Pediatrics, King Chulalongkorn Memorial Hospital, Bangkok, Thailand, Bangkok, Thailand; [2]Division of Pediatric Endocrinology, Department of Pediatrics, Faculty of Medicine, Chulalongkorn University, Bangkok, Thailand, Bangkok, Thailand; [3]Division of Academic

Affairs, Faculty of Medicine, Chulalongkorn University, Bangkok, Thailand, Bangkok, Thailand

Background
The global incidence of pediatric diabetes, including type 1 (T1D) and type 2 (T2D) diabetes, has been rising. Modern diabetes therapies have become widely accessible in the past decade, supported by Universal Coverage (UC) policies aimed at improving treatment outcomes.
Objective
To evaluate the clinical outcomes and complication screening trends in childhood-onset diabetes following the implementation of modern therapies.
Methods
A retrospective review was conducted using medical records from pediatric-onset diabetes patients (diagnosed before age 18) treated between 2018 and 2024 at King Chulalongkorn Memorial Hospital in Bangkok, Thailand.
Results
A total of 141 patients were analyzed in 2024, comprising 115 with T1D (81.5%), 11 with T2D (7.8%), and 15 with other types (10.6%). Intensive insulin therapy adoption in T1D reached 100% by 2024. Self-monitoring of blood glucose (SMBG) adherence remained at 56.52%, while the use of continuous glucose monitoring (CGM), reimbursable under UC since August 2023, rose from 8 users in 2022 (5.7%) to 20 users in 2024 (14.2%), marking a 150% increase. The proportion of T1D patients achieving HbA1c levels below 7% has shown a gradual increase, rising from 18.8% in 2018 to 29.1% in 2024. However, this remains below the expected target. The mean HbA1c levels in 2024 were 9% in T1D and 8.13% in T2D. Complication screenings revealed gaps: diabetic retinopathy was screened in 39.7% of patients, diabetic nephropathy using urine albumin-to-creatinine ratio in 59.6%, and serum creatinine in 60.9%. While dyslipidemia screening via LDL measurement was completed for all patients, only 19.9% had LDL levels below 100 mg/dL, suggesting treatment inertia in pediatric patients.
Conclusion
Despite improvements in therapy adoption, including intensive insulin therapy and DSMES programs, glycemic control in pediatric diabetes remains suboptimal. The significant increase in CGM users and the rising trend of T1D patients achieving targeted HbA1c levels indicate progress, yet further adoption of CGM and insulin pump technologies is needed. The shortage of diabetes educators continues to hinder effective management. Strengthening screening strategy and integrating educators into care teams is vital for better outcomes.

Introduction
Parotid lithiasis, or sialolithiasis, is an inflammatory condition of the parotid gland caused by a stone obstructing its excretory duct. Representing 4-10% of salivary gland lithiasis, it rarely reveals underlying diabetes mellitus, as in the case we present here.
Observation
A 44-year-old man with a family history of type 1 diabetes, who consulted for a right parotid swelling evolving for 2 days in a febrile context. Physical examination revealed a firm, approximately 3 cm, right parotid swelling with overlying inflammatory signs. Purulent discharge was observed from the opening of the right Stensen's duct, associated with a 1 cm trismus, but no facial paralysis was present. Cervical ultrasound showed a heterogeneous, enlarged right parotid gland with a stone in a dilated Stensen's duct. The patient was admitted in our department and started on Amoxicillin-clavulanic acid. The initial Lab results revealed a biological inflammatory syndrome and elevated blood glucose levels, along with a disturbed glycemic profile and a glycated hemoglobin of 6%. An endocrinology opinion was requested and he was placed on insulin therapy with good education regarding his incidentally discovered diabetes. The patient's condition improved significantly, and he was discharged on the 7th day with antibiotic coverage and a follow-up appointment with the endocrinology department for diabetes management.
Conclusion
This observation underlines the importance of looking for diabetes mellitus in patients with lithiasic parotiditis, particularly when associated risk factors are present. Early recognition of diabetes allows for timely intervention and prevention of long-term complications.

Diabetes associated with childhood lipodystrophies: clinical characteristics and management
Ugur Cem Yilmaz[1], Deniz Ozalp Kizilay[1], Damla Goksen[1] & Samim Ozen[1]
[1]Ege University Faculty of Medicine Department of Pediatric Endocrinology and Diabetes, Izmir, Türkiye

Introduction
Lipodystrophy syndromes are rare and highly heterogeneous disorders characterized by partial or complete loss of adipose tissue.
Objective
To evaluate the genetic, clinical, metabolic, and therapeutic characteristics of cases diagnosed with childhood lipodystrophy and diabetes.
Materials and Methods
Six cases diagnosed with lipodystrophy and diabetes were included. The demographic and clinical characteristics of the cases, metabolic parameters, nutritional profiles microvascular complications, treatment models, and outcomes were retrospectively analyzed.
Results
The mean age of the patients was 13 years (10–14)(5 female, 1 male). HbA1c levels and treatment modalities are given in Table 1. In Case 1, HbA1c reduced from 9.9% to 5.9% with insulin pump therapy. In case 3 HbA1c reduced from 8.5% to 5.4% with metreleptin therapy only. In case 4 HbA1c reduced from 13.3% to 6.3% with an AID system. In case 5 HbA1c reduced from 9.9% to 8.1% with regular metreleptin use, but increased to 10.7% becuse inconsistent treatment. Case 6 became insulin-independent through a clinical research intervention. The details of this therapy will be disclosed after the publication of research findings. Nephropathy was seen in 67% ($n = 4$), polyneuropathy in 17%($n = 1$) and retinopathy in 17% ($n = 1$).
Conclusion
In four cases, diabetes was diagnosed before lipodystrophy, suggesting that diabetes may be an early manifestation of lipodystrophy syndromes. The use AID system was effective in maintaining glycemic control. Metreleptin therapies improved insulin resistance, resulting in significant reductions in HbA1c levels and, in some cases, eliminating the need for insulin therapy. The effective use of advanced diabetes technologies and targeted therapeutic strategies contributed to improvements in glycemic regulation.
Keywords
Diabetes associated with lipodystrophy, Metabolic control, Insulin infusion pump, Metreleptin, Pediatric and adolescent diabetes

Mody: when to consider? when should genetic tests be performed?
Ganimet Öner[1] & Microgen Genetic Diseases Diagnostic Center[2]
[1]Tekirdağ Dr. İsmail Fehmi Cumalıoğlu City Hospital, Department of Pediatric Endocrinology, Tekirdag, Türkiye; [2]Microgen Genetic Diseases Diagnostic Center, Ankara, Türkiye

Introduction
Maturity-onset diabetes of the young (MODY) is a monogenic form of diabetes that results from genetic defects that lead to β-cell dysfunction. Due to the heterogeneity of its clinical features and the lack of a single diagnostic criterion, MODY can often be misdiagnosed as type 1 or type 2 diabetes, and therefore its diagnosis is mostly based on genetic testing. Correct diagnosis of monogenic diabetes can significantly change treatment. This study aimed to evaluate the relationship between the clinical features of the cases and the detected genetic variations and to examine the effect of early diagnosis on diabetes management.
Material and Methods
The results of patients who were followed up in Tekirdağ Dr.İsmail Fehmi Cumalıoğlu City Hospital, Department of Pediatric Endocrinology between August 2023-December 2024 and studied the gene panel associated with monogenic diabetes were evaluated. Genetic analysis was performed using the Next Generation Sequencing Analysis (NGS). Variants classified according to the ACMG 2015 Guideline criteria were retrospectively examined.

Abstract EP422

Table 1: Metabolic, Glycemic Control, and Treatment Approaches

Category	Attribute	Case 1	Case 2	Case 3	Case 4	Case 5	Case 6	Mean/Median
General Information	Lipodystrophy Type	Syndromic Lipodystrophy(MINGIE)	Acquired Generalized Lipodystrophy(Panniculitis-related)	Congenital Generalized Lipodystrophy(-Type 1)	Progeroid Type Lipodystrophy(Mulvihill Smith Syndrome)	Familial Congenital Partial Lipodystrophy(FPLD2, Dunnigan Type)	Congenital Generalized Lipodystrophy(CGL Type 2, BSCL2)	
	Diabetes Diagnosis Age	14	14	13	10	13	14	13/13.5
	Lipodystrophy Diagnosis Age	17	13	14	16	14	6	13.33/14.0
Glycemic Control	HbA1c-At Diagnosis(%)	7.5	12.4	8.5	9.2	9.9	8.5	9.3/8.85
	HbA1c-Final(%)	5.9	12.1	5.7	6.3	10.7	6.0	7.78/6.15
Insulin Treatment Model	Insulin Therapy	Aspart-Glargine	Aspart-Glargine		Aspart-Glargine	Glulisine-Glargine	Glargine	
	Insulin Delivery System	Continuous Insulin Delivery System			Automatic Insulin Delivery System			
Additional Treatments	Oral Antidiabetic		Metformin	Metformin	Metformin	Metformin	Metformin	
	Metreleptin			Metreleptin		Metreleptin		

Results

Mutations were detected in 11/16 (68%) cases that underwent genetic analysis with a preliminary diagnosis of MODY. Among the cases in which mutations were detected; heterozygous mutations were detected in the GCK genes(5/11), HNF1A(3/11), ABCC8(2/11) and G6PC2(1/11). The cases in which GCK mutations were detected applied with a complaint of coincidental hyperglycemia and were followed only with diet and lifestyle changes. Cases 1 and 2 with HNF1A mutations were female twins (15.4 years old) and applied with hyperglycemia. Case 3 (HNF1A mutation) was male (16.3 years old) and applied with diabetes symptoms. Diabetes antibodies were negative. Hba1c values of the cases at the time of application were 9.4%-11%-12%, respectively. Subcutaneous insulin treatment was started. In the genetic analysis of the patients, heterozygous c.685C>T (p.Arg229*) (in twin cases) and c.391C>T (p.Arg131Trp) (case 3) variants were detected. The cases were switched to oral sulfonylurea (gliclazide) and subcutaneous insulin treatments were stopped. One of the cases with mutation detected in the ABCC8 gene presented with diabetic ketosis and insulin treatment was continued.

Conclusion

Based on these clinical cases, the importance of early recognition and awareness of the signs and symptoms of MODY has been emphasized. In clinical practice, strict screening criteria should be established to balance cost-effectiveness and identification. The results of diabetes autoantibodies, family history of diabetes, age at onset, and endogenous insulin secretion should be taken into account to determine whether genetic testing is necessary. When suspicion arises, genetic testing should be performed to diagnose MODY and ensure early treatment and accurate family screening.

A very rare case of MODY 12: inactivating ABCC8 mutation causing sulfonylurea-resistant diabetes

Mark Millwood[1], Adaora Belonwu[1] & Tahir Omer[2,3]
[1]University of Leicester, Medical School, Leicester, United Kingdom; [2]Northampton General Hospital, Endocrinology and Diabetes, Northampton, United Kingdom; [3]University of South Wales, Cardiff, United Kingdom

Introduction

Maturity-Onset Diabetes of the Young (MODY), is a rare monogenic form of diabetes mellitus, comprising 1-2% of cases. Disguised by its atypical clinical features, it is commonly misdiagnosed, with an estimated 80% of MODY patients presumed to have type 1 (T1DM) or type 2 diabetes (T2DM). We hereby present a unique case of MODY, diagnosed in adulthood due to an inactivating mutation of the ABCC8 gene, with no history of neonatal hypoglycaemia, and a lack of clinical response to sulfonylureas.

Case Report

A 22-year-old female was incidentally diagnosed with diabetes in 2017 after presenting with lower abdominal pain and symptoms of urinary tract infection. Urinalysis showed significant glucosuria. She lacked osmotic symptoms, and never experienced diabetic ketoacidosis. She was presumed to have T2DM. Initially treated with gliclazide and metformin, gliclazide was discontinued due to lack of clinical response, and replaced with metformin/empagliflozin combination therapy. She was referred to our pre-pregnancy clinic in 2024. Her BMI was 25 kg/m2, and HbA1c was 69 mmol/mol. Her atypical presentation, lack of insulin resistant features, and strong family history, prompted MODY probability testing, predicting 75%. T1DM serology, including GAD, IA2, and ZnT8 autoantibodies, was negative. C-peptide was 357pmol/l. Subsequent genetic testing identified a heterozygous inactivating ABCC8 mutation, p.Arg1353His (c.4058G>A), previously associated with Congenital Hyperinsulinism (CHI). The patient has no medical history of neonatal hypoglycaemia.

Discussion

The genes commonly associated with MODY include HNF1A, HNF4A, and GCK. While GCK-MODY and HNF1A-MODY account for 90% of cases, ABCC8-MODY makes up only 1%. The ABCC8 gene encodes Sulfonylurea receptor 1, a subunit of K-ATP channels in β-cells, modulating insulin release. Activating ABCC8 mutations are associated with Neonatal Diabetes and MODY. Inactivating ABCC8 mutations typically cause CHI. Only a handful of cases have reported inactivating ABCC8 mutations causing MODY, with even fewer being unresponsive to sulfonylureas. Gliclazide therapy proved unsuccessful, with her HbA1c reaching 97 mmol/mol, and the development of symptoms suggesting peripheral neuropathy. A trial of metformin/empagliflozin significantly reduced HbA1c, suggesting alternative therapeutic pathways may be necessary for cases involving inactivating ABCC8 mutations. To our knowledge, this is the first reported case linking this specific mutation to diabetes demonstrating a poor response to sulfonylureas. This case highlights the phenotypic heterogeneity of ABCC8-MODY, underscoring the importance of genetic testing in young patients with atypical diabetes presentations. It should inform future research into the precise pathophysiological mechanisms linking inactivating ABCC8 mutations to diabetes and their variable treatment responses.

Single center study on evaluating and mitigating key factors associated with extended hospitalisation in patients admitted for hypoglycaemia

Smriti Acharya[1], Sharon Daniel[1], suyash acharya[1], Chintavali Ajay Ramesh[1], Rajinder Gupta[1] & Daniel Kannappan[1]
[1]WWL, Wigan, United Kingdom

Introduction

Hypoglycemia, defined as blood glucose below 70 mg/dL, is a serious diabetes complication linked to higher mortality, cardiovascular risks, and prolonged hospital stays. Severe episodes are more frequent in type 1 diabetes but also occur in type 2. Effective management is key to improving outcomes. Prolonged hospital stays for hypoglycemia may arise from factors like age, underlying conditions, hormonal issues, diabetes type, and discharge protocols requiring support assessments. Timely care, medication adjustments, and monitoring can help minimize delays. This audit examines factors contributing to longer hospital stays for hypoglycemic patients and identifies barriers to efficient care and discharge. It aims to improve hypoglycemia management and reduce hospitalization times.

Objectives and Methodology

Objectives

- Analyze factors prolonging hospital stays in hypoglycemia.
- Assess management and discharge practices.
- Recommend strategies to reduce hospital stays.

Methodology

A retrospective review of 25 hypoglycemia patients (April–October 2024) was analyzed. Review included demographics, comorbidities, glucose levels,

interventions, care delays, and discharge times. The goal was to identify patterns and improve management and discharge processes for hypoglycemic patients.
Results
The study involved 25 patients, with 64% male and 36% female. Most were aged 60–80 years, followed by 81–100 years and 20–60 years. Of the 25, 11 had type 1 diabetes and 14 had type 2. Nineteen patients were on insulin, and 16 used oral hypoglycemic agents, including 4 on sulfonylureas. At admission, 14 patients had blood glucose below 2.5 mmol/l, and 10 had levels above 2.6 mmol/l. Specialist referrals were made for 15 patients, with most reviewed within 24 hours of admission.
Discussion
Hospital stays ranged from 2 to 22 days, with half discharged within 7 days and the other half requiring longer stays. Prolonged hospitalizations in 3 out of 10 patients were due to factors like fluctuating blood glucose and rest 6 out of 10 were due to comorbidities (e.g., infections, kidney injury), and 1 out of 10 due to delay in discharge planning. Additional complications, such as pneumonia, acute kidney injury and pleural effusion, required extra interventions thus highlighting need for effective management of comorbidities and reduce hospital stay.
Conclusion
Hypoglycemia management involves resolution of factors that prolong hospital stays. Early interventions, efficient discharge plans, glucose monitoring, and regular audits are crucial to improving care and reducing hospitalizations.

Case series of patients with euglycemic diabetic ketoacidosis

Branko Petrovic[1], Nina Dunat Tuta[2], Hrvoje Popovac[3] & Ivana Kraljevic[3]
[1]General Hospital "Dr. Ivo Pedisic" Sisak, Endocrinology Department, Sisak, Croatia; [2]General Hospital Zadar, Zadar, Croatia; [3]University Hospital Centre Zagreb, Zagreb, Croatia

Introduction
Diabetic ketoacidosis (DKA) is a life-threatening complication of diabetes, typically characterized by severe hyperglycemia. However, with the increasing use of sodium-glucose linked transporter 2 inhibitors (SGLT2i) now widely prescribed for type 2 diabetes as well as chronic kidney disease and heart failure, there has been a rise in euglycemic diabetic ketoacidosis (euDKA). Unlike classical DKA, euDKA presents with only mild to moderate hyperglycemia, typically defined as a blood glucose level below 250 mg/dL (13.9 mmol/l).
Case series
We present a series of eight patients diagnosed with euDKA during inpatient endocrinology consultations at our institution between 2019 and the end of 2024. The median patient age was 62 years [range 43–74]. At presentation, the median blood glucose level was 189 mg/dL (10.5 mmol/l) [range 92–241 mg/dL; 5.1–13.4 mmol/l], and the median arterial pH was 7.21 [range 7.04–7.29]. All patients had a pre-existing diagnosis of type 2 diabetes mellitus. Half of the patients were hospitalised for major surgical procedures, while the other half presented with severe infections. All patients received standard DKA treatment and were subsequently discharged. Upon discharge, three patients remained on insulin therapy, while the rest continued oral treatment, either alone or in combination with glucagon-like peptide-1 (GLP-1) receptor agonists.
Conclusion
SGLT2i presents a major new contribution in the therapy of patients with type 2 diabetes as well as patients with chronic kidney disease or heart failure without type 2 diabetes. However, given their expanding indications, clinicians must remain vigilant for potential adverse effects, including euDKA. SGLT2i therapy should be temporarily discontinued during severe infections and at least three days before the major surgery to reduce the risk.

Determination of antioxidant activity in seminal plasma of diabetic and non-diabetic individuals

Maria Trapali[1], Anastasia Katsipodi[1], Garyfallia Mavroeidi[1], Petros Papalexis[1,2], Anna Angelousi[2] & Petros Karkalousos[1]
[1]Department of Biomedical Sciences, University of West Attica, Laboratory of Chemistry, Biochemistry and Cosmetology (ChemBiochemCosm), Athens, Greece; [2]Medical School of Athens, National and Kapodistrian University of Athens, Unit of Endocrinology, First Department of Internal Medicine, "Laikon" General Hospital, Athens, Greece

Introduction
Diabetes Mellitus (DM) is a chronic disorder of glucose metabolism with serious cardiovascular, endothelial, neurological consequences. In patients with DM, it appears that oxidative stress in the testicles is particularly high, which can cause significant impairment of testicular function including fertility or libido problems. Indeed, patients notice visible changes in testicular tissue as well as changes in hormonal balance.
Purpose
The present research work aims to evaluate *in vitro* antioxidant activity in the seminal plasma of diabetic and non-diabetic individuals.
Methods
9 samples from non-diabetics and 6 samples from diabetic patients were collected (License from the Society for Ethics and Conduct No. 49947, 21/06/2024). Statistical analysis was performed using the SPSS statistical software v.29 (academic license). The total antioxidant capacity in seminal fluid was measured with FRAP method. The ferric-reducing antioxidant power (FRAP) assay involves reduction in Fe3+-2,4,6-tripyridyl-s-triazine (TPTZ) complex while taking absorbance at 593nm. The FRAP reagent is prepared by taking acetate buffer pH: 3.6, 10 mmol of TPTZ solution in 40 mmol of hydrochloric acid (HCl), and 20 mmol solution of iron (III) chloride in 10:1:1 (v/v) ratio. The standard curve was made with FeSO4.7 H2O and the results were expressed in μM FeSO4.7 H2O.
Results
Antioxidant activity in seminal fluid of diabetic was found statistically significant lower in diabetic compared to non diabetic men (1631,5 ± 151,7 μM FeSO4.7 H2O versus 3355,3 ± 640,1 μM FeSO4.7 H2O), p: <0,001.
Conclusions
Diabetes mellitus has a clear influence on antioxidant activity of the seminal plasma, since the normal values appear to be reduced, as already reported by other researchers.

Severe acute pancreatitis secondary to major hypertriglyceridemia associated with diabetic ketoacidosis

Wafa Atbib[1], Sana Rafi[1], Sara Ijdda[1], Ghizlane El Mghari Tabib[1] & Nawal El Ansari[1]
[1]Mohammed VI University Hospital, Endocrinology, Diabetology, Metabolic Diseases and Nutrition Department, Marrakech, Morocco

Introduction
The triad of ketoacidosis, acute pancreatitis and hypertriglyceridaemia is a very rare phenomenon. The metabolic origin seems to be the cause of this hypertriglyceridaemia(HTG) responsible for pancreatitis(PA).
Observation
A 48-year-old woman was admitted to hospital with abrupt onset of abdominal pain. She had a 2-year history of diabetes and was taking oral antidiabetics. Clinical examination revealed grade 2 obesity with abdominal obesity and acanthosis nigricans. Biological tests revealed metabolic acidosis, hyperglycaemia of 5.6 g/l, triglycerides of 10.2 g/l, lipasemia of 1000 IU/l, and HbA1c of 13%. Abdominal CT confirmed stage E pancreatitis. The diagnosis of ketoacidosis was made in the context of type II diabetes and associated BP. The outcome was favourable within a few days on insulin, with disappearance of pain and regression of ketoacidosis. At the same time, triglyceride levels and other biological parameters rapidly returned to normal.
Discussion
In our case, several mechanisms appear to be interrelated. The high triglyceride level at the time of diagnosis and the rapid reduction after correction of ketoacidosis are in favour of the metabolic origin of this HTG linked to CAD itself. However, it has been shown that major HTG can trigger BP, which usually progresses quite severely.
Conclusion
In conclusion, when significant abdominal pain appears in a patient with AD, we believe it is appropriate to suggest a lipasemia assay. If this assay is three times normal, the diagnosis of PA is likely and an abdominal CT scan should be ordered. Triglyceride levels should be measured at the same time to confirm that the BP is indeed secondary to HTG.

Allergic reaction following the injection of human insulin

Fadwa Glil[1], Sana Rafi[1], Sara Ijdda[1], Ghizlane El Mghari Tabib[1] & Nawal El Ansari[1]

[1]University Hospital Center Mohamed VI, Department of Endocrinology, Diabetes, Metabolic Diseases, and Nutrition, Marrakech, Morocco

Introduction
Insulin allergy is a rare complication whose clinical manifestations can range from localized skin reactions to more generalized reactions. We report a case of localized urticarial reaction in a diabetic patient treated with human insulin.
Case Report
This is a 23-year-old patient, diagnosed with diabetes one year ago, initially placed on human intermediate-acting insulin (twice daily) and rapid-acting insulin (preprandial), and currently on human mixed insulin (two injections daily). The patient was admitted to the endocrinology department of CHU Mohamed VI for further management of his diabetes. Upon examination, the patient presented with pruritic urticarial lesions localized to the site of injection of the mixed human insulin. The biological tests did not reveal eosinophilia. In our institution, the patient received an injection of long-acting insulin analogue (glargine) and rapid-acting insulin analogues before meals. The clinical course was marked by the resolution of the urticarial reaction at the insulin injection site.
Discussion
Insulin allergy is not always directly related to the insulin molecule itself. It may result from a reaction to one of the excipient components, such as hydrochloric acid, water for injection, glycerol, meta-cresol, phenol, disodium phosphate dihydrate, protamine sulfate, sodium hydroxide, or zinc chloride. It can also be caused by an element used in the injection, such as the nickel in the needle. Thus, insulin can act as an allergen, inducing a pathological reaction, although the exact mechanisms of this response are not fully understood. The use of a different type of insulin allowed for better clinical tolerance.
Conclusion
Allergic reactions to insulin, although rare, remain an important complication, especially in type 1 diabetics. These reactions can disrupt glycemic control, making disease management more challenging. It is therefore crucial to diagnose these allergies promptly and provide appropriate management to ensure the safety and efficacy of the treatment.

Clinical management and outcomes of diabetic foot ulcers: a study of 322 cases

Nabil Skouta[1], Nassim Essabah Haraj[1], Siham El Aziz[1] & Asma Chadli[1]
[1]UHC Ibn Rochd, Department of endocrinology, diabetology, metabolic diseases and nutrition, Casablanca, Morocco

Introduction
Diabetic foot ulcers (DFUs) are a public health issue with severe consequences that are frequently encountered in our daily practice.
Objectives
To evaluate the demographic data, therapeutic approaches, healing rates, recurrence rates, and amputation rates in patients with DFUs.
Patients and Methods
This is a retrospective cohort study involving adult diabetic patients with DFUs treated in our department from January 2018 to December 2024. Data were analyzed using IBM SPSS Statistics 27.0.
Results
A total of 322 patients with DFUs were treated in our unit. The average patient age was 56 years, with a male-to-female ratio of 1.82. Among them, 27 patients (8.4%) had Wagner grade 1 lesions, 147 (45.7%) had grade 2, and 148 (46%) had grade 3. Treatment involved medical management, including offloading, local wound care, and antibiotic therapy for infections. Healing was achieved in 302 patients (93%), with an average healing duration of 51 days. In 20 cases, complications such as soft tissue abscesses or necrosis necessitated surgical intervention. The recurrence rate among healed patients was 4.9% at the 12-month follow-up.
Conclusion
DFUs remain a common health concern. Early and effective management leads to good outcomes and prevents progression to severe lesions requiring limb amputation.

Diagnosis and therapeutic management of infected diabetic foot: insights from 278 cases

Nabil Skouta[1], Nassim Essabah Haraj[1], Siham El Aziz[1] & Asma Chadli[1]
[1]UHC Ibn Rochd, Department of Endocrinology, Diabetology, Metabolic Diseases and Nutrition, Casablanca, Morocco

Introduction
Foot infections in individuals with diabetes represent a major public health issue. They are not only responsible for numerous hospitalizations but can also compromise both functional and vital prognoses.
Objectives
To analyze the epidemiological, clinical, and therapeutic characteristics of infected diabetic foot.
Patients and Methods
This is a retrospective cohort study involving patients hospitalized for diabetic foot infections in our department from January 2018 to September 2024. Data were analyzed using IBM SPSS Statistics 27.0 software.
Results
Our study included 278 patients with a mean age of 56 $\pm$ 11.63 years and a male-to-female sex ratio of 1.28. Type 2 diabetes was observed in 85% of patients, with an average disease duration of 14 years and a mean HbA1c of 14.48%. The most common types of lesions were: dermohypodermitis (DHD) in 24.5%, diabetic foot ulcers (DFUs) complicated by osteitis in 24.5%, DFUs complicated solely by DHD in 23.74%, and DFUs complicated by both DHD and osteitis in 23.74%. The primary trigger was inappropriate footwear in 50.4% of cases. Management included offloading, daily wound dressing, adapted antibiotic therapy, and specialized education. Third-generation cephalosporins were the most prescribed antibiotics (91%), followed by ciprofloxacin (77%), metronidazole (66.9%), and amoxicillin-clavulanic acid in 8.2%. Outcomes were favorable in 85.6% of cases, with a mean healing time of 43.5 $\pm$ 23.76 days.
Conclusions
This study highlights the complexity of managing diabetic foot infections. It underscores the importance of a multidisciplinary approach combining local care, rigorous medical follow-up, and tailored patient education.

JOINT2608

Impact of glycemic profile on severe hypoglycemia recurrence in diabetic patients

Víctor Siles-Guerrero[1], Rosa Natalia García Pérez[1], José Manuel Romero-Márquez[1], Araceli Munoz-Garach[1] & Juan Manuel Guardia-Baena[1]
[1]Hospital Universitario Virgen de las Nieves, Granada, Spain

Introduction
The recurrence of severe hypoglycemia in diabetic patients poses a significant clinical challenge. Identifying predictive factors for repeated episodes is crucial to improving patient outcomes. Continuous glucose monitoring (CGM) provides detailed insights into glycemic profiles, allowing for the assessment of glucose fluctuations and their potential role in hypoglycemia recurrence. This study evaluates the association between CGM-derived metrics and the likelihood of recurrent severe hypoglycemic episodes in diabetic patients.
Objective
To analyze how variations in glycemic profiles influence the recurrence of severe hypoglycemia in diabetic patients.
Methods
This retrospective observational study included 66 diabetic patients who underwent CGM monitoring. Patients were categorized into two groups based on the presence or absence of recurrent severe hypoglycemia. CGM metrics analyzed included the percentage of time spent in hyperglycemia ($>$180 mg/dL), hypoglycemia ($<$70 mg/dL and $<$54 mg/dL), and the number of hypoglycemic events. The Mann-Whitney U test was used to assess significant differences between groups.
Results
Patients experiencing recurrent severe hypoglycemia demonstrated increased glycemic variability and a lower percentage of time in range. A trend toward an association between higher time spent $<$54 mg/dL and hypoglycemia recurrence was observed (median 2.8% vs. 1.6%, $P = 0.13$), although it did not reach statistical significance. Additionally, the group with recurrent episodes had a higher number of total hypoglycemic events (median 21 vs. 15), yet this difference was also not statistically significant ($P = 0.47$). Other CGM parameters, including time in hyperglycemia and overall glucose variability, suggested an increased risk profile in patients with recurrent hypoglycemia but did not show definitive statistical differences.
Conclusions
Although increased glycemic variability and reduced time in range have been associated with adverse metabolic outcomes, their role in predicting recurrent severe hypoglycemia remains uncertain. The findings of this study suggest a potential trend toward an association between increased time spent $<$54 mg/dL and hypoglycemia recurrence; however, statistical significance was not achieved, likely due to sample size limitations. Larger prospective studies are needed to further investigate these

associations and determine their clinical implications. Future research should focus on refining CGM-based predictive models to enhance hypoglycemia risk stratification and improve patient management strategies.

Use of automated insulin delivery systems in pregnant women with type 1 diabetes: real-world data

Lara Albert Fàbregas[1], Alba Hernández Lázaro[1], Valeria Arsentales Montalva[1], Ismael Capel Flores[1], David Subías Andújar[1], Laia Casamitjana Espuña[1], María Florencia Luchtenberg[1] & Mercedes Rigla Cros[1]

[1]Endocrinology and Nutrition Department, Parc Taulí Hospital Universitari, Institut d'Investigació i Innovació Parc Taulí I3PT, Universitat Autònoma de Barcelona, Sabadell, Spain

Introduction

The use of commercially available automated insulin delivery (AID) systems during pregnancy remains controversial. In this retrospective study, we evaluated the glycemic and pregnancy outcomes, and AID parameters of 13 women who received AID therapy (9 Minimed 780G and 4 Control-IQ) at our hospital between 2021 and 2024. We obtained CGM and insulin pump data from online platforms and assessed diabetes complications, maternal, and fetal outcomes using the medical records.

Results

The median age was 34 years (IQR: 31–39), with a median diabetes duration of 22 years (IQR: 16-29) and a median BMI of 23 kg/m^2 (IQR: 22-32). 62% of the pregnancies were planned. TIR $>70\%$ was achieved in 9/12 (1st trimester), 9/13 (2nd trimester), and 7/13 (3rd trimester) pregnancies. Insulin dose, daily carbs and number of meals increased throughout pregnancy whereas the carbohydrate-to-insulin ratio gradually declined (Table 1). At delivery, gestational age was 37.3 weeks (37–38). 7/13 women had a cesarean section and 2/13 had mild pre-eclampsia. 7/13 newborns were large for gestational age and 4/13 were admitted to the neonatal intensive care unit (one spontaneous preterm birth and one spontaneous hemoperitoneum).

Conclusion

AID systems help maintain glycemic control during pregnancy without increasing the rates of hypoglycemia.

Table 1: Glycemic parameters and pump data through the pregnancy.

	Initial (First visit)	First Trimester (4-15 weeks' gestation)	Second Trimester (16-27 weeks' gestation)	Third Trimester (28-delivery)
HbA1c (%)	6.3 (6.3-6.6)	6.3 (6.2-6.5)	5.9 (5.8-6.1)	6.0 (5.9-6.3)
glucose management indicator (%)	6.6 (6.5-6.8)	6.4 (6.3-6.7)	6.4 (6.3-6.5)	6.3 (6.2-6.4)
Mean sensor glucose (mg/dL)	136 (126-144)	129 (126-139)	128 (125-134)	125 (123-130)
Coefficient of Variation (%)	29 (28-32)	31 (29-33)	30 (29-31)	28 (27-30)
63-140 mg/dL (%)	60 (56-66)	66 (58-70)	67 (59-71)	70 (65-77)
$>$ 140 mg/dL (%)	39 (33-44)	33 (29-41)	32 (27-38)	29 (23-35)
$<$ 63 mg/dL (%)	0.2 (0-1)	1 (1-2)	2 (1-2)	1 (1-2)
Total daily insulin dose (UI)	40 (32-46)	41 (30-52)	45(34-63)	59(44-72)
Total insulin per body weight (UI/kg)	0.56 (0.50-0.69)	0.61 (0.53-0.68)	0.58 (0.52-0.79)	0.71 (0.61-0.80)
Daily Carbs (g)	133(116-159)	160 (130-171)	175(148-186)	175 (162-181)
Number of meals/day	4.7 (4.3-5.2)	5.3 (4.7-6.2)	6.1 (4.6-7)	6.4 (4.8-6.5)
ICR breakfast (g/UI)	6.6 (4.2-7.9)	6.2 (4-7.7)	4.8 (3.2-6.8)	4.4 (3.3-5.9)
ICR lunch (g/UI)	6.2 (5.2-7.9)	6.4 (4.8-7.5)	5.6 (4.6-7.4)	4.8 (4.1-6.6)
ICR dinner (g/UI)	6.6 (5.2-9.2)	7.6 (4.9-8.7)	6.4 (5.0-7.1)	5.2 (4.2-6.2)

Data are presented as median (IQR); ICR, insulin-to-carbohydrate ratio

Influence of socioeconomic factors on breastfeeding adherence in a group of diabetic women

Haifa Abdesselem[1], Chaima Sdiri[1], Emna Bornaz[1], Fatma Boukhayatia[1], Asma Ben Brahim[1], Rym Yahyaoui[1], Kamilia Ounaissa[1] & Chiraz Amrouche[1]

[1]National Institute of Nutrition and Food Technology, Department of Nutritional Diseases (D), Tunis, Tunisia

Introduction

Several international programs support breastfeeding among the general population and vulnerable groups, such as diabetic women, in order to increase the prevalence of breastfeeding. The aim of our study was to determine the impact of socioeconomic factors on breastfeeding adherence among diabetic women.

Methods

We conducted a descriptive observational cross-sectional study involving 52 patients with type 1 or type 2 diabetes who attended the Nutrition "D" Department at the National Institute of Nutrition of Tunis, two months after childbirth. We asked each patient about their socioeconomic conditions and breastfeeding practices.

Results

The mean age of our patients was 35 ± 0.4 years [ext: 23-44]. The majority (80%) had type 2 diabetes, while 20% had type 1 diabetes. Two months after childbirth, the rates of exclusive and partial breastfeeding were found to be 44% and 33%, respectively. Most women (63%) had a moderate socioeconomic level, while 31% had a low socioeconomic level. Rural residency was found in 10% of cases. Sixty-three percent of the patients were unemployed. Only 42% of those who were working had returned to work two months after childbirth. Husband encouragement of breastfeeding was observed in 77% of cases. Not returning to work and receiving support from the husband for breastfeeding were associated with higher breastfeeding rates ($P = 0.007$ and $P < 0.001$, respectively).

Conclusion

In summary, socioeconomic factors are crucial in determining whether diabetic women can successfully adhere to breastfeeding practices. Addressing these factors through policy interventions and community support programs could improve breastfeeding rates among this population.

Epidemiology of type 1 diabetes in children: a 5-year study

Mariem Ben Slima[1], Sana Kmiha[1], Yassmine Mkhinini[1], Rim Belhadj[1], Imen Chabchoub[1], Hajer Aloulou[1] & Thouraya Kammoun[1]

[1]Hedi Chaker University Hospital, Department of Pediatrics A, Sfax, Tunisia

Introduction

ype 1 diabetes (T1D) is a chronic autoimmune disease with a constantly increasing incidence worldwide, including in children. Its early and effective management is essential to avoid acute complications, such as diabetic ketoacidosis (DKA), and long-term complications. In our region, few studies have been conducted to analyze the epidemiological and clinical characteristics of pediatric T1D, hence the need for a retrospective study to better understand the factors influencing the onset and evolution of this disease in children. The aim of this study was to analyze the epidemiological, clinical, biological, and immunological characteristics of Type 1 Diabetes (T1D) in children.

Patients and Methods

A retrospective study of T1D cases in children under 14 years old, hospitalized at CHU Hédi Chaker, Sfax, between January 2018 and December 2022.

Results

We collected 207 cases with an average hospital incidence of 41.4 children per year. The mean age of the children was 7.35 ± 3.74 years, with 82 children under 6 years old and 125 between 6 and 14 years old. A winter predominance was observed (31.4%). Diabetic ketoacidosis (DKA) at presentation was noted in 58.5% of cases, more frequently in children under 6 years old ($P = 0.02$); it was severe in 45.2% of cases. The mean blood glucose was 23.63 ± 8.23 mmol/l. Autoantibodies were positive in 88% of children, mainly anti-GAD (71.9%). After a mean follow-up of 2.25 ± 1.5 years, 35.7% of children were readmitted, primarily for DKA (12.6%), severe hypoglycemia (10.6%), and diabetes imbalance (23.2%). A satisfactory metabolic control was observed in 17.6% of cases.

Conclusion

The incidence of pediatric T1D is increasing, particularly in young children. Despite awareness programs and diagnostic advances, in our region, inaugural DKA remains common, highlighting the need to strengthen prevention and early screening.

Diabetic ketoacidosis (DK) in the context of COVID-19: epidemiological and clinical insights

Fatma Ben Abdessalem[1,2], Taieb Ach[1], Gorchene Asma[1,2], Sahli Jihene[2,3], Imen Halloul[1,2], Wiem Saafi[1,2], Hamza Elfekih[4], Ghada Saad[1,2] & Yosra Hasni[1,2]

[1]Department of Endocrinology, University Hospital of Farhat Hached Sousse, Tunisia, 2- University of Sousse, Faculty of Medicine of Sousse, 4000, Sousse, Tunisia, Sousse, Tunisia; [2]University of Sousse, Faculty of Medicine of Sousse, 4000, Sousse, Tunisia, Sousse, Tunisia; [3]Department of Preventive medicine, University Hospital of Farhat Hached Sousse, Tunisia, Sousse, Tunisia; [4]University of Sousse, Faculty of Medicine of Sousse, Farhat Hached University Hospital, Endocrinology Diabetology Department, 4000, Sousse, Tunisia, Sousse, Tunisia

DKA is a potentially life-threatening complication of DM with an increased incidence over the last few decades. Coronavirus disease(COVID-19) has been incriminated in the pathophysiology of new-onset diabetes mellitus via the development of islet autoimmunity. The aim of this work is to compare the epidemiological and clinical characteristics of new onset DKA before COVID-19 with those during the pandemic. This is a cross-sectional analytical study carried out in the Diabetology&Endocrinology department of Farhat Hached University Hospital of Sousse. The study population included all the patients who had been hospitalized for new onset DKA between the year 2018 and 2022, divided in two groups: Group1(G1):patients hospitalized before COVID-19 since the first of March of 2018 until first of March 2020 and Group2(G2):patients hospitalized during COVID-19 since second of March 2020 until 28thFebruary 2022. A metabolic, renal, hormonal, and immunological assessment has been requested. A total of 340 patients were evaluated:137 were registered in G1, while 203 were registered in G2. The mean monthly incidence of DKA before COVID-19 pandemic was statistically different from that observed during COVID-19 with a mean of 5.75±4.29 DKA per month in G1 vs 8.42±4.87 DKA per month in G2(***P* = 0.049).**The study of the temporal trend of hospital cases of DKA showed a significant upward trend with a change in the average monthly percent change of +0.2, with ***P* = 0.037.**The sex ratio(H/F) remained comparable before and during COVID-19($P = 0.287$). The median age of the two populations was 39 [Q1-Q3]=[25–53] years old and 41 [Q1-Q3]=[27– 57] years old with a $P = 0.531$. Familial history of auto-immunity was comparable between the two groups. The median duration of polyuria and polydipsia before DKA was comparable in the two groups with a median period of 30 [Q1–Q3]=[20.75–60] days in G1 vs 30 [Q1–Q3]=[15–90] days in G2 ($P = 0.171$). The median weight loss in kilograms before the diagnosis was estimated at 8 [Q1–Q3]=[5–13] Kg in G1 vs 10 [Q1–Q3]=[6–15] Kg in G2($P = 0.688$). Clinical presentation of DKA including signs of intracellular and extracellular dehydration, weight loss, blood pressure, heartbeat were comparable between the two groups. Goiter was more significantly reported in G1 with 11.6% in G1 vs 3.4% in G2($P = 0.018$). The emergence of COVID-19 occurred amidst a backdrop of an already existing pandemic that is DM, creating a multitude of challenges for the healthcare system worldwide and adding to the burden of an already overstretched health system.

Hyperuricemia : is it a cardiovascular risk factor?

Siwar Saoudi[1], Ramla Mizouri[2], Rym Ben Othman[2], Hadhemi Belhassen[2], Faten Mahjoub[3], Berriche Olfa[4], Nadia Ben Amor[5] & Jamoussi Henda[4]

[1]Institute of Nutrition of Tunis, Tunis, Tunisia; [2]Institute of Nutrition, Tunis, Tunisia; [3]Institute of Nutrition, Tunis, Tunisia; [4]Institute of Nutrition, Tunis, Tunisia; [5]National Institute of Nutrition, Tunis, Tunisia

Introduction

Hyperuricemia is common in diabetic subjects, especially type 2, particularly in obese patients. Our aim was to investigate the prevalence and risk factors of hyperuricemia in diabetics subjects.

Methods

It was a descriptive cross sectional study conducted in department A of the institute of Nutrition of Tunis which included patients with type 2 diabetes. Hyperuricemia was defined by a uric acid level that exceed 360mg/l.

Results

The total number of patients who participated in the study was 112. The characteristics of the patients were respectively : age 49±9.8 years, Body mass index (BMI) 31± 3.7Kg/m^2, HbA1c 9.8±1.57%. The mean waist circumference was 119.1 ± 18.5 cm. The mean duration of diabetic patients was 9±7 years. Hyperuricemia was present in 32.8%, with a mean level of 408 ± 22.6mg/l. A history of stroke, coronary artery disease and arteriopathy were found respectively in 12.4%,14.5% and 34% of cases. Also 75% of subjects presented microangiopathic complications, with 43% having a diabetic neuropathy, 26% with diabetic nephropathy. As for the metabolic profile, 98.1% with low HDLc, high LDLc in 59.7%, high triglycerides in 76.4 %. Hyperuricemia was positively correlated with BMI ($p = 0.007$), waist circumference ($p = 0.01$) and duration of diabetes ($p = 0.009$). Hyperuricemia was significantly more frequent with diabetic nephropathy ($p = 0.031$) and with dyslipidemic patients ($p = 0.001$). Thus, 89% of patients met the International Diabetes Federation definition of metabolic syndrome.

Conclusion

In conclusion, Hyperuricemia was common in our study. It was positively correlated with BMI, waist circumference, length of diabetes, diabetic nephropathy and dyslipidemia, making it a cardiovascular risk factor.

Generalized lipodystrophy masquerading as obesity and insulin resistance

Jamala Mammadova[1]

[1]Yeni Klinika Hospital, Pediatric Endocrinology, Baku, Azerbaijan

A 14-year-and-8-month-old girl presented with a primary complaint of rapid weight gain. She had a history of progressive enlargement of her hands and feet since childhood. Excessive hair growth on her body was noted at the age of 10. Menarche occurred at 13 years, but no subsequent menstrual cycles were reported. One year prior, the patient had been diagnosed with obesity and insulin resistance, for which Metformin was prescribed; however, she did not adhere to the prescribed treatment regularly. The patient was born to consanguineous parents. Her family history revealed that two male siblings had died shortly after birth, while one female and one male sibling were healthy. On physical examination, her weight was 67.6 kg (+1.71 SDS), height 169.5 cm (+0.58 SDS), and BMI 23.5 kg/m^2 (+0.96 SDS). Distinct facial features were noted, including a large mandible, triangular facies, and an acromegaloid appearance. Additionally, she had large hands and feet, muscle hypertrophy, acanthosis nigricans, hirsutism, hepatomegaly, and labial hypertrophy. Her physique was characterized by excessive fat accumulation in the upper back, reduced fat tissue in the pelvic region, and subcutaneous fat loss in the lower extremities, giving her a pronounced muscular appearance. Laboratory evaluations revealed the following abnormalities: Fasting glucose :86.2 mg/dL, insulin :132.4 µU/mL, HbA1c:7.6%, ALT:139 IU/l, AST :73 IU/l, FSH:3.76 µg/dL, LH:5.25 mIU/mL, total testosterone :1.43 ng/mL, IGF1:0,7 and leptin :3.9 ng/mL. The lipid panel and other tests were within normal limits (Table 1). Imaging studies demonstrated grade 3 hepatosteatosis on abdominal ultrasound, nephrolithiasis on renal ultrasound, and polycystic ovarian syndrome (PCOS) on pelvic ultrasound.

Table 1. Laboratory values of cases

Paramater	Value	Reference Range
Fasting glucose (mg/dl)	86.2	74-106
Fasting Insulin (µu/ml)	132.4	2.6-24.9
C-peptide (ng/mL)	9.42	0.78-5.19
Two-hour postload glucose (mg/dl)	180	74-106
Two-hour postload insulin (µu/ml)	905	2.6-24.9
HbA1c (%)	7.6	4-6
ALT (IU/l)	139	6-33
AST (IU/l)	73	10-32
Total cholesterol (mg/dl)	147	<170
Triglycerides (mg/dL)	99	35-130
HDL (mg/dl)	50.8	
	35-75	
LDL (mg/dl)	76	100-129
Leptin (ng/mL)	3.9	4.4-24.5
fT3 (pg/dl)	3.65	2.56-5.01
fT4 (ng/dl)	1.2	0.98-1.63
TSH (µIU/mL)	1.5	0.35-5.60
ACTH (pg/mL)	33	2-49
Cortisol (µg/dL)	8.6	3-21
FSH (µg/dL)	3.7	2-10
LH (mIU/mL)	5.2	0.61-16.3
E2 (pg/Ml)	26	36.5-196
Total Testosterone (ng/mL)	1.4	0.02- 0.4
DHEA-S (µg/dL)	107.9	51-321
İGF-1(ng/mL)	0.7	153-485

Echocardiography findings were normal. Based on the clinical findings, generalized lipodystrophy type 2 was suspected, prompting genetic testing. Metformin therapy was reinitiated.

Measurement of insulin secretion during oral glucose tolerance test for prediction of obesity treatment success

Tzvetelina Totomirova[1], Mila Arnaudova[2] & Nikolay Kostadinov[3]
[1]Military Medical Academy, Sofia, Bulgaria; [2]Mbal Vita, Sofia, Bulgaria; [3]MU Asen ZLatarov, Burgas, Bulgaria

Background
Oral glucose tolerance test (OGTT) is used for diagnosis of diabetes and insulin resistance. There are different modifications of OGTT with measurement of glucose and insulin level on 0, 30, 60, 120 and additional minutes. But weather OGTT is presenting information for treatment effect.
The aim of our study is to assess the importance of measurement of insulin secretion during oral glucose tolerance test for predicting obesity treatment success.
Materials and methods
Our survey include 109 patients (59 women, 50 men, mean age 40.01 ± 11.80years). Patients were divided into three groups and were assigned to treatment with diet, metformin or GLP-1 agonist. All patients underwent OGTT with measurement of glucose and insulin, which was performed on minute 0, 60 and 120. The groups did not differ by gender, weight, BMI or age. Assessment of weight and BMI was done in six months period. The treatment effect was defined as more than 10% weight loss.
Results
Satisfactory treatment results were found in patients with increased insulin level at 0 min (15.2 ± 3.5 vs 11.3 ± 3.1mU/l, $P < 0.05$) and 60 min (145.2 ± 26.5 vs 87.3 ± 25.1mU/l, $P < 0.05$). There was no difference between insulin levels on 120 min in responders and non-responders (45.2 ± 12.5 vs 39.3 ± 9.1mU/l, $P > 0.05$). Insulin levels of 0 and 60 min demonstrated moderate positive correlation with percentage of weight loss ($r = 0.564$) in group only on diet or metformin, but not in GLP1 agonist treated group.
Conclusion
Measurement of insulin level during OGTT presents information about insulin secretion curve and could be used for prediction of treatment effect in obese patients receiving only diet or metformin, but not in GLP1 agonist treated patients

Screening for celiac disease in children with type 1 diabetes, is it necessary? twenty-five years of experience in a single center

Roland Schweizer[1], Julia Bung[1], David Majer[1], Franziska Liebrich[1], Susann Herrlich[1], Andreas Neu[1] & Julian Ziegler[1]
[1]Pediatric Diabetology, University Children's Hospital, Tübingen, Germany

Patients with type 1 diabetes (T1D) have an increased risk of developing additional autoimmune diseases. The risk of developing celiac disease (CD) is 3-4 times higher in children with T1D. Guidelines recommend regular screening for transglutaminase antibodies (TgAb) in T1D children. CD could be an additional burden for T1D children as both diseases affect food intake. We describe the screening practice for CD during the last 25 years in our outpatient clinic in children with T1D. Methods: We retrospectively analysed the development of CD-specific antibodies in our patients with T1D (diabetes onset since 1998). We did not always recommend endoscopy when CD-specific antibodies (TgAb, endomysium (EAb), gliadin) were positive and patients had no CD-specific symptoms. Results: We analysed 304 patients. 122 had CD-specific antibodies. In 98 of them, they disappeared after a short time or were only slightly elevated. The diagnosis of CD was confirmed in 12. All 12 showed CD-specific symptoms such as failure to thrive, anaemia, hypoglycaemia or gastrointestinal problems. In 6 patients, even severely elevated EAb and/or TgAb disappeared on average after 7.1 years (range 4.9 to 13.5 years) on gluten-containing diet. The remaining 6 had antibodies without CD-specific symptoms by the end of the observation period. The time with antibody-positivity was 4 years (range 1.8 to 11.6 years).
Conclusion
We conclude that even highly elevated CD-specific antibodies can disappear in children with T1D and therefore screening for CD-specific antibodies is only useful in symptomatic children with T1D.

Development of disease-modifying therapies for early-stage type 1 diabetes: insights from the EDENT1FI project

Felix Reschke[1], Elisabeth Niemoeller[2], Jurgen Vercauteren[3], Erik Christiansen[4], Jessica Dunne[4], Laura Knecht[5], Esther Latres[6], Julia Mader[7], Vit Neumann[8], Thomas Pieber[7], Rebecca Playle[9], Peter Taylor[9], Julia Townson[9] & Colin Dayan[9]
[1]Childrens Hospital AUF DER BULT, Centre for Endocrinology, Diabetology, Metabolism & Clinical Research, Hanover, Germany; [2]Sanofi, Frankfurt, Germany; [3]KU Leuven, Leuven, Belgium; [4]Novo Nordisk, Soeborg, Denmark; [5]Sanofi, Bridgewater, United States; [6]Breakthrough T1D, New York City, United States; [7]Medical University of Graz, Graz, Austria; [8]Charles University and University Hospital Motol, Prague, Czech Republic; [9]Cardiff University, Cardiff, United Kingdom

Background and Objectives
The EDENT1FI project aims to advance early diagnosis and intervention for Type 1 Diabetes (T1D), focusing on reducing the progression of the disease and delaying insulin therapy. This project involves screening 200,000 children in Europe for islet autoantibodies, identifying early-stage T1D, and offering targeted disease-modifying therapies (DMTs) to preserve beta-cell function. WP4, dedicated to developing protocols or administering DMTs, investigates interventions aimed at halting or slowing beta-cell destruction, with the potential to dramatically alter the clinical course of T1D.
Methods
The EDENT1FI initiative includes six work packages (WP). WP1 handles screening programs across Europe, WP2 explores psychosocial impacts, WP3 establishes follow-up protocols, WP4 focuses on the development and testing of DMTs, WP5 manages communication strategies, and WP6 ensures project governance. WP4's adaptive trial designs aim to test multiple DMTs, incorporating biomarkers such as C-peptide and glucose tolerance to evaluate efficacy in preserving beta-cell function and delaying progression to insulin dependency. The data is collected from multiple countries, ensuring a comprehensive understanding of the disease progression.
Results
WP4 is developing innovative therapeutic strategies using adaptive trials to assess the efficacy of DMTs for T1D. Key biomarkers, including C-peptide and glucose levels, will be used to identify children and adolescents who are at risk of rapid disease progression. Preliminary results suggest that DMTs can potentially preserve beta-cell function, delaying the onset of insulin dependence. By using adaptive trial designs, WP4 can provide insights into the most effective interventions for managing early-stage T1D.
Conclusion
EDENT1FI, through WP4, establishes the framework to support future disease-modifying therapy trials that could revolutionize the treatment of early-stage T1D. By delaying insulin therapy and preserving beta-cell function, these therapies have the potential to improve long-term health outcomes for children and adolescents with T1D. This collaborative effort leverages advanced biomarkers, adaptive trial designs, and international expertise to offer a more personalized and effective approach to managing early-stage T1D.

HbA1c measurement: comparison of biorad D10 (Hplc) and sebia capillarys 2 methods

Raneen Sliman[1]
[1]Ziv Medical Center, Zefat, Israel
Raneen Sliman MSc, Elena Bukovetzky,PhD, MHA, MA, Samar Nafafa MSc, Ziv Medical Center

Background
HbA1c test provides information on metabolic control in diabetes and could also be used for its Diagnosis, it is essential to have accurate and precise HbA1c

methods covering a range of measurement principles. We report an evaluation of the Biorad D10 kit (Hplc) versus Sebia capillarys 2 Kit (capillary electrophoresis).
Methods
Measurements of HbA1c were carried out in whole blood samples (K3edta tubes) from 111 patiens from different departments in Ziv medical Center- Israel using both Sebia Capillarys 2 Flex piercing (Capillary Electrophoresis) and analyzers Biorad D 10 (HPLC method).
Results
There was a good concordance between the results of capillary electrophoresis and HPLC (R2 = 0.97, *P* 0.0001) There is no significant difference between the results obtained from both technique.
Conclusions
both technique suitable for the clinical application in the analysis of HbA1c. it is concluded that the results obtained after testing samples in Sebia capillarys Flex Piercing II and Biorad D10 are in a good concordance and there is no significant difference in the results obtained. The advantage of using Biorad D10 has benefit of shorter testing time Whereas Sebia capillarys can detecte underlying hemoglobinopathies and high throughput.

Factors associated with gestational weight gain in pregnant women with gestational diabetes mellitus

Gintare Naskauskiene[1,2], Diana Ramasauskaite[1,2], Agne Bartuleviciene[1,2], Gintautas Domza[1,2] & Zydrune Visockiene[1,2]
[1]Vilnius University Faculty of Medicine, Vilnius, Lithuania; [2]Vilnius University Hospital Santaros klinikos, Vilnius, Lithuania

Background
Studies disagree that higher pre-pregnancy body mass index (pre-BMI) is associated with more significant weight gain during pregnancy. We aimed to assess factors associated with GWG in women with gestational diabetes mellitus (GDM).
Methods
The study involved 215 singleton pregnant women diagnosed with GDM who delivered at Vilnius University Hospital Santaros Klinikos from 2019 to 2023. Based on pre-BMI, women were categorized into group 1 - BMI < 18.5- 24.9 kg/m^2; group 2-BMI 25-29.9; group 3 - BMI ≥ 30. According to the Institute of Medicine, the cut-off points for weight gain were set at ≤16 kg, ≤11.5 kg, and ≤9 kg for groups 1, 2, and 3, respectively. The association of pre-BMI, fasting plasma glucose up to 14 weeks of gestation (FG14w), FG, fasting insulin (FI), HOMA-IR, lipid profile, and CRP at weeks 24-28 with GWG was analyzed.
Results
There were 123 (57.2%),52 (24.2%) and 40 (18.6%) women in group 1, 2 and 3 respectively. The mean age was 31.9 ± SD 4.05 and did not differ between the groups. Excess weight gained 22 (17.9%), 14 (26.9%), and 12 (30%) of women in groups 1, 2, and 3, respectively. The biggest GWG was in group 1 – 12.5 ±4.9 kg, followed by groups 2- 8.9±5.5 and 3 - 5.7±5.5 (*P*<0.001). HOMA IR was 2.0 ± 1.4, 3.0 ± 2.4, and 4.4 ± 3.4 (*P*<0.001); HDL chol - 2.0 ± 0.4, 1.9 ± 0.4 and 1.7 ± 0.3 (*P*<0.001) in group 1, 2 and 3 respectively. FG14w, FG24-28w, hCRP, triglycerides (TG), and FI differed significantly between the groups (*P*<0,001 for all). Pre-BMI, HDL chol, and FG24-28w explained 24% of GWG variance in the whole group (R2 adjusted = 0.24, *P*<0.001). Only HDL chol correlated significantly with GWG in group 2, explaining 13% of the variance (R2 adjusted = 0.13, *P* = 0.005) and resulting in a significant OR of 19.2 (95% CI 2.2-166.4) and AUC of 0.81 (95% CI 0.6 - 0.9). None of the variables demonstrated a statistically significant association with GWG in groups 1 and 3.
Conclusions
GDM women with the highest pre-BMI gained the least weight during pregnancy. Pre-BMI, HDL chol, and FG24-28w were significant determinants of GWG in the whole group, but only HDL chol remained significant in women with pre-pregnancy overweight. Further research is needed to explore other possible factors related to GWG in women with GDM.

Diabetic foot in patients with type 1 diabetes : a challenging complication (a study of 56 patients)

Hajar Sabaoui[1], Nassim Essabah Haraj[1], Siham El Aziz[1] & Asma Chadli[1]
[1]CHU Ibn Rochd, Clinical Neuroscience and Mental Health Laboratory, Endocrinology, Diabetology, Metabolic Diseases and Nutrition Department, Casablanca, Morocco

Introduction
Diabetic foot is a high-risk complication of type 1 diabetes, poorly described but responsible for severe morbidity and amputations.
Objectives
To analyze the epidemiological, diagnostic, therapeutic, and evolutionary characteristics in type 1 diabetics with diabetic foot.
Patients and Methods
This descriptive retrospective study was conducted among patients with type 1 diabetes hospitalized for diabetic foot in our department from January 2018 to September 2024. Data were analyzed using IBM SPSS Statistics 27.0.1.
Results
Our study included 56 patients, with an average age of 37.71 years (range: 17-68 years). Males predominated with a sex ratio of 3.3. The average duration of diabetes was 19 years. The mean HbA1c was 11%. For insulin therapy: 65% were on a premixed regimen and 35% on a basal-bolus regimen. 62.5% of the patients were at very high cardiovascular risk: dyslipidemia in 34%, hypertension and smoking in 21.4%, and obesity in 14.2%. Macroangiopathy was dominated by peripheral artery disease in 32% of cases. Microangiopathy was dominated by diabetic retinopathy and peripheral neuropathy in 66.1% and 58.2% of cases, respectively. The initial cause of the lesions was inappropriate footwear in 59% of cases. The most common type of lesion was diabetic foot ulcer in 84% of cases: 29.7% associated with dermohypodermitis, and 42% complicated by osteitis. Management was medical in 91% of cases, with 8.9% requiring surgical treatment, and 3.5% undergoing amputation.
Conclusions
The occurrence of diabetic foot in patients with type 1 diabetes is linked to glycemic imbalance and the presence of degenerative complications, notably peripheral artery disease, retinopathy, and peripheral neuropathy. The evolution is favorable in most cases.

Impact of glycemic imbalance on diabetic foot ulcer healing

Ezzahoum Zaynab[1], Nassim Essabah Haraj[1], Siham El Aziz[1] & Asma Chadli[1]
[1]Ibn Rochd University Hospital. Faculty of Medicine and Pharmacy, Hassan II University, Department of Endocrinology, Diabetology, Metabolic Diseases, and Nutrition Ibn Rochd University Hospital, Casablanca, Laboratory of Clinical Neurosciences and Mental Health Faculty of Medicine and Pharmacy, Hassan II University, Casablanca, Morocco

Introduction
Diabetic foot is a major public health concern, with a high rate of amputations. The complications of diabetic foot disease (DFD) are mainly due to diabetic neuropathy, arteriosclerosis, and infections of ulcers. Offloading of wounds is essential for treating high-risk ulcers. Preventing recurrences relies on patient education, proper foot care, and appropriate offloading.
Objective
To assess the impact of glycemic imbalance on clinical indicators such as delayed wound healing and progression to amputation.
Patients and Methods
A descriptive statistical study was conducted on 276 patients with poor glycemic control (HbA1c > 8%) followed at the diabetic foot consultation in the Endocrinology and Metabolic Diseases Department at Ibn Rochd University Hospital, Casablanca.
Results
The average age was 57 years, with a male predominance of 64.86%. The average duration of diabetes was 14.5 years, and the average HbA1c was 13%. Of the patients, 80.28% were treated with insulin therapy, while 19% were on oral antidiabetic drugs (OAD). The main reason for consultation was diabetic foot ulcers (59.12%) and diabetic ulcer with dermohypodermatitis (40%). The majority of patients had poor footwear as the main trigger factor (68%), followed by post-traumatic causes (11.54%), ischemia (10%), and others. Among the 276 patients with poor glycemic control (HbA1c > 8%), 108 had osteitis. Delayed

healing (> 15 days) was observed in 247 patients (89%), and 34 of these patients underwent amputation.
Conclusion
It is well established that glycemic imbalance is a factor associated with delayed wound healing. In particular, the benefit of systematic insulin therapy in these patients leads to improved healing outcomes.

JOINT3983
Microbiological spectrum of diabetic foot infections (a study of 46 cases)
Hajar Sabaoui [1], Nassim Essabah Haraj[1], Siham El Aziz[1] & Asma Chadli[1]
[1]CHU Ibn Rochd, Clinical Neuroscience and Mental Health Laboratory, Endocrinology, Diabetology, Metabolic Diseases and Nutrition Department, Casablanca, Morocco

Introduction
Diabetic foot infections are common and serious, leading to prolonged hospitalizations and increased morbidity and mortality. Understanding the bacteriological profile of these infections is essential to improve patient management. The aim of our study is to establish the microbial flora found in these lesions.
Patients and Methods
This is a descriptive retrospective study conducted on 46 patients hospitalized in our department for diabetic foot who underwent bacteriological sampling. Data were analyzed using Python with the Pandas library.
Results
Our cohort included 46 patients with an average age of 54 years, 76% of whom were over 40 years old. Males predominated with a sex ratio of 6.6. The average delay in management was 45 days. More than half of the lesions were classified as stage B Texas University (54.3%), with 41% classified as Texas 3B. The treatment duration exceeded 6 weeks in more than 80% of cases. The infections were dominated by Gram-positive cocci (47.8%), Gram-negative bacilli (21.7%), and Enterobacteriaceae (13%). The most frequently implicated bacteria were Staphylococcus, Enterococcus faecalis, Enterobacter cloacae, Escherichia coli, followed by Pseudomonas aeruginosa, Morganella morganii, Proteus mirabilis, and Streptococcus. The absence of bacteria in some samples may be due to inadequate sampling or prior antibiotic use.
Conclusions
Diabetic foot infections are common, often managed late, and require prolonged antibiotic therapy. This study provides a detailed profile of the bacteria involved to guide antibiotic selection and improve management.

Lipid profile and micro and macrovascular complications in LADA diabetes at hospital universitario de canarias, spain
Selena Rodríguez Fernández[1], Óliver Quintero Rodríguez[1], Kevin Díaz Gorrín[1], Javier Panizo Fra[1], Ana León Ocando[1], Laura Mesa Suárez[1], Elena Rodríguez Sosa[1], Macarena Sánchez-Gallego Alonso[1] & Itiziar Aznar Ondoño[1]
[1]Hospital Universitario de Canarias, Endocrinology and Nutrition, Santa Cruz de Tenerife, Spain

Introduction
Latent Autoimmune Diabetes in Adults (LADA) constitutes the most prevalent form of autoimmune diabetes in adults. Its estimated prevalence ranges from 2% to 12%, although this figure can vary depending on demographics (higher in Northern Europe and China) and the diagnostic criteria used, as these are not yet definitively established. Patients with LADA exhibit an intermediate range of characteristics between type 1 (DM1) and type 2 (DM2) diabetes. In metabolic syndrome, they have a frequency similar to or higher than DM1, but lower than DM2 (with lower dyslipidemia, insulin resistance index, and better blood pressure control). At the onset, they have a lower risk of microvascular complications compared to DM2 patients. However, this risk progressively increases as the glycemic profile worsens. Regarding the lipid profile, there are no detailed descriptions or specific recommendations for managing dyslipidemia in this type of diabetes. However, in general, for diabetic patients with dyslipidemia, the American Diabetes Association (ADA) recommends initiating treatment with moderate or high-potency statins, as well as interventions targeting lifestyle habits.
Material and Methods
A descriptive and cross-sectional study was conducted to assess the lipid profile and the presence of micro and macrovascular complications in patients with LADA diabetes. A sample of 42 patients, aged between 26 and 77 years (mean age 50.9 years), with 42.8% being male, was evaluated between 2022 and 2024 in the Endocrinology Department of the Hospital Universitario de Canarias, Spain. 92.8% of patients had the mentioned parameters assessed in 2024, while the rest were evaluated in 2023.
Results
A retrospective evaluation was conducted for the following: total cholesterol, LDL cholesterol, HDL cholesterol, triglycerides, use of lipid-lowering treatment, percentage of LDL target achievement (according to the SCORE2 guideline), presence of microalbuminuria, use of ACE inhibitors/Angiotensin II receptor blockers (ARBs), and the presence of micro and macrovascular complications (acute myocardial infarction, diabetic retinopathy, or diabetic neuropathy).
- Total cholesterol: 177.95 mg/dL
- LDL cholesterol: 98.05 mg/dL
- HDL cholesterol: 59.15 mg/dL
- Triglycerides: 99.5 mg/dL
  - Average values of variables:
  - Micro/macrovascular complications: 14.28%
  - Positive microalbuminuria: 7.14%
  - Percentage of patients reaching LDL target: 31.70%
  - Treatment with ACE inhibitors/ARBs: 26.19%

Conclusion
Given the importance of cardiovascular risk factors and the presence of micro and macrovascular complications, larger and more specific studies are necessary to assess the lipid profile, its management, and the prevalence of complications in patients with LADA diabetes.

JOINT397
Correlation between visceral fat, insulinrésistance and age in type 1 diabetes patients
Samir Mkaouer[1], Zeineb Rekaya[1], Meriem Yazidi[1], Elyes Kamoun[1], Nadia Khessairi[1], Ibtissem Oueslati[1], Fatma Chaker[1] & Melika Chihaoui[1]
[1]CHU La Rabta, Endocrinology Department, Tunis, Tunisia

Introduction
The prevalence of metabolic syndrome (MS) and insulin resistance (IR) increases with age. This association is poorly studied in patients with type 1 diabetes (T1D). The aim of our study was to evaluate the association between IR, MS and age in young adults with T1D.
Methods
We conducted a cross-sectional study including 68 patients with T1D. The study subjects were young adults, aged between 18 and 45 years. Each patient underwent a physical examination (anthropometric parameters and blood pressure), a fasting biological sample collection for the measurement of HbA1c, lipid parameters and C reactive protein (CRP), an evaluation of body composition by DXA Scan to measure the visceral fat mass (VFM). Visceral fat mass proportion (%VFM) was calculated by the formula: [VFM (g)/Weight (g)] x 100. High visceral fat mass (HVF) was defined by a %VFM > 1,1 in men and > 0,7 in women. MS was diagnosed according to the International Federation of Diabetes (IDF) criteria.
Results
The study population consisted of 29 men (42.6%) and 39 women (57.4%). The mean age was 29.4 ± 7.23 years. The median duration of diabetes was 11 years (4.2–17.0), with a range from 1 to 29 years. MS was observed in 14 patients (20.6%). HVF was present in 15 patients (23.4%). MS was not associated with age in T1D patients ($P = 0.621$). T1D patients with HVF were significantly older than T1D without HVF (34.3 ± 8.38 vs 28.3 ± 6.40; $P = 0.005$). An age above 30 years old was significantly more observed in T1D patients with HVF than patients without HVF (73% vs 40,8%; $P = 0.027$).
Conclusion
In our study, age was not associated with MS in patients with T1D. This could be explained by the young age of our population. Yet an age above 30 was associated with visceral fat which is correlated with IR and can increase cardiovascular risk.

Association between diabetes mellitus and severity of epistaxis: a retrospective study
El Omri Malika[1], Hadil Ben Kahla[1], Misbah Linda[1], Souhir Chelly[2], Hamza Elfekih[3], Mouna Bellakhdhar[1] & Kermani Wassim[1]

[1]Farhat Hached University Hospital, Department of Ear, Nose, Throat and Head and Neck Surgery, Sousse, Tunisia; [2]University Hospital Centre Farhat Hached, Occupational Health Department, Sousse, Tunisia; [3]Farhat Hached University Hospital, Department of Endocrinology and Diabetology, Sousse, Tunisia

Introduction
Epistaxis is a common condition encountered in otorhinolaryngology, generally benign, but it can occasionally present as a severe and life-threatening event. For patients with diabetes mellitus (DM), epistaxis may be a sign of underlying vascular complications. This study aims to evaluate the relationship between diabetes and the severity of epistaxis and its implications for management strategies.
Methods
A retrospective cross-sectional analytical study was conducted at the Department of Otolaryngology–Head and Neck Surgery of Farhat Hached University Hospital, encompassing patients consulting and/or admitted for epistaxis between January 2015 and December 2022.
Results
A total of 720 cases were analyzed. Of these, the majority (87.9%) were classified as benign and managed on an outpatient basis, while 12.1% of patients presented with severe epistaxis necessitating hospitalization. A significant prevalence of cardiovascular diseases was observed, including hypertension (32.9%), diabetes (12.8%) and dyslipidemia (6.9%). Other noteworthy medical conditions included chronic kidney disease ($n = 19$; 2,6%) and haematological pathologies ($n = 11$; 1,5%). Despite the prevalence of diabetes (12.8%), no statistically significant correlation was found between diabetes and the severity of epistaxis. Contrary to previous studies suggesting a direct association between DM and severe epistaxis, our findings suggest that diabetes may act as a predisposing factor by inducing vascular changes such as endothelial dysfunction and impaired hemostasis. Additionally, diabetes mellitus may contribute to atherosclerotic changes in the nasal vessels, increasing their fragility and susceptibility to bleeding. The coexistence of cardiovascular conditions, such as hypertension and dyslipidemia, which are frequently associated with diabetes, may further exacerbate the risk of epistaxis in this population.
Conclusion
Diabetes mellitus may increase the risk of epistaxis through its effects on vascular integrity, though its role in determining the severity of the condition remains uncertain. Further large-scale, prospective studies are needed to elucidate the underlying pathophysiological mechanisms and refine management strategies for diabetic patients presenting with epistaxis.
Keywords
Epistaxis – Bleeding – Diabetes Mellitus - Severity criteria - Risk Factors – Management.

Electroconvulsive therapy and the onset of diabetes: a rare but critical complication in children
Meliha Esra Bilici[1]
[1]Zonguldak Bülent Ecevit University School of Medicine, Department of Pediatric Endocrinology, Zonguldak, Türkiye

Objective
Electroconvulsive therapy (ECT) was approved for adolescents with severe conditions under specific conditions since 2004. However, its use in children and adolescent populations is less common. Studies on ECT's impact on blood sugar in adults have highlighted its diabetogenic effects. It is recommended that glycemic control be achieved before ECT in diabetic patients, while in non-diabetic patients, consecutive blood glucose monitoring is advised following ECT sessions. In pediatric populations, however, data and experience in this area are limited. This case report presents a 13-year-old male with normoglycemia before ECT who was subsequently diagnosed with diabetes mellitus. The aim is to raise awareness of this potential complication in children and adolescents undergoing ECT.
Case Presentation
A 13-year-old boy with early-onset psychosis and treatment-resistant ADHD had been on medication, including fluoxetine, olanzapine, quetiapine, and mianserin for the past two months. Due to treatment failure, ECT was planned. Two days before starting ECT, the patient had HbA1c of 5.5% and blood glucose level of 94 mg/dL. After undergoing 3 ECT sessions (10,25, and 35 joules, spaced 3 days apart) and a final session 15 days later (50 and 65 joules), the patient developed polyuria, polydipsia, and weight loss over the past week. Physical examination showed a height-SDS of -0.88, BMI-SDS of -0.34, and Tanner Stage 4 puberty without syndromic findings. Upon admission to our deparment, the patient's had blood glucose: 441 mg/dL, HbA1c:9.1%, insulin level :38.68 uIU/mL, and C-peptide : 2.72ng/mL (0,6-4). No acidosis or ketosis was present. Ophthalmic examination showed no optic atrophy. Antibodies tested positive for Anti-glutamic acid decarboxlyse level with 5.4 (positive$>$5) and moderate islet cell antibodies 0.7(0,7-1.0), while anti-insulin antibodies were negative. Further investigations investigations showed normal lactate, ammonia, lead, mercury, copper levels and aryl sulfates A and tandem mass and amino acids in urine and blood. Measles IgG/IgM were negative. No mutations were found in the MODY and WFS-1 and 2 gene panels. Despite basal insulin and oral antidiabetic treatment, glycemic control was not achieved. After 34 ECT sessions, the patient's C-peptide decreased to 0.49, and he is now on basal-bolus insulin at 1.1 units/kg/day.
Conclusion
Considering the uncertainty surrounding the etiology of childhood psychiatric disorders and the potential impact of ECT on glycemic control, the effect of ECT on beta cell reserve in children should be further evaluated. A multidisciplinary approach is essential during the ECT treatment process in children, with careful attention to hyperglycemic complications and more frequent monitoring of blood glucose levels.

JOINT476
Atezolizumab-induced autoimmune diabetes mellitus: clinical case
Olena Antonyuk[1]
[1]Kyiv, Kyiv, Russian Federation

Background
Atezolizumab, a PD-L1 inhibitor, has significantly improved outcomes in advanced bladder cancer. However, immune checkpoint inhibitors (ICIs) can cause immune-related adverse events, including autoimmune diabetes mellitus (ADM). Although immune-related T1DM is a rare complication, it has been increasingly reported with ICIs, including nivolumab, pembrolizumab, and atezolizumab. The estimated incidence of ICI-induced diabetes ranges from 0.2% to 1.4%, with most cases occurring within 1–6 months after initiation of therapy.
Case Presentation
A 46-year-old military officer with stage IV bladder cancer (pT4pN0M0, G3) was hospitalized on **March 6, 2024**, due to progressive fatigue, polyuria, polydipsia, and severe hyperglycemia (29.8 mmol/l). He had previously undergone multiple transurethral resections (TURs), radical cystectomy with Bricker urinary diversion (July 2023), and four cycles of gemcitabine-cisplatin chemotherapy (July–October 2023). In January–February 2024, he received two cycles of atezolizumab (T-centrix). Within weeks, he developed worsening hyperglycemia. Laboratory tests confirmed new-onset T1DM: glucose 26.65 mmol/l, ketonuria 3.9 mmol/l, and positive autoimmune markers—glutamic acid decarboxylase antibodies (GADA: 85.1 U/mL) and islet cell antibodies (ICA: 43.7 U/mL). The C-peptide level was markedly reduced (0.33 ng/mL), indicating β-cell destruction. No prior history of diabetes or autoimmune diseases was noted. The patient was started on basal-bolus insulin therapy and intravenous hydration. Over the hospitalization period, glycemic control improved, with glucose levels stabilizing (7.5–15 mmol/l). He was discharged after treatment with recommendations for endocrinology and oncology follow-up, regular HbA1c monitoring, and continued glycemic management. Atezolizumab-induced diabetes has been documented in several case reports. A systematic review of ICI-related diabetes cases found that median onset occurs within 6–12 weeks of therapy initiation, often presenting with diabetic ketoacidosis (DKA). Atezolizumab-related cases remain less frequent than those linked to PD-1 inhibitors, but the mechanism is believed to involve T-cell–mediated β-cell destruction, similar to classic autoimmune diabetes.
Conclusion
This case highlights atezolizumab's potential to induce autoimmune diabetes, likely via immune-mediated β-cell destruction. The onset of hyperglycemia within weeks of ICI therapy underscores the importance of regular glucose monitoring in patients receiving immune checkpoint inhibitors. Early detection and timely intervention can prevent life-threatening complications.

Use of diabetes app to help improve management of adolescent type 1 dm patients

Steven Ghanny[1], Anna Aluf[1], Kristi Caporoso[1] & Javier Aisenberg[1]
[1]Hackensack University Medical Center, Hackensack, United States

Introduction
Patients use technology based platforms for most daily activities, including managing their health. This is especially true of most adolescents, who prefer to use health based websites and text messaging platforms that involve health management. The management of Type 1 DM in adolescents can be challgening, given that many of these patients have poor diabetes control during this time period. Providers have been trying to find new and innovative ways to manage these patients, in order to improve their diabetes control. Given that adolescents prefer to use app based technology for their health management, they would benefit from an app to help in their diabetes care. Our group previously did a pilot study, where adolescent Type 1 DM patients received a smartphone with pre-loaded apps to help manage their diabetes care. In review of the data, most participants in the study had improvements in their diabetes outcomes. However, the partcipants preferred to have one app that they could download to their own phone to help manage their diabetes.
Objectives and hypotheses
Use of an app to improve the management of adolescent Type 1 DM patients.
Methods
Our group has a created an app with the aid of Equiva Health. Within the app, we have included a communication tab, where the participants can send HIPAA protected texts to providers, as well as have appointments via Zoom; an education tab with different modules that reviews diabetes education; a glucose monitoing tab, which has embedded CGM and glucometer monitoring apps; a fitness and nutrition tab that includes apps for carbohydrate counting. The study will focus on adolescent Type 1 DM patients, 12-22 years of age. Patients will have a baseline HbA1C or GMI and repeat HbA1C or GMI 3 months after using the app. Calls to the office, admissions to the hospital and hypoglycemia episodes will also be tracked at baseline and after using the app. The study team will include a physician, an advanced practice nurse and a social worker.
Results
Results acquisition is in process.
Conclusions
Given the preference of adolescents to use technology to manage their health, as well as our previous study data, we anticipate that this app will help improve diabetes management in adolescent Type 1 DM patients. The acquisition and analysis of the data obtained from this study will lead to continued app improvements and development of additional app features.

Parenting style and glycemic control in adolescents with type 1

Soukaina Lahlou[1], Nassim Essabah Haraj[1], Siham El Aziz[1] & Asma Chadli[1]
[1]CHU Ibn Rochd, Clinical Neurosciences and Mental Health Laboratory, Department of Endocrinology, Diabetology, Metabolic Diseases and Nuttition, Casablanca, Morocco

Introduction
The role of parents in the management of adolescents with type 1 diabetes (T1D) is crucial, as it can significantly influence the management of the disease in our young patients. The way parents interact with their child can affect the adolescent's motivation to maintain good blood sugar control.
Objective
Our study aims to examine the role of parenting style in achieving metabolic control in adolescents with type 1 diabetes.
Materials and methods
This is a descriptive cross-sectional study including parents of children with type 1 diabetes (T1D) aged 15–18 years, followed in our department, who attended consultations with their children. Glycemic control was assessed by HbA1c, and parental educational style was evaluated using a questionnaire. Parental Authority Questionnaire and Parental Helplessness Questionnaire.
Results
The study included 100 patients, with a sex ratio (F/M) of 1.5. The average age of the population was 16 years, and the mean duration of diabetes was 5 years. The average HbA1c was 10.6%. Among the patients, 86% were treated with analogs, while 14% used human insulin. Overall, the permissive educational style was dominant, accounting for 80%, followed by the authoritarian that counted for 11%. For patients with HbA1c within the target range, 85% of parents adopted a cooperative educational style. Meanwhile, among patients not achieving HbA1c targets, the majority of parents adopted permissive educational style.
Conclusions
In line with our hypothesis, a cooperative parenting style is associated with better glycemic control in adolescents, while a permissive and authoritarian parenting style predicts worse outcomes.

JOINT289

Higher prevalence of mental health impairment in youth with diabetes and association of higher HbA1c with physical complaints

Miriam Eilers[1], Katrin Heldt[1], Susanne Maeder[1] & Dagmar l'Allemand[1]
[1]Ostschweizer Kinderspital, 9006 St. Gallen, Switzerland

Introduction
An increased prevalence of mental health impairments has been reported for adolescents with type 1 diabetes (T1D). Although psychosocial factors bear the potential to have a detrimental impact on glycemic control, health professionals are insufficiently trained to recognize and accommodate problems in this field.
Objectives
We aimed to determine the prevalence and the type of mental health impairment in adolescents in our outpatient diabetes clinic and to assess the relationship between mental health problems and glycemic control.
Methods
YSR11-18R assesses the scales: anxious/depressive, regressive/depressive, physical complaints, social problems, thinking, and repetitive problems, attention problems, rule-breaking and aggressive behaviour and measures socially desirable behaviours. Student's t tests were used to compare the results in two groups, patients with good (HbA1c $< 7.7\%$), and less good glycemic control (HbA1c $> 7.7\%$).
Results
In 29 adolescent patients (15 girls, 14 boys), aged 14.9 years (range: 13-18), median HbA1c was 7.8% (range 6.1-14.3%). In 3 questionnaires manifest psychiatric comorbidities were detected, while 3 showed less severe psycho-pathologies, thus 10 percent of YSR tests in our cohort were abnormal. The individual problem scales showed that highest T-values (means $\pm$ SD) were achieved in the fields regressive/depressive (T 55.7 $\pm$ 9), anxious/depressive (T 55.79 $\pm$ 9) and attention problems (T 55.6 $\pm$ 6.4). HbA1c $< 7.7\%$ was associated with significantly less ($P = 0.03$) physical complaints; adolescents with HbA1c > 7.7 had a tendency towards rule-breaking behaviour ($P = 0.08$). High scores were obtained in the socially desirable responses (Highest score 2, mean 1.53 $\pm$ 0.30 SD). Good glycaemic management was associated with fewer physical complaints, while adolescents with impaired glycemic control showed a tendency towards rule-breaking behaviour.
Conclusions
There is an increased prevalence of psychosocial impairment in T1D adolescents but poor glycemic control is mainly associated with physical complaints. YSR testing allows for detection of psychologic problems in adolescents with T1D and thus could allow for targeted interventions.

Beyond blood sugar: body composition changes in children with T1DM

Chitrakshi Tewari[1], Praveen Kumar[1], Preeti Singh[1], Medha Mittal[2] & Anju Seth[1]
[1]Lady Hardinge Medical College, New Delhi, India; [2]Chacha Nehru Bal Chikitsalaya, Delhi, India

Background
Type 1 Diabetes Mellitus (T1DM) is characterized by insulin deficiency, leading to a catabolic state at diagnosis. While intensive insulin therapy facilitates a rapid and complex reshaping of body composition, the effects on body fat and lean mass, particularly in children, remain underexplored, especially in the Indian context. This study aims to evaluate the impact of insulin therapy on body composition in children with newly diagnosed T1DM over a 10–12-week period and compare it with healthy controls.

Methods
42 children with newly diagnosed T1DM (aged 5–18 years) and 42 healthy controls were included. Clinical assessments, anthropometry, and Body Impedance Analysis (BIA) were performed at diagnosis and after 10–12 weeks for cases, and once for controls. BIA parameters analysed were body fat mass (FM), fat-free mass (FFM), percent fat mass (%FM), percent fat-free mass (%FFM), fat mass index (FMI), and fat-free mass index (FFMI).
Results
At diagnosis, children with T1DM had significantly lower weight Z-scores (-0.58), BMI Z-scores (-0.87), and Triceps skinfold thickness (TSFT) (-4.31) compared to controls. BIA revealed reduced FM (-2.90), FMI (-1.71), and %FM (-9.13%) in the T1DM group. The FFM and FFMI showed no significant difference between the groups, though %FFM was higher in T1DM children indicating a relatively lower proportion of fat mass in cases. After 10-12 weeks of insulin therapy, children with T1DM demonstrated significant increases in weight Z-scores (0.44), BMI Z-scores (0.59), TSFT (0.35 mm), FM (0.77 kg), FMI (0.44 kg/m^2), and %FM (2.07%). FFM (1.03 kg) and FFMI (0.59kg/m^2) also increased, while %FFM decreased, suggesting a shift towards increased fat storage On follow-up, T1DM children matched controls in weight and BMI-Z-scores but had lower FM (-2.13 kg), FMI (-1.28 kg/m^2), and %FM (-7.06%) with higher %FFM (6.77%).
Conclusion
Children with newly diagnosed T1DM exhibit lower body fat mass and BMI at diagnosis, primarily due to insulin deficiency. Insulin therapy leads to an increase in both fat and fat-free mass, with a greater impact on FM, but could not match healthy controls by 10–12 weeks, particularly in terms of fat mass. These findings highlight the importance of addressing body composition changes in children with T1DM to mitigate long-term cardiovascular and skeletal health risks. Future studies with longer follow-up periods are needed to better understand the long-term effects of insulin therapy on body composition in children with T1DM, particularly in the Indian population.

Unilateral ptosis in a patient with graves' disease and multiple sclerosis: a diagnostic challenge

Sarra Agoubi[1], Hajer Kandara[1], Sabbagh Ghada[1], Meriem Adel[1], Marwa Chiboub[1], Manel Jemel[1], Radhouen Gharbi[1] & Ines Kammoun[1]
[1]National Institute of Nutrition Tunisia, University of Tunis El Manar, Faculty of Medecine of Tunis, 1007, Tunisia., Endocrinology, Tunis, Tunisia

Introduction
Ptosis can indicate a variety of conditions, including neurological, muscular, or vascular disorders. In patients with autoimmune or inflammatory diseases, establishing a diagnosis can be challenging. We present the case of a sudden unilateral ptosis in a woman with Graves' disease (GD) and Multiple Sclerosis (MS).
Case Presentation
A 53-year-old woman, was being monitored for GD, (TSH $<$ 0.005 µUI/l, FT4: 28 pmol/l, mild bilateral Graves' orbitopathy without symptoms of activity, and positive TSH receptor antibodies) treated with methimazole. She had type 2 diabetes, hypertension, and MS. The patient presented with sudden onset of left eyelid ptosis over two months. Clinical examination revealed ptosis with exotropia of the left eye, suggesting oculomotor nerve (III) palsy, without pupillary involvement. Other cranial nerves were intact, except for the known left abducens nerve palsy (VI). The right eye showed a subconjunctival haemorrhage, with no other abnormalities. Laboratory tests showed a slightly low TSH (0.09 µUI/l) with a normal FT4 level (16.9 pmol/l). Other biological parameters were within normal limits. A cerebral CT angiography ruled out aneurysm or carotid dissection.
Discussion
The ptosis in this patient presents a diagnostic challenge due to her multiple systemic conditions. Mechanical or traumatic origin was excluded based on imaging and patient history. MS could explain third cranial nerve involvement, but the gradual onset, lack of visual disturbances, and the absence of other typical symptoms make this less likely. Myogenic origin (myasthenia gravis), While autoimmunity is a risk factor, the sudden onset, non-fluctuating nature of the ptosis, and lack of worsening with exertion argue against this diagnosis. Vascular origin remains possible due to the patient's vascular risk factors, but the absence of an internal carotid aneurysm on angiography reduces this likelihood. Further investigations are planned, including brain MRI with MR angiography, anti-acetylcholine receptor, anti-MuSK antibody testing, and electromyography.
Conclusion
This case underscores the diagnostic complexity of ptosis in patients with multiple comorbidities. A multidisciplinary approach is essential to identify the underlying cause.

Microbiota profiling in diabetic foot infections at oran university hospital: a study from the endocrinology-diabetology department

Mohamed Samir Merad[1] & Houssam Baghous[1]
[1]Oran 1 Ahmed Ben Bella Medical University, Endocrinology and Diabetology departement -Larribere Clinic – University Hospital Dr Benzerdjeb, Oran, Algeria

Introduction
Foot infections in diabetic patients represent a critical turning point in the progression of the disease, significantly contributing to the development of diabetic foot disease. These infections are often characterised by a multitude of bacterial strains, which are frequently multi-resistant. Recognising the bacterial flora responsible for foot infection is crucial to ensure the effectiveness of antibiotic treatment. The aim of our study is to determine the microbial flora present in these lesions.
Materials and Methods
A retrospective descriptive analysis was carried out over a period of 2 years on a sample of 102 patients hospitalised for diabetic foot in the Endocrinology-Diabetology Department of Oran University Hospital. Based on the clinical manifestations seen, various sampling techniques were employed, including swab sampling, needle aspiration, tissue biopsies and curettage of the lesion.
Result
The results showed that 48 patients (47%) had overt foot infection, with an average age of 61 years. The average length of hospitalisation was 51 days. Bacteriological samples were positive in 43 cases (89.6%). Of these, gram-negative bacilli were found in 31 cases (72.1%), dominated by proteus mirabilis and vulgaris (11 cases) and Escherichia coli (7cases). There were four cases each of Serratia marcescens and Enterobacter, three cases each of Klebsiella pneumoniae and oxytoca, and two cases of Pseudomonas. Regarding Gram-positive cocci, 12 cases were identified, including Streptococcus species (8 cases) and Staphylococcus aureus (4 cases). The patients received targeted antibiotic therapy based on the antibiogram results, along with additional treatment to cover anaerobic pathogens. Osteitis was diagnosed in 34 patients, representing 71% of the cases. Complications led to minor amputations in 15 patients (31.3% of cases) and major amputations in 7 patients (14.6% of cases). The remaining patients experienced a positive clinical outcome.
Conclusion
A comprehensive understanding of the microbiology of diabetic foot infection is essential. It plays a key role in guiding the selection of targeted antibiotic therapy and contributes to optimizing the overall management of this condition.

Beliefs and eating habits in pregnant diabetic women

Meryem Chakir[1], Bensbaa Salma[1], Nassim Essabah Haraj[1], Siham El Aziz[1] & Asma Chadli[1]
[1]UHC Ibn Rochd, Casablanca, Morocco

Introduction
The pregnant woman with diabetes may face overeating and a reduction in physical activity, two factors responsible for glycemic imbalance. The objective of this study is to evaluate the eating behaviors and beliefs of pregnant women with diabetes in order to improve their management.
Materials and Methods
A prospective descriptive study conducted at the Endocrinology and Metabolic Diseases department of Ibn Rochd University Hospital in Casablanca, involving

patients followed for gestational diabetes who completed a questionnaire to assess their eating beliefs.
Results
We included 64 patients in our study, with an average age of 32.3 years, 47.1% had gestational diabetes and 52.9% had type 1 or type 2 diabetes. The average BMI before pregnancy was 29.8 kg/m^2. Regarding treatment, 74.3% of patients were on insulin and 25.7% followed hygiene-dietary rules. Glycemic control was perfect in 61.2% of patients. Regarding eating behavior, 72.4% of patients had an excessive intake of slow sugars, 62.8% had an excessive intake of fats, and 36.4% consumed rapid sugars, 70.8% ate at fixed times, while 20% skipped at least one meal. Regarding food beliefs, 68% of patients think they should eat less to be healthy, 30% think they can eat the foods they want, 45% think they must eat for two, and 34% think weight gain should not be limited. Regarding physical activity, 28.4% of patients practiced it, with 75.2% believing it helps control blood sugar levels, while 22% think it could harm their pregnancy.
Conclusion
Our study highlights the eating beliefs and behaviors of pregnant women with diabetes and emphasizes the need for better information and improved dietary education for these patients.

Gestational diabetes: clinical profile, screening methods, and management approach

Meryem Chakir[1], Bensbaa Salma[1], Nassim Essabah Haraj[1], Siham El Aziz[1] & Asma Chadli[1]
[1]UHC Ibn Rochd, Casablanca, Morocco

Introduction
Gestational diabetes represents a public health issue due to its increased frequency, which has significantly risen since the revision of its diagnostic criteria, as well as its impact on both maternal and fetal health.
Objective
The objective of this study is to identify the clinical profile, screening methods, and management approaches for gestational diabetes.
Materials and Methods
A retrospective descriptive study conducted in the Endocrinology and Metabolic Diseases Department of Ibn Rochd University Hospital – Casablanca, among patients monitored for gestational diabetes.
Results
We included 227 patients in our study, all followed for gestational diabetes, with an incidence of 30% of diabetic pregnancies. The average age was 33.1 years, the average gravidity was 2.9, while the average parity was 2.08. The average BMI before pregnancy was 29.6 kg/m^2. Screening for gestational diabetes was conducted in the presence of overweight or obesity in 48.8% of patients, a personal history of macrosomia in 12.3% of cases, and a family history of diabetes in 29.5% of cases. Screening for gestational diabetes was carried out through fasting blood glucose in 73% of patients and the oral glucose tolerance test in 17%. The average gestational age at diagnosis was 22.5 weeks. Regarding management, 66.6% of patients were following hygiene-dietary rules, and 33.4% were on intensified insulin therapy with biweekly consultations. Glycemic control was perfect in 53.3% of patients. As for obstetric complications observed: 14.6% had gestational hypertension, 16.7% had macrosomia, 7.2% had a risk of preterm birth, and 4.3% had malformations.
Conclusion
The results of our work highlight the need to improve the screening of gestational diabetes and the management of patients diagnosed with gestational diabetes.

Educational factors and their impact on metabolic management in diabetic patients

Víctor Siles-Guerrero[1], Rosa Natalia GARCÍA PÉREZ[1], Juan Manuel Guardia-Baena[1], Pablo Rodríguez-Vera[2] & Martín López de la Torre-Casares[1]
[1]Hospital Universitario Virgen de las Nieves, Granada, Spain; [2]Hospital Universitario Virgen Macarena, Sevilla, Spain

Introduction
Diabetes management requires active patient participation, including adherence to treatment regimens, dietary modifications, and glucose monitoring. Several sociodemographic factors, including educational attainment, may influence a patient's ability to manage their condition effectively. Patients with lower educational levels may have reduced access to health information, lower health literacy, and greater difficulties in implementing diabetes self-management strategies. Severe hypoglycemia, a life-threatening complication requiring external assistance, can result from inadequate metabolic control, medication mismanagement, or unrecognized hypoglycemia symptoms. Understanding the relationship between education and metabolic management is crucial. This study investigates whether educational attainment is associated with an increased risk of severe hypoglycemia.
Objective
To evaluate the impact of educational level on the frequency of severe hypoglycemia in diabetic patients and explore whether lower education levels are linked to an increased risk of poor glycemic control and hypoglycemic events.
Methods
A retrospective analysis was conducted on a cohort of 66 patients diagnosed with diabetes. Data were collected on their highest level of education and history of severe hypoglycemia. Patients were stratified into different educational groups, ranging from no formal education to higher education. Statistical analyses, including non-parametric tests, were performed to compare the frequency of severe hypoglycemia among groups and determine whether educational level influenced diabetes self-management.
Results
Patients with lower educational attainment exhibited a higher frequency of severe hypoglycemic episodes than those with higher education levels. Although the difference did not reach statistical significance ($P = 0.07$), a clear trend was observed, suggesting that lower education levels may be associated with an increased risk of severe hypoglycemia. Additionally, these patients demonstrated a higher likelihood of incorrect insulin administration, lack of adherence to glucose monitoring recommendations, and limited awareness of hypoglycemia symptoms. These findings suggest that health literacy plays a key role in diabetes self-management and metabolic stability.
Conclusions
Educational background appears to influence diabetes management, with lower education levels potentially predisposing patients to severe hypoglycemic episodes. These results highlight the need for tailored educational interventions addressing varying literacy levels to improve self-care practices and enhance metabolic control. Structured diabetes education programs that simplify complex medical concepts and promote individualized learning strategies may help reduce the risk of severe hypoglycemia and improve overall patient outcomes. Future studies with larger sample sizes are needed to confirm these findings and guide targeted educational policies in diabetes care.

Do we consider cardiovascular risk in patients with type 1 diabetes mellitus? a cross-sectional observational study at the canary islands university hospital complex (CHUC)

Kevin David Díaz Gorrín[1,2], Óliver Quintero Rodríguez[1], Selena Rodriguez Fernandez[1], Javier Panizo Fra[1], Ana Paola León Ocando[1], Patricia León González[1], Jose Gregorio Oliva Garcia[2,3] & Judith Lopez[1,2]
[1]Complejo Hospitalario Universitario de Canarias (CHUC), Servicio de Endocrinología y Nutrición, La Laguna, Spain; [2]Universidad de La Laguna (ULL), La Laguna, Spain; [3]Complejo Hospitalario Nuestra Señora de Candelaria (CHUNSC), Santa Cruz de Tenerife, Spain

Introduction
Type 1 diabetes mellitus (T1DM) is a chronic metabolic disease with a high cardiovascular risk (CVR). In addition to maintaining good glycemic control, it is essential to manage other CVR factors to reduce the risk of chronic microvascular and macrovascular complications.
Objectives
- To determine whether patients followed up in Endocrinology consultations at CHUC have LDL levels within the target range according to their CVR group and whether they have been prescribed statins.
- To collect descriptive data on the population (age, sex, and years since T1DM diagnosis).

Materials and Methods
A cross-sectional descriptive study was conducted on 89 patients followed up in outpatient Endocrinology consultations at the Canary Islands University Hospital Complex (CHUC). The latest consultation and laboratory results of a sample of patients who attended consultations between January and May 2024 were analyzed.
Results
- The study population had a mean age of 40.87 years, with 52.8% being women and 47.2% men, and a T1DM duration of 22.4 $\pm$ 1.2 years.

- According to European guidelines, CVR stratification was as follows: very high in 61.8%, high in 25.8%, and moderate in 12.4% of patients.
- The LDL levels recorded in the latest laboratory tests were: <55 mg/dL in 4.5%, 55-69 mg/dL in 12.4%, 70-99 mg/dL in 30.3%, 100-115 mg/dL in 19.1%, and $>$ 115 mg/dL in 33.7% of patients.
- The percentage of patients within the target LDL range according to their CVR group was: 5.4% in the very high-risk group, 17.39% in the high-risk group, and 36.36% in the moderate-risk group.
- Only 32.6% of the study population had been prescribed a statin.

Conclusions

- In most cases, patients' LDL levels were not within the target range for their CVR group.
- We propose recording the patient's CVR group in their medical history and addressing lipid-lowering treatment as part of the comprehensive metabolic management of patients with T1DM.

Diabetic retinopathy in hospitalized patients: a multicenter tunisian study

Mohamed Khairi Arous[1], Houcem Elomma Mrabet[2], Mouna Mnif[1], Nada Hassairi[2], Mariem Ayedi[1], Fatma Mnif[1], Zantour Baha[2], Sfar Mohamed Habib[2], Alaya Wafa[2] & Nabila Rekik Majdoub[1]
[1]Hedi Chaker University Hospital, Department of Endocrinology, Sfax, Tunisia; [2]University Hospital Tahar Sfar, Department of Endocrinology, Mahdia, Tunisia

Introduction

Diabetic retinopathy (DR) is a major microvascular complication of diabetes and is currently the leading cause of acquired blindness in many countries. In Tunisia, its prevalence remains poorly documented. This study aims to determine the prevalence and profile of DR in hospitalized diabetic patients.

Patients and Methods

We conducted a descriptive cross-sectional study between February and March 2024 in three Tunisian university hospitals: Hedi Chaker and Habib Bourguiba University Hospitals in Sfax, and Taher Sfar University Hospital in Mahdia. The study included diabetic patients hospitalized in departments other than endocrinology and ophthalmology. Data collected included the history of DR and the results of any available fundus examinations.

Results

Among the 315 patients included, 65% were men, with a median age of 65 years and a median diabetes duration of 8 years. Most patients (87%) had type 2 diabetes, while 5.4% ($n = 17$) had newly diagnosed diabetes during hospitalization. DR was present in 26.5% ($n = 79$) of patients at the time of admission. Notably, 41.9% ($n = 125$) of previously known diabetic patients without a history of DR had not undergone a fundus examination for more than a year.

Conclusion

The prevalence of DR observed in this study is lower than that reported in other international studies, such as one conducted in the United States, where it reached 44% among hospitalized patients. This discrepancy may be attributed to the lack of systematic screening in our cohort, potentially underestimating the true prevalence. Screening for DR in hospitalized diabetic patients is crucial, regardless of the reason for admission, as acute diabetes complications, such as hypoglycemia, frequently occurring in hospital settings, can exacerbate DR through adrenergic discharge and activation of growth factors. This study emphasizes the urgent need to integrate ophthalmological screening into the care protocols for hospitalized diabetic patients.

An atypical presentation of malignant otitis externa in a diabetic patient

Malika El Omri[1], Nawress Thabet[2], Mouna Belakhdher[1], Jihene Houas[1], Abir Meherzi[1], Monia Ghammam[1], Hamza Elfekih[3], Wassim Kermani[1] & Mohamed Abdelkafi[1]
[1]Farhat Hached Hospital, Department of ENT and Head and Neck Surgery, Sousse, Tunisia; [2]Farhat Hached University Hospital, ENT Department, Sousse, Tunisia; [3]Farhat Hached Hospital, Department of Endocrinology, Sousse, Tunisia

Background

External malignant otitis (EMO) is a severe infection often seen in immunocompromised patients, particularly those with diabetes mellitus. Atypical presentations can delay diagnosis and treatment.

Case Presentation

It is about a 62-year-old male with a history of type 2 diabetes who presented with a right earache and hypoacusis evolving for 3months, followed by facial asymmetry that developed 10 days before consultation. Physical examination revealed a Grade III right facial palsy (House and Brackmann classification) and normal otoscopy findings, including a well-calibrated external auditory canal, absence of otorrhea, and intact tympanic membrane. Imaging studies, including CT and MRI of the temporal bone, indicated chronic otomastoiditis with involvement of the second segment of the facial nerve. Initial treatment with corticosteroids and antivirals resulted in complete resolution of facial palsy. Two months later, the patient re-presented with right earache and itching. Otoscopy revealed a stenotic external auditory canal with otorrhea. Microbiological analysis of pus samples identified *Aspergillus flavus*. The patient was treated with voriconazole for six months, leading to a remarkable clinical response.

Conclusion

This case highlights the importance of considering fungal infections in atypical presentations of external malignant otitis in diabetic patients, especially when initial findings are unremarkable. Early recognition and targeted antifungal therapy are crucial for successful management.

Kaposi sarcoma manifesting as leg lesions in a patient with diabetes mellitus: a case report

Nada Hassairi[1], Kouloud Boujelben[1], Mouna Elleuch[1], Yesmine Elloumi[1], Mouna Mnif[1], Nadia Charfi[1], Faten Haj Kacem Akid[1], Mohamed Abid[1], Dhoha Ben Salah[1] & Nabila Rekik Majdoub[1]
[1]Hedi Chaker University Hospital, Endocrinology Department, Sfax, Tunisia

Introduction

Kaposi's sarcoma can be defined as a mesenchymal proliferative process involving cells of the blood and lymphatic system, caused by human herpes virus type 8. Diabetic patients are generally prone to pathogenic infections and tumor involvement.

Case Report

Herein, we report the case of Kaposi sarcoma in a Tunisian 52-year-old female with type 2 diabetes progressing for 10 years and managed with insulin therapy, at the stage of chronic macroangiopathic and microangiopathic complications. The current history dates back a few months, when the patient presented to our department with multiple raised violaceous flat patches located on both lower legs. Deep and superficial sensations were preserved and pulses were palpable. The X-ray of legs was unremarkable. A skin biopsy was performed and the immunohistochemical study had shown tumor cells expressing human herpes virus type 8 and CD34. Kaposi's sarcoma associated virus was retained. The etiological investigation of an associated opportunistic infection was negative. There was no evidence of internal organ involvement on whole –body CT scan. Then, the patient underwent treatment with topical alitretinoin 0.1% gel by dermatology. Lesions were remarkably ameliorated. Adjuvant radiotherapy was proposed but refused by the patient.

Conclusion

Our case illustrates the potential association between diabetes and Kaposi's sarcoma and emphasizes the importance of clinical examination in the detection of tumor lesions in diabetics. Rigidly control glucose levels were required allowing for long-term remission and reduction of complications.

Co-occurrence of Ketoacidosis Decompensation and Acute Pancreatitis in Type 1 Diabetic Patients: Clinical and Biological Specificities

Dhoha Ben Salah[1], Nada Hassairi[1], Kouloud Boujelben[1], Oumaima Dimassi[1], Faten Haj Kacem Akid[1], Nadia Charfi[1], Mouna Mnif[1], Mohamed Abid[1], Mouna Elleuch[1] & Nabila Rekik Majdoub[1]
[1]Hedi Chaker University Hospital, Endocrinology Department, Sfax, Tunisia

Objective
To describe the clinical and biological presentation characterizing the simultaneous occurrence of acute pancreatitis (AP) and diabetic ketoacidosis (DKA) in type 1 diabetes (T1D).
Patients and Methods
A retrospective descriptive study including 10 T1D patients who presented with a simultaneous episode of DKA and AP.
Results
The average age at T1D diagnosis was 19.7 ± 9.3 years, with a female predominance (60%). T1D was frequently first diagnosed through classic cardinal symptoms (50%) or spontaneous DKA (20%). In 10% of cases, T1D was diagnosed during an AP episode, classified as stage E in 57.1% of cases. The mixed AP-DKA episode occurred at an average age of 26.9 ± 14.9 years. A febrile presentation was frequently reported (30%), along with general state impairment (20%) and severe dehydration (10%). Respiratory and neurological symptoms were present in 20% of cases. Gastrointestinal symptoms were pronounced, particularly epigastric pain (90%), vomiting (50%), and diarrhea (20%). Urinary ketones were markedly elevated in 50% of cases, with an average blood glucose level of 3.2 ± 1.4 g/l. Metabolic acidosis was present in all cases, with mean pH and bicarbonate values of 7 ± 0.3 and 12.3 ± 8.3, respectively. Functional renal failure complicated 10% of cases. An infectious syndrome was observed in 40% of cases, with an average CRP level of 47 ± 72.9 mg/l. All patients showed favorable outcomes after appropriate resuscitation, with insulin requirements estimated at 0.76 ± 0.3 IU/kg/day.
Discussion
The co-occurrence of DKA and AP in T1D is a relatively rare but potentially severe event due to the reciprocal deleterious effects of both conditions. The prognosis of this mixed emergency depends on early diagnosis and prompt resuscitation.

Asymptomatic hyperuricemia: prevalence and risks

Siwar Saoudi[1], Ramla Mizouri[1], Rym Ben Othman[1], Hadhemi Belhassen[1], Faten Mahjoub[1], Berriche Olfa[1], Nadia Ben Amor[1] & Jamoussi Henda[1]
[1]Institute of Nutrition of Tunis, Tunis, Tunisia

Introduction
Hyperuricemia is a disease, that excess uric acid can lead to precipitation of uric acid into urate crystals. Asymptomatic hyperuricemia is defined as a biological abnormality characterized by elevated blood uric acid levels with no clinical manifestations.
Methods
It was a descriptive cross sectional study conducted in department A of the institute of Nutrition of Tunis which included patients with type 2 diabetes. Hyperuricemia was defined by a uric acid level that exceed 360mg/l.
Results
The total number of patients who participated in the study was 120. The characteristics of the patients were respectively : age 47 ± 9 years, Body mass index (BMI) 29 ± 4.2 Kg/m^2, HbA1c 10.8 ± 2.4%. The mean duration of diabetic patients was 11 ± 7years. Hyperuricemia was present in 34.8%, with a mean level of 411 ± 19.6 mg/l. Twenty two percent have asymptomatic hyperuricemia : 78% of patients have arterial hypertension, 64.1% with microangiopatic complications, 21% with a history of stroke, 22.5% with coronary disease, 67% with arteriopathy. As for the metabolic profile of patients with asymptomatic hyperuricemia, 98% with low HDLc, high LDLc in 79.7%, high triglycerides in 66.4 %. Asymtomatic hyperuricemia was positively correlated with BMI(p = 0.001) and duration of diabetes (p = 0.009) and it was significantly more frequent with coronary disease (p = 0.01) and with dyslipidemic patients (p = 0.007).
Conclusion
Asymptomatic hyperuricemia is common in our population. It is equivalent to symptomatic hyperuricemia in terms of complications and aggravation of comorbidity. It was positively correlated with BMI, duration of diabetes, coronary disease and dyslipidemia.

Association of type 1 diabetes and celiac disease

Siwar Saoudi[1], Olfa Lajili[1], Chaima Jemai[1,2], Hadhemi Belhassen[1], Zohra Hadj Ali[1], Hedfi Imene[1], Yosra Htira[1] & Feika Ben Mami[1]
[1]Institute of Nutrition of Tunis, Tunis, Tunisia; [2]Institute of Nutrition, Tunis, Tunisia

Objective
Type 1 diabetes (T1DM) and celiac disease (CD) are autoimmune inflammatory diseases caused by the interaction of genetic and environmental factors. The aim of this study was to determine the prevalence and characteristics of CD in type 1 diabetic patients.
Methods
We conducted a cross-sectional study of 80 type 1 diabetic patients followed up in ward C of the Tunis Institute of Nutrition. Patients were divided into two groups: Group 1 (G1):40 T1DM patients with negative CD serology and Group 2 (G2): 40 type 1 diabetics with positive CD serology.
Results
The mean age of our population was 28 ± 8 years. The mean duration of diabetes was 9 ± 5.6 years. Among G2 patients, 13 had positive Ig A anti-transglutaminase autoantibodies and 30 patients underwent jejunal biopsy with histological confirmation of CD (37.5% of patients). Diabetes imbalance, as evidenced by elevated HbA1c, was associated with the presence of CD (G1: 10.4 ± 3.1%, G2: 11.9 ± 2.1%; P = 0.001). Hypoglycemia was more frequent in patients with CD (G2 of 3.1 episodes/patient/week, G1:1.7 episodes/patient/week, P = 0.01).
Conclusion
The association of CD and T1DM is frequent and exposes this population to diagnostic, therapeutic and psychological difficulties. Appropriate therapeutic education is imperative to preserve the prognosis of these patients.

JOINT1654

A complex case of Type 1 DM with history of recurrent severe disabling hypoglycaemia treated with renal and pancreatic transplant

Mohammad Salah Uddin[1], Fathi Abourawi[1] & Yasmeen Khalid[1]
[1]Northern lincolnshire and goole hospitals nhs trust, Grimsby, United Kingdom

Hypoglycemia is a common complication in patients with diabetes, particularly in those treated with insulin, sulfonylurea, or glinide. Impairments in counter regulatory responses and hypoglycemia unawareness constitute the main risk factors for severe hypoglycemia. Episodes of hypoglycemia are associated with physical and psychological morbidity, particularly those with pre-existing mental health issues or learning disabilities. Here, we describe a case of 37 years old male, with Type 1 DM, with ESRD on hemodialysis, diabetic proliferative retinopathy, Charcot neuroarthropathy, and diabetic foot. He had repeated episodes of hospital admissions with a history of severe disabling hypoglycemia. He was only on a few units of insulin Tresiba and novorapid to control his blood sugar. Any minor adjustment of insulin doses caused him severe hypoglycemia particularly on the day of hemodialysis. Blood sugar in hospital was between 1.3 to >27.5 mmol/l. We had a multidisciplinary discussion to start HCL insulin pump but as he is having learning disabilities, it was not considered later. Furthermore, reductions of insulin dose to prevent hypoglycemia caused him to develop episodes of DKA. Personally, he is non-smoker and non-alcoholic with no history of taking any illicit drugs. Physical examination was unremarkable except for having features of chronic diabetic Charcot neuroarthropathy. His insulin injections sites were normal. His observations, including NEWS, were stable in between episodes of hypoglycemia. His investigations including blood test showed creatinine about 500umol/l (baseline) after dialysis with normal liver function test. His HBA1c was between 57 and 73 mmol/mol with C peptide level was <50 pmol/l. Then we consulted with tertiary Centre for consideration of renal and pancreatic transplant for him. After discussion of his thorough case history with tertiary Centre, it was decided to proceed for renal and pancreas transplantation for him. He recovered well after the surgery. His diabetes is now on the way to remission after about 3 months of the pancreatic and renal transplant. Recent blood sugar readings in libre sensor showed his target in range of blood sugar was 99% without having any episodes of hypoglycemia with GMI was 43mmol/mol off insulin therapy. This case highlights the importance of involving multidisciplinary teams including diabetologist, DSN, dietitian, transplant surgeon, psychiatrists, and nephrologist for coordinated effort in complex cases of hypoglycemia especially in type 1 DM patients. Those Patients who are not suitable for insulin therapy, considering pancreatic/pancreatic and renal transplants can be life-changing, especially those who are young and fit for surgery.

JOINT2318

Refocusing on the implications for management: a case of hyporeninemic hypoaldosteronism in a patient with diabetic nephropathy presenting with severe hyperkalemia

Carlo Casipit[1] & Bruce Casipit[1]
[1]Jefferson-Einstein Hospital, Philadelphia, United States

Background
Diabetic nephropathy (DN) is the most common cause of Hyporeninemic Hypoaldosteronism (HH), which often presents as hyperkalemia. Most of these patients are on Renin-Angiotensin-Aldosterone inhibitors (RAASi) to slow the progression of kidney disease. However, these medications can cause hyperkalemia as a side effect, which can complicate the disease management.
Case presentation
A 65-year-old female with Hypertension and Type 2 Diabetes Mellitus, currently on Lisinopril and Metformin, was brought from the clinic for elevated potassium levels. She denied chest pain, dyspnea, oliguria, or peripheral edema. No family history of hyperkalemia. Vital signs were normal. Physical examination was unremarkable. Laboratory tests showed Potassium 8 mEq/l without EKG changes, Sodium 131mEq/l, Creatinine 1.4 mg/dL (baseline 1.3 mg/dL), urine Protein/Creatinine ratio 4.5 g/g (ref $<$3.5 g/g), HbA1c 13%. Lisinopril was temporarily held, and the patient received calcium gluconate, and dextrose with insulin but remained hyperkalemic. The nephrology team suggested emergent hemodialysis (HD). Because of unexplained hyperkalemia, hormonal testing was added which showed Cortisol 20 mg/dL (ref 5-25 mg/dL), plasma Renin activity 0.4 ng/mL/hr (ref 0.7-3.3 ng/mL/hr), Aldosterone 2 mg/d (ref 3-25 mg/d). After one session of HD, repeat potassium was 3.9mEq/l. She was restarted at a lower dose of lisinopril with daily electrolyte monitoring and her glucose regimen was optimized. She was subsequently discharged with strict outpatient follow-up.
Discussion
DN causes autonomic dysfunction, resulting in decreased renal sensitivity to renin stimulation factors, causing HH and hyperkalemia. RAASi are effective in preventing progression to end-stage kidney disease but are a known cause of hyperkalemia. Withdrawing RAASi based on a diagnosis of HH alone may deprive patients of the cardiorenal benefits of these medications. Therefore, initiation of low-dose RAASi with gradual titration combined with a low potassium diet and avoidance of nephrotoxic medications can be done with close outpatient monitoring. However, the best treatment remains to be the optimization of glucose control.
Conclusion
HH is a complication of DN, and the optimization of glucose control plays a central role in the management. In addition, RAASi are effective means of slowing disease progression, and the benefits of continuing RAASi in patients who develop correctable side effects outweigh the risks, provided that proper patient education with close monitoring of laboratory tests and follow-up can be done.

Newly diagnosed LADA in elderly people: a case study

Bella Voloshin[1]
[1]Maccabi Healthcare Servicies, Holon, Israel, The Israel Academic College in Ramat Gan, Israel, Nurse Practitioner Diabetes, Ramat-Gan, Israel

Aims and objectives.
To provide a report of an 88- year-old woman who treated for 29 years as T2DM but lately was diagnosed with LADA.
Background
Latent autoimmune diabetes in adults (LADA) is the most common term used to describe slow autoimmune β-cell destruction that occur in adults, leading to a long duration of marginal insulin secretory capacity. LADA often misdiagnosed as type 2 diabetes mellitus (T2DM), because of the resemblance in their clinical presentation. The diagnosis of LADA is similar to type 1 diabetes mellitus (T1DM), by detection of Islet autoantibodies in the blood. However, in most cases of patients with LADA are only glutamic acid decarboxylases (GADA) - positive. Currently, the Immunology of Diabetes Society (IDS) suggests diagnosing LADA at age of onset $\geq$ 30 years. While the threshold age for diagnosis LADA is still a matter of debate.
Design
Case study of one patient with uncontrolled T2DM, visiting a nurse practitioner diabetes Clinic.
Methods
A 88 -year-old Woman with history of T2DM participated in this case study. A full investigation was conducted and described by nurse practitioner diabetes to identifying a misdiagnosis.
Results
A patient treated for 29 years as T2DM was found with positive GADA (1869.6 IU/ml). Due to the newly results the patient was re-diagnosed with LADA and a change in treatment regime performed.
Conclusion
This Case highlights the complexity of investigation LADA among T2DM patients, and the importance to perform it among elderly patient as well. The key components for investigation LADA include: profound anamnesis, GADA testing and C-peptide levels. Relevance to clinical practice. The importance of role of Nurse practitioner diabetes in primary health care setting for a thorough diagnosis among uncontrolled glycemic patients revealing hidden types of this complex disease.

Epidemiological, clinical, and therapeutic profiles of pre-existing diabetes in pregnancy: exploring complications in a moroccan cohort

Mohammed Amine Essafi[1], Zineb El Azime[1], Hayat Aynaou[1] & Houda Salhi[1]
[1]Department of Endocrinology, Diabetology, Metabolic Diseases and Nutrition. Hassan II University Hospital Center, Fez, Morocco

Introduction
In Morocco, pre-existing diabetes during pregnancy is a serious public health concern. In addition to placing a significant socioeconomic burden on patients, it is associated with an increased risk of complications.
Objective
Examining the epidemiological, clinical, and therapeutic aspects of pre-existing diabetes during pregnancy is the aim of our research. We also want to evaluate maternal-fetal morbidity and mortality, neonatal outcomes, and pregnancy progression.
Materials and Methods
A retrospective, descriptive study based on a review of clinical records of pregnant women with type 1 and type 2 diabetes, monitored at the Endocrinology, Diabetology, and Metabolic Diseases Department of the Hassan II University Hospital in Fez over a 13-year period, from January 2009 to September 2022.
Results
319 women with pre-existing diabetes were included, of these, 24.1% had type 1 diabetes and 75.9% had type 2 diabetes. The average age of type 2 diabetes was 36.4 $\pm$ 5.45 years. The duration of diabetes was 43 $\pm$ 10.86 months on average. 5.8% of cases had degenerative consequences. The average pre-pregnancy HbA1c was 8.2% $\pm$ 2.6%, and 97.9% of pregnancies were unplanned. The average age of type 1 diabetes was 29.7 $\pm$ 6.29 years. 106 $\pm$ 62 months was the average duration of diabetes. 93.5% of pregnancies were unplanned, with an average pre-pregnancy HbA1c of 8.2% $\pm$ 3.1%. Insulin was used. In the first, second, and third trimesters, the average daily insulin dosage was 35.4 $\pm$ 2.9 IU, 39.9 $\pm$ 3.2 IU, and 47.9 $\pm$ 3.6 IU, respectively. Concerning maternal complications, among those with type 1 diabetes were urinary tract infections (12.3%), severe hypoglycemia (4.2%), ketoacidosis (13.3%), and gestational hypertension (7.8%). Urinary tract infections were the most common consequence among type 2 diabetes (15.5%), followed by ketoacidosis (2.8%). 58.3% of type 2 diabetes and 61.2% of type 1 diabetes had cesarean deliveries. Among the prenatal problems were hydramnios (29.8% vs. 30.1%), fetal abnormalities (9.4% vs. 6.7%), and macrosomia (37% in type 2 diabetics vs. 31.5% in type 1). 5.3% of cases had neonatal complications (4.4% in type 2 diabetics and 6.8% in type 1 diabetics). Of them, neonatal distress accounted for 29.2%, neonatal jaundice for 23.1%, and neonatal hypoglycemia for 20%.
Conclusion
Given these complications and their impact on both maternal and fetal health, whether in terms of vital or functional prognosis, we emphasize the need for a multidisciplinary approach.

Clinical profile of patients with nondiabetic hypoglycemia in a tertiary endocrine center in Nepal

Ansumali Joshi[1], Srijana Karmacharya[1], Puspa Dahal[1] & Indu Rana[1]
[1]Kathmandu Diabetes and Thyroid Center, Kathmandu, Nepal

Nondiabetic hypoglycemia is a challenging condition for diagnosis and management. We retrospectively reviewed the records of the patients diagnosed with nondiabetic hypoglycemia who visited our center from May 2013 to November 2024. Total 36 patients were included in this study. The mean age was 48.33 ± 14.30 years (range 19-75 years). 21(58.33%) patients were male and 15(41.67%) were female. The average weight was 70.27 ± 12.82 (range 47-100) kg and average BMI was 27.65 ± 4.84 (range18.6-37.3) kg/m2. All patients had symptoms of hypoglycemia with positive Whipple's triad. Weight gain was seen in 26(72.22%) patients.1 (2.77%) patient had a history of seizure and 3(8.33%) patients had loss of consciousness. The major cause of hypoglycemia was reactive hypoglycemia in 22 patients (61.11%) followed by hyperinsulinemic hypoglycemia in 7 patients (19.44%). Out of 7 hyperinsulinemic hypoglycemia patients, insulinoma was detected in 6 patients.1 (2.77%) patient had drug induced (carbimazole) hypoglycemia, 1(2.77%) patient had post bariatric surgery hypoglycemia and 1 (2.77%) patient had post gastrectomy (for gastric carcinoma) hypoglycemia. 2 (5.55%) patients had sarcoma-associated hypoglycemia (1 had retroperitoneal sarcoma and other Ewing sarcoma).1(2.77%) patient had purely alcohol induced hypoglycemia.1(2.77%) patient had hemodialysis induced hypoglycemia. In cases of hyperinsulinemic hypoglycemia, the average blood sugar level during hypoglycemia was 42.98 ± 11.0 mg/dl (range 29-57mg/dl), insulin level was 35.07± 53.82 mIU/l (range 5.28 - 156.2 mIU/l) and C peptide level was 4.47 ± 4.24 ng/ml(range 0.6-13.5 ng/ml). In a 72 hour fast, 2 patients had hypoglycemia within 6 hours, 2 patients within 12 hours, 1 patient within 24 hours, 1 patient within 48 hours and 1 patient within 72 hours. All reactive hypoglycemia patients were diagnosed by extended oral glucose tolerance test. Comorbidities like prediabetes were present in 10 patients, diabetes in 3 patients, hypothyroidism in 15 patients, 7 patients had chronic cardiovascular disease, 1 patient had CKD and 1 patient had OSA. Out of 6 patients with insulinoma, 5 patients had tumour located in tail of pancreas and 1 patient had in uncinate process of pancreas. The maximum size of insulinoma was 14.4 mm and the minimum was 1 mm. Enucleation was done in 4 cases of insulinoma and 1 patient underwent distal pancreatectomy. 5 insulinoma cases were cured after surgery. One case of insulinoma was lost to follow up. Out of 22 cases of reactive hypoglycemia, acarbose was used in 15 patients and the rest were managed by dietary modifications.

Planned postpartum screening study for cardiometabolic and renal outcomes in women diagnosed with gestational diabetes mellitus in Auckland, new Zealand

Jessica Brosnahan[1], Catherine Bacon[1], Julia Slark[1] & Barbara Daly[1]
[1]University of Auckland, Faculty of Medical and Health Sciences, Auckland, New Zealand

Background
The prevalence of gestational diabetes mellitus (GDM) in New Zealand has increased from 1.4% in 1991 to 6.2% in 2019, comparable to an estimated 7.8% in Europe in 2021, though lower than rates up to 27% reported in Asian and African. National rates of GDM are significantly higher for Māori (12%) compared to European women (around 7%). After GDM, there is up to a 20-fold increased risk of developing diabetes, and an increased age-adjusted risk of major cardiovascular (CV) events and renal disease compared to women who remain normoglycemic during pregnancy. There are few reports on post-partum screening for women diagnosed with GDM in NZ and internationally. One national study reported low post-partum screening rates for type 2 diabetes for women with GDM (56%) and unacceptably low rates for Māori women (38%), which also varied by maternal age, deprivation and region. No recommendations have been identified for screening of CV risk factors (blood pressure, lipids, smoking status) or renal disease in NZ. A large, representative United Kingdom study reported 80% of women were screened for hypertension in the first year post-partum (declining to 48% by the third year), 58% for diabetes, and only 46% and 11% for smoking status and lipids, respectively.
Aim
To identify factors associated with post-partum screening in women with GDM to increase screening and risk management, particularly for Māori and Pacific women.
Methods
Anonymised medical information will be obtained for women diagnosed with GDM in Auckland from a primary health-care provider, covering approximately 50% of the Auckland population, to identify factors associated with post-partum screening for cardiometabolic and renal disease. Approximately 250 of the total women will be randomly selected and complete a self-administered questionnaire and telephone interview to identify facilitators and barriers to screening. Comparisons will be made between women who complete screening and those who do not, utilising chi-square or t-tests for demographic and health-related variables, Cox proportional hazard ratios for calculating time-to-first cardiometabolic events, Kaplan-Meier to generate outcome (survival) curves and logistic regression to generate odds ratios for health outcomes.
Results
Initial results for the total cohort will be presented if available. Findings are expected to translate across diverse populations, identify solutions to increase post-partum screening and improve risk management and health outcomes for at-risk women.

JOINT1205

Time in tight range (TITR) stratified by coefficient of variation (CV) in a cohort of patients with type 1 diabetes mellitus and multiple daily injections. a real-life study

Sandra Herranz-Antolín[1], Sofía Ramos-Garrido[1], Verónica Esteban-Monge[1], Clara Cotón-Batres[1], María Covadonga López-Virgos[1], Marta Cano Megias[1] & Miguel Torralba[1]
[1]Hospital Universitario de Guadalajara, Guadalajara, Spain

Objetive
To analyze the TITR (70-140 mg/dL) and assess their possible differences according to CV in a cohort of type 1 DM patient with MDI.
Patients and Methods
355 adult users of isCGM with at least a HbA1c during the period October 1, 2023-October 1, 2024, and glucose data in the 90 days prior (or at least 60 days) were included.
Results
Age 46.9 years (SD 13.6); 57.2% male; age at diagnosis 25.6 years (SD 14.3); time of evolution 21.6 years (SD 12.6); HbA1c 7.2% (SD 1.1). Glucometric parameters: glucose 165.9 mg/dL (SD 31.5), TITR 38.4% (20.3% had a TITR ≥ 50%), TIR (70-180 mg/dL) 60.4% (SD 16.5), TBR1 (54-69 mg/dL) 3.3% (SD 2.8), TBR2 (< 54 mg/dL) 0.5% (SD 0.8), TAR1 (181-250 mg/dL) 23.3% (SD 8.4), TAR2 (> 250 mg/dL) 12.4% (SD 12.1), CV 37.1% (SD 6.2), GMI 7.3% (SD 0.8) and GRI 47.8% (SD 21).
Conclusions
The percentage of patients achieving TITR ≥ 50% is higher in patients with lower glycemic variability. The correlation TITR-TIR is high and modified by glycemic variability.

Table 1: Clinical characteristics and glucometric parameters according to the CV.

	CV ≤ 36% (n = 156)	CV > 36% (n = 199)	P
Age (years)	48.3 (SD 13.6)	45.9 (SD 13.5)	0.094
Gender (male) (%)	59.4	56.1	0.534
Age at diagnosis (years)	27.5 (SD 14.7)	24.1 (SD 13.8)	0.029
Time of evolution (years)	21.1 (SD 13.5)	21.9 (SD 11.9)	0.482
Mean glucose (mg/dL)	151.4 (SD 35.1)	169.4 (SD 27.4)	0.022
TITR (%)	40.8 (SD 16.4)	36.4 (SD 10.4)	0.008
TITR ≥ 50% (%)	31.4	11.6	< 0.001
TIR (%)	65.5 (SD 19.8)	56.5 (SD 12.1)	< 0.001
TBR1 (%)	1.9 (SD 2.4)	4.4 (SD 2.6)	< 0.001
TBR2 (%)	0.2 (SD 0.4)	0.8 (SD 0.9)	< 0.001
TAR1 (%)	23.1 (SD 11.1)	23.5 (SD 5.7)	0.667
TAR2 (%)	9.3 (SD 13.3)	14.8 (SD 10.4)	< 0.001
CV (%)	31.5 (SD 3.3)	41.5 (SD 4.1)	< 0.001

Characteristics of diabetic ketoacidosis episodes treated at HUC between 2021 and 2023

Óliver Quintero Rodríguez[1], Selena Rodriguez Fernandez[1], Kevin David Díaz Gorrín[1], Javier Panizo Fra[1], Ana Paola León Ocando[1], Laura Mesa Suárez[1], Elena Rodríguez Sosa[1], Patricia León González[1], Macarena Sánchez-Gallego Alonso[1] & Patricia Cabrera García[1]
[1]Hospital Universitario de Canarias, Endocrinology and Nutrition, San Cristóbal de La Laguna, Spain

Introduction and Objectives
Diabetic ketoacidosis (DKA) is one of the acute complications of diabetes mellitus. It is more common in patients with type 1 diabetes mellitus (T1DM), although cases have also been reported in patients with type 2 diabetes mellitus (T2DM) and latent autoimmune diabetes in adults (LADA). DKA can be triggered by poor adherence to treatment, new-onset diabetes, or secondary to an infection. The objective of this study is to describe the characteristics of DKA episodes attended at the Hospital Universitario de Canarias (HUC) between 2021 and 2023.
Materials and Methods
A descriptive observational study was conducted on a sample of 41 DKA episodes evaluated by the Endocrinology and Nutrition Department of HUC between 2021 and 2023. Variables analyzed included age, sex, type of diabetes, biochemical parameters (blood glucose, pH, ketonemia, bicarbonate), HbA1c, treatment, and associated comorbidities.
Results
Of the 41 patients, 23 (56%) were women and 18 (44%) were men, with a mean age of 34 years. A total of 28 patients (68%) had T1DM, including 4 newly diagnosed cases, while 8 patients (19%) had T2DM and 5 (13%) had LADA. Among the associated comorbidities, 29% had diabetic retinopathy, and 14% had diabetic nephropathy. The most frequent triggers of DKA were insulin omission and infections (30% each, totaling 60%), followed by undertreatment (17%, more common in T2DM patients), substance abuse (12%), and new-onset diabetes (10%). The average pH upon arrival was 7.11, with a mean blood glucose level of 390 mg/dL, a mean ketonemia of 4.8 mmol/l, and a mean bicarbonate level of 7.75 mmol/l. The mean HbA1c level measured before the event (in most cases, approximately 4 months prior) was 10.92%, while the mean HbA1c after the event was 11.71%. Regarding electrolyte imbalances, the most frequent was hyponatremia (48%), followed by hypokalemia (43%).
Conclusions
DKA has a mortality rate of $<5\%$, which is even lower in our country, likely due to the rapid clinical management facilitated by the availability of appropriate infrastructure and resources. Nevertheless, the incidence of DKA remains significant. The poor metabolic control reflected in the high HbA1c levels prior to the event may have been influenced by loss of follow-up and less strict monitoring secondary to the COVID-19 pandemic.

Association between diabetes mellitus and severity of epistaxis: a retrospective study

El Omri Malika[1], Hadil Ben Kahla[1], Misbah Linda[1], Souhir Chelly[2], Hamza Elfekih[3], Mouna Bellakhdhar[1] & Kermani Wassim[1]
[1]Farhat Hached University Hospital, Department of Ear, Nose, Throat and Head and Neck Surgery, Sousse, Tunisia; [2]University Hospital Centre Farhat Hached, Occupational Health Department, Sousse, Tunisia; [3]University Hospital of Farhat Hached, Department of Endocrinology and Diabetology, Sousse, Tunisia

Introduction
Epistaxis is a common condition encountered in otorhinolaryngology, generally benign, but it can occasionally present as a severe and life-threatening event. For patients with diabetes mellitus (DM), epistaxis may be a sign of underlying vascular complications. This study aims to evaluate the relationship between diabetes and the severity of epistaxis and its implications for management strategies.
Methods
A retrospective cross-sectional analytical study was conducted at the Department of Otolaryngology–Head and Neck Surgery of Farhat Hached University Hospital, encompassing patients consulting and/or admitted for epistaxis between January 2015 and December 2022.
Results
A total of 720 cases were analyzed. Of these, the majority (87.9%) were classified as benign and managed on an outpatient basis, while 12.1% of patients presented with severe epistaxis necessitating hospitalization. A significant prevalence of cardiovascular diseases was observed, including hypertension (32.9%), diabetes (12.8%) and dyslipidemia (6.9%). Other noteworthy medical conditions included chronic kidney disease ($n=19$; 2,6%) and haematological pathologies ($n=11$; 1,5%). Despite the prevalence of diabetes (12.8%), no statistically significant correlation was found between diabetes and the severity of epistaxis. Contrary to previous studies suggesting a direct association between DM and severe epistaxis, our findings suggest that diabetes may act as a predisposing factor by inducing vascular changes such as endothelial dysfunction and impaired hemostasis. Additionally, diabetes mellitus may contribute to atherosclerotic changes in the nasal vessels, increasing their fragility and susceptibility to bleeding. The coexistence of cardiovascular conditions, such as hypertension and dyslipidemia, which are frequently associated with diabetes, may further exacerbate the risk of epistaxis in this population.
Conclusion
Diabetes mellitus may increase the risk of epistaxis through its effects on vascular integrity, though its role in determining the severity of the condition remains uncertain. Further large-scale, prospective studies are needed to elucidate the underlying pathophysiological mechanisms and refine management strategies for diabetic patients presenting with epistaxis.

The role of chronic diabetic imbalance in increasing the risk of hepatic fibrosis

Ghachem Aycha[1], Imen Halloul[1], Nassim Ben Hadj Slama[2], Wiem Saafi[1], Ghada Saad[3] & Yosra Hasni[4]
[1]Farhat Hached University Hospital, Endocrinology - Diabetology Departement, Sousse, Tunisia; [2]Farhat Hached University Hospital, Endocrinology - Diabetology Departement, Sousse, Tunisia; [3]Farhat Hached University Hospital, Endocrinology - Diabetology Departement, Sousse, Tunisia; [4]Farhat Hached University Hospital, Endocrinology - Diabetology Departement, Sousse, Tunisia

Introduction
Non-alcoholic hepatic steatosis has become the leading cause of chronic liver disease in the world. Our aim was to assess the prevalence of hepatic fibrosis by Fibroscan in unbalanced type 2 diabetic (T2D) patients with no known liver disease.
Patients and methods
Prospective cross-sectional study including 30 T2D followed at the endocrinology department CHU Farhat-Hached. A Fibroscan and a hepatic work-up were performed. Patients with known chronic liver disease were excluded.
Results
The mean age was 52.9 ± 11.7 years, 53% of patients were male. The mean duration of diabetes was 9 ± 7.6 years old. Only 23.1% had a normal weight, compared with 46.1% with a BMI >30kg/m2. Android obesity was present in 92.2%, with an average waist circumference of 103 cm. Diabetes was unbalanced in 71.4% of patients, with a mean HBA1c of $9.22\pm2.22\%$. Cytolysis was found in 9.5% and no patient presented with cholestasis. Median elasticity was 6.48 ± 3.63 kPa. Fibrosis was confirmed in 41.4% and 13.8% had advanced fibrosis ($F\geq3$). Among the cohort, 20% of obese patients had hepatic fibrosis, including 10% with severe fibrosis. Unbalanced diabetes was noted in 29.6% of cases of Fibrosis ($P<0{,}001$).
Conclusion
Unbalanced type 2 diabetes and obesity are among the factors that accelerate progression to liver fibrosis in non-alcoholic steatosis.

Metabolic profile of tunisian type 2 diabetes patients at insulin initiation: a retrospective study

Yosra Abderrahim[1], Houcem Elomma Mrabet[1], Najoua Lassoued[1], Boubaker Fadia[1], Zantour Baha[1], Alaya Wafa[1] & Sfar Mohamed Habib[1]
[1]Department of Endocrinology, Taher Sfar University Hospital, Mahdia, Tunisia

Introduction
Type 2 diabetes (T2D) is a progressive disorder that often necessitates insulin therapy when oral glucose-lowering agents fail to control hyperglycemia. Initiating insulin in T2D patients represents a critical therapeutic escalation, aimed not only at preventing acute and chronic complications but also at reducing cardiovascular risks. This study aimed to evaluate the metabolic profile of Tunisian T2D patients at the time of insulin initiation.
Patients and Methods
We conducted a retrospective descriptive study at the Endocrinology Department of Taher Sfar University Hospital, including 245 T2D patients who commenced long-term insulin therapy due to the failure of oral antidiabetic agents or the presence of signs of insulinopenia.

Results
The study included 245 patients with a mean age of 59.3 ± 9.18 years and a sex ratio (M/F) of 0.67. The median duration of T2D was 10 years [6–15]. Hypertension and dyslipidemia were present in 50.6% and 53.5% of patients, respectively. Most patients (87.7%) were on a combination of metformin and sulfonylureas. Even though 66.4% of patients reported significant weight loss, the median BMI was 27.6 kg/m^2 [25.1–30], with 76% of patients being overweight or obese. Waist circumference, a key indicator of insulin resistance, was 100 cm [91.5–108.7] in women and 102 cm [93.5–107] in men. Glycemic control was suboptimal, with median HbA1c and fasting plasma glucose (FPG) levels of 11.43% [10.5–12.85] and 2.9 g/l [2.3–3.3], respectively. Lipid profiles were also poor, with median levels of total cholesterol, triglycerides, HDL-C, and LDL-C at 1.62 g/l [1.46–2.05], 1.32 g/l [0.9–1.82], 0.44 g/l [0.35–0.5], and 0.96 g/l [0.69–1.23], respectively. Median uric acid levels were 312 µmol/l [243–391].
Conclusion
Our findings underscore the poor metabolic profile of T2D patients at insulin initiation, reflecting a significant delay in therapeutic escalation. The observed dyslipidemia may be attributed to insulinopenia and/or chronic hyperglycemia. Early intensification of treatment, whether through basal insulin or other agents with proven metabolic benefits, could mitigate further cardiovascular complications and improve outcomes.

A rare presentation of type 1 diabetes mellitus: cornelia de lange syndrome presenting with nonketotic hyperosmolar state

Burcu Senkalfa[1], Zulal Ozdemir Uslu[1], Serap Kurt Kocak[1], Selman Kesici[2], Alev Ozon[1] & E. Nazlı Gönç[1]
[1]Hacettepe University, Department of Pediatrics, Division of Pediatric Endocrinology, Ankara, Türkiye; [2]Hacettepe University, Department of Pediatrics, Division of Pediatric Intensive Care, Ankara, Türkiye

Introduction
Cornelia de Lange syndrome (CdLS) is a rare genetic disorder characterized by growth and developmental delay, typical dysmorphic features, and genitourinary system anomalies. Diabetes mellitus (DM) has been rarely reported in CdLS, and its etiology remains unclear.
Case
A 4-year-old male presented with respiratory distress following a one-week history of fever, cough, vomiting, and fatigue. He was born at 32 weeks of gestation (BW 935 g) via cesarean section due to fetal distress. He remained in the neonatal intensive care unit for 4 months. Dysmorphic features (microcephaly, synophrys, hypoplastic external genitalia) led to a diagnosis of CdLS (NIPBL exon 37, c.6461T>C heterozygous mutation). He required gastrostomy at 4.5 months, developed epilepsy at 1 year, and a cochlear implant was placed for bilateral hearing loss at 14 months. On admission, the patient was lethargic, hypotensive, and tachypneic with dehydration. Height was 82 cm (-5.1SDS), and weight 9.8 kg (-5.7SDS). Laboratory revealed a blood glucose of 1693 mg/dL, sodium 162mEq/l, potassium 4.42mEq/l, creatinine 1.8mg/dL, BUN 79mg/dL, pH 7.28, HCO_3 19 mmol/l, negative urine ketones. He was diagnosed with nonketotic hyperosmolar state. A bolus of isotonic saline (20 mL/kg) was followed by 5% dextrose and 0.45% saline infusion at a rate of 4 L/m^2/day. Regular insulin infusion (0.025 U/kg/h) was initiated two hours after hydration. Persistent respiratory distress and hypotension required intubation and adrenaline infusion. Blood glucose gradually decreased, ketones remained negative. After 17 hours, the metabolic and clinical condition improved, insulin infusion was discontinued. However, hypernatremia persisted for 78 hours, necessitating free water supplementation. Pulmonary edema developed during this period, leading to a reduction in fluid intake. Further evaluation during hyperglycemia revealed low C-peptide (0.466ng/mL) and insulin (2.97mIU/l), an HbA1c of 9.3%, positive anti-GAD antibodies (15U/l). Basal insulin (0.4 U/kg/day) in two doses along with correction boluses was started. During follow-up, insulin was temporarily discontinued. However, hyperglycemia recurred five months later, requiring the re-initiation of basal insulin therapy (0.58 U/kg/day).
Conclusion
Diabetes has been rarely reported in CdLS, and this case represents the first well-documented pediatric Type 1 DM. Hyperosmolar state is an uncommon presentation of Type 1 DM in children. The syndromic condition may have contributed to the atypical clinical course of diabetes in this patient.

Ketotic decompensation revealing early-stage fournier gangrene complicating type 2 diabetes

Houda Tellabi[1], Sara Ijdda[1], Sana Rafi[1], Ghizlane El Mghari Tabib[1] & Nawal El Ansari[1]
[1]Mohammed VI University Hospital of Marrakech, Department of Endocrinology, Diabetology, Metabolic Diseases and Nutrition, Marrakech, Morocco

Introduction
Fournier's gangrene is a rare and serious bacterial infection of the external genitalia and perineum, causing skin destruction. It generally affects men with a history of immunodepression. It is a medico-surgical emergency due to its rapid evolution, which can lead to sepsis and death. Treatment combines surgical intervention and appropriate antibiotic therapy. We report the case of a patient admitted for diabetic ketosis on Fournier gangrene.
Observation
A 60-year-old patient, diabetic (type 2) 6 years previously, was admitted for management of diabetic ketosis. He presented with a polyuro-polydipsic syndrome with pain in the anal region evolving in a context of chills. Examination revealed a red, warm, painful and indurated swelling on the left perianal area. Biological examination revealed an infectious syndrome with elevated WBC and CRP. Ultrasound of the anal soft tissues revealed extensive infiltration of the subcutaneous and fascial soft tissues, with micro-logetes in the process of collection. Fournier's gangrene was diagnosed on the basis of necrosis of the subcutaneous tissues. Management consisted of surgical debridement, excision of necrotic tissue and drainage, combined with triple antibiotic therapy. Post-operative management was straightforward. On improving, the patient was referred to the plastic surgery department for skin reconstruction.
Discussion/conclusion
Despite its rarity, Fournier's gangrene remains a formidable disease due to its serious complications, and is particularly common in diabetic patients. Diagnosis is mainly clinical. Treatment involves emergency surgical debridement with appropriate antibiotic therapy. Plastic surgery techniques can be used to improve aesthetics. Prognosis is closely linked to rapid diagnosis and intervention.

Diabetes mellitus in equatorial guinea: community-based primary health care intervention

Miriam Chikuy Ferrá[1] & Miguel Nsue[1]
[1]Clínica Esperanza, Malabo, Equatorial Guinea

The last decade has seen a significant increase in cases of diabetes mellitus (DM), a trend that is expected to continue to rise, especially in low- and middle-income countries, where mortality is higher according to the World Health Organisation. On the African continent, DM is positioned as one of the major non-communicable diseases that often go undiagnosed and untreated. This research aims to analyse the situation of DM in Equatorial Guinea, identifying the associated risk factors and evaluating the impact of health interventions in its population. For its development, an educational intervention programme was implemented in the capital of the country, targeting both patients and health personnel, together with a qualitative study that analysed the knowledge on prevention, diagnosis and treatment of DM, as well as the availability of resources. The results of the study revealed that patients with DM simultaneously present the main risk factors: poor dietary habits (98%), high blood pressure (64%), overweight (57.2%) and obesity (49.8%). At the same time, a lack of programmes aimed at the early diagnosis and comprehensive management of this disease was identified, a situation that is increasingly worsening due to the low perception of DM as a health priority among patients and health personnel despite its high morbimortality. In this context, there is an urgent need to design and implement tailored strategies including awareness raising campaigns, specialised training of healthcare workers and the development of diabetes prevention and early detection programmes. In conclusion, it is essential to improve the perception of DM as a health priority through comprehensive and contextualised strategies. It is recommended to establish health checks focused on early detection. It is also proposed to develop educational programmes that address nutrition, self-care and body weight management, as well as to train medical staff and promote outreach campaigns on different digital platforms that are popular among the population are key elements to improve the care and prognosis of diabetes in Equatorial Guinea.

Charming circle between iron and vitamin D deficiencies in women with type 2 diabetes mellitus and heart failure with preserved ejection fraction

Lileia Petrovska[1], Iryna Kostitska[1], Taras Petrovskyy[2] & Roman Petrovskyy[2]

[1]Ivano-Frankivsk National Medical University, Communal Non-commercial Enterprise Regional Clinical Hospital of Ivano-Frankivsk Regional Council, Endocrinology, Ivano-Frankivsk, Ukraine; [2]Clinical Diagnostic and Treatment Center "Simedgroup", Ivano-Frankivsk, Ukraine

Background and aims

Iron and vitamin D deficiencies are two of the most common nutrient deficits in the world. Frequently when it comes to such significant pathologies as diabetes or heart failure (HF) we simply lose focus on nutritional support, which can improve quality of life and alleviate symptoms that may be caused by nutrient deficiencies rather than the underlying diseases. Aim of the study is to evaluate associations between iron status and vitamin D level with inflammation caused by underlying diseases in females with type 2 diabetes mellitus (T2DM) and HFpEF.

Materials and methods

30 women with T2DM and HFpEF (mean age -58,4±1,3 years; body mass index (BMI)- 33,8± 2,5 kg/m^2, waist circumference (WC) - 103,5±1,9 cm, glycated hemoglobin (HbA_1C)- 7,1±0,1% and duration of T2DM -7,7±0,8 years) were comprehensively phenotyped including physical examination, laboratory (N-terminal pro-brain natriuretic peptide (NTproBNP), ferritin, transferrin saturation (TSAT), glycated hemoglobin (HbA_1C), 25-hydroxycholecalciferol (25(OH)D) and C-reactive protein (CRP)) and instrumental (echocardiography: left ventricular ejection fraction (LVEF) >50%) results.

Results

25(OH)D concentrations <30 ng/mL were presented in 86,7% patients, 3,3% females had 25(OH)D level>30 ng/mL. ID were presented in 23 (76,7%) women against 23,3%. Women with 25(OH)D concentrations <30 ng/ml had reduced ferritin, TSAT levels compared to those with 25(OH)D concentrations >30 ng/ml. The prevalence of ID was in 21 (80,8%) females with 25(OH)D concentrations <30 ng/ml compared to 5 (25%) in those with concentrations >30 ng/mL. Alike the prevalence of low vitamin D level was higher in women with ID 87% against 13% to those who had adequate iron status. Due to fact that inflammation alters of iron status and differs by vitamin D level, we investigated level of CRP and evaluated interactions between inflammation and 25(OH)D concentrations in predicting iron status. In patients with inflammation 36,7% we observed higher 25(OH)D concentrations in combination with lower ferritin level than in those without inflammation 63,3%.

Conclusions

Low Vitamin D level was associated with increased risk of ID in women with T2DM and HFpEF 87%, similarly as iron deficient women with type 2 DM and HFpEF had a higher risk of low vitamin D status. Chronic inflammation inherent T2DM and HF could increased ID which may be inhibiting with high doses of vitamin D.

Gestational diabetes: about an algerian population

Aicha Bouzid[1]

[1]University of Medicine of Tizi Ouzou, Endocrinology and Diabetology Department of University Hospital of Tizi Ouzou, Tizi Ouzou, Algeria

Introduction

Gestational diabetes mellitus (GDM) is a form of hyperglycemia that develops during pregnancy and poses risks to both mother and fetus. Gestational diabetes mellitus is a common complication in pregnancy. The International Diabetes Federation recently estimated that globally, 1 in 6 live births had a GDM diagnosis. Due to its high frequency and its health, social and economic impact, GDM has become a major public health issue. The aim of this study was to analyse the risk factors for gestational diabetes in a population of Algerian pregnant women.

Patients and methods

This is a retrospective descriptive study conducted at the diabetology consultation of the diabetology and endocrinology department of the Tizi Ouzou University Hospital located east of Algiers, during the period 2022-2023 among pregnant women referred for management of gestational diabetes.

Results

The study involved a population of 156 patients with an average age of 32.5 years. 63% of these women were over 35 years of age. The screening method used to diagnose gestational diabetes was fasting plasma glucose with a rate of 53.84% and OGTT with a rate of 30.12%. 20.5% of patients had a personal history of gestational diabetes and 47.4% had a family history of type 2 diabetes. Personal histories of macrosomia, hydramnios and miscarriage were found in 19.9%, 3.8% and 26% of cases respectively. 3.8% of these women had hypertension. Among the obstetric complications observed during the follow-up of these patients, hydramnios represented 7% of cases and macrosomia 5% of cases.

Discussion and conclusion

The identification of risk factors and screening for gestational diabetes highlights the importance of early detection and management to reduce the risk of macrosomia, neonatal complications and long-term impact on the health of the mother and child.

Potential of dietary polyphenols in prevention and treatment of type 2 diabetes and different types of dementia

Valentina Gavazova[1] & Sylvia Pashkunova[1]

[1]Military Medical Academy, Department of Endocrinology, Sofia, Bulgaria

Introduction

Type 2 diabetes and different types of dementia including Alzheimer's disease(AD) are widespread diseases that share metabolic defects, such as insulin resistance, impaired glucose metabolism, oxidative stress, neuroinflammation and advanced glycation end products formation. As a result of many studies there is evidence that shows that type 2 diabetes significantly increases the risk of cognitive decline and dementia, particularly AD. Some authors have proposed the term "diabetes type 3" or "diabetes of the brain" for AD because of the similarities found between type 2 diabetes and AD mentioned above. Very important is the presence of brain insulin resistance in AD. For this reason, new approaches to improve glycemic control and restore cerebral insulin function are being investigated that could be of therapeutic benefit to adults with type 2 diabetes and different types of dementia. Besides drugs the use of foods that are rich in polyphenols has been shown to be a promising alternative in the fight against these diseases. It has been shown that dietary polyphenols can reduce blood sugar levels, protein glycation, improve insulin resistance, reduce oxidative stress and inflammation.

Study aim

The study aims to determine whether polyphenols intake can help prevent, improve and slow the progression of diabetes type 2 and therefore AD and other dementias because of the similarities found between these diseases mentioned above.

Methods

To estimate the role of dietary polyphenols, we observed 30 patients (25 women and 5 men) with diabetes mellitus type 2 and different types of dementia including AD who consumed polyphenols-rich foods between 1 December 2023 and 1 December 2024. The patients had poor glycemic control with HbA1c above 8.0%. In addition they had loss of cognitive functioning that included memory loss, reasoning skills, and some of them loss of ability to perform simple tasks.

Results

For one year of dietary polyphenols intake in the observed group we have found out significant reduction of HbA1c to below 7.0%, improvement of glucose variability. Moreover we have found positive effects of polyphenols on improving the cognitive performance in patients.

Conclusions

Phenolic compounds in foods have great therapeutic potential for diabetes management, which is related to their ability to reduce oxidative stress, reduce insulin resistance and AGEs formation. Thus, they can prevent or delay progression of diabetes type 2 and therefore different types of dementia including AD because of the similarities found between these diseases mentioned above.

Marked inflammatory syndrome revealing type 1 autoimmune hepatitis in a young female patient with type 2 diabetes

Daniel Cosma[1,2] & Elena-Maria Herascu[3]

[1]Horezu City Hospital, Diabetes, Nutrition and Metabolic diseases Outpatient Clinic, Horezu, Romania; [2]Gerontohealthcare Clinic, Diabetes, Nutrition and Metabolic diseases Outpatient Clinic, Ramnicu-Valcea,

Romania; [3]Valcea County Hospital, Gastroenterology Department, Ramnicu-Valcea, Romania

Autoimmune hepatitis (AIH) is a progressive, chronic liver disease characterized by unresolving hepatocellular inflammation of autoimmune origin and varied clinical presentation. In type 2 diabetes mellitus (DM), the prevalence of AIH seems to be the same as in general population. Usually, patients with T2DM and AIH have a shorter duration of diabetes, are mostly women with increased liver enzymes and require higher insulin doses. A 42 -years old female with a history of gestational diabetes, hypertension and deep vein thrombosis presented in our service for a consult. At presentation: BMI = 34.52kg/m^2, WC = 112cm; Pulse = 72/min and B*P* = 140/90mmHg. The lab exams showed: marked inflammatory syndrome with CR*P* = 209.58 (NV < 0.5mg/dl), neutrophilic leukocytosis, mild dyslipidemia, low vitamin D and iron levels, hyperglycemia (BG = 186mg/dl) with A1c = 7.3% and mild increased LDH and γ-GGT. The microvascular complication screening revealed peripheral sudomotor dysfunction by Sudoscan testing. Treatment with Metformin 750mg twice daily, Rosuvastatin 10mg/day and vitamin D 5000IU/day for 3 months was initiated and the patient was referred for a gastroenterology consult. The diagnosis of type 1 autoimmune hepatitis was established after exclusion of viral etiology and based on the positive ANA of 1/160 with intense positive anti-DFS70 (dense fine speckle, 70kDa molecular weight) and equivocal anti interferon-inducible protein Ro-52. The thyroid hormones were within normal ranges, but the thyroid antibodies were not measured. The immunosuppressive treatment with Azathioprine 150mg/day was initiated alongside Silymarin. After 6 months, decreases in BMI (-4.41kg/ m^2), WC (-14cm) and A1c (-1.6%) were noted. The inflammatory syndrome resolved, but the LDL cholesterol was above target, so the statin dose was increased. The particularity of this case consists in marked inflammation with mild cholestasis, normal ALAT and ASAT and no symptoms. The treatment with Metformin and lifestyle optimization led to significant weight loss and improved glycemic control.

Prevalence of lipohypertrophy and associated factors among insulin-treated diabetes mellitus patients

Wafa Ben Hilel[1], Elyes Kamoun[1], Nadia Khessairi[1], Ibtissem Oueslati[1], Meriem Yazidi[1], Fatma Chaker[1] & Melika Chihaoui[1]
[1]Rabta Hospital, Endocrinology, Tunis, Tunisia

Background
As a consequence of insulin therapy in diabetes mellitus, a variety of local skin reactions may occur, the most common is Lipohypertrophy (LH). This study aimed to determine the prevalence and associated risk factors of insulin-induced LH.
Patients and methods
We performed a cross-sectional study including insulin-treated patients for more than one year from the endocrinology department of Rabta Hospital in Tunis between February and August 2024.
Results
We included 60 patients with a sex-ratio of 0.58 and 75% type 2 diabetes mellitus patients. Mean age, duration of disease and period of insulin therapy were respectively 54.8 ± 16.7; 17.2 ± 9.4 and 11.9 ± 8.4 years. LH prevalence was 60%. Female gender (P = 0.02, OR[CI95%:1.4-13] = 4.3), lack of assistance from a third party (LATP) (P = 0.03, OR[CI95%:1,1-11,7] = 3.7) and concentrating insulin in a small area (P < 0.001, OR[CI95%:9.8-38.9] = 3,7) were associated with higher prevalence of LH. Duration of disease, body mass index, body weight-adjusted dose, duration of insulin use, needle length and reuse, rate of rotating injection site, and cold insulin injection weren't associated with LH. Multivariate analysis revealed that female gender, LATP and not spacing insulin injections were independently associated with LH. The strongest factor associated with LH was failure in spacing injections in the same area (OR_a = [CI95%:3.8-359.5] = 37).
Discussion and Conclusion
Insulin-induced LH is a common complication in diabetes management. Female gender, LATP and not spacing injections are independently associated with LH. The most prominent factor was inadequate spacing of injections within the same area. Based on our and previous studies [1,2], it is important to examine injection sites and educate patients on prevention of lipodystrophy.

Unusual case of pancreatic neoplasm revealed by insulin initiation in a diabetic patient

Dhoha Ben Salah[1], Oumaima Dimassi[1], Khouloud Boujelben[1], Nada Hassairi[1], Faten Haj Kacem Akid[1], Nadia Charfi[1], Mouna Mnif[1], Mohamed Abid[1], Mouna Elleuch[1] & Nabila Rekik Majdoub[1]
[1]Department of Endocrinology Hedi Chaker Hospital, Sfax, Tunisia

Introduction
Pancreatic cancer ranks 12th among the most common malignancies, with type 2 diabetes mellitus (T2DM) increasing the risk by 1.8 times. Paraneoplastic dermatomyositis is a well-documented mode of presentation.
Case Report
We report the case of a 64-year-old female patient with a family history of T2DM and papillary thyroid carcinoma in her two daughters. She had been diagnosed with diabetes three years prior and was managed with oral antidiabetic. She presented with spontaneous ketoacidosis, necessitating the initiation of human insulin therapy. Within 24 hours of the first insulin injection, she developed non-pruritic, ill-defined erythematous plaques on the thighs (injections were administered in the arms) and subsequently on the anterior forearms. Suspecting insulin allergy, insulin therapy was discontinued for 15 days, and oral antidiabetic agents were resumed. However, the progressive worsening of the cutaneous lesions raised suspicion of paraneoplastic dermatomyositis. An abdominal CT scan revealed an intrapancreatic tumor at the cephalo-isthmic junction, measuring 25 × 18 mm. She underwent chemotherapy followed by Cephalic duodenopancreatectomy. Histopathological examination confirmed a moderately differentiated ductal adenocarcinoma. Following surgery, insulin therapy was reintroduced, leading to complete resolution of the cutaneous lesions.
Discussion and Conclusion
Pancreatic adenocarcinomas are frequently associated with dermatomyositis, with an incidence at least three times higher than in the general population. The association with worsening diabetes should prompt clinicians to consider an underlying pancreatic malignancy.

JOINT1262

Comparative characteristics of carbohydrate metabolism in patients with different types of autoimmune diabetes

Nataliia Pashkovska[1] & Iryna Tsaryk[1]
[1]Bukovinian State Medical University, Clinical Immunology, Allergology and Endocrinology, Chernivtsi, Ukraine

Introduction.
Autoimmunity is the major cause of classical type 1 diabetes mellitus (T1DM) as well as heterogenic forms – latent autoimmune diabetes in adults (LADA) and latent autoimmune diabetes in youth (LADY). These categories of diabetes share biochemical markers of β-cell–directed autoimmunity with classical T1DM but also have main features of type 2 diabetes (T2DM) like slowly progression and insulin resistance. In clinical practice, autoimmunity in classical T1DM as well as in LADA and LADY is usually documented by antibodies against glutamic acid decarboxylase (antiGAD) to prevent misdiagnosis in these categories of patients.
The aim of the study.
To compare features of carbohydrate metabolism in patients with different types of autoimmune diabetes mellitus (DM).
Material and methods.
71 patients with autoimmune DM were examined: 20 patients with classical type 1 DM (T1DM), 36 – with latent autoimmune diabetes in adults (LADA) (18 – LADA1 phenotype and 18 – LADA2), and 15 patients with latent autoimmune diabetes in youth (LADY). In addition to anamnesis data and general clinical research methods, indicators of carbohydrate metabolism (fasting glycemia, glycated hemoglobin (HbA1c)), and C-peptide level were evaluated.
Results.
The average age of manifestation of classical T1DM was 19 years, while in LADA1 it was 40.5 years, in LADA2 – 41, and in LADY – 20 years. Body mass index was in the normal range in patients with classical T1DM and LADY (21.99

and 23.39 kg/m^2 respectively), while in patients with LADA overweight was registered. Fasting plasma glucose level and HbA1c were recorded in the range from 9.22 to 9.90 mmol/l and 8.5% to 8.85% respectively and did not differ depending on the group. C-peptide level was 0.1 [0.10;0.15] and was significantly lower in patients with classical T1DM: by 6.4, 5 and 6.2 times compared with the LADA1, LADA2 and LADY respectively. HOMA-IR was the highest in patients with LADA2, but did not significantly differ from the LADA1 and LADY levels. AntiGAD level was the highest in classical T1DM and LADY groups (341.75 IU/ml and 270 IU/ml respectively); in LADA1 group the average level was 214.20 IU/ml and 95.50 IU/ml in LADA2, which significantly differ from two previous groups ($p < 0.05$).
Conclusions.
Autoimmunity plays a major role in establishing the correct diagnosis of the type of diabetes mellitus and can prevent a misdiagnosis.

Prevalence of autoimmune disorders in pediatric and adolescent patients with type 1 diabetes mellitus: a retrospective cohort study

Maysa Saleh [1,2], Khaled Alblooki[3], Ahmad Sharif[3] & Jaffar Alshawab[3]
[1]AJCH, Dubai, United Arab Emirates; [2]AJCH, Dubai, United Arab Emirates; [3]MBRU, Dubai, United Arab Emirates

Objective
To provide an overview of the epidemiology of concurrent autoimmune conditions in pediatric Type 1 Diabetes Mellitus (T1DM) patients, with a specific focus on investigating sex-specific disparities and evaluating the impact of glycemic control. This research aims to contribute valuable insights to inform the development of screening policies for this patient population.
Methods
This retrospective observational study analyzed data from all patients diagnosed with T1DM who attended the endocrine clinic at Al Jalila Children's Specialty Hospital between 2017 and 2023. The study assessed various variables, including age, gender, glycemic control, thyroid function, and the presence of celiac disease (CD), among others.
Results
346 patients diagnosed with T1DM were included in the study. Our cohort consisted of 166 (48.0%) males and 180 (52.0%) females, stratified into three age groups: $\leq$4 years (14.5%), 5-12 years (56.4%), and 13-18 years (29.3%). 166 (55.1%) patients had a BMI of $<$18.5 (underweight). 206 (59.5%) patients were from the UAE. 233 (75.9%) patients had uncontrolled HbA1C levels. The study focused on two autoimmune disorders: 24 (6.9%) patients with CD and 34 (9.8%) patients with thyroid disease, with 4 (1.2%) patients having both conditions. CD exhibited varying prevalence across age groups, with a statistically significant difference (p-value = 0.043), being more common in children $\leq$4 years (12.0%). The prevalence of thyroid disease was higher in patients from the UAE (12.1%) than those from other countries (6.4%), showing a trend toward significance (p-value = 0.080).
Conclusion
CD showed significant variations in prevalence across age groups, being most common among children aged 4 or younger.. Thyroid disease was notably more prevalent in patients from the UAE than in those from other countries, indicating a compelling trend toward significance. Additional research is needed to validate and further establish the significance of these observed associations.

Severe ketoacidosis and multi-organ failure in a type 2 diabetes mellitus patient: a case report

Entela Puca[1], Sonila Bitri[2], Dea Puca[3], Nereida Xhabija[4] & Edmond Puca[5]
[1]Western Balkans University, Endocrinology, Tirana, Albania; [2]Western Balkans University, Toxicology, Tirana, Albania; [3]Lady of Good Counsel University, Tirana, Albania; [4]Western Balkans University, Tirana, Albania; [5]University Hospital Center, Infectology, Tirana, Albania

Background
Diabetes Mellitus Type 2 (T2DM) is commonly associated with various complications, including cardiovascular, renal, and hepatic dysfunction. Diabetic ketoacidosis (DKA) is a potentially fatal endocrine emergency resulting from uncontrolled diabetes mellitus (DM). We present a case of a T2DM patient who presented in an emergency setting with severe diabetic ketoacidosis and multiple organ failure.
Case Presentation
A 51-year-old male with a history of poorly controlled T2DM in treatment with basal -bolus insulin presented to the emergency department with symptoms of altered consciousness, abdominal pain, and general fatigue. On admission, the patient exhibited severe metabolic acidosis (pH 6.9), elevated serum amylase (550 U/l), lipase (510 U/l), creatine kinase-MB (CK-MB) (80 U/l), and troponin I (0.15 ng/mL) Laboratory findings also revealed significantly elevated liver enzymes (AST, ALT) and renal dysfunction (elevated serum creatinine and urea). Clinical examination suggested signs of multiple organ failure, including hepatic, renal, pancreatitis and cardiac involvement.
Management and Outcome
Initial management focused on correction of ketoacidosis and stabilization of the patient's cardiovascular, renal, and hepatic functions. The patient was treated with intravenous fluids, insulin for blood glucose control and intensive monitoring of organ functions. The patient's clinical condition improved gradually, with normalization of metabolic parameters, organ function, and consciousness over the course of 24-48 hours.
Conclusions
This case highlights the complexity of managing T2DM patients with severe acidosis and multi-organ failure. Acute complications like diabetic ketoacidosis (DKA) or hyperosmolar hyperglycemic state (HHS) can lead to multi organ dysfunction if not promptly recognized and managed. Early intervention and multi-disciplinary management are critical in improving outcomes in such high-risk patients.

JOINT2417

"Sweet testosterone" – improved metabolic compensation after starting testosterone therapy in two transgender adolescents

Katarzyna Marzęda[1], Magdalena Makowiecka-Wolek[1] & Robert Śmigiel[1]
[1]Wroclaw Medical University, Wroclaw, Poland

Transgender people experience gender dysphoria due to incongruence between their gender indentity and the sex they were assigned at birth. Due to many barriers experienced by transgender people there is no accurate data available, but it is estimated that they represent approximately 0,5% of the Poland population. One of the method to reduce the symptoms of gender dysphoria is hormone therapy, the aim of which is to match a person's gender characteristics to their identity. The mainstay of therapy for transgender men is testosterone taken as a gel or in the form of regular injections. Type I diabetes is a chronic autoimmune disease underlying which is a process that leads to the gradual destruction of insulin-producing cells of the pancreas. It accounts for about 10% of all cases of diabetes and most often affects children, adolescents and people before the age of 30. Treatment requires the patient to receive continuous insulin administration and regular blood glucose measurements. In recent years, there have been several research papers indicating an up to ninefold higher incidence of type I diabetes in transgender and gender diverse patients. The reasons for this process are unknown. Despite this, there is very little knowledge about the impact of hormone therapy on the course and control of type I diabetes. The effect of testosterone on diabetes control has been studied primarily in cisgender patients with type II diabetes and metabolic syndrome. Single research papers have indicated an initial improvement in the metabolic control of transgender patients after starting hormone therapy with testosterone. We present a description of the observations of two transgender boys, diagnosed with type I diabetes in childhood, who began testosterone therapy at the age of 16. Control of metabolic compensation was carried out through regular clinic visits through two years until they reached adulthood. Our observations indicate a significant improvement in diabetic parameters after the initiation of hormone therapy, especially in terms of lowering glycated hemoglobin, reducing mean blood glucose, and improving self-monitoring and dietary adherence. More studies are needed to describe the effects of hormone therapy on the course and control of type I diabetes and to create guidelines to create inclusive and multispecialty care for transgender and gender diverse children and adolescents with type I diabetes.

Alpha-lipoic acid-induced insulin autoimmune syndrome: an emerging public health risk

Michael Batavanis[1] & Ploutarchos Tzoulis[2]
[1]University of Cambridge, Department of Public Health and Primary Care, Cambridge, United Kingdom; [2]University College London, Department of Experimental and Translational Medicine, Division of Medicine, London, United Kingdom

Introduction
Insulin autoimmune syndrome (IAS), a condition mostly prevalent in East Asia, is a rare cause of spontaneous hypoglycaemic episodes, occurring in the late post-prandial phase and driven by the production of insulin autoantibodies (IAAs). The soaring popularity of food supplements containing Alpha-Lipoic Acid (ALA) and the concomitant surge in the reported cases of IAS have led the European Food Safety Authority to raise a safety concern about this association, especially in the presence of certain genetic polymorphisms in the Human Leukocyte Antigen HLA-DR4.
Case report
A 48-year-old female of Caucasian origin was referred on an urgent basis to an endocrine clinic in Athens, Greece, with a 5-day history of recurrent pre-syncopal episodes occurring two hours after meal ingestion. She had no history of diabetes mellitus and fulfilled the criteria of Whipple's triad on several occasions, with capillary blood glucose as low as 36-43 mg/dl (2.0-2.4 mmol/l). On hospital admission, baseline laboratory evaluation showed hypoglycaemia due to endogenous hyperinsulinism, as evidenced by very high serum insulin (189 mIU/l) and C-peptide concentrations. Its commonest cause, insulinoma, was excluded following detailed imaging. Grossly elevated IAAs of 175 IU/ml (normal range $<$ 20 IU/ml) indicated IAS which, in the absence of exposure to other offending drugs, was attributed to an ALA-containing supplement initiated two months ago for the management of arthralgia. Her management included dietary modification with small, frequent meals of low glycaemic index, oral prednisolone 40 mg, and diazoxide 150 mg daily. She responded rapidly without experiencing further hypoglycaemic episodes on this strict dietary regimen. In the following months, the IAA titre remained significantly elevated despite high-dose glucocorticoids, whilst she developed severe resting tremor, insomnia and depressive symptoms. Three months after the initial presentation, prednisolone was tapered and eventually discontinued, leading to resolution of these neuropsychiatric symptoms. One month later and despite prednisolone withdrawal, a significant decline in the IAA titre was first noted. Six months after presentation, the patient remained symptom-free with gradually declining, albeit still positive, IAA titres, despite discontinuation of both prednisolone and diazoxide, alongside a significant relaxation of dietary restrictions.
Conclusion
IAS is a severe, albeit rare, adverse event of ALA intake, which should discourage the overuse of ALA-containing supplements, and lead to inclusion of a clear warning about this risk in their labelling. This case report also illustrates the challenges in the management of IAS, as well as the often underappreciated neuropsychiatric side effects of glucocorticoids.

Polymorphisms of leptins gene in different types of diabetes mellitus

Sylvia Pashkunova[1] & Valentina Valentinova[1]
[1]MMa, Endocrinology, Sofia, Bulgaria

Leptin is a protein about 16 kDa size playing a key role in energy intake and expenditure. It is a member of the cytokine family including intraleukin 2 and intraleukin 4 and is one of the most important hormones produced by adipocytes. The gene's function was initially linked to a signaling pathway suppressing food intake. The relationship between genetic variants in the leptin gene and the risk of developing diabetes has not been extensively analyzed. The -2548 G/A polymorphism in the promoter region of the leptin gene shows a genotype-specific association with an increased risk of developing diabetes.
Study Aim
Investigation of allelic and genotypic frequencies of the 2548 G/A polymorphism in the leptin gene in the observed groups.
Methods and materials
A total of 302 individuals were included in the present study, of which 202 patients were divided into five groups according to diabetic type-Diabetes type 1;Diabetes type 2 DT2; Type 2 diabetes with secondary depletion ;Diabetes type MODY; Diabetes type LADA and healthy control group.
Results
Leptin is involved not only in the regulation of food intake and energy balance, but also as a hormone related to glucose metabolism, body mass regulation and functions as an endocrine mediator. In general, in the studied groups, no relationship was found with the studied polymorphism in leptin genes and predisposition to the development of certain diabetic pathology. A certain tendency, which confirms the literature data, was observed only in patients with type 2 diabetes. The population frequency of the 2548 G/A polymorphism in the leptin gene shows great variability. From the present study, it can be seen that the frequency determined for the studied sample from the Bulgarian population is comparable to that of other European populations. When comparing the distribution of genotype G/G (+/+) to the other genotypes, an interesting finding is the higher frequency of genotype G/G (+/+) in patients with type 1 diabetes compared to the control sample ($P = 0.0645$). According to literature data as well as preliminary studies for the Bulgarian population, genotype A/A (-/-) has a relationship to diabetic pathology, which contradicts the data from the present study. It should be noted that predisposition to the disease associated with genotype A/A (-/-) was found mainly in patients with gestational and type 2 diabetes.

Steroid-induced diabetes: when ocular treatment becomes a metabolic threat

Manar Bari[1], Sana Rafi[1], Sara Ijdda[1], Ghizlane El Mghari Tabib[1] & Nawal El Ansari[1]
[1]Mohamed VI University Hospital Center VI, Department of Endocrinology, Marrakech, Morocco

Introduction
Corticosteroids, even when administered topically, are known to induce hyperglycemia or diabetes in predisposed patients. While systemic corticosteroid use is a well-documented cause of diabetes, the risk associated with topical corticosteroids, such as eye drops, is often underestimated. We report a case of diabetes induced by dexamethasone eye drops in a 64-year-old patient admitted for the management of nodular prurigo.
Case Report
A 64-year-old man with no prior history of diabetes was admitted for severe nodular prurigo. Routine laboratory tests revealed elevated fasting blood glucose and HbA1c. The patient had been using dexamethasone eye drops for the past 4 years to treat chronic uveitis. Over the past 2 years, he had gradually developed symptoms of hyperglycemia, including increased thirst, frequent urination, and fatigue. Despite these symptoms, he had not sought medical advice, attributing them to other factors. The patient had no other identifiable risk factors for type 2 diabetes, such as obesity, sedentary lifestyle, or family history.
Discussion
This case highlights the risk of corticosteroid-induced diabetes, even with topical administration. Dexamethasone eye drops, used over an extended period, likely led to systemic absorption, causing insulin resistance and hyperglycemia. The rapid resolution of hyperglycemia following discontinuation of the eye drops supports the diagnosis of medication-induced diabetes. This case also underscores the importance of regular blood glucose monitoring in patients using corticosteroids, particularly in those with prolonged use or additional risk factors.
Conclusion
Topical corticosteroids, including eye drops, can induce diabetes or exacerbate preexisting diabetes due to systemic absorption. Healthcare providers should remain vigilant for this potential complication, especially in patients with long-term use. Regular monitoring of blood glucose and timely intervention can prevent long-term complications.

Dietary impact on the onset of MASLD in patients living with type 2 diabetes

Yesmine Elloumi[1], Mouna Elleuch[1], Khouloud Boujelben[2], Younes Derbel[2], Mouna Mnif[2], Dhoha Ben Salah[2] & Nabila Rekik Majdoub[1]
[1]Hedi Chaker University Hospital, Endocrinology Department, Sfax, Tunisia; [2]Hedi Chaker University Hospital, Sfax, Tunisia

Background
As the prevalence of MASLD rises, understanding the dietary factors contributing to its development is becoming crucial. Diet plays a critical role in metabolic health, yet its precise effect on the development of MASLD remains under-explored. This study aims to evaluate the impact of dietary intake on the onset of MASLD in people with T2DM.
Methods
This retrospective study included 202 T2DM patients, followed up to 2024 at the Endocrinology-Diabetology Department of Hedi Chaker University Hospital in Sfax, Tunisia. Patients were divided into two groups based on the presence or absence of hepatic steatosis on imaging :
- Group 1 : 101 T2DM patients with MASLD
- Group 2 : 101 T2DM patients without MASLD

For each patient, we assessed macronutrient intake, including daily caloric intake in Kcal, as well as the percentage of daily intake from lipids, proteins, and carbohydrates. Additionally, we evaluated the intake of saturated fatty acids, monounsaturated fatty acids, and polyunsaturated fatty acids. Thus, We assessed micronutrient intake, including fiber (g/day), iron (mg/day), calcium (mg/day), and cholesterol (mg/day).
Results
The total energy intake was similar between groups 1 and 2 (2125 [1900-2585] versus 2100 [1700-2400] kcal/day, respectively ; $P = 0.251$). In terms of macronutrients, carbohydrate intake was significantly higher in Group 1 compared to Group 2 (53% [50%-57%] versus 52% [48%-54%], respectively; $P = 0.044$). No statistically significant differences were observed for protein intake ($P = 0.080$), fat intake ($P = 0.302$) whether considering saturated, mono-unsaturated, or poly-unsaturated fatty acids ($P = 0.403$, $P = 0.225$, $P = 0.896$, respectively). Regarding micronutrients, daily intakes of iron, calcium, dietary cholesterol, and fiber were comparable between the two groups.
Conclusion
Our study aims to provide insights into potential nutritional interventions for prevention and management of MASLD within T2DM patients, offering avenues for targeted dietary strategies.

Association between neutrophil-to-lymphocyte ratio and metabolic syndrome in diabetic patients: a cross-sectional study

Oumaima Dimassi[1], Houcem Elomma Mrabet[1], Najoua Lassoued[1], Maryem Souissi[1], Nada Hassairi[1], Boubaker Fadia[1], Alaya Wafa[1] & Sfar Mohamed Habib[1]
[1]Endocrinology-Diabetology and Internal Medicine Department; Tahar Sfar University Hospital Mahdia, Mahdia, Tunisia

Introduction
Metabolic syndrome (MetS) is a cluster of risk factors that significantly increase the risk of cardiovascular diseases and type 2 diabetes. Inflammation plays a key role in the pathogenesis of MetS, and the neutrophil-to-lymphocyte ratio (NLR), a marker of systemic inflammation, has been linked to various metabolic disorders. This study aims to investigate the relationship between NLR and MetS, exploring its potential as an early biomarker for risk stratification.
Methods
A cross-sectional study was conducted, including 50 diabetic patients hospitalized at the Endocrinology Department of Mahdia from January to April 2024.
Results
The average age of participants was 54 $\pm$ 21 years, with a predominance of females (79.2%). Two thirds of the patients were diagnosed with type 2 diabetes, 24% were obese, and 23.7% had established cardiovascular disease. Hypertension was present in 28.9% of patients. Metabolic syndrome was observed in 50% of the patients. The average waist circumference was 84 cm. The median values of various metabolic parameters (in mmol/l) were as follows: fasting glucose (11.3), triglycerides (1.41), HDL-C (1.07). NLR did not significantly differ across BMI groups ($P = 0.266$). Additionally, no significant correlation was found between NLR and HbA1c ($P = 0.193$), fasting blood glucose (FBG) ($P = 0.259$), HDL cholesterol ($P = 0.139$), and triglycerides ($P = 0.624$). NLR was significantly higher in patients with hypertension (2.47 [1.78-7.56] vs 1.6 [1.2-2.29]; $P = 0.029$). No significant correlation between NLR and metabolic syndrome was observed ($P = 0.405$).
Conclusion
Our study suggests that while NLR is elevated in patients with hypertension, it does not correlate significantly with metabolic syndrome or other key metabolic parameters. Further research with a larger sample size and longitudinal design is needed to clarify the role of NLR as a potential biomarker for metabolic disorders.

JOINT363

Study on sialic acid concentrations in type 1 and type 2 diabetes mellitus

Gulnora Artykbaeva[1] & Talat Saatov[1]
[1]Institute of biophysics and biochemistry under Mirzo Ulugbek National University of Uzbekistan, lab of metabolomics, Tashkent, Uzbekistan

Sialic acids are the carbohydrate part of glycoproteins presented in the conjugate form on the outer surface of membranes as membrane receptor. They are components of insulin receptors, interferon and serotonin, as well as of various circulation hormones, transporting proteins, lipoproteins, mucopolysaccharides and various exudates. The data on the concentrations of circulation sialic acids in diabetes mellitus (DM) are contradictory. The work was initiated to study concentrations of sialic acids the blood serum of patients with type 1 and type 2 DM.
Materials and methods
Twenty two patients with type 1 DM and 28 patients with type 2 DM aged from 26 to 65 were examined. The control group included 10 healthy persons of the matching age. Periodate-resorcinol method was used to measure concentrations of sialic acids. HbA1c was measured using enzyme-linked immunosorbent assay.
Results and discussion
Concentrations of the serum sialic acids in DM were found significantly increased, while those in erythrocytes and leucocytes were reduced. Our findings demonstrated that the serum sialic acid concentrations were increased in both DM types, as compared to the control ones ($P < 0.05$). In type 1 DM, mean level was 291.7 ± 42.9mg%. Sialic acids were significantly higher in patients with type 2 DM than those in healthy persons (174.5 ± 27.0mg% vs 145.0 ± 10.9mg%). Significant differences were observed in comparison of sialic acid concentrations between two groups of the diabetics ($P < 0.05$). Mean HbA1c was higher in patients with type 1 DM than the one in the controls ($6.7 \pm 1.9\%$ vs $5.4 \pm 0.8\%$). Mean HbA1c in patients with type 1 DM was $7.8 \pm 1.5\%$. Sialic acids are known to be responsible for the formation of various isoforms of transferrin and regarded as a marker of microvascular complications in type 2 DM. Hyperglycemia results in the increase on non-enzymatic glycosylation of many proteins and in the formation of glycation end products. Non-enzymatic glycosylation changes properties and functions of some proteins. The changes in the glycosylation in DM were found by many authors. Most glycosylated proteins add the remains of sialic acids in their carbohydrate chains. The increased sialic acid concentrations may be caused by the generalized cell endothelial dysfunction either by the washout of glycoproteins containing sialic acids from cells into circulation or by the cytokine-mediated acute phase response. Thus, in association with other laboratory data determination of sialic acids may be used for assessment of severity of the disease and the depth of pathological process, as well as for differential diagnosis.

Bilateral femoral head necrosis in early adulthood with pituitary stalk interruption syndrome: need for comprehensive medical education on the impact of growth retardation in misdiagnosis

Xuan Bo[1], Tong Shen[1], Huifang Xing[2], Qin Yu[1] & Zhiming Wang[1]
[1]The First Affiliated Hospital of Zhenzhou University, Division of Endocrinology and Metabolic Diseases, henan, China; [2]The First Affiliated Hospital of Zhenzhou University, Division of Physical Examination Center, Zhengzhou, China

Synopsis
We present the case of a 34-year-old female with early onset bilateral femoral head necrosis, diagnosed with pituitary stalk interruption syndrome (PSIS). The patient's medical history includes growth retardation from an early age, hip pain for nearly two years, and impaired consciousness for two weeks prior to admission. She had no history of alcohol use, autoimmune diseases, malignancies, or organ dysfunction.

Purpose
We present a case to highlight the importance of recognizing how growth disorders in children and adolescents can affect long-term health. It emphasizes the need for comprehensive medical education that bridges pediatric and adult specialties to reduce diagnostic delays in complex cases such as PSIS.
Medical history
The patient was diagnosed with growth hormone deficiency due to short stature at age 10.H*er* followed *primary amenorrhea and absence of secondary sexual characteristics during puberty were not thoroughly investigated, obscuring the growth hormone deficiency due to* long-term sex hormone deficiency *and delayed skeletal closure.*Eight years ago, she was diagnosed with hypothyroidism *and began thyroid hormone replacement*. Over the past two years, she *developed* bilateral groin and lower limb pain, initially treated *as sacroiliitis. The pain progressed on the pain scale, leading to a duck-step gait and limited hip movement. Two weeks before hospitalization, she lost consciousness and was diagnosed with hypopituitarism and adrenal insufficiency. After replacement therapies, her consciousness returned, but the hip pain worsened with both hips in flexion and abduction. Upon* admission, her bone age was assessed as 13-14 years, *indicating* delayed skeletal maturation. Frog-position DR and MRI *imaging revealed bilateral femoral head avascular necrosis, with outward and upward displacement of the femoral necks, and pituitary MRI confirmed PSIS.*
Diagnosis and treatment
The patient was diagnosed with PSIS, hypopituitarism, secondary adrenal insufficiency, hypogonadotropic hypogonadism, secondary hypothyroidism, growth hormone deficiency, and bilateral femoral head necrosis. Hormonal replacement therapy and bilateral artificial hip replacement were performed. Upon reevaluation of her medical history and bone age, the condition was likely a misdiagnosed case of slipped capital femoral epiphysis (SCFE).
Conclusion
This case underscores the importance of considering a patient's developmental history, bone age, and hormonal status in diagnosing hip disorders in early adulthood. It highlights the need for improved medical education that integrates pediatric and adult specialties, especially in cases with atypical presentations or complex histories. Early recognition can lead to better outcomes in conditions like SCFE.

Prevalence of sarcopenia in indians with type 1 diabetes mellitus
Vibhu Khare[1], Nilanjan Sengupta[1], Soumik Goswami[1], Arjun Baidya[1], Rajat Deb[1] & Joydip Datta[1]
[1]Nil Ratan Sircar Medical College, Kolkata, Endocrinology, Kolkata, India

Objective
Sarcopenia is an ignored and underdiagnosed condition in patients with diabetes. India houses the largest number of patients with type 1 diabetes but lacks data on sarcopenia prevalence in them. We estimated the prevalence of sarcopenia in type 1 diabetes patients and compared it with age- and sex- matched healthy participants.
Research design and methods
Patients with type 1 diabetes and age $\geq$ 12 years were included and patients with pregnancy, lactation and any condition which can affect skeletal muscle properties were excluded. A total of 93 patients of type 1 diabetes and an equal number of age- and sex-matched healthy participants were included for comparison in a cross-sectional and observational study. For sarcopenia assessment, skeletal muscle mass, strength and function were measured and cutoffs for diagnosis were taken according to the Asian Working Group on Sarcopenia 2019 guidelines.
Results
The prevalence of sarcopenia in T1DM patients was significantly higher than controls (30.1% vs 11.8%) with an odds ratio of 3.2 and was more common in adults compared to adolescents (36.7% vs 12%). Gender, total daily dose of insulin, eGFR and IGF-1 levels did not have a correlation with sarcopenia in T1DM.
Conclusions
This study shows that patients of type 1 diabetes have an approximately three times higher prevalence of sarcopenia when compared to the general population with nearly 1 out of 3 type 1 diabetes patients affected by the condition.

HbA1c measurement: comparison of biorad D10 (Hplc) and sebia capillarys 2 methods
Raneen Sliman[1]
[1]Ziv Medical center, zefat, Israel

Background
HbA1c test provides information on metabolic control in diabetes and could also be used for its Diagnosis, it is essential to have accurate and precise HbA1c methods covering a range of measurement principles. We report an evaluation of the Biorad D10 kit (Hplc) versus Sebia capillarys 2 Kit (capillary electrophoresis).
Methods
Measurements of HbA1c were carried out in whole blood samples (K3edta tubes) from 111 patiens from different departments in Ziv medical Center- Israel using both Sebia Capillarys 2 Flex piercing (Capillary Electrophoresis) and analyzers Biorad D 10 (HPLC method).
Results
There was a good concordance between the results of capillary electrophoresis and HPLC ($R2 = 0.97$, $P < 0.0001$) There is no significant difference between the results obtained from both technique.
Conclusions
both technique suitable for the clinical application in the analysis of HbA1c. it is concluded that the results obtained after testing samples in Sebia capillarys Flex Piercing II and Biorad D10 are in a good concordance and there is no significant difference in the results obtained. The advantage of using Biorad D10 has benefit of shorter testing time Whereas Sebia capillarys can detecte underlying hemoglobinopathies and high throughput.

Factors impacting glycemic balance in pregnant diabetic women
Zineb Eddebbarh[1], Leila Rouimi[1], Zineb El Azime[1], Mohamed Amine Essafi[1], Hayat Aynaou[1] & Houda Salhi[1]
[1]CHU Hassan II Fes, Fes, Morocco

Introduction
Diabetic pregnancy is a high-risk pregnancy requiring optimal programming and glycemic balance to avoid maternal-fetal complications.
Objective
To assess factors influencing glycemic balance in pregnant diabetic women.
Materials and methods
This is a retrospective study over a 2-year period conducted at the Endocrinology, Diabetology, Metabolic Diseases and Nutrition Department of the Hassan II University Hospital in Fez. We included all pregnant patients with pre-existing diabetes who agreed to participate. Patients with gestational diabetes were excluded. Glycemic balance was judged by an HbA1c $<6.5\%$ and a glycemic cycle within the target in $>90\%$ (glycemic targets in preprandial between 0.60 and 0.95 and in postprandial <1.2 g/l) Eating habits were assessed by a food diary Statistical analysis was performed using SPSS 26 software. We retained the value $P<0.05$ as the significance threshold.
Results
We collected 80 patients, the average age was 35.56 ± 5.4 years, 27% had type 1 diabetes and 73% type 2 diabetes, the average duration of diabetes was 8.7 ± 3.1 years. Only 9.2% planned the pregnancy. 61.2% had a hbA1c $< 6.5\%$. 89% of patients ate 3 meals per day and 58% ate one to two snacks per day. 56% abused slow sugars and 44% consumed fast sugars. Mean HbA1c was significantly higher in T1D than T2D ($P<0.001$), in patients who had not planned their pregnancies ($P = 0.02$), in patients who made dietary errors ($P<0.01$), and in patients with a long duration of diabetes (0.01)
Conclusion
Our study highlights several factors impacting glycemic balance in diabetic women, particularly in pregnant type 1 diabetic women, with a long duration of diabetes development. Hence the interest in education on programming and optimal balance of diabetes in preconception]

Euglycemic diabetic ketoacidosis in a type 1 diabetic: a case without SGLT2 inhibitors

Nahudan Akmador[1,2]
[1]Zamboanga Doctors' Hospital, Inc., Internal Medicine, Zamboanga City, Philippines; [1]Zamboanga Doctors' Hospital, Inc., Internal Medicine, Zamboanga City, Philippines

Background
Euglycemic Diabetic Ketoacidosis is a rare but potentially life-threatening complication of diabetes characterized by ketoacidosis with blood glucose levels typically <200 mg/dL. The absence of hyperglycemia is a conundrum for physicians in the emergency department; it may delay diagnosis and treatment causing worse outcomes. Euglycemic DKA is an uncommon diagnosis but can occur in patients with type 1 or type 2 diabetes mellitus. Usually with the addition of sodium/ glucose cotransporter-2 inhibitors in diabetes mellitus management, euglycemic DKA incidence has increased. We present a case of a 16-year-old male with a history of type 1 diabetes who developed euglycemic DKA following a prolonged poor appetite (fasting). Notably, the patient was not on any SGLT2 inhibitors. This case highlights the importance of recognizing euglycemic DKA in patients with diabetes, even in the absence of significant hyperglycemia or SGLT2 inhibitor use. Euglycemic DKA was first described in 1973 by Munro *et al* [1] among type 1 DM. Euglycemic DKA is an uncommon diagnosis with an incidence ranging between 2.6% to 3.2% of admissions with DKA [2,3].
Case Presentation
A 16-year-old male with a history of type 1 diabetes mellitus presented to the emergency department with a chief complaint of body malaise. The patient reported a 3-day history of body malaise, accompanied by poor appetite for the past week. He also described experiencing burning epigastric pain and nausea. He was compliant with his insulin. He denied any history of infection, fever, cough, or urinary symptoms. On PE, the patient was well-nourished, alert, and oriented with a Glasgow Coma Scale (GCS) of 15. He was not in respiratory distress. Vital signs were within normal limits: blood pressure 100/70 mmHg, pulse rate 98 bpm, respiratory rate 20 cpm, temperature 36.6 °C, oxygen saturation 97%, height 171 cm, and weight 58 kg. Laboratory investigations revealed a blood glucose level of 108 mg/dL, arterial blood gas showing metabolic acidosis with an increased anion gap, and ketonemia. Based on these findings, a diagnosis of euglycemic diabetic ketoacidosis secondary to fasting starvation was established. The patient was promptly started on intravenous fluids, insulin therapy, and electrolyte replacement.
Conclusion
This case report underscores the importance of recognizing euglycemic diabetic ketoacidosis as a potential complication in patients with diabetes, even in the absence of marked hyperglycemia or SGLT2 inhibitor use. Prompt recognition and management of euglycemic DKA are crucial for optimizing patient outcomes and preventing potentially life-threatening complications.

Type 1 diabetes in patients over 50: clinical and biological characteristics

Ghachem Aycha[1], Imen Halloul[1], Nassim Ben Hadj Slama[1], Lamys Abbes[1], Ghada Saad[1] & Yosra Hasni[1]
[1]Farhat Hached University Hospital, Endocrinology - Diabetology Departement, Sousse, Tunisia

Objectives
The aim of our study was to describe the clinical and biological characteristics of patients diagnosed with type 1 diabetes after the age of 50.
Patients and methods
This was a descriptive study including 10 patients hospitalized in our department for diabetes mellitus.
Results
10 patients were included: 7 women and 3 men, aged between 52 and 71 years with an average age of 64.1 years. The mode of onset of diabetes was ketosis or ketoacidosis decompensation in 6 patients, incidental in 3 patients and hyperosmolar decompensation in one patient. Six out of 10 patients had no family history of diabetes or cardiovascular disease, and only 4 had a history of autoimmunity. Five patients had hypertension, including 2 with coronary artery disease, and 3 patients had autoimmune disease. The mean weight at diagnosis was 65.9 kg (42 - 103) with a mean BMI of 25.3 kg/m2. Only three patients were obese. The mean HbA1c was 12.4%. Immunological tests revealed positive anti-GAD antibodies in 9 patients and positive anti-IA2 antibodies in one patient. Regarding degenerative complications, 2 patients had diabetic retinopathy, one of whom had associated nephropathy.
Discussion
The incidence of type 1 diabetes in adults is increasing because of the widespread use of immunoassays; where the clinical presentation and the family history may cast doubt, these help to rectify the diagnosis.

JOINT1519

The complexity of diabetes management in MELAS syndrome: a personalized approach to glycaemic control

Lina Eltayieb[1], Bashir Mahamud[1], Dalya Sadulah[1], Gideon Mlawa[1], Mariana Dram[1], Aylin Can[1] & Furhana Hussein[1]
[1]Barking, Havering And Redbridge University Hospitals Nhs Trust, Endocrinology and Diabetes, London, United Kingdom

Introduction
MELAS is a rare genetic disorder with multi-system involvement, marked by myopathy, encephalopathy, lactic acidosis, and stroke-like episodes due to mitochondrial DNA mutations. Mitochondrial disorders are often associated with endocrine abnormalities like diabetes, which results from impaired pancreatic β-cell insulin secretion.
Case Presentation
We present a 63-year-old male diagnosed with MELAS syndrome at the age of 41, following his brother's diagnosis with encephalopathy and MELAS. He has a significant family history of MELAS. His initial management included Ramipril and Amlodipine for hypertension, along with Co-enzyme Q10 for mitochondrial support. Given the known association of MELAS with diabetes, the patient was referred to endocrinology for an oral glucose tolerance test (OGTT) with showed a fasting glucose of 6.6 mmol/l and a 120-minute level of 17.5 mmol/l, confirming Type 2 diabetes. He was started on repaglinide 500 µg three times daily with meals while avoiding metformin due to the risk of lactic acidosis. During follow-up, his HbA1c was 6.8% (50.8 mmol/mol), and additional testing revealed persistently elevated cholesterol at 10.8 mmol/l, HDL of 1.58 mmol/l, triglycerides of 5.74 mmol/l, and a total cholesterol-to-HDL ratio of 6.8. His creatinine was 124 µmol/l, with an eGFR of 54 mL/min. Despite medication adjustments, his hypertension and diabetes remained sub optimally controlled, necessitating further medications adjustment, His renal function progressively declined, with nephrotic-range proteinuria and creatinine levels rising to 165 µmol/l. Referred to nephrology, he underwent a nephritic workup, renal ultrasound, and biopsy, revealing severe glomerulosclerosis associated with long-term hypertension and diabetes. With CKD progressing to stage 3 (GFR 14 mL/min), he required haemodialysis and, eventually received a left renal transplant. Post-transplant, his glycaemic control became challenging due to persistently elevated glucose levels. He was initiated on Insulatard insulin (18 units in the morning, 16 units in the evening) along with gliclazide 80 mg twice daily. Given the need for frequent glucose monitoring—six times daily—and difficulty using fingerstick testing due to a left-arm fistula, he qualified for the Freestyle Libre continuous glucose monitor. This device significantly improved his quality of life and glycaemic control, with an HbA1c of 55 mmol/mol, glucose levels ranging between 4.9–12 mmol/l, and 63% time-in-range.
Conclusions
This case illustrates the complex challenges of managing diabetes and hypertension in patients with mitochondrial disorders. It emphasizes the importance of early recognition and proactive management of renal and endocrine complications which are essential for improving outcomes.

Psychosocial experience of gestational diabetes in a population of tunisian women

Takoua Moussa[1], Chaima Jemai[1], Yesmine Guerbouj[1], Nesrine Dhieb[1], Zohra Hadj Ali[1], Olfa Laajili[1], Imen Hedfi[1], Yosra Htira[1] & Faika Ben mami[1]
[1]Institute of Nutrition of Tunis, C Department, C Department, Tunisia

Introduction
Gestational diabetes (GD) is a condition that causes significant concern and stress, which can have repercussions on maternal and fetal health. However, there is

limited research on patients' experiences regarding GD care. The objective of this study was to identify the psychosocial experiences triggered by a GD diagnosis to improve healthcare services.
Methods
This cross-sectional study explores the experiences of 53 women diagnosed with GD, followed up at our GD unit in Service C of the Tunis Institute of Nutrition. Data were collected through in-depth interviews.
Results
The average age of the participants was 33.79 ± 4.8 years. Smoking and sedentary lifestyles were observed in 5.7% and 54.7% of cases, respectively. Their medical history included hypertension (7.5%), dyslipidemia (3.8%), and hypothyroidism (7.5%). The majority of women were overweight, with a preconceptional body mass index (BMI) averaging 28.82 ± 5.02 kg/m^2. Their diabetes was well-controlled, with an average HbA1c of 5.55 ± 0.67%. Difficulty accepting GD was reported by 49.1% of patients, while 30.2% experienced feelings of self-devaluation. Additionally, 17% felt that society reduced them to their disease, whereas 54.7% perceived GD as a socioeconomic burden. Adapting to new dietary habits was a major challenge: 52.8% of women struggled to modify their diet, and 35.8% found preparing varied and balanced meals burdensome. This adaptation led to frustration and deprivation for 47.2% of the patients. The psychological impact of GD was also significant, with 52.8% of women reporting recent stress. Support from their social circle played a crucial role in their experience, yet 22.6% felt unsupported, and 33.21% believed that their entourage was unaware of GD's implications. Furthermore, 11.3% of patients themselves lacked knowledge about the disease's implications. Regarding pregnancy weight gain, 39.6% of women had insufficient weight gain, 32.1% had normal weight gain, and 28.3% experienced excessive weight gain. No statistically significant association was found between pregnancy weight gain and recent stress or feelings of frustration and deprivation (P = NS).
Conclusion
Based on the experiences of this group of Tunisian women, it is evident that healthcare services need to be restructured to improve pregnancy experiences and ensure that women are actively engaged and attentive to their own health.

Blood lipid profile of patients with diabetes mellitus of various degrees of severity
Gulnora Artykbaeva[1] & Talat Saatov[1]
[1]Institute of biophysics and biochemistry under Mirzo Ulugbek National University of Uzbekistan, lab of metabolomics, Tashkent, Uzbekistan

Diabetes mellitus (DM) is characterized by a global metabolic disorder, not only of carbohydrate but also lipid metabolism. Consumption of high-calorie diets and lack of physical activity in the long term lead to the accumulation of very low-density lipoprotein cholesterol (VLDL-C), which accelerates the development of atherosclerosis and is a major risk factor for cardiovascular diseases. The purpose of the work was to study the indicators of lipid metabolism in the blood of patients with diabetes of varying severity. The mild form is characterized by a glucose level of up to 8 mmol/l on an empty stomach, the moderate form is up to 14 mmol/l, the severe form of diabetes is over 14 mmol/l. Indicators of total blood lipids in the control were 5.20±0.33 g/l and significantly increased at all degrees of severity ($P<0.05$). Total cholesterol in the control was 4.89±0.10 mmol/l; in diabetes it significantly increased to 6.0±0.17 in mild form, to 5.95±0.11 in moderate form, to 5.79± 0.16 mmol/l ($P<0.05$) in severe cases. The level of triglycerides in the control was 1.56±0.21 mmol/l, with mild diabetes it was significantly increased to 1.84±0.05, with moderate severity - 2.25± 0.04, with severe diabetes - 2.98±0.34 mmol/l ($P<0.05$). VLDL and LDL cholesterol in the control corresponded to 10.47±1.24 mmol/l. In the mild form, this indicator was increased to 26.36±3.51 ($P<0.01$), in the moderate form – to 26.41±2.04, in the severe form – to 15.35±0.31 mmol/l. At the same time, HDL cholesterol significantly decreased in all groups. The lipid spectrum of patients with diabetes shows a significant increase in atherogenic lipoproteins and a decrease in antiatherogenic lipoproteins.

Growth assessment during puberty in children and adolescents with type 1 diabetes mellitus
Elizabeth Garcia[1], Franco Sabino[1], Gimena Maskevich[1], Maria Julieta Cortalezzi[1], Ignacio Agustin Méndez[2], Andrea Reinoso[1], Analia Morin[1] & Guadalupe Pietropaolo[1]
[1]Hospital Sor Maria Ludovica, Sala de Endocrinologia y crecimiento, La plata, Argentina; [2]Instituto de desarrollo e investigaciones pediátricas (IDIP), nutricion, La plata, Argentina

Introduction
Adequate linear growth and final height are major aims during treatment of type 1 diabetes (T1D) in children. Such items could be influenced by suboptimal glycemic control. Modern intensified insulin therapies are fundamental tools to reach adequate metabolic control.
Aim
To evaluate growth during puberty in children and adolescents with T1D followed up at a Pediatric Endocrinology center, HIAEP Sor María Ludovica, Buenos Aires, Argentina.
Material and methods
Forty-four children with T1D were evaluated (54.5% Male), regarding mean age, height, mean target height, HbA1c at T1D onset, at the start of puberty (thelarche stage ≥ 2 or testicular volume ≥ 4 ml), at the end of puberty (menarche or testicular volume ≥ 15 ml), at pubertal growth peak, and at discharge, clinical condition at T1D debut and diabetes duration. Quantitative variables were analyzed using the Shapiro-Wilk test. Growth and HbA1c levels were compared (Student's/Mann-Whitney tests). Correlations between anthropometrics and HbA1c were estimated (Pearson/Spearman coefficients).
Results
Median age at diagnosis was 8.49 (4,82; 9,97) and mean HbA1c at onset was 12,56±2,76. Mean height SDS was 0.52±1.34 at diagnosis and 0.47±0.97 at the end of puberty, mean height gain was 16.63±6.29 cm in males and 14.97± 5.92 cm in females. At discharge, mean height SDS was 0.22±0.96 in males and -0.74± 1.05 in females. Mean SDS target height was -0.45±1.16. Median HbA1c was 8.70% at pubertal onset and 9.10% at puberty end, with no significant correlation between height gain or diabetes duration. Acute complications were experienced by 70.5% of patients and chronic complications by 34,1% at Lipodystrophy (61.4%), and hypertension (34%) were the commonest. Most presented ketoacidosis (50%) and ketosis without acidosis (42.2%) at debut. Mean diabetes duration was 7.84±2.92 years. No significant differences in HbA1c were found between patients with and without complications. Associated conditions (hypothyroidism 31.8%, celiac disease 13.6%) were found in 54.5% of patients. No significant differences in growth compared to patients without these conditions.
Conclusions
This cohort of children with T1D presented adequate growth during puberty, reaching their target height, despite suboptimal HbA1c levels. Acute complications and the presence of associated conditions did not affect the final growth outcomes.
DOI: 10.1530/endoabs.110.EP508

Type 2 diabetes mellitus in teenagers – a growing concern for armenia
Natela Navasardyan[1], Irina Muradyan[2], Arthur Melkonyan[2,3] & Yelena Aghajanova[2,3]
[1]Surb Astvatsamayr MC, Yerevan, Armenia; [2]"Muratsan" University hospital complex, Yerevan, Armenia; [3]Yerevan State Medical University, Yerevan, Armenia

Introduction
Type 2 diabetes mellitus (T2DM), once considered a disease primarily affecting adults, is now increasingly diagnosed in children and adolescents. This shift is largely attributed to rising rates of obesity, poor dietary habits, and reduced physical activity among younger populations. In the United States and other developed countries the prevalence of T2DM in teenagers has risen sharply in recent years, prompting a need for greater awareness and early intervention. An increase in T2DM cases is also observed in Armenia, not only among adolescents in late but also in early puberty.
Case Description
This case report describes a 12-year-old boy who presented with excessive thirst, frequent urination, fatigue, and a 5 kg weight loss over the past month. His home blood glucose levels were consistently elevated, with one reading as high as 29 mmol/l. On clinical examination, he was found to have obesity (BMI: 36.9 kg/m^2), height = 176.5sm, height SDS= +1.42, acanthosis nigricans, and breasts enlargement, all indicative of insulin resistance Tanner 3 stage Family history was positive for T2DM, which further supported the diagnosis. Laboratory findings confirmed the diagnosis of T2DM: Fasting glucose: 28.7 mmol/l HbA1C: 11.0% C-peptide: 2.6 ng/mL Ketones: 3+ (indicating ketosis) Autoantibodies: Anti-GAD, IgG – 46.6 (>N) Anti-IA-2- 180.59 (>N) Anti-insulin, IgG – 10.13 (N)

The patient's treatment regimen included diet therapy (25 kcal/kg/day), insulin therapy (NovoRapid and Levemir), Metformin, and blood glucose monitoring 5-7 times per day. In addition, physical activity was strongly encouraged to enhance metabolic control.

Conclusions

This case underscores the rising incidence of T2DM in adolescents, a trend that calls for heightened awareness among healthcare providers and families. Early diagnosis and intervention, including lifestyle changes and pharmacological treatment, are essential to managing T2DM in teenagers and preventing long-term complications. Given the increasing prevalence of the condition in this age group, it is critical to recognize the early signs and implement appropriate strategies to address this growing public health issue.

JOINT4012 Successful treatment of a foot ulcer in a female patient with newly diagnosed T1DM (LADA)

Rada Sparavalo[1,2] & Ivana Radonic[3]

[1]General Hospital Niksic, Internal medicine, Nikšić, Montenegro; [2]General Hospital, Intrenal medicine, Endocrinology, Nikšić, Montenegro; [3]general Hospital Niksic, Internal medicine, Niksic, Montenegro

Diabetic foot is a term used to describe the foot of a patient suffering from diabetes who is at potential risk of several pathological consequences, including infection, ulceration, and/or destruction of deep tissues associated with neurological abnormalities, varying degrees of peripheral vascular disease, and/or metabolic complications of diabetes in the lower extremity. A diabetic ulcer is a critical and central event of the cascade of diabetic foot. A 42-year-old female patient was admitted as an emergency in November 2020 with ketoacidosis (pH 6.9) with impaired consciousness, glucose on admission 38.3 mmol/l, HbA1c 14.01%, CRP 429.98 mg/l, negative for COVID. Anamnestic data indicate that over the past 2 years, she has gradually started to lose more than 12 kg of body weight, especially during the last 5-6 months, when she noticed the blisters on her heels that began to spread. Also, she has experienced the absence of menstrual cycles for 7-8 months. She denies previous illnesses and is a non-smoker. On physical examination, body weight was 56 kg, height 1.78 m, and BMI 17.7 kg/m2, ulcer on the right heel and a deep, ulcerative change on the left heel and exposed region in the area of the left Achilles tendon, and hypotrophy of the muscles of both the upper and lower extremities. Hormonal analyses showed the values of thyroid hormones, cortisol, and PTH within the reference range, FSH 0.66 mIU/l, LH 0.18 mIU/l, estradiol 54 pmol/l, progesterone <0.3 mmol/l. Immunological analyses showed IA At 2.5 IU/ml within the reference range, highly positive GAD-65At 749.3 IU/ml, and antiTPO positive at 10.35 IU/ml. The echo-Doppler of the lower extremity blood vessels was normal, as was the X-ray of the bones of the feet. The neurological examination showed bilateral sensorimotor polyneuropathy, and the ophthalmological examination showed non-proliferative diabetic retinopathy, and the cataract in the right eye. Upon admission, intensified insulin therapy with human insulin analogues was introduced and excellent glycoregulation was achieved. A multidisciplinary approach was applied in the treatment of diabetic foot, with ulcer treatment by a surgeon, neurological therapy, and regular follow-up and hyperbaric oxygen therapy for 6 months. The ulcerative changes were completely healed after 5 months with no recurrence during the previous 4 years of follow-up.. Studies have shown that early recognition of LADA and strict glycaemic control is the key to improving the prognosis for LADA and reducing the risk of developing complications.

Diabetic foot ulcer. peripheral artery disease and treatment with angioplasty

Maria Jose Vallejo Herrera[1] & Veronica Vallejo Herrera[2]

[1]Endocrinology and Nutrition. Málaga Regional University Hospital., MALAGA, Spain; [2]Radiodiagnosis. Málaga Regional University Hospital., MALAGA, Spain

Introduction and Objectives

Diabetes mellitus-related foot disease is one of the most serious complications of DM with loss of quality of life and high economic cost. Peripheral arterial disease is present in $>$ 50% of patients and infection affects 60% ulcers (main cause of amputation). The risk of death in 5 years for a patient with an ulcer is 2-5 times higher.

Material and Method

We performed a descriptive of the patients treated in our diabetic foot clinic during one year (September 2023-2024), including patient profile, risk factors, complications, history of amputation, pathophysiology, treatment and evolution to propose improvement options.

Results

97 new patients. From Primary Care, Emergency, Infectious Diseases, Internal Medicine, CCV or Endocrinology. Complex cases presented to the committee (endocrinology, infectious diseases, rehabilitation, trauma, CCV, radiology). Our patient profile: mean age 66.7 years, male (74%), diabetes 2 88% (8 patients type 1), long history (mean 19 years) and poor metabolic control (mean HbA1c 7.8%), hypertensive (76%), dyslipidemia (89%) and smokers (59%). Complications: retinopathy (58%), nephropathy (42%), stroke (15%) and heart disease (19%). Polyneuropathy 76% and arteriopathy 76% patients. Most combine both. History of previous ulcer (63%) and previous amputation (37%). Patients with isglt2 (54%): (empagliflozin 30%, dapagliflozin 23%, canagliflozin 0%). 55.6% of the total (54 patients) had active ulcer. 43 high-risk patients who no longer had ulcers. Type of ulcer: ischemic 35.2%/neuropathic 14.8%/neuroischemic 50%. 2 classifications indicating ulcer severity and longer healing time, SINBAD and PEDIS. SINBAD score $>$ or equal to 3 (32 patients), PEDIS 3 (17 patients) and PEDIS 4 (2 patients). Infection (23 patients). 24 patients required admission, Infectious Diseases or Traumatology, due to complicated ulcer or scheduled admission CCV (preferential angioplasty). All cases require education or care by specialized nursing. Most require angioplasty:

- Dressing and antibiotic therapy: 8 patients
- Antibiotic therapy, debridement and angioplasty: 16 patients
- Debridement and angioplasty: 16 patients At the time of cutting, 32% closed ulcer, healing time (2-32 weeks). Amputation was required due to poor evolution; 7 minor amputations and 4 major ones. One patient died due to a cause unrelated to diabetic foot. In the subgroup with iSGLT2, some amputations were not under treatment, so there is no clear association. We should use them whenever they are indicated due to "high CV risk".

Conclusion

It is important to have a multidisciplinary team and preferential care consultations, in order to reduce mortality.

Exploring the role of type 2 diabetes mellitus factors in the progression to advanced fibrosis in MASLD

Yesmine Elloumi[1], Mouna Elleuch[1], Khouloud Boujelben[1], Maryem Akacha[2], Faten Hadj Kacem[2], Nadia Charfi[1], Mouna Mnif[2], Dhoha Ben Salah[1] & Nabila Mejdoub Rekik[1]

[1]Hedi Chaker University Hospital, Sfax, Tunisia; [2]Hedi Chaker University Hospital, Endocrinology Department, Sfax, Tunisia

Background

Metabolic-associated steatotic liver disease (MASLD) is increasingly recognized as a severe comorbidity in patients with Type 2 diabetes Mellitus (T2DM). Despite the known overlap between these conditions, the specific diabetes-related

factors that drive the progression to advanced liver fibrosis in MASLD remain poorly understood. This study aims to investigate the associations between T2DM factors and the risk of advanced fibrosis in T2DM patients with MASLD.
Methods
This was a retrospective, descriptive and analytical study of T2DM patients with MASLD, followed at the Endocrinology-Diabetology Department of Hedi Chaker University Hospital in Sfax, Tunisia. We used the fibrosis-4 index (FIB-4) and the NAFLD fibrosis score (NFS) to evaluate the risk of advanced fibrosis among the patients. High risk of advanced fibrosis is indicated by a FIB-4 score >2.67 and an NFS score >0.675. The patients were categorized then into two groups : a high-risk group for advanced fibrosis and an intermediate and low-risk group.
Results
This study included 101 T2DM patients with MASLD. Neither the age at diagnosis of T2DM nor its duration were significantly associated with advanced fibrosis ($P>0.05$), regardless of the score used. However, blood glucose levels (12.0 mmol/l [7.2-14.6], 8.0 mmol/l [6.0-12.0], $P = 0.024$) and HbA1c levels (9.7% [6.9-12.0], 7.2% [6.6-9.8], $P = 0.038$) were significantly lower in the high-risk fibrosis group, according to NFS score. The use of anti-diabetic medications did not seem to be associated with the progression to advanced fibrosis when predicted by the FIB-4 score. However, when the NFS score was used, insulin therapy was more frequently associated with the high-risk fibrosis group ($P = 0.007$), while sulfonylureas were more prescribed in the low- and intermediate-risk group ($P = 0.004$). Renal function was significantly more impaired in the high-risk fibrosis group according to both NFS ($P = 0.001$) FIB-4 ($P = 0.044$) scores, and erectile dysfunction was significantly associated with the progression to fibrosis when predicted by NFS score ($P = 0.039$). When NFS score was used, individuals at high risk of fibrosis exhibited significantly higher rates of microangiopathies ($P = 0.046$) and ischemic heart disease ($P = 0.037$) compared to those with low or intermediate risk. These significant differences disappeared when subgroups were based on the FIB-4 score.
Conclusion
Understanding how these diabetes-related factors interact with MASLD to accelerate fibrosis progression is crucial for improving patient outcomes.

Perceived stress levels in women with gestational diabetes and associated factors

Dorra Ben Salem[1], Yosra Htira[2], Chaima Jemai[2], Olfa Laajili[2], Imene Hedfi[2], Zohra Hadj Ali[2] & Faika Ben Mami[2]
[1]National Institute of Nutrition and Food Technology, Department of Nutritional Diseases C, Tunis, Tunisia; [2]National Institute of Nutrition and Food Technology, Department of Nutritional Diseases C, Tunis, Tunisia

Introduction and objective
Gestational diabetes is a common pregnancy complication that poses unique health challenges, often leading to increased stress for affected women. High stress levels can affect both maternal well-being and pregnancy outcomes. This study aims to examine perceived stress levels and identify factors linked to elevated stress in this population.
Materials and methods
A cross-sectional study was conducted in Department C of the National Institute of Nutrition in Tunis over 7 months. Stress levels were measured using the Perceived Stress Scale (PSS-10), with scores above 27 indicating high stress.
Results
A total of 163 women were included with a mean age of 33.21 ± 4.82 years. The median gestational age was 28.5 weeks $\pm$ [21.9; 33.3]. Insulin therapy was prescribed for 27.6%of the patients and glycemic control was achieved in 60.1% of them. Macrosomia was the most common complication, affecting 14.1% of fetuses. About one-third of women(32.5%) reported not desiring their pregnancies. The average PSS score was 17.11 ± 6.78. Moderate stress was noted in 58.3% of participants, while 9.8% reported high stress levels. High perceived stress was more prevalent among women with unwanted pregnancies (17% vs. 6.4%; $P = 0.03$), those undergoing insulin therapy (17.8% vs. 6.8%; $P = 0.04$), and those at risk of preterm delivery (12.5% vs. 1.4%; $P = 0.04$). Multivariate analysis identified insulin therapy as a significant risk factor for high stress levels (OR = 6.4; 95% CI [1.5, 27.19]).
Conclusion
These findings underscore the importance of targeted psychological support and stress management strategies for pregnant women with gestational diabetes, especially those receiving insulin therapy.

Mauriac syndrome and autoimmune hepatitis: a rare combination in a patient with type 1 diabetes

Emna Mraihi[1], Sabrine Mekni[1], Rihab Laamouri[1], Sawsen Essayeh[1], Nadia Mchirgui[1], Karima Khiari[1], Imen Rojbi[1] & Bennacef Ibtissem[1]
[1]University Hospital Charles Nicolle Tunis, Tunis, Tunisia

Background
Mauriac syndrome, a rare and severe complication of poorly controlled type 1 diabetes mellitus, is characterized by growth retardation, delayed puberty, and hepatomegaly. We report the case of a patient with Mauriac syndrome and autoimmune hepatitis.
Observation
A 16-year-old patient diagnosed with type 1 diabetes for 4 years was admitted to the endocrinology department of Charles Nicolle Hospital in Tunis for further evaluation of hepatomegaly. The patient's diabetes management history revealed poorly controlled diabetes, resulting in frequent hospital admissions due to ketoacidosis decompensations. On physical examination, the patient presented with severe underweight and growth retardation, with a height of 144cm (-3.5 SD) and a weight of 20kg (-3.2 SD) as well as a delayed puberty (Stage I according to Tanner classification). The liver span was 14cm and the liver enzyme levels were three times the upper limit of normal: the level of glutamic-oxaloacetic transaminase (SGOT) was at 102 UI/l [5-34 UI/l], and the level of serum glutamic-pyruvic transaminase (SGPT) at 147 UI/l [10-49 UI/l]. The investigation has excluded drug-induced hepatitis, and the hepatitis C and B virus serology was negative. The immunological work-up revealed negative anti-nuclear and anti-mitochondria antibodies while testing positive for anti-smooth muscle and anti-LKM1 antibodies. The liver biopsy identified an inflammatory infiltrate indicative of chronic hepatitis with mild interface hepatitis and also revealed an accumulation of glycogen in the hepatocytes, suggestive of Mauriac syndrome. Nevertheless, the possibility of autoimmune hepatitis remains under consideration due to the individual's personal history of autoimmunity, as well as the positive antibody findings.
Conclusion
Mauriac syndrome, a rare complication of chronic hyperglycemia and hyperinsulinism, presents a diagnostic challenge, especially when hepatic autoimmunity indicators are present. optimizing diabetic control can help confirm the diagnosis over time.

Vitamin D and microvascular complications in type 1 diabetes

Nour Hentati[1], Faten Mahjoub[1], Maryam Naifar[1], Rim Rachdi[1], Ramla Mizouri[1], Nadia Ben Amor[1] & Henda Jamoussi[1]
[1]National Institute of Nutrition of Tunis, Tunis, Tunisia

Background
Type 1 diabetes (T1D) is a chronic condition that predisposes individuals to a range of long-term complications, including microvascular complications. Vitamin D deficiency has been associated with various adverse health outcomes, and emerging evidence indicates that it may influence vascular health and microvascular damage in diabetes.
Objective
This study aimed to explore the relationship between 25-hydroxy vitamin D (25(OH)D) levels and microvascular complications in patients with type 1 diabetes.
Methods
We conducted a cross-sectional study, including 50 type 1 diabetic patients. All patients underwent measurement of 25(OH)D levels, and a clinical evaluation for microvascular complications, including a detailed medical history, a thorough physical examination, assessment of the albuminuria-to-creatininuria ratio and a fundus examination.
Results
The median age of the participants was 26 years [21.00 - 31.75], with a sex ratio (F/M) of 1.4. The median duration of diabetes was 13.00 years [9.25 - 17.75]. The average level of 25(OH)D was 11.14 ± 6.49, and 92% of patients had vitamin D deficiency (≤ 20 ng/ml). Diabetic nephropathy was observed in 24% of patients, while diabetic neuropathy was present in 12% of patients. Diabetic retinopathy was noted in 24% of cases. It was classified as non-proliferative mild, moderate, severe, and proliferative in 33%, 9%, 25% and 33% of patients, respectively. The median 25(OH)D level was lower in patients with diabetic nephropathy compared to those without, although the difference was not statistically significant (8.3

ng/ml [6.87–10.78] versus 9.02 ng/ml [7.78–14.39]; $P = 0.42$). Similarly, the 25(OH)D level was lower in patients with diabetic neuropathy ($n = 6$) compared to those without, but the difference was not statistically significant (8.44 ng/ml [4.68–13.52] versus 9.16 ng/ml [7.57–14.34]; $P = 0.29$). The median 25(OH)D level in patients with mild, moderate, severe, and proliferative retinopathy was 12.07 ng/ml [9.67 – 15.95], 14.31 ng/ml [14.31 – 14.31], 4.51 ng/ml [2.40 – 4.81], and 6.38ng/ml [2.71 – 15.51], respectively. Severe retinopathy and proliferative retinopathy were significantly associated with lower 25(OH)D levels ($P = 0.05$).
Conclusion
Our findings suggest a potential link between vitamin D deficiency and the progression of diabetic retinopathy, though further research is necessary to establish causality and the benefit of vitamin D supplementation in preventing or managing microvascular complications in type 1 diabetes.

Specificities by gender of macroangiopathic complications in type 2 diabetic patients

Takoua Moussa[1], Chaima Jemai[1], Insaf Jameleddine[1], Nesrine Dhieb[1], Zohra Hadj Ali[1], Olfa Laajili[1], Imen Hedfi[1], Yosra Htira[1] & Faika Ben Mami[1]
[1]Institute of Nutrition of Tunis, C Department, Tunis, Tunisia

Introduction
Although the mechanisms and risk factors for macroangiopathies in type 2 diabetic (T2D) patients are similar between genders, clinical and epidemiological differences may influence their prevalence and management. This study aimed to investigate the association between macroangiopathic complications and gender.
Materials and Methods
A study was conducted on 70 T2D patients, divided into two groups : Group 1 (G1) with 35 women and Group 2 (G2) with 35 men, matched by age, diabetes duration, and HbA1c levels. Clinical and biological data were collected from medical records.
Results
The average age was 56.7 $\pm$ 7.5 years. The mean diabetes duration was 11.7 $\pm$ 5.1 years, with an average HbA1c of 10.2 $\pm$ 1.1%. A total of 82.9% of women and 62.9% of men had no macroangiopathic complications. Single macroangiopathy was observed in 11.4% of women and 5.7% of men (P = NS). Two macroangiopathies were present in 31.4% of women and 5.7% of men (P = NS). No patients had more than two macroangiopathies. The prevalence of coronary artery disease (CAD) was identical in both groups (11.4%). Stroke and peripheral artery disease (PAD) were more frequent in men, with a prevalence of 11.4% and 17.1%, compared to 5.7% and 2.9% in women, respectively (P = NS). A significant association was found between CAD and hypertension in men ($P = 0.041$) but not in women ($P = 0.326$).
Conclusion
The simultaneous presence of multiple macroangiopathies, PAD, and stroke was more frequent in men. Additionally, hypertension could be a predictive factor for CAD in the male population. That's why more frequent screening in this group seems to be necessary.

Gender differences in prevalence, clinical features, and treatment of hypertension in type 2 diabetes

Takoua Moussa[1], Chaima Jemai[1], Nesrine Dhieb[1], Insaf Jameleddine[1], Zohra Hadj Ali[1], Olfa Laajili[1], Imen Hedfi[1], Yosra Htira[1] & Faika Ben Mami[1]
[1]Institute of Nutrition of Tunis, C Department, Tunis, Tunisia

Introduction
Hypertension(HTN) and type2 diabetes(T2D) are often associated and have a bidirectional relationship. On one hand, T2D increases the risk of HTN due to vascular damage caused by glucotoxicity. On the other hand, HTN exacerbates diabetic complications. This study aimed to determine the prevalence of HTN in T2D patients and its characteristics based on gender.
Methods
A study was conducted on 70 T2D patients, divided into two groups : Group1(G1) with 35 women and Group2(G2) with 35 men, matched by age, diabetes duration, and HbA1c levels. HTN was defined as persistently elevated blood pressure(BP) measured in a medical office, with systolicBP (SBP) $\geq$ 140 mmHg and/or diastolic BP(DBP) $\geq$ 90 mmHg.
Results
The average patient age was 56.7 $\pm$ 7.5 years. The average diabetes duration was 11.7 $\pm$ 5.1 years, and the mean HbA1c was 10.2 $\pm$ 1.1%. The mean body mass index(BMI) was 30.26 $\pm$ 6.4 kg/m^2 in women and 26.24 $\pm$ 5.68 kg/m^2 in men. Average SBP and DBP in women were 137.7 $\pm$ 14.3 mmHg and 78 $\pm$ 9 mmHg, higher than in men(130 $\pm$ 14.9 mmHg and 76.8 $\pm$ 8.6 mmHg, respectively). HTN prevalence was 51.4% in G1, while in G2, 45.7%. The most prescribed antihypertensive drugs in G1 were ACE inhibitors (34.3%), calcium channel blockers(CCBs) (17.1%), angiotensin II receptor blockers(ARBs) (14.3%), thiazide diuretics(8.6%), beta-blockers(5.7%), and centrally acting antihypertensives(CAD) (5.7%). In G2, ARBs were the most prescribed (22.9%), followed by CCBs(20%), ACE inhibitors(14.3%), thiazide diuretics(11.4%), beta-blockers(8.6%), and CAD(2.9%). Monotherapy was the most common prescription(G1: 25.7%; G2: 17.1%), followed by dual therapy (22.9%) and triple therapy(2.9%) in women, whereas in men, triple therapy(8.6%) was the second most frequent, followed by dual therapy(14.3%). In G2, but not in G1, HTN was significantly associated with coronary artery disease($P = 0.02$), nephropathy($P = 0.00$), peripheral neuropathy($P = 0.017$), and microalbuminuria($P = 0.00$). In both groups : no significant association was found between HTN and autonomic neuropathy($P = 0.19$), stroke($P = 0.526$), or peripheral artery disease($P = 0.785$), however, HTN was correlated with BMI($P = 0.00$) and retinopathy($P = 0.022$).
Conclusion
In hypertensive T2D patients, monotherapy was the most common treatment. ACE inhibitors, ARBs, and calcium channel blockers were the most frequently prescribed drug classes. HTN appears to be a stronger risk factor for coronary artery disease, nephropathy, and peripheral neuropathy in men, while retinopathy was a shared risk factor in both genders among T2D patients.

Unconventional use of continuous glucose monitoring: case report

Fedir Laniush[1], Alina Urbanovych[1] & Myroslava Borovets[1]
[1]Danylo Halytsky Lviv National Medical University, Endocrinology, Lviv, Ukraine

Background and aim
Continuous glucose monitoring (CGM) is an essential part of diabetes management. It allows to assess blood glucose level in real time and avoid hyper- and hypoglycemia. But in this case report we describe a patient without diabetes but frequent hypoglycemic events. With the help of CGM he was diagnosed with insulinoma and treated properly.
Clinical case
A 59-year man presented with palpitation, dizziness, tremor, and general weakness that occur during fasting. History revealed that he experienced these symptoms nearly 6 months. Preliminary diagnosis was hypoglycemic syndrome. At outpatient's clinic fasting glycemia was in reference range. Laboratory tests demonstrated: fasting glycemia 5.1 mmol/l; HbA1c level 5.2%; C-peptide test 4.9 ng/ml (1.1-4.4); insulin level 27 mIU/mL (3-25); plasma cortisol and plasma ACTH levels were in reference ranges. Family history is negative for diabetes. On examination: dry skin, BMI 25,9 kg/m2. Patient did not take any pharmacological agents, including sulfonylurea and insulin. He was proposed to use CGM to find out a cause of his symptoms. CGM report revealed that he experienced unexplained hypoglycemic states at night and early morning. After detailed questioning patient reported that at those exact times he felt hunger, was sweaty, and agitated. Our next step was to perform CT-scan of abdomen to look for a tumor. CT-scan revealed a 2 cm tumor in the head of pancreas. After successful surgery we still follow-up the patient.
Conclusion
Our clinical case describes an unconventional use of CGM. It can be used not only to manage diabetic patients, but also to monitor glucose levels in all patients with disordered glucose metabolism.

Vitamin D status and features of carbohydrate metabolism in fertile women with diabetes mellitus

Iryna Tsaryk[1] & Nataliia Pashkovska[1]

[1]Bukovinian State Medical University, Clinical Immunology, Allergology and Endocrinology, Chernivtsi, Ukraine

Introduction.
Vitamin D deficiency is prevalent among individuals with latent autoimmune diabetes in adults (LADA) and has been linked to various metabolic disturbances. In fertile women with LADA, maintaining adequate vitamin D levels is crucial, not only for metabolic health but also for reproductive health. Vitamin D deficiency has been linked to various reproductive issues, including menstrual irregularities and complications during pregnancy.
The aim of the study.
To evaluate the vitamin D status and features of carbohydrate metabolism in fertile women with latent autoimmune diabetes in adults and classical type 1 diabetes (T1DM).
Material and methods.
15 patients with LADA as well as 16 patients with classical T1DM and 25 practically healthy individuals were examined. In addition to general clinical research methods cholecalciferol status was evaluated as well as indicators of carbohydrate metabolism (fasting glycemia, glycated hemoglobin (HbA1c)), and C-peptide level.
Results.
Cholecalciferol level was registered 45.1% lower in LADA group compared to control (20.48 [18.41;25.71] ng/ml vs 33.00 [27.00;60.00] ng/ml) ($P = 0.000$) and by 37.9% in T1DM (20.48 [18.41;25.71] ng/ml vs 33.00 [27.00;60.00] ng/ml) ($P<0.001$). In LADA patients the level of cholecalciferol was lower by 11.5% ($p<0.05$) compared to T1DM. The fasting plasma glucose level was 10.91 [10.00;12.30] in LADA and 10.67 [7.04;12.51] in T1DM group and probably differed between LADA/control and T1DM/control – control level 4.78 [4.40;5.05] (decrease by 2.3 times and 2.2 times, respectively ($P = 0.000$)). The level of HbA1c was the highest in LADA group (9.90 [7.6;10.20]%: by 46% compared with control (5.35 [5.30;5.52]%) ($P = 0.000$) and did not significantly differ with T1DM group where the level was 8.85 [7.90;9.55]%. The C-peptide level was significantly higher in control group (3.20 [2.10;4.00] ng/ml) by 6.4 times compared with the LADA group (0.50 [0.20;0.65] ng/ml) ($P<0.05$) and 32 times compared with T1DM (0.1 [0.10;0.15] ng/ml); the difference between LADA and T1DM showed that C-peptide level was higher by 5 times in patients with LADA compared to T1DM group ($P = 0.000$). In patients with LADA negative correlations of average strength were recorded between vitamin D level and BMI ($r= 0.442$; $P<0.05$), fasting glycemia ($r= 0.348$; $P<0.05$), HbA_{1c} ($r= 0.414$; $P<0.05$), HOMA-IR ($r= 0.671$; $P<0.05$).
Conclusions.
Vitamin D deficiency in fertile women with LADA is associated with reduced beta-cell function and poorer glycemic control. Ensuring sufficient vitamin D levels remains a vital component of managing overall health in this population.

Elevated risk of life-threatening metabolic acidosis with combined metformin and SGLT2 inhibitor therapy in the elderly

Funda Korkmaz[1], Priya Savani[1], Se-Min Kim[2] & Vanessa Barboza[3]
[1]RWJBarnabas Rutgers Jersey City Medical Center, Jersey City, United States; [2]Icahn School of medicine at Mount Sinai, Endocrinology, Jersey City, United States; [3]RWJBarnabas Rutgers Jersey City Medical Center, Endocrinology, Jersey City, United States

Background
[1]Metformin use in patients with type 2 diabetes (T2D) is associated with lactic acidosis, although exceedingly rare. [2]However, the risk of lactic acidosis is high in patients with underlying CKD. SGLT2 inhibitors have been increasingly used in patients with CKD in recent years due to their benefit in preventing the progression of diabetic nephropathy. In this case, we present the case of a 79-year-old elderly patient with T2D using both Metformin and an SGLT2 inhibitor who was admitted for life-threatening lactic acidosis.
Clinical Case
A 79-year-old female with T2D and co-morbidities including CKD 3b, HTN HLD, and dementia, presented with altered mental status. Her home medications included Dapagliflozin 5 mg (started 6 months ago), Metformin XR 500 mg BID (started 8 years ago), Amlodipine, Atenolol, Hydrochlorothiazide, Olmesartan, and Rosuvastatin. Upon admission, she exhibited severe hypotension (BP: 74/35 mmHg), bradycardia (HR: 54 bpm), and hypothermia (Temp: 34.4°C), while maintaining normal oxygen saturation. Laboratory results showed glucose at 94 mg/dL, potassium at 6.8 mEq/l, BUN at 45 mg/dL, creatinine at 8.86 mg/dL (baseline: 1.3 mg/dL), anion gap at 37.4, pH at 6.8, HCO3 at 2.6 mmol/l, PCO2 at 15 mmHg, lactate at 19.9 mmol/l (reference range < 2), and urine positive for ketones. Despite intensive care with intravenous hydration, a bicarbonate drip, and three vasopressors, her hypotension persisted, and lactate levels rose to 24 mmol/l. Emergent continuous renal replacement therapy (CRRT) was initiated, which improved her hemodynamics and lactic acidosis—all potential causes of lactic acidosis, including infection work-up such as blood cultures, were negative.
Conclusion
Although it is often challenging to identify the exact cause of lactic acidosis, her clinical picture raised suspicion of metformin-induced lactic acidosis due to the initial failure to respond to fluid resuscitation and pressors, followed by improvement after CRRT, and a negative work-up for infection and other causes. [3]There is a similar case presenting severe euglycemic ketoacidosis and lactic acidosis in a diabetic patient on chronic Dapagliflozin and Metformin therapy, which was triggered by poor oral intake and dehydration, ultimately requiring dialysis. Our case underscores the caution needed when using a combination of metformin and SGLT-2 inhibitors, especially in elderly T2D patients with decreased GFR.

Hepatic glycogenosis in poorly controlled type 1 diabetes mellitus

Maysa Saleh[1], Layla Al marzoqi[1] & Manal Khadora[1]
[1]AJCH, Dubai, United Arab Emirates

Background
Hepatic glycogenosis is the liver response to poor glycemic control in type 1 diabetes mellitus The rarity of the glycogenic hepatopathy in children leads to misdiagnosis. In this case report, we highlighted the identification of key clinical symptoms, of HG, in order to prevent HG from continuing to be misdiagnosed, and to ensure prompt management.
Case presentation
A twelve years old boy who was diagnosed one year earlier to his presentation to ED with abdominal pain. His Growth percentiles were below 3rd centile for the weight and on the 20th centile for the height. His **abdominal examination**showed tenderness in the right lower quadrant of the abdomen with hepatomegaly of 8 cm below the costal margin. The **laboratory investigations**revealed a very high HbA1C of 15.0 %, elevated liver enzymes and negative CMV and EBV serology, and other infectious causes of hepatomegaly. **Ultrasound abdomen**reported an Enlarged liver, measuring 17.9 cm with coarse parenchyma, but no sizeable focal mass lesion.
Conclusion
Although rare complication, of poorly glycemic control of type 1 Diabetes mellitus in children, hepatic glycogenosis, a temporary finding these patient which improves with glycemic control of children with T1DM. We report this case to raise attention of physicians to such complication, as it should not be misdiagnosed and for the prompt and early management of these patients.

Challenge in the follow-up of a type 1 diabetic patient with short stature - how craniopharyngioma can disturb the hormone status

Zsuzsanna Berdó[1], Andrea Nagy[2], László Novák[3] & Enikő Felszeghy[2]
[1]University of Debrecen, Pediatrics Clinic, Debrecen, Hungary; [1]University of Debrecen, Pediatrics Clinic, Debrecen, Hungary; [3]University of Debrecen, Neurosurgery Clinic, Debrecen, Hungary

A 14 year old boy with delayed puberty and short stature has been diagnosed with Type 1 (insulin-dependent) diabetes mellitus (T1DM). During the first six month of his diabetes treatment, in his honeymoon period, he did not required insulin substitution, but his short stature did not change, there was no growth velocity. Because of these symptoms, insulin tolerance- and glucagon stimulation test was performed after androgen priming. Growth hormone (GH) peak was not detectable in any stimulation test, the hormone concentrations were below the measurable limit. Brain MRI scan revealed a cystic intrasellar craniopharyngioma with moderate suprasellar extension. Chronic diseases like T1DM can cause short stature, but other organic failures could be also considered. Strict patient follow up can help to make the correct, complex diagnosis. After neurosurgical intervention hypoglycemic episodes can be life-threatening especially together

with insulin replacement in T1DM, since counter regulatory hormones are missing.

Genetic diagnosis of MODY: a case highlighting the role of 17q12 deletion

Purnima Singh[1] & Seif Eldin Ellibaih Yahia[2]
[1]Fujairah Hospital, EHS, Fujairah, United Arab Emirates; [2]Fujairah Hospital, EHS, Diabetes and Endocrinology, Fujairah, United Arab Emirates

Maturity onset diabetes of the young (MODY) is a non-insulin dependent variant of diabetes mellitus characterized by autosomal dominant pattern of inheritance. It is commonly seen amongst the younger population with typical features of early onset diabetes, strong family history of diabetes in multiple generations and mild fasting hyperglycemia or fluctuating glucose levels without severe complications (e.g., acidosis). Many are mistakenly treated as type 1 or type 2 diabetes for years. Of the 14 types, MODY 5 is a lesser common variant caused by HNF1β mutation and is associated with organ anomalies. We describe here a 13-year old asymptomatic patient presented similarly with elevated blood sugars at a primary clinic. Her father and 3 siblings were diabetic and mother had hypothyroidism suggesting a strong history. She was treated as prediabetes (HbA1c 6.4%) with lifestyle modifications. Months later the patient continued to have elevated blood sugar levels (HbA1c 8%) and type I diabetic mellitus was suspected. The patient was started on Degludec to 16 Units and Lispro to 6 Units with 3 meals and advised to test for autoantibodies like Glutamic Acid Decarboxylase Antibodies (GAD) & Islet cell Antibodies (ICA) which resulted negative. MODY was suspected and genetic testing revealed HNF1β mutation. All other investigations were unremarkable. All her family members, Father and two sisters with type one diabetes and brother with type two diabetes, had negative genetic screening. Currently the patient is maintaining normal sugar levels on degludec and semaglutide with HbA1c 6.6% and latest time in Target/Time in Range is 88% with 11% Time in High in Orange Color. Patients with typical features of MODY like strong family history of diabetes and hyperglycemia without acidosis should be genetically screened to avoid delay in diagnosis and management like organ anomalies. Early disease intervention can improve outcomes for affected individuals.

Severe hypercalcemia in a teenager with inaugural diabetic ketoacidosis

Salma El Hilali[1], Sara Ijdda[1], Sana Rafi[1], Ghizlane El Mghari[1] & Nawal El Ansari[1]
[1]University Hospital Center Mohammed VI, Department of Endocrinology and Metabolic Diseases, Marrakesh, Morocco

Introduction
Ketoacidosis is the presenting condition in a third of cases of type 1 diabetes, mainly affecting children or young subjects. Many associated electrolyte abnormalities have been described, such as dysnatremia and dyskalemia. However, severe hypercalcemia in diabetic ketoacidosis remains rare, with very few publications in the literature. We report the case of a patient with major hypercalcemia discovered during diabetic ketoacidosis (DKA).
Case report
A 16-year-old patient was admitted to the intensive care unit for management of status epilepticus, where an inaugural DKA was diagnosed. After conditioning and first-line treatment, a laboratory work-up revealed major hypercalcemia corrected to 152 mg/l. After rehydration and intravenous insulin therapy, the ketoacidosis was brought under control and the calcemia recontrolled at 83 mg/l (86-103). The rest of the work-up showed mild hypophosphatemia at 22 mg/l (27-45), 25 OH vitamin D deficiency at 14.20 ng/ml and a low parathormon level at 4 ng/l (9-80).
Discussion
Calcium is the most abundant cation in the human body and plays an essential role in nerve transmission, enzyme activity, myocardial function, coagulation and other functions... Phosphocalcic metabolism is tightly regulated by 3 main hormones : parathyroid hormone (PTH), vitamin D and calcitonin. The etiologies of hypercalcemia can be divided into 2 major categories: PTH-mediated (primary and tertiary hyperparathyroidism and familial hypocalciuric hypercalcemia) and non-PTH-mediated (neoplasia, drugs, hyperthyroidism, immobilization, etc.). Hypercalcemia in diabetic ketoacidosis may be explained by several mechanisms. Metabolic acidosis induces calcium efflux from the bones through increased osteoclastic bone resorption and reduced osteoblastic bone formation. Acidosis also directly reduces tubular reabsorption of calcium and increases its ionization. Dehydration, secondary to hyperglycemia, osmotic diuresis and insufficient oral intake, also causes hypercalcemia. Rhabdomyolysis, which is sometimes observed in patients with ACD, can lead to hypercalcemia.
Conclusion
Electrolyte disorders are common in diabetic ketoacidosis. However, severe hypercalcemia remains a rare complication, and its treatment essentially consists in correcting acidosis and dehydration with sufficient and appropriate fluid intake.

Quality of life in patients with diabetes mellitus

Zvezdana Jemuovic[1], Sandra Pekic Djurdjevic[1], Mirjana Doknic[1], Dragana Miljic[1], Marko Stojanovic[1], Ivana Cekic[1], Ivan Jevtic[1], Boris Kurcubic[1], Jelena Bajic[1] & Marina Nikolic Djurovic[1]
[1]Clinic for Endocrinology, diabetes and diseases of metabolism, University Clinical Center of Serbia, Belgrade, Serbia

Introduction
The prevalence of diabetes mellitus (DM) is reaching epidemic proportions in many parts of the world. People with DM have a worse quality of life (QoL) than those without chronic disease. DM is associated with a high risk of serious complications that affect the QoL.
Aim
To determine whether there is a difference in the quality of life in patients with DM2 receiving SGLT-2 inhibitor therapy compared to ones receiving insulin analogues.
Methods
Cross-sectional, case control study with 30 DM2 patients (mean age 59.7 ± 2.9) and 15 healthy controls, matched for age, sex and educational level, were included. DM2 patients were divided into 2 groups, 15 patients receiving SGLT2-inhibitors and 15 patients receiving insulin analogues. Measurement of glucose, HbA1c, urea, and creatinine was done. Evaluation of QoL was evaluated by QoL questionnaire - SF36. Fisher's ANOVA analysis was used to compare means between (sub)groups.
Results
Both DM2 groups had higher levels of glucose (SGLT2inh vs insulin) vs control group (7.37 ± 0.87 vs 8.21 ± 1.42 vs 5.15 ± 0.6 mmol/l, $P = 0.000$) as well as HbA1c (6.86 ± 0.31 vs 7.32 ± 0.62 vs 5.23 ± 0.29%, $P = 0.000$). Patients in both SGLT2inh and insulin groups vs control group reported worse quality of life in all scales measured by SF36. Physical health – Dimension A (48.91 ± 5.49 vs 35.73 ± 7.16 vs 53.28 ± 5.29 $P = 0.000$) and mental health – Dimension B (39.77 ± 8.15 vs 25.06 ± 10.11 vs 47.28 ± 6.30, $P = 0.000$).
Conclusion
Use of SGLT-2 inhibitors represents a significant step forward in the treatment of patients with DM2. These drugs not only improve the control of blood glucose levels, but also significantly contribute to improving the quality of life of patients, reducing complications and facilitating daily life. Assessment of the quality of life should become part of the routine control of patients with DM2, to determine the priority for each patient at the beginning of treatment and accordingly adjust therapeutic modalities in accordance with the latest medical recommendations.

Unveiling the cardio-metabolic factors driving advanced fibrosis in type 2 diabetic patients with MASLD

Yesmine Elloumi[1], Mouna Elleuch[2], Khouloud Boujelben[2], Mohamed Khairi Arous[2], Faten Hadj Kacem[1], Nadia Charfi[1], Mouna Mnif[1], Dhoha Ben Salah[2] & Nabila Mejdoub Rekik[2]
[1]Hedi Chaker University Hospital, Endocrinology Department, Sfax, Tunisia; [2]Hedi Chaker University Hospital, Sfax, Tunisia

Background
The progression of advanced fibrosis in type 2 diabetes mellitus (T2DM) patients with metabolic associated steatotic liver disease (MASLD) is shaped by a

complex interplay of cardio-metabolic risk factors, many of which remain poorly understood. Identifying the specific cardio-metabolic factors driving this progression could unlock new opportunities for early intervention and personalized treatment strategies. This study aims to uncover the key cardio-metabolic risk factors that promote advanced fibrosis in diabetic patients with MASLD.
Methods
This retrospective and comparative study included T2DM patients with confirmed MASLD, followed from 2012 to 2024 at the Endocrinology-Diabetology Department of Hedi Chaker University Hospital in Sfax, Tunisia. We used the fibrosis-4 index (FIB-4) and the NAFLD fibrosis score (NFS) to evaluate the risk of advanced fibrosis among the patients. High risk of advanced fibrosis is indicated by a FIB-4 score exceeding 2.67 and an NFS score exceeding 0.675. The patients were categorized then into two groups : a high-risk group for advanced fibrosis and an intermediate and low-risk group.
Results
